Abstract. Due to the high greenhouse gas emissions and energy consumption caused by cement production, in recent years, studies have focused on geopolymer concrete produced without the cement. Various precursors are used in alkali-activated geopolymer mixtures. The availability and cost of these precursors is a concern. In addition to providing high strength, it is desired that the precursor used are locally accessible and low-cost. In this study, a low-cost marl obtained from local resources of Konya province is used as a geopolymer precursor. Raw marl was calcined at 800 °C in order to increase its reactivity before being used in mixtures. NaOH and Na_2SiO_3 were used together as activators. The binder dosage of the geopolymer mortar was selected as 675 kg/m^3, water/binder ratio as 0.6, NaOH molarity as 10 M, activator/binder ratio as 1, Na_2SiO_3 ratio as 2.5. In order to investigate the effect of the resting period before thermal curing on the compressive strength of geopolymer mortars, samples with 0 (reference sample), 6, 12 hour, and 1, 3, 7, 14 days resting periods were produced and after resting period samples cured at 80 c for 24 hours. The samples were subjected to compressive strength test on the 28th day.The compressive strength of the samples with all pre-curing rest periods increased compared to the sample cured by direct heat without a resting period. The sample with a 3-day rest period provided the highest strength with a 25% increase compared to the reference mixture.

Keywords: Geopolymer mortar; precursor; calcined marl; thermal curing; pre-curing rest period

1. Introduction

Cement is one of the most produced and consumed products in the world (Scrivener et al., 2018; Fode et al., 2023). It is responsible for approximately 7% of global carbon dioxide emissions due to the high temperatures required in production processes and the consumption of natural resources (Meyer, 2009). Because of this, research has concentrated on figuring out how to use less cement while still preserving the strength and durability required to lower carbon emissions and lessen the consequences of climate change. One of the steps taken in this regard is geopolymer concrete produced without the need for Portland cement. Geopolymers are inorganic polymers formed by the chemical reaction of aluminum and silicon-rich materials (kaolinite, fly ash, slag, metakaolin, clay, etc.) via alkali activator. The selection of binder materials for geopolymer concrete production depends on factors such as availability, cost, and type of application.

There are many parameters affecting the strength of geopolymer concrete and mortars. Studies investigating the effects of factors such as precursor type, activator type, activator amount, curing temperature, curing time on the strength of geopolymer concrete/mortars are frequently encountered in the literature. Most studies have focused on the effects of curing temperature and curing time. However, the time interval between casting and curing (resting period) has rarely been investigated by researchers. In a study examining the effects of the resting period before curing on fly ash geopolymers, it was reported that the resting period increased the reaction products and caused a denser microstructure, thus increasing the mechanical strength. In addition, it has been reported that the water permeability, capillarity coefficient, and porosity of the samples decreased compared to the reference samples (Durak et al., 2021). There are studies reporting that the compressive strength of fly ash-based geopolymers increases with the increase of the pre-resting period up to a certain limit (Harle, 2017; Hardjito et al., 2005). When the effect of the pre-resting period on the properties of metakaolin-based geopolymers was examined, a short resting period initially increased the reaction rate, but decreased the total reaction level. It also increased the porosity and decreased the compressive strength. The extension of the resting period improved the porosity and increased the reaction level, modified the gel structure and densified the matrix (Tian et al., 2024).

There is no study in the literature investigating the effects of pre-resting period on calcined marl-based geopolymers. In this study, marl obtained from local resources of Konya province was calcined and used as

[*] Corresponding author, E-mail: akaroglu@ktun.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_965

geopolymer precursor. The effects of resting period before curing on the strength of calcined marl geopolymer mortars were investigated.

2. Materials and methods

2.1. Materials

The XRD analysis results of raw marl obtained from local sources in Konya province of Turkey are shown in Figure 1. The semi-quantitative mineralogical analysis results are given in Table 1.

The raw material was first sieved through a 2.36 mm sieve and calcined for 1 hour in a 15 °C/min heat ramp oven after the oven reached 800 °C and left to cool at room temperature. After cooling, it was ground in a ball mill for 1 hour.

CEN standard sand was used as aggregate in the preparation of geopolymer mortars.

The water/binder ratio of all mixtures was selected as 0.6. Sodium hydroxide solutions were prepared by mixing 98% pure solid pellet NaOH with pure water and stored in closed glass jars at room temperature for 24 hours. 2 Module, 40 bome (40% Na_2SiO_3, 60% water) Na_2SiO_3 solution was commercially supplied.

Table 1. Results of Semi-Quantitative Mineralogical Analysis of Marl

Content	Calcite	Mica	Quartz	Feldspar	Smectite	Illite	Kaolinite
Amount (%)	29	23	6	5	17.7	15.5	3.7

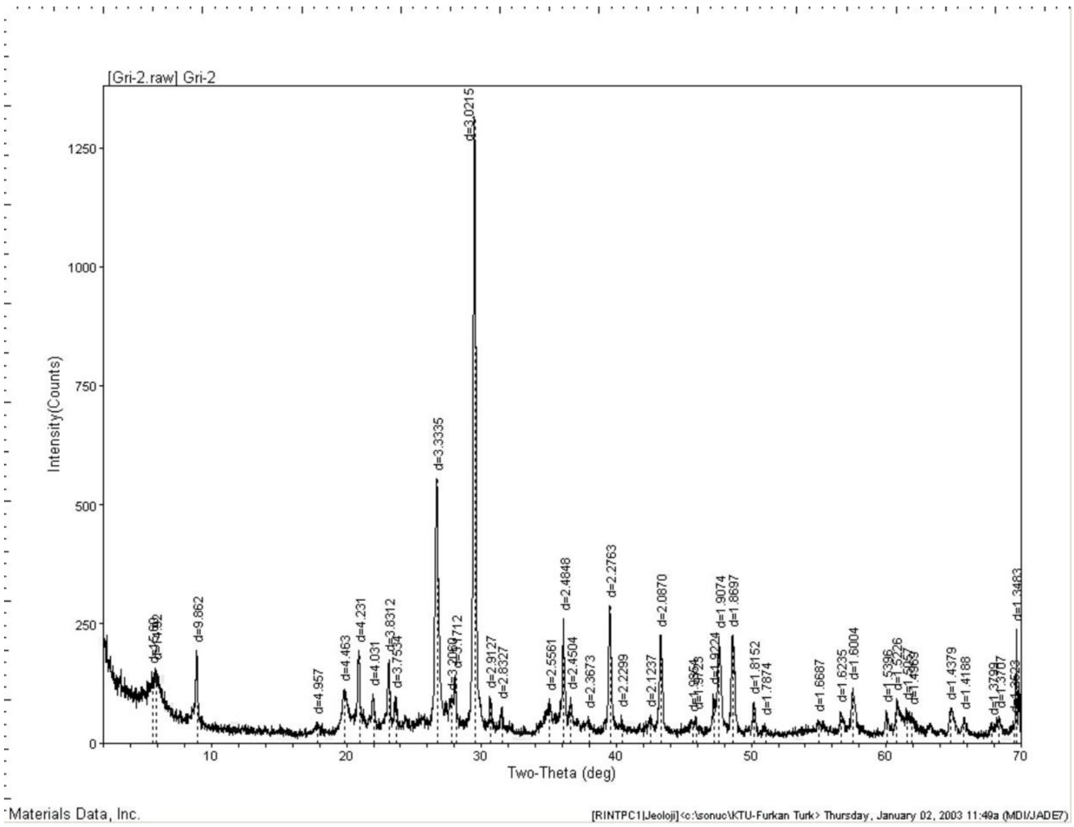

Fig. 1. XRD analysis of raw marl

2.2. Preparing of mixtures

Mixing ratios are presented in Table 2. No additional water was used in the mixtures, the total water/binder ratio included in the mixture from alkali activator solutions was selected as 0.6, binder/sand 0.5, and Na_2SiO_3/NaOH 2.5.

Sodium hydroxide, sodium silicate solutions were first mixed in a separate container and then added to the binder. The mixture was mixed at low speed for 30 seconds. Then sand was added for 30 seconds. Then the mixer was stopped and the container was scraped with a spatula, including all sides and bottom, and rested for 60 seconds. The mortar was mixed again at high speed for the next 60 seconds. After the mixing process of the geopolymer mortars was completed, they were placed into 50x50x50 mm molds. As presented in Table 2, the samples with rest periods of 0 hours (reference), 12 hours, 24 hours, 3 days, 7 days and 14 days were stored at room conditions. At the end of the rest periods, they were cured at 80 °C for 24 hours and stored by wrapping them in a bag until the test day.

Table 2. Mixtures and resting time

Sample	Binder (g)	Sand (g)	NaOH (g)	Na_2SiO_3 (g)	Resting Time (g)	Curing Temperature
R0	675	1350	193	482	0 hour	80 °C
R1/4	675	1350	193	482	6 hours	80 °C
R1/2	675	1350	193	482	12 hours	80 °C
R1	675	1350	193	482	24 hours	80 °C
R3	675	1350	193	482	3 days	80 °C
R7	675	1350	193	482	7 days	80 °C
R14	675	1350	193	482	14 days	80 °C

2.3. Compressive strength test

On the 28th day, the samples were subjected to a compressive strength test. Compressive strength test were carried out according to ASTM C1928 "Standard Test Method for Compressive Strength of Alkali Activated Cementitious Material Mortars" standard. The loading rate was selected to be 0.9 kN/s. Three cube samples were tested for each resting period and average values were obtained.

3. Results and discussion

The compressive strength results of alkali-activated calcined marl-based geopolymer mortar samples, which were subjected to a certain pre-resting period before thermal curing and then subjected to thermal curing at 80 °C for 24 hours, are presented in Figure 2. The compressive strengths of the samples were 32.62, 34.79, 39.83, 40.58, 40.86, 39.79, 38.54 MPa.

An increase in compressive strength was observed with the increase in pre-resting period. Although a slight decrease was observed after the 3-day resting period, the compressive strength increased for all samples compared to the R0 sample without any pre-resting. The compressive strength of the R3 sample increased by 25% compared to the R0 sample. Therefore, it was found that the pre-resting period was important in terms of the strength properties of geopolymer mortars.

The reasons for the strength increase in the samples cured after pre-resting were interpreted as follows in the literature: It was concluded that when there was no resting period before high-temperature curing, the rapidly formed gel covered the undissolved precursor particles and prevented further reactions (Tian et al., 2024). It shows that a pre-resting period at room temperature allowed the reactive species from the precursor material to be effectively dissolved without significant polymerization and condensation. In the presence of effectively dissolved species, heat curing after the pre-rest period causes a rapid and advanced polymerization and condensation process. In addition, geopolymer formation occurs by the interaction of the precursor material with alkaline solutions and heat. The presence of water is very important in this process because water helps the movement of ions and the progress of the reaction. However, water evaporates rapidly during heat curing and the geopolymerization process ends when it evaporates completely. This usually causes the reaction to be incomplete. If the evaporation of water is slowed down and the process is held longer, geopolymerization can be completed. A longer geopolymerization reaction time and slower water evaporation during this period may result in a more efficient geopolymerization process and a geopolymeric product with improved qualities (Durak et al., 2021). Thus, a stronger and higher quality geopolymer can be obtained. In the pre-rest period, time is given for the reaction to take place at room temperature without water evaporation, and it is thought that the strength increases in this way.

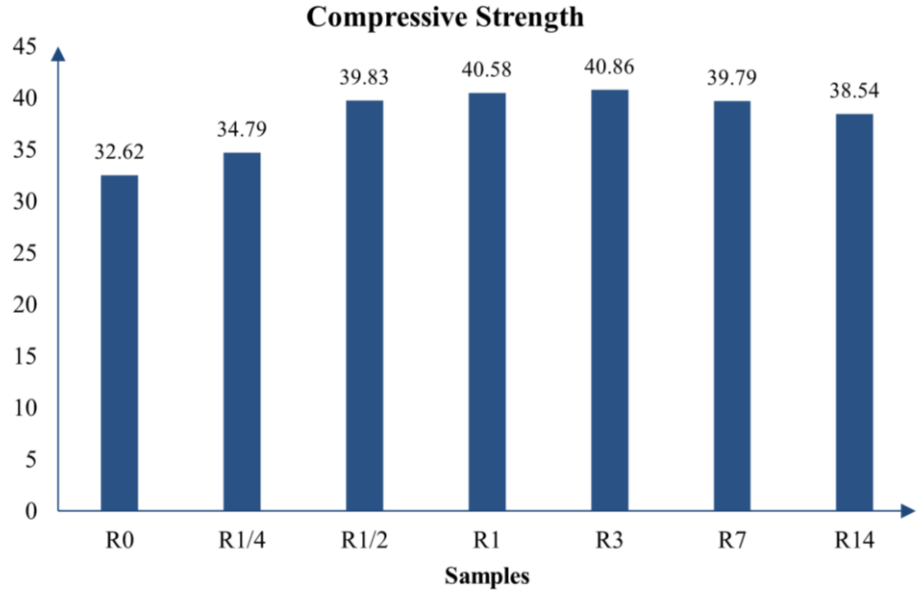

Fig. 2. 28th day compressive strength of samples

It was concluded that the application of pre-curing resting period improves the geopolymerization process and compressive strength. Therefore, it is concluded that resting period is of critical importance in terms of strength properties.

4. Conclusions

This work investigated the influence of pre-curing rest period on calcined marl geopolymer properties, and the main conclusions from the article are:

- A rest period before curing improved the compressive strength of calcined marl geopolymer mortars.
- The compressive strength of the sample with a 3-day resting period increased by 25% compared to the sample directly cured.
- Although some decrease in compressive strength was observed at rest periods longer than 3 days, rest periods up to 14 days exhibited higher compressive strength compared to the reference sample.
- These results are consistent with other studies in the literature.

Abstract. Inside Autonomous vehicle technology, is a revolution that will lead to radical changes in transport systems for the smart cities of the future. In this study, the impacts of autonomous vehicles on traffic safety and urban transport in Turkey are discussed. Based on literature reviews and analyses of existing technologies, the potential of autonomous vehicles in reducing traffic accidents, their capacity to improve the safety of road users and their contribution to sustainable transport goals will be evaluated. In the context of Turkey's specific traffic infrastructure, driver behaviour and legal regulations, problems that may be encountered during the adaptation of autonomous vehicles will be discussed. In this context, the importance of infrastructure adaptation requirements, data sharing and integration, change in driver-passenger habits, public awareness and legal regulations will be emphasised. In addition, Turkey will be compared with other countries in terms of autonomous vehicles. As a result, the impact of autonomous vehicles on urban transport will be evaluated in terms of increasing traffic safety, reducing accident rates and reducing traffic congestion. A multidisciplinary approach will be proposed for the effective management of this process. In addition, it is aimed to contribute to transport policies for the smart city concept in Turkey.

Keywords: Autonomous vehicles; Smart cities; Traffic safety; Urban transport; Sustainability

1. Introduction

Autonomous vehicle technology is one of today's fastest developing and remarkable innovative transportation solutions. Developed by combining advanced technologies such as artificial intelligence, sensors, radar systems and machine learning, autonomous vehicles have the capacity to move safely and effectively without the need for human intervention. With the potential to improve traffic safety, reduce carbon emissions and make transportation systems more efficient, these vehicles are attracting great interest from both the public and private sectors. Research and pilots in different parts of the world show how autonomous vehicles can revolutionize urban transportation, logistics and personal transportation.

There are significant differences between the level of adaptation of autonomous vehicle technologies in Turkey and the world. While investments in this technology have increased in developed countries, some cities have initiated special regulations and infrastructure works for the integration of autonomous vehicles into traffic. For example, countries such as the US, Germany and Japan have accelerated the process of establishing legal frameworks for the testing and use of autonomous vehicles. In Turkey, there is growing interest in autonomous vehicle technology, but applications in this field are mostly limited to academic research and limited-scale pilot projects. For autonomous vehicles to become widespread, key challenges such as infrastructure deficiencies, legal regulations and society's adaptation to this technology need to be overcome.

This study aims to analyze the changes that may occur in our lives with the spread of autonomous vehicles and what needs to be done to adapt to these changes. The main focal points of the research are the transformations in transportation systems, impacts on traffic safety, environmental gains and potential risks. In addition, dimensions such as social acceptance of this technology, economic impacts and infrastructure requirements will also be examined in detail. It will be discussed what role autonomous vehicles can play in Turkey's transportation systems and urban planning and what strategic steps should be taken to take advantage of this technology.

In this context, the aim of this study is not only to assess the potential impacts of autonomous vehicles, but also to provide policy, infrastructure and regulatory recommendations to maximize these impacts. This study, which will be discussed from both national and global perspectives, aims to contribute to future transportation policies.

2. Literature review

Autonomous vehicles (AVs) are revolutionizing transportation technologies with their ability to move without human intervention. Thanks to advanced sensors, artificial intelligence (AI) and machine learning algorithms, these vehicles are capable of sensing their environment and making real-time decisions (B, 2023; Pettersson & Karlsson, 2015; Zhao et al., 2018). Rapid advances in sensor technology and machine learning are accelerating the proliferation of autonomous vehicles by increasing the reliability and safety of these systems (Pettersson & Karlsson, 2015; Zhao et al., 2018).

While autonomous vehicles offer significant advantages in terms of traffic safety, environmental sustainability and transportation efficiency, public perception and acceptance of these technologies play a critical role in the adoption process. Research shows that users' biggest concern is safety and demand the highest safety standards for AVs (Bęczkowska, 2023; Kyriakidis et al., 2015). While the perception of risk and trust in technology directly affect the level of acceptance of these vehicles, the lack of experience with autonomous vehicles constitutes a significant obstacle in this process (Raue et al., 2019; Nielsen & Haustein, 2018).

Technological advances have the potential to not only increase individual safety, but also improve overall traffic flow and reduce traffic congestion. Research shows that autonomous vehicles can communicate with each other, enabling more coordinated driving behaviors and leading to improvements in traffic management (Yang et al., 2017; Wang et al., 2017). This can contribute to solving traffic problems without the need to expand road infrastructure (Chen, 2017). Moreover, the integration of autonomous vehicles into public transportation systems can provide advantages such as increasing accessibility and reducing operating costs (Guo, 2023; Ni et al., 2020). However, the integration of autonomous vehicle technology into society is not limited to technical developments. Many critical issues such as legal regulations, ethical issues, and safety verification mechanisms must be addressed in this process (Gao, 2023; Paden et al., 2016). In countries like Turkey, with its unique traffic culture, infrastructure deficiencies, and regulatory needs, the process of adapting to this technology is more complex. Traffic density, behavioral characteristics of drivers and pedestrians, and complex road conditions in Turkey are factors that need to be taken into account for the safe integration of autonomous vehicles.

3. Material-method

The development process of driverless vehicle technology has been systematically categorized by defining certain levels. In this context, the US National Highway Traffic Safety Administration (NHTSA) has conducted studies aimed at standardization in this field by classifying vehicles into various levels according to the characteristics and functionality levels of autonomous elements involved in the production and use stages of automobiles. This classification allows vehicles to be graded according to the scope of the autonomous technologies they incorporate, the level of need for human intervention and their control capabilities in driving environments. This system is an important reference for understanding the technical capabilities of autonomous vehicles and establishing regulatory frameworks. Accordingly, the levels and grades determined for autonomous vehicles are expressed as follows (NHTSA, 2013):

- Level 0: Vehicles without any autonomous system.
- Level 1: Vehicles with at least one of any critical navigation systems that operate independently of each other, not at the driver's discretion.
- Level 2: Vehicles with at least one of any automated driving systems that are under the driver's control and operate independently of each other.
- Level 3: Vehicles that can be expressed as partially driverless vehicles, where the user can use the vehicle in manual mode at any time, as well as switch to autonomous mode when needed.
- Level 4: Fully autonomous vehicles that are completely closed to driver support, managed by fully autonomous systems and in which all driving functions are used by the vehicle itself, and do not allow human intervention.

Fig. 1 shows the different levels of automation that autonomous vehicles are categorized into.

3.1. The impact of autonomous vehicles on future transportation

The future of transportation systems will be shaped by the integration of autonomous vehicles, and this change will have profound impacts on safety infrastructure, technological requirements, environmental impacts and economic outcomes. Fig. 2 shows the potential impact areas of autonomous vehicles.

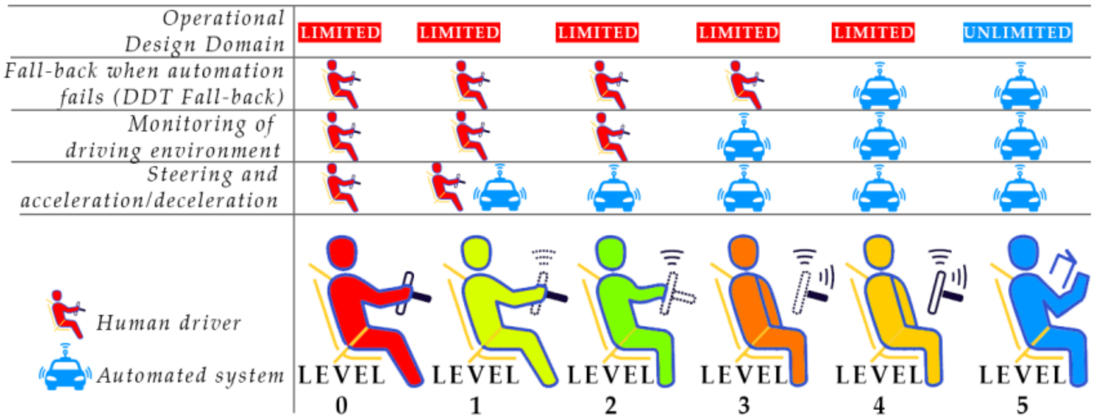

Fig. 1. Levels of driving automation (Kozlowski et. al.,2024)

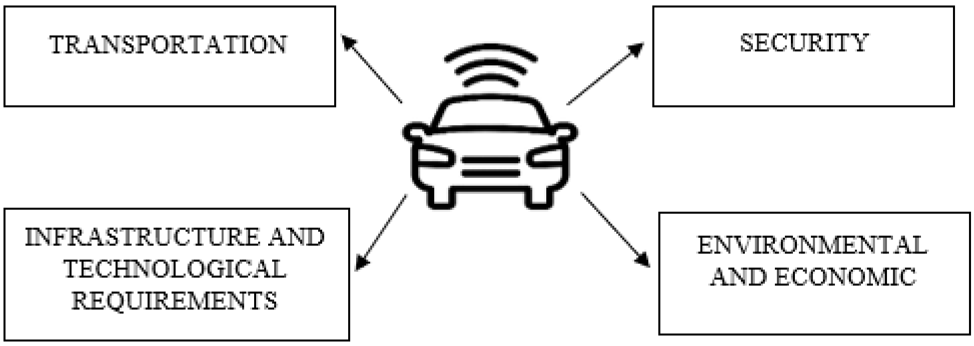

Fig. 2. The impacts of autonomous vehicles on future transportation

3.1.1. The impact of autonomous vehicles on transportation

3.1.1.1. Integration with public transportation
Autonomous minibuses and robotaxi services can be integrated with traditional public transport systems to increase the coverage and efficiency of transportation networks. By facilitating access to areas outside of fixed routes, such applications can support demand for public transport and contribute to lower urban traffic congestion by reducing the use of individual vehicles. They can also improve the user experience by providing solutions to the last mile problem of public transport systems.

3.1.1.2. Passenger and freight transportation
Autonomous vehicle technology has the potential to revolutionize the logistics industry in particular. Autonomous trucks make it possible to reduce human error, optimize fuel consumption and lower operational costs. These developments offer great advantages in terms of shortening delivery times and increasing overall efficiency in the supply chain. In terms of passenger transportation, shared autonomous vehicle models can contribute to sustainable urban transportation by enabling more efficient use of transport capacity.

3.1.1.3. Accessibility and transportation equality
Autonomous vehicles offer important opportunities for individuals with limited access to transportation systems. They can provide an independent and safe transportation alternative, especially for the elderly, people with disabilities and communities that cannot benefit from transportation infrastructure. This can support social participation and access to economic activities by increasing the mobility of individuals who cannot be an active part of social life. This would represent a significant advance in transportation equality.

3.1.1.4. Urban mobility
Autonomous vehicles have an important role in making urban transportation smarter and more sustainable. Thanks to advanced sensor systems and artificial intelligence algorithms, these vehicles can analyze traffic flow in real time and provide a more orderly and safer ride. Contributions such as reducing traffic congestion, reducing the need for parking space and minimizing carbon emissions allow for an improved quality of life in cities. At the

same time, a holistic improvement in urban mobility can be achieved by promoting a more integrated and user-friendly public transport experience.

3.1.2. Impacts on security

3.1.2.1. Decrease in traffic accidents

Autonomous vehicles have the potential to drastically reduce human errors thanks to advanced sensor systems, radars, cameras and AI-supported decision-making mechanisms. Eliminating risks arising from human behavior such as inattention while driving, fatigue, alcohol use, excessive speed, etc. can lead to a significant reduction in the number and severity of traffic accidents. This contributes not only to preventing loss of life, but also to reducing economic losses and the burden on the healthcare system.

3.1.2.2. Pedestrian and bicycle safety

Autonomous vehicle technologies can improve the safety of pedestrians and cyclists in traffic with sensors and advanced detection systems that increase environmental awareness. By recognizing road users earlier and minimizing reaction time, vehicles can greatly reduce the likelihood of collisions. It enables safe driving decisions to be made by analyzing risky situations in advance, especially at intersections, school zones and busy pedestrian crossings. This creates a more inclusive and safer environment for all users of urban transportation.

3.1.2.3. Emergency response

Thanks to their real-time data processing and environmental analysis capabilities, autonomous vehicles can make fast and effective decisions in unexpected dangerous situations. This capability makes it possible to take evasive maneuvers before a potential collision or to anticipate risky situations and implement preventive measures. In addition, it can shorten response times and reduce life risks in times of crisis with features such as giving way to emergency vehicles in traffic jams and automatically notifying authorities in case of an accident.

3.1.2.4. Risks in transition

The transition to fully autonomous systems is critical as a period when manual drivers and autonomous vehicles share the same road network. In this period, behavioral differences between human drivers and AI-based systems can pose significant safety risks. Situations such as unpredictable maneuvers, failure to use signals, and failure to fully comply with traffic rules by human drivers may not be predicted by the algorithms of autonomous vehicles. Therefore, special regulations, infrastructure investments and public awareness-raising practices for mixed traffic environment are of great importance in the transition process.

3.1.3. Infrastructure and technological requirements

3.1.3.1.Intelligent road and traffic systems

In order for autonomous vehicles to operate safely and efficiently, they must be able to communicate with their environment continuously and in real time. At this point, V2V (Vehicle-to-Vehicle) and V2I (Vehicle-to-Infrastructure) communication systems are of great importance. Thanks to these systems, vehicles can reduce accident risks and optimize traffic flow by transmitting information such as speed, location and road conditions to each other. In addition, smart traffic lights, intersections with sensors and digital information boards integrated into the infrastructure support the decision-making processes of autonomous systems and contribute to the creation of a smarter transportation network.

3.1.3.2. Road and lane arrangements

For the sensor systems of autonomous vehicles to function correctly, road markings, signage and traffic signs must be clear and up to standard. Inadequate road markings or poor surface conditions can make it difficult for autonomous systems to navigate and make decisions. Therefore, with the proliferation of autonomous vehicles, road infrastructure needs to be re-evaluated, smart intersection designs and lane arrangements need to be adapted to autonomous driving systems. These investments both increase driving safety and ensure that systems work in harmony.

3.1.3.3. Autonomous vehicle charging and maintenance infrastructure

Autonomous vehicles powered by electric motors require increasing the capacity of existing charging infrastructure. Without widespread and fast charging stations, large-scale deployment of these vehicles will not be possible. Moreover, the complex technological hardware of autonomous systems requires a restructuring of maintenance and repair processes. Unlike traditional vehicle maintenance services, new maintenance protocols need to be developed, such as software updates, sensor calibrations and control of artificial intelligence systems. This leads to the emergence of new areas of specialization in the technical service infrastructure.

3.1.3.4. Digital security and data management

Autonomous vehicles generate and process large amounts of data through sensors, GPS systems and communication networks. This data plays a critical role in both driving decisions and traffic management. However, this also brings security threats such as cyber-attacks and data breaches. Securing autonomous vehicles requires integrating technologies such as strong encryption protocols, authentication systems and cyber firewalls. In addition, transparent and ethical data management policies should be developed on how the data collected is stored, with whom it is shared and for what purposes it is used to protect user privacy.

3.1.4. Environmental and economic impacts

3.1.4.1. Reduced carbon emissions

If the majority of autonomous vehicles are powered by electric systems, this could significantly reduce fossil fuel consumption compared to conventional internal combustion engine vehicles. This can play an important role in combating global warming by contributing to the reduction of carbon emissions from transportation. Moreover, promoting electric autonomous vehicles as part of sustainable transportation policies can facilitate the achievement of national and international environmental goals.

3.1.4.2. Energy efficiency

Artificial intelligence and sensor systems used in autonomous vehicles can analyze traffic density, road conditions and weather conditions to determine the shortest and least energy-intensive routes. In addition, these systems can reduce sudden stop-starts and exhibit more balanced and efficient driving behaviors. When all these factors come together, fuel or energy consumption is minimized, resulting in significant energy savings on both an individual and societal level.

3.1.4.3. Improved air quality in cities

Integrating autonomous vehicle technology with electric systems can directly contribute to improving air quality in urban centers. Reduced particulate matter (PM) and nitrogen oxide (NOx) emissions, especially from diesel-fueled vehicles, can reduce the incidence of respiratory diseases. These improvements can have a positive impact on public health, especially in large and densely populated cities, while increasing environmental comfort levels.

3.1.4.4. Employment and economic transformation

The proliferation of autonomous technologies in the transportation sector may directly affect professions such as taxi, bus and truck drivers. While some jobs may decline over time, employment opportunities may arise in new fields such as software development, artificial intelligence engineering, data analytics, maintenance and hardware services. Managing this structural transformation in a balanced way is important to avoid sudden losses in the labor market and to provide new skills. Hence, the need for vocational training and reskilling programs will increase.

3.1.4.5. Impacts on urban planning

Autonomous vehicles reduce the need for parking spaces, allowing large areas to be reclaimed, especially in urban centers. Areas traditionally reserved for car parking can be transformed into green spaces, pedestrian paths, cycling routes or social spaces. This contributes to making cities more livable and sustainable. Furthermore, road infrastructure can be used more efficiently as autonomous vehicles improve traffic flow, which can open up new opportunities in urban transportation planning.

4. Results

With advancing technologies, transportation systems are undergoing radical changes, and autonomous vehicles are at the center of this transformation. These vehicles, which will shape the traffic of the future, offer many potential advantages such as increasing safety, reducing traffic congestion, improving energy efficiency and increasing accessibility in transportation. However, there are also challenges such as technical inadequacies, high costs, legal and ethical uncertainties. Moreover, while new business models and economic opportunities emerge with the proliferation of this technology, risks such as workforce losses in traditional transportation sectors are also on the agenda. The assessments made in this context show that a balanced and multidimensional approach should be developed in the process of integrating autonomous vehicles into transportation systems. Figure 3 presents the strengths, weaknesses, opportunities and threats of autonomous vehicles.

Strengths

1.Potential to Reduce Traffic Accidents: Autonomous vehicles have a low error rate, potential to reduce accidents.

2. Improving Traffic Flow: Congestion can be reduced through V2V communication and intelligent traffic management.

3. Artificial Intelligence and Technology Development: High engineering competence and rapid technology adoption in Turkey.

4. Environmental Benefits: Route planning that reduces fuel consumption and emissions.

5. Young Population and Technology Aptitude: Younger population is more prone to autonomous vehicles.

Weaknesses

1.Lack of Legislation: Legal regulations are not clear enough.

2.Inadequate Infrastructure: Infrastructure deficiencies, especially the inadequacy of smart signaling systems.

3.User Insecurity: Public perception of technology as unreliable, high risk perception.

4.Lack of Education and Awareness: Insufficient training and awareness for effective use of technology.

5.High Costs: High initial costs.

Opportunities

1. International Collaborations: Joint projects and technology transfer with developed countries.

2.Smart City Projects: Smart city projects in Turkey offer opportunities for autonomous vehicles.

3.Energy Efficiency and Sustainability: Contributing to environmental goals.

4.Local Production Opportunities: Supporting autonomous production with local production vehicles such as TOGG.

5.Tourism and Transportation Transformation: Integrating autonomous vehicles in tourism and transportation.

Threats

1.Cybersecurity Risks: The risk of autonomous vehicles being hacked.

2.Ethical Issues: Ethical decisions to be made in the event of an accident (who to save, etc.).

3.High Implementation Costs: High infrastructure renewal and integration costs.

4.Legal Issues: Uncertainties of liability in autonomous vehicle accidents.

5.Social Acceptance and Resistance: Distrust of the technology and loss of existing jobs.

Fig. 3. Strengths, weaknesses, opportunities and threats of autonomous vehicles

In terms of technological infrastructure, developed countries such as the United States, Germany, and Japan have made significant strides in integrating autonomous vehicles (AVs) and intelligent transportation systems (ITS). These countries have advanced digital infrastructures with the widespread adoption of 5G technology, enabling real-time data exchange and seamless communication between vehicles and infrastructure. Furthermore, high-resolution mapping and sensor systems are widely deployed, allowing for improved navigation and enhanced vehicle autonomy. The communication infrastructure, including Vehicle-to-Vehicle (V2V) and Vehicle-to-Infrastructure (V2I) systems, is well established, facilitating coordinated traffic management and safe AV operation. In contrast, Turkey has initiated the gradual implementation of 5G technology, though it is not yet available across all cities. The development of smart traffic management systems and real-time monitoring is concentrated in major cities, leaving rural areas underserved. Additionally, advancements in mapping technologies and data-sharing infrastructure are ongoing, but there is still considerable work needed to achieve the level of integration seen in more technologically advanced nations.

Developed countries have established detailed regulatory frameworks for the testing and use of autonomous vehicles. For example, in the United States, several states have legal provisions allowing the testing and deployment of AVs on public roads. These regulations also cover crucial aspects such as insurance, data security, and driver responsibility, ensuring a structured and safe deployment of AVs. Japan and Germany have similarly crafted comprehensive laws to accommodate autonomous driving technologies.Turkey, however, is still in the early stages of developing specific regulations for AVs. While there have been some discussions about integrating autonomous vehicles into the national transportation system, there is a lack of established legal guidelines regarding data privacy, safety standards, and the interaction of autonomous vehicles with other road users. As the technology progresses, regulatory frameworks in Turkey will need to be adapted to address these emerging challenges.

In developed countries, public awareness of autonomous vehicles and smart transportation systems is relatively high. Citizens are more inclined to embrace technological innovations, and there is a greater willingness to adapt to the changes brought by autonomous mobility. This readiness facilitates the smoother integration of AVs into the existing transport infrastructure. In Turkey, however, while there is a growing interest in autonomous technologies, public awareness remains limited. Awareness campaigns and educational initiatives are necessary to inform users about the benefits and safety features of AVs. Furthermore, driving behaviors and adherence to traffic laws are crucial factors that may influence the successful integration of autonomous vehicles. In particular, it is essential to foster a driving culture that aligns with the autonomous driving technology's capabilities to ensure smoother transitions to AV-centric transportation systems.

In developed countries, the environmental benefits of autonomous vehicles are becoming increasingly evident. The widespread adoption of electric and autonomous vehicles has contributed to a reduction in carbon emissions, helping to meet climate goals. Additionally, smart transportation systems, such as intelligent traffic management and dynamic pricing, have optimized traffic flow and reduced congestion, further supporting sustainability. Turkey is experiencing a gradual increase in the use of electric vehicles (EVs); however, the adoption rate remains lower compared to that in developed nations. Traffic congestion and air pollution remain significant issues, particularly in major cities like Istanbul and Ankara, where vehicle numbers and emissions continue to rise. The introduction of AUS can play a crucial role in addressing these challenges, offering solutions for traffic management and environmental improvements. By integrating smart systems and promoting electric vehicle use, Turkey can reduce its carbon footprint and improve overall urban mobility.

In conclusion, while Turkey has made strides in developing autonomous and intelligent transportation systems, it still lags behind more advanced nations in terms of technological infrastructure, legal frameworks, and public awareness. The successful integration of autonomous vehicles in Turkey will require a multi-faceted approach, including investment in infrastructure, legal reform, and public education, to fully realize the potential benefits of these innovations in the transportation sector.

5. Conclusion

The rapid development and adoption of autonomous vehicles (AVs) and Intelligent Transportation Systems (ITS) hold immense potential for transforming urban mobility, improving safety, and promoting environmental sustainability. As demonstrated by the comparison between developed countries and Turkey, significant advancements have been made in infrastructure, regulatory frameworks, and public awareness in regions such as the United States, Germany, and Japan. However, Turkey still faces several challenges in fully integrating these technologies into its transportation system.

The integration of autonomous vehicles and smart transportation systems in Turkey is an ongoing process, with progress being made in major urban areas. However, to achieve the full benefits of these technologies, it is essential to address gaps in technological infrastructure, regulatory frameworks, and public awareness. Currently, Turkey's digital and regulatory infrastructure is under development, and its adoption of autonomous vehicles is not as widespread as in other developed countries. While there is interest in electric and autonomous vehicles, there is a need for stronger incentives and a supportive ecosystem to accelerate this transition.

The environmental and traffic management challenges faced by Turkey's rapidly growing urban population can be significantly mitigated by the widespread adoption of AUS and electric vehicles. By optimizing traffic flow, reducing emissions, and promoting sustainable mobility, these technologies can contribute to a more efficient and cleaner transportation system. Suggestions:

- Rapid Expansion of 5G Technology: To facilitate the effective functioning of autonomous vehicles and smart transportation systems, the rapid nationwide rollout of 5G technology should be prioritized. This will support real-time communication, vehicle-to-vehicle (V2V) and vehicle-to-infrastructure (V2I) systems, and enhanced data sharing capabilities.
- Integration of Smart Traffic Management Systems: Investment in smart traffic signalization systems and advanced traffic monitoring infrastructure should be accelerated. This includes the integration of AI-based

solutions that can manage traffic flow dynamically, reduce congestion, and prioritize autonomous vehicles, ultimately leading to smoother and safer traffic conditions.

- Development of Legal and Regulatory Frameworks: Turkey must expedite the development of comprehensive laws and regulations for autonomous vehicles, ensuring that safety standards, insurance policies, and data privacy laws are clearly defined. A national regulatory framework should be established for the testing, deployment, and use of AVs on public roads, taking into account global best practices.
- Public Awareness and Education: To ensure a smooth transition to autonomous and smart transportation systems, it is crucial to raise public awareness. Public information campaigns about the benefits and safety of autonomous vehicles should be launched. Additionally, pilot projects and test drives should be organized in major cities to build trust and familiarity with the technology among the public.
- Promotion of Electric Vehicles (EVs): To enhance environmental sustainability, incentives for electric vehicles should be expanded. Subsidies, tax breaks, and government-supported charging infrastructure would encourage individuals and businesses to adopt EVs, contributing to a reduction in carbon emissions and air pollution.
- Addressing Traffic Congestion: Smart transportation systems, such as dynamic pricing and intelligent route management, should be adopted to optimize traffic flow, reduce congestion, and improve the efficiency of both autonomous and traditional vehicles. Additionally, policies that encourage car-sharing and the use of public transport can help alleviate the strain on urban road networks.
- Collaboration with International Stakeholders: Collaborating with international experts, private sector partners, and research institutions can help accelerate the development of Turkey's autonomous vehicle infrastructure. Learning from the experiences of countries with established AV and AUS systems can guide Turkey in overcoming challenges and maximizing the potential of these technologies.

The future of transportation in Turkey hinges on the integration of autonomous vehicles and intelligent transportation systems. These technologies offer the potential to address traffic congestion, reduce emissions, and improve safety, but achieving these benefits will require concerted efforts across multiple sectors. By investing in technology, legal frameworks, public education, and infrastructure, Turkey can position itself as a leader in smart mobility, ensuring that its transportation system becomes more efficient, sustainable, and inclusive for all citizens.

Investigating the effect of polyamine fatty acid on the moisture sensitivity of warm mix asphalt mixtures

Sepehr Saedi *[1], Mohsen Seyedi[1], Sepanta Naimi[1]

[1] *Altinbas University, Department of Civil Engineering, 34200 Istanbul, Türkiye*

Abstract. The moisture sensitivity of warm mix asphalt (WMA) is a critical factor in the damage process of asphalt pavements. Therefore, using anti-stripping additives to mitigate moisture-induced changes is essential. This study investigated the effect of a Polyamine Fatty Acid (PFA) additive on improving WMAs' moisture sensitivity. To achieve this, various amounts of the additive, specifically 0.2%, 0.25%, 0.3%, 0.35%, and 0.4% by weight of the binder, were incorporated into the mixtures. A series of tests were conducted, including the boiling water test, saturated Marshall stability test, and modified Lottman tensile strength test. The results demonstrated that the additive samples exhibited better moisture resistance under saturated conditions than those without. Notably, the use of 0.35% of this additive significantly enhanced the moisture damage resistance of the prepared mixtures to an acceptable level.

Keywords: Warm mix asphalt**,** Polyamine Fatty Acid , Moisture damage, Stripping, Tensile strength

1. Introduction

The use of warm mix asphalt (WMA) technology has significantly increased in recent years, primarily to protect the environment and reduce energy consumption. However, despite its numerous benefits, WMA is still used less frequently than hot mix asphalt (HMA) due to its comparatively lower performance. One key factor contributing to the lower performance of WMA is its high sensitivity to moisture (Zhang et al., 2025). In challenging weather conditions, stresses are applied to the surface layer, increasing the strain. Inadequate supervision, traffic, and water play a key role in the damage of asphalt concrete coatings. Water causes the loss of adhesion at the contact surfaces between the bitumen and aggregate particles. This type of early adhesion loss is typically referred to as "stripping" in asphalt coatings (Naser et al., 2023). The sensitivity of hot mix asphalts to moisture-induced damage is critical for assessing the vulnerability of the surface layer. When aggregates detach from the asphalt mix, the mix's strength decreases. This reduction in strength can lead to several issues within the layers, including cracking, detachment, and rutting caused by wheel pressure (Kok & Yilmaz 2009). Factors such as the properties of bitumen, characteristics of the aggregate materials, the features of asphalt mixes, quality control during compaction, and the impact of dynamic traffic loads play an important role in creating moisture sensitivity and exacerbating the damage (Hesami et al., 2015).

In surface layer design, there are significant differences between laboratory results and those obtained under real-world conditions. In the lab, mechanical results are generally better than those obtained in real-world conditions. Specifically, with the Marshall compaction method, the volume of voids in practice is usually higher than the volume of voids observed in laboratory tests (Brown & Bitutest 1995).

In a study, lime filler and anti-stripping liquid were tested as materials to prevent stripping in WMA. The findings revealed that the anti-stripping liquid was more effective at reducing stripping compared to lime filler. However, taking into account economic considerations and the necessity to meet technical standards to prevent stripping, the combination of these two materials emerged as the best mixture for achieving optimal performance. This combination is especially recommended in situations where both cost savings and technical efficiency are priorities (Mahdi et al., 2024). The use of the Sasobit Redox additive in various gradations demonstrated its ability to enhance the moisture resistance of WMAs. This improvement is attributed to an increase in the indirect tensile strength (ITS) of the mixtures. Test results indicated that the most significant enhancement in ITS occurred with the addition of 2.5% Sasobit Redox to the gradations (Taher et al., 2024). Research indicates that adding carbon fibers to hot asphalt mixtures increases their resistance to water damage and enhances the ability of bitumen to bind the aggregate materials together. This improvement ultimately boosts the performance and longevity of asphalt concrete (Saedi & Oruc 2020). Studies have shown that Nano-Zycotherm helps make warm mix asphalts

*Corresponding author, E-mail: Sepehr.saedi@altinbas.edu.tr

https://doi.org/10.31462/icearc2025_ce_tra_009

(WMAs) more resistant to moisture, but its impact on rutting failure remains unclear. In contrast, Sasobit improves the strength and stiffness of WMAs and reduces their vulnerability to permanent deformation (Behbahani et al., 2016).

Research has shown that adding Evotherm and paraffin wax is not effective in reducing moisture susceptibility in asphalt mixtures (Yu et al., 2016). The results from Nicholson stripping tests indicate that both nano-bentonite and fatty Arbocel additives significantly improve the adhesion between aggregates and bitumen in Warm Mix Asphalts (WMAs). Consequently, it is recommended that WMAs modified with these additives are particularly effective in resisting stripping, especially in cold and wet regions. Both nano-bentonite and fatty Arbocel enhance the moisture resistance of WMAs. The test results show that the highest Tensile Strength Ratio (TSR) was found in samples containing 0.7% nano-bentonite and 0.3% fatty Arbocel. Although these additives require lower mixing temperatures, which usually increase a mixture's sensitivity to moisture, the inclusion of nano-bentonite and fatty Arbocel effectively counteracts the functional weaknesses associated with moisture-induced damage. This makes them a valuable choice for enhancing the performance of asphalt mixtures in wet conditions (Saedi & Oruc 2020).

2. Materials and methods

2.1. Aggregates

In this study, basalt aggregates were utilized. Table 1 displays the characteristics of both coarse and fine aggregates.

Table 1. Aggregate characteristics

Characteristic	Code	Unit	Results
Coarse Specific gravity	ASTM C-127-15	gr / cm3	2.881
Fine Specific gravity	ASTM C-128-15	gr / cm3	2.747
Filler specific gravity	ASTM C-128-15	gr / cm3	2.887
Los Angeles	ASTM C-131	%	11
water absorb	ASTM C-127-15	%	0.96
Elongated- Flat	ASTM D-4791	%	11.5
Crushed content (two faces)	ASTM D-5821	%	98

2.2. Binder

In this study, the binder used is PG 58-22, produced by Tupras Company. The physical characteristics of the used binder are outlined in Table 2.

Table 2. The physical properties of PG 58-22 binder

Test	Code	Unit	Results
Specific Gravity	ASTM D-70	gr/cm3	1.022
Ductility	ASTM D-113	cm	>100
Viscosity	AASHTO T316	Pa.s	135
Dynamic shear (G*/sin)	AASHTO T315	KPa	60
Flash Point	AASHTO T48	˚C	230

2.3. Polyamine fatty acid

Table 3 presents some physical properties of the additive, including Polyamine Fatty Acid, utilized in this research.

Table 3. The physical properties are additive

	Polyamine Fatty Acid
Physical form	Liquid
Flash Point	Up to 180$^{˚C}$

2.4. Samples provided

The samples tested in this study were cylindrical, with a diameter of 4 inches (101.6 mm) and an approximate height of 2.5 inches (63.5 mm). To prepare the samples, various aggregate components were weighed and mixed in a container before being poured into a Marshall mold. Each side of the mold received 75 blows to simulate heavy traffic conditions. After compaction, the samples were removed from the mold 24 hours later using special jacks and prepared for further testing. Six types of mixtures were prepared: asphalt without additives and asphalt containing 0.2%, 0.25%, 0.3%, 0.35%, and 0.4% by weight of the binder, following the modified Marshall method (Saedi 2024).

2.5. Boiling water test

In this test, we visually assess different levels of stripping after boiling an uncondensed asphalt mixture for 10 minutes. We begin by pouring 500g of water into a container and heating it until it reaches boiling. Next, we add 250g of the uncondensed sample to the boiling water, stirring every three minutes for 10 minutes. After boiling, we let the container cool to room temperature, then pour out the water for further analysis. The mixture is placed on a white surface, and we remove any bitumen that has floated to the water's surface to prevent it from reappearing. Observing the stripped material will help us determine the failure criterion (Fakhri 2021).

2.6. Immersion marshall test

The Immersion Marshall test is used to evaluate the moisture sensitivity of asphalt mixtures. According to AASHTO T-165, the specimens are divided into two distinct groups. Conditioned specimens are immersed in water for 48 hours at a temperature of 60°C, while unconditioned specimens are immersed for 30 minutes at the same temperature. After immersion, the Marshall stability test is performed on both groups of samples. The retained Marshall stability (RMS) is then calculated using Equation (1).

$$RMS\% = \frac{MSconditined}{MSunconditioned} * 100 \tag{1}$$

where, MSconditined is the average Marshall stability of conditioned samples and MSunconditioned is the average Marshall stability of unconditioned samples (Saedi 2024).

2.7. Lottman tensile strength test

Latman has conducted an indirect tensile test to assess the moisture sensitivity of asphalt mixtures under real traffic service conditions. In this test, as outlined in the AASHTO T283 code, one group of samples is tested in a dry condition, while another group is conditioned with moisture before testing. The Indirect Tensile Strength Ratio (TSR) is calculated by comparing the indirect tensile strength of the saturated samples to that of the dry samples (Saedi & Oruc 2022).

$$ITS = \frac{2Pmax}{\pi Dt} \tag{2}$$

$$TSR = (ITS\ wet/ITSdry) \times 100 \tag{3}$$

3. Results and discussion

The results of the experiments were discussed and analyzed based on each case.

3.1. Boiling water

The visual test results are shown in Figure 1. These findings indicate that incorporating modified bitumen with PFA significantly enhances the adhesion strength between the aggregates and the bitumen. It appears that PFA helps form a strong bond, ensuring a more stable connection between the aggregates and the bitumen. Upon closer examination of the results, it is evident that the mixture's resistance to stripping improves as the percentage of PFA increases. This suggests that higher concentrations of PFA contribute to greater durability and performance in WMAs, particularly by enhancing bond stability and reducing the likelihood of stripping under challenging conditions.

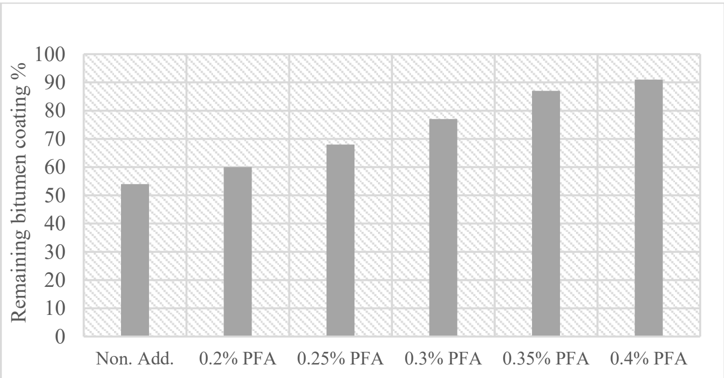

Fig. 1. The result of the boiling water test

3.2. Immersion marshall

Figure 2 presents the findings of the current study. The results indicate that increasing the percentage of PFA up to 0.35% significantly enhances the immersion Marshall value.

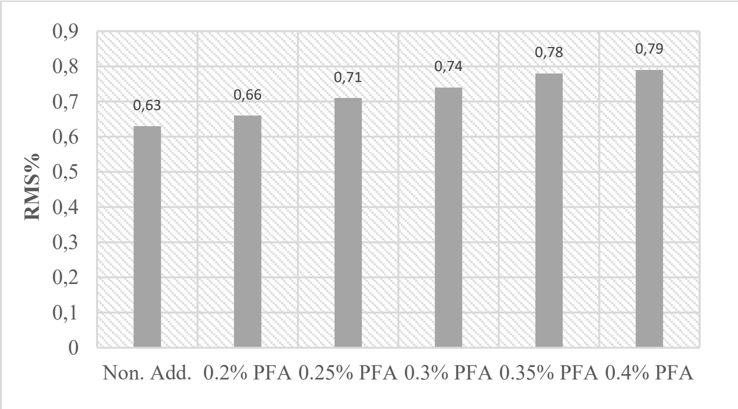

Fig. 2. The results of the Immersion Marshall Test

PFAs exhibit amphiphilic behavior due to the presence of both hydrophilic functional groups, such as amino ($-NH_2$) and carboxyl ($-COOH$) groups, and hydrophobic hydrocarbon chains. These active sites facilitate chemical interactions with mineral surfaces within asphalt mixtures, particularly by forming ionic or covalent bonds with the polar sites on aggregate particles. This molecular interaction significantly enhances the adhesive bonding between the bitumen binder and aggregates, which is critical for the mechanical integrity of the asphalt mixture.
Furthermore, the incorporation of polyamine fatty acids contributes to the formation of a denser and more uniform microstructural matrix. This microstructure acts as a barrier to water penetration, thereby mitigating moisture-induced damage mechanisms such as stripping. The resultant compact texture not only improves resistance to water infiltration but also supports the long-term durability of the mixture. Empirical evaluations, such as the immersion Marshall stability test, indicate a notable improvement in performance under water-saturated conditions for asphalt mixtures containing these additives. This enhancement is particularly relevant for WMAs, which are inherently more susceptible to moisture damage due to reduced mixing temperatures and potential limitations in binder-aggregate interaction. By addressing this vulnerability, polyamine fatty acid additives may contribute to an extended service life and enhanced moisture resistance of WMAs.

3.3 Lottman test
The results of the tensile strength ratio of the samples are shown in Figure 5.

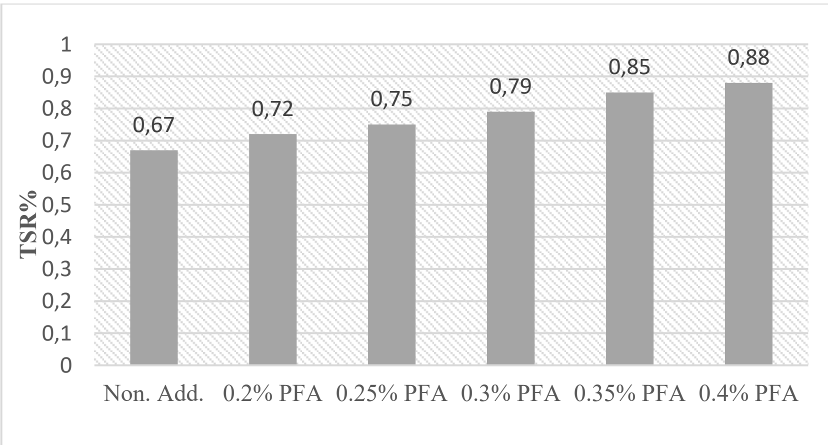

Fig. 3. The results of the Latman test

As shown, the TSR of mixtures with 35% is above 80%, and they all pass the Superpave limit. It can be stated that the FRP additive increases the resistance of the mixtures to moisture. Polyamines affect the tensile strength ratio by improving the chemical bonds between bitumen and mineral aggregates. These additives enhance the asphalt's ability to resist tensile stresses by forming hydrogen and covalent bonds while also preventing the bitumen from overheating and degrading. Additionally, polyamines significantly improve the performance of asphalt in wet conditions by mitigating the negative effects of moisture and other environmental factors. As an additive in warm mix asphalts, polyamine-based amino acid additives positively impact the tensile strength ratio. By improving the adhesion of bitumen to mineral aggregates, reducing asphalt's susceptibility to moisture and temperature variations, and enhancing the overall stability of the asphalt, these additives increase the performance and durability of the asphalt. This is particularly beneficial in areas exposed to harsh weather conditions or heavy traffic, where the use of such additives can substantially extend the lifespan of the asphalt. Therefore, incorporating polyamine amino acids into asphalt mixtures is an effective strategy for enhancing the performance of these materials, which can reduce road and highway maintenance and repair costs.

4. Conclusions

This study aimed to evaluate the effects of Polyamine Fatty Acid additives on the performance of the warm mix asphalts against water damage. Below are the results of the investigation.

- The results of the boiling water test show that the PFA additives fully function as an anti-stripping agent, such that increasing the percentage of this additive in the mixture improves its performance against the stripping phenomenon.
- PFAs help in the densification of warm mix asphalt samples by creating microscopic matrices, and denser samples exhibit better Marshall stability in both dry and saturated conditions.
- The RMS index is one of the important factors in determining the behavior of asphalt mixtures against moisture damage. According to the results, PFAs play a significant role in improving this index. Therefore, it can be said that this type of additive can address the weaknesses of warm mix asphalt mixtures in this regard.
- Based on the results of the Latham test, adding 0.35% of the PFA-containing additive provides the specified acceptance limit for warm mix asphalt mixtures. Therefore, it can be concluded that the optimal amount of this additive in warm mix asphalt mixtures is 0.35%.
- Given that moisture weakness leads to premature failure of warm mix asphalt mixtures, the use of the PFA additive can play a beneficial role in increasing the service life of these types of pavements and reducing maintenance and repair costs.

Abstract. Maintaining a safe following distance is crucial for ensuring driving safety in tunnels, as its violation can increase the likelihood of accidents and disrupt traffic flow. This study examined the impact of a visual marking system known as "chevrons," applied at 50-meter intervals on the asphalt, designed to encourage drivers to maintain proper following distances in tunnel environments. The research was conducted in a driving simulator at the Autonomous Driving Techniques and Driver Behaviour Detection Laboratory at Erzincan Binali Yıldırım University, involving 65 participants. Through simulator-based experiments, driver behavior was evaluated under varying traffic densities and speed limits to assess the effectiveness of the chevron markings. The findings demonstrated that chevron markings positively influenced driver behavior. Drivers showed increased awareness, reduced their speed, and adjusted their following distances more appropriately. Moreover, the markings contributed to lower stress levels and facilitated better decision-making in traffic. These improvements were particularly evident under heavy traffic conditions, where maintaining safe distances is typically more challenging. Overall, the study concluded that chevron markings offer a practical and effective solution for enhancing in-tunnel traffic safety. Their implementation can help reduce accident rates and improve traffic flow, particularly in densely trafficked tunnels. As a low-cost and easy-to-implement strategy, this approach has strong potential for broader application in future tunnel designs and intelligent traffic management systems. The chevron system represents a promising contribution to safer and more sustainable transportation infrastructure.

Keywords: Tunnel safety; Chevrons marking system; Driver behaviour; Traffic flow analysis; Simulator based experiment

1. Introduction

Road transportation represents one of the most essential infrastructure systems facilitating the mobility of individuals, goods, and services on a global scale. However, the safety and sustainability of this system vary considerably depending on road types and environmental conditions. Highway tunnels, with their low illumination, monotonous surroundings, and limited visual cues, create a weak and insufficient visual environment that can lead to visual illusions and impair drivers' ability to accurately perceive their speed (Wan et al., 2018). Driving in enclosed road environments, such as tunnels, requires particular attention and behavioral adaptation from drivers (Ozturk et al., 2024). In this context, various engineering solutions have been developed to enhance driver performance and promote safe driving behavior, especially in physically constrained settings like tunnels. Studies have shown that chevron alignment signs improve drivers' focus on the roadside, reduce stress levels, and contribute to speed reduction in curves, thereby encouraging safer driving behavior in confined spaces (Wu et al., 2013). Fiolić et al. (2023) emphasized that well-designed and properly positioned road markings and signs can significantly improve driver behavior and enhance overall traffic safety. Traffic control devices including pavement markings like chevrons are considered vital components of road safety strategies aimed at influencing driver behavior and enhancing roadway safety (Babić et al., 2020). While vertical chevron signs have been extensively studied, recent research has begun to explore the potential benefits of horizontal chevron markings applied directly to the road surface (Fig. 1).

https://doi.org/10.31462/icearc2025_ce_tra_029

Fig. 1. Chevron applications in real highways (Mock Theory Test, 2025; Sabre Roads, 2025)

These markings are hypothesized to support following distance awareness and speed adaptation, especially under heavy traffic or low visibility. This represents a novel direction in traffic safety research and forms the foundation of the current study. So this study conducted a simulator-based study to evaluate how horizontal chevron markings influence driver behavior in tunnel environments. Amini et al. (2023) highlighted that driving simulators constitute a robust and reliable method for investigating driver behavior, offering a controlled and replicable environment to examine complex and high-risk scenarios that are impractical to study in real-world traffic conditions.

To investigate the impact of chevron markings on tunnel driving safety, an experimental simulator-based study was conducted at the Autonomous Driving Techniques and Driver Behavior Observation Laboratory of Erzincan Binali Yıldırım University. The sample included 65 participants with diverse backgrounds in age, gender, and driving experience. Each participant engaged in simulated driving scenarios involving tunnel environments with and without chevron markings, under varying traffic densities and speed limits.

2. Literatue review

In the literature, chevron signs are predominantly examined as vertical traffic control devices placed along road edges to warn drivers about upcoming horizontal curves. These vertical signs function as visual cues intended to enhance curve perception and promote speed reduction (Wu et al., 2016). For instance, Zhao et al. (2015) analyzed the impact of chevron alignment signs on driver performance under various roadway geometries and concluded that such signs significantly improved vehicle positioning and speed control on curves. Similarly, Babić et al. (2022) focused on how different chevron color combinations influence driver behavior in simulated rural road environments. Their results showed that all chevron variants reduced driving speeds, with fluorescent and white background signs being the most effective. These findings collectively highlight that the design and placement of vertical chevron signs play a critical role in curve negotiation and road safety, emphasizing the importance of visual contrast and clarity in guiding driver behavior. Research also suggests that properly spaced chevron signs can encourage drivers to reduce their speed when entering and traveling through curves (Srinivasan et al., 2010). In the U.S. studies have primarily examined the influence of chevrons on vehicle dynamics such as speed and lane positioning, as well as on criteria for optimal placement to enhance their effectiveness (Zhao et al., 2015). Zhao et al. (2017) examined the effects of differently colored chevron signs on drivers' visual responses and speeds in order to enhance curve safety under snowy and icy road conditions. Using visual feedback metrics such as fixation duration and pupil size, the study found that proper color selection helped drivers reduce their speed when approaching curves and made it easier for them to perceive road alignment. These findings provide valuable references for highway warning systems and intelligent vehicle design.

A study conducted in Denmark reported that nearly 45% of injury accidents on freeways involve vehicles traveling in the same direction; however, on freeways equipped with chevron markings, fewer rear-end accidents were observed as drivers maintained safer following distances (Greibe, 2010). Another study in Western Australia highlighted that enhanced chevron alignment markers could reduce crashes by up to 47% when combined with other delineation treatments (Palamara et al., 2014). In a study by Helliar-Symons and Butler (1995), French-designed chevron markings were tested on the M1 motorway in the UK, where inverted "V" shaped patterns were applied at 40-meter intervals on the nearside and center lanes. Drivers were instructed via roadside signs to "Keep apart, 2 chevrons." Their findings indicated that these markings contributed to a 56% reduction in accidents compared to control sections. It was also observed that the positive effect on safety extended up to 18 kilometers beyond the start of the chevron-marked area. Although the intervention primarily targeted multi-vehicle collisions, a significant decrease in single-vehicle accidents was also recorded, suggesting that chevron markings may broadly enhance driving behavior and overall roadway safety (Helliar-Symons & Butler, 1995). Merat & Jamson (2013) conducted a simulator-based study following a consultation workshop with highway engineering experts. Based on these workshops, three engineering treatments were selected and implemented: transverse rumble strips, chevron markings, and variable message signs (VMS) (Fig. 2).

Fig. 2. The chevrons (left) rumble strips (middle) and VMS (right) used in the study (Merat & Jamson, 2013)

In the study, chevrons (commonly used in the UK to indicate safe following distances) were applied across all three lanes, with markings spaced every 40 meters over a 3 km section of road. In their study, Merat & Jamson (2013) found that all three low-cost engineering treatments effectively alleviated driver fatigue, with no significant difference in the alerting effects of the treatments. Historically, chevrons in the UK have primarily used to encourage speed reduction, such as on motorways (Helliar-Symons et al., 1995). Voigt & Kuchangi (2009) evaluated the impact of converging chevron pavement markings on speed reduction on freeway-to-freeway connector ramps. They found that the chevron markings effectively reduced vehicle speeds, with a significant reduction of approximately 4 mph observed for heavy trucks. The speed reduction varied based on vehicle class and location along the curve, indicating that chevron markings are an important factor in influencing driver behavior and improving safety on ramp curves. A study conducted in Georgia and New Mexico examined the effects of different curve delineation treatments on vehicle speed and placement on rural two-lane highways. The research found that chevron signs, particularly those with retroreflective materials, played a key role in improving vehicle positioning by reducing encroachment into opposing lanes and shifting vehicles toward the centerline.

While chevrons were part of a broader range of treatments, including post-mounted delineators and raised pavement markers, the findings highlight the importance of chevron markings, especially in enhancing lane positioning and promoting safer driving behaviors. Notably, the chevrons used in this study were vertical signs, and their effectiveness in reducing speed variability and improving curve-following behaviors suggests that clear curve delineation, including chevrons, helps drivers better recognize upcoming curves and adjust their driving accordingly (Zador et al., 1987). Hunter et al. (2014) highlighted that a somewhat nontraditional but potentially effective method to reduce excessive speeds is by altering drivers' perception of a road's traversable speed. One such approach, first proposed in Japan over two decades ago, involves the use of converging chevron pavement markings, which have recently gained increasing attention in the United States. Hunter et al. (2014) found that chevron markings led to significant crash reductions of 76% and 87% in the 20 months after installation, compared to only 15% and 20% reductions at control ramps. These results indicated that the chevrons effectively enhanced safety, prompting the identification of additional sites with high potential for safety improvements. Chevron or herringbone pavement markings have been shown to significantly reduce vehicle speed and improve drivers' lane positioning (Godley et al., 2002; Charlton, 2007a, b). These treatments are also effective in emphasizing perceptual cues at critical locations such as highway curves, ramps, or tunnels, enhancing overall safety (Retting et al., 2000; Gilmore et al., 2013).Wan et al. (2018) conducted an experimental study to examine the influence of sidewall marking angles and lengths on drivers' speed perception in low-luminance highway tunnels, utilizing a three-dimensional tunnel model within a driving simulator. Their findings indicated that appropriately configured sidewall markings led to an overestimation of speed by drivers, thereby increasing sensitivity to speed variations and contributing to the regulation of unintended acceleration. They concluded that this effect could support efforts to reduce speeding behavior and enhance overall driving safety in tunnel environments.

A review of the literature reveals that various chevron applications (including both horizontal and vertical markings) have generally produced positive outcomes in improving driver behavior and enhancing road safety. Vertical chevron signs have been shown to improve curve perception, promote speed reduction, and enhance lane positioning. Horizontal chevron markings have also demonstrated effectiveness in reducing vehicle speeds and influencing drivers' perceptual judgments. However, it is evident that there is a limited number of studies specifically investigating the effects of horizontal chevron markings in tunnel environments, highlighting the need for further research in this area.

3. Material and methods

3.1. Driver properties and driving simulator

In the simulator tests, 65 drivers (14 female, 51male) attended in the driving simulator tests voluntarily (mean age = 38.7 years, SD = 10.3; age range: 21–76). All test drivers held valid driving licenses ranging from 2 to 37 years of experience (mean = 17.9 years). Volunteer drivers were randomly selected from various age and gender groups within the tunnel's surrounding area, minimizing demographic and cultural bias. While some had prior simulator experience, all were familiar with tunnel driving because of the hihgh tunnel roads in Türkiye. An tthical approval was granted by the university's ethics committee for the test with volunteer drivers. In the study, all driving tests took place at the Driving Simulator and Traffic Analysis Laboratory at Erzincan Binali Yıldırım University. The used simulator, based on a Fiat Egea hatchback with operational pedals, steering, and gearbox, integrates visual and audio systems with developed software. The visual output is displayed on a 60° curved screen (8 m × 2.5 m), projecting images of all tunnel environments to match real New Zigana Tunnel conditions given in Fig. 3 (Kircher & Ahlstrom, 2012). Projector calibration was based on real-world luminance measurements to ensure simulation accuracy during the tests.

(a)) (b)

Fig. 3. (a) Inside view and (b) outside view of the developed simulator system

A special simulator software was developed to record and examine driver behavior, including speed, trajectory, and timing. This software has a synchronization ability for vehicle control inputs, projection visuals, and sound at the same time. The developed software and connected system offers full HD visual fidelity with a 60° field of view. Speed and gear indicators are also projected onscreen to supply easy utilization to test drivers, and an in-vehicle camera records driver behavior and surroundings. The driving experiments took place between April and July 2024, with all volunteer drivers. Prior to the test sessions, participants received introductory information about the tunnel route and the simulator system. To help drivers acclimate to the simulator's controls, such as the gears, steering, and braking, each completed a 1 km neutral practice route that included a tunnel segment. This initial session ensured they were comfortable with the system before beginning the main test. After the familiarization run, participants proceeded to drive the 6.3 km test route, completing three separate scenario runs. Before the driving tests, all attendees were fully informed about all audio-visual recordings and simulator system definetly (Fig. 4).

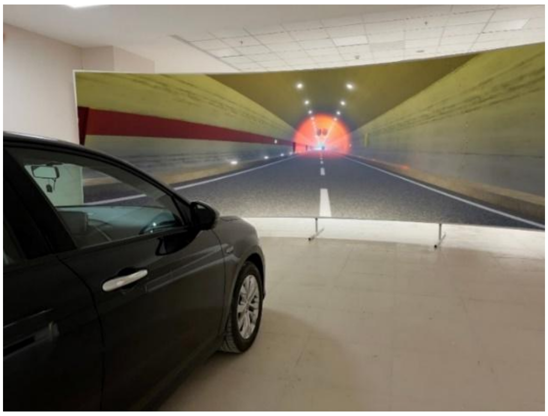

Fig. 4. A typical view of driving simulator platform

3.2. Virtual tunnel design and chevrons

The simulated road was modeled on the Zigana Tunnel in Trabzon, Türkiye, a twin-tube tunnel spanning 29 km (14.5 km per tube), making it Europe's longest and the world's third-longest twin-tube tunnel (General Directorate of Highways, 2024) (Fig. 5). The simulation replicated tunnel infrastructure, including lighting, wall patterns, signage, advertisements, shoulders, emergency lanes, and ventilation shafts. In the developed simulator, the 6.3 km test route featured two lanes in each direction, a posted speed limit of 80 km/h, minor gradients, and a 0.6 km horizontal curve. Weather conditions were set to sunny, and traffic volume was maintained at approximately 500 vehicles/hour, reflecting typical peak-hour conditions observed on examined road site. To match real-world driving conditions, traffic flow remained free of congestion. Tests were conducted in the morning to minimize fatigue effects. Although the simulator lacked lateral motion axes, realism was enhanced through a wide field of view, authentic vehicle controls, realistic sound effects, and detailed 3D environments, including accurate tunnel geometry and traffic simulation. Real roadside photographs were overlaid in the simulation software to create an authentic visual environment. All environmental and infrastructural elements of the Zigana Tunnel were accurately integrated into the virtual scene. Free-flow traffic conditions were consistently applied in all experiments, replicating actual tunnel conditions. The geometric characteristics of the developed virtual scenario is given in Table 1.

Fig. 5. Schematic view of New Zigana Tunnel project

Table 1. Properties of the virtual tunnel

Tunnel Lighting Colour	Lane Number	Lane Width (Left + Right) (m)	Lateral Clearance (Left + Right) (m)	Sidewalk Width (Left + Right) (m)	Interval Between Two Checrons
White	2	3.50 + 3.50	0.50 + 0.50	1.00 + 1.00	50

3.3. Aplication of chevrons in virtual scenario and measurements

In the tunnel road scenario simulated using a driving simulator, chevron markings were applied to evaluate their impact on driver behavior and safety. Chevron patterns, typically used to visually guide drivers and create an illusion of speed, were integrated into the simulated tunnel environment to examine their effectiveness in enhancing lane discipline, reducing vehicle speed, and improving overall spatial awareness. The immersive simulator setup allowed for precise monitoring of driver responses, including changes in speed, steering stability, and lane positioning, under consistent traffic and lighting conditions (Fig. 6).

Fig. 6. Different images for chevron applications in the New Zigana Tunnel

Driving performance was evaluated in three main areas: average vehicle speeds and driver characteristics. Vehicle speeds were continuously recorded at a rate of nine times per second using the simulator software. Upon completing the simulator session, participants filled out a questionnaire capturing demographic information such as gender, age, driving license duration, familiarity with the route etc. Additionally, they provided feedback on the simulator's performance, including the realism of the 3D modeling, the quality of the vehicle controls, and the effectiveness of the sound system.

4. Analysis and results

4.1. Speed analysis

Vehicles' mean spot speeds at entry, exit, and average speeds were collected and analysed to study driving behaviours. The measured standard deviation, mean, minimum, and maximum values of vehicle speeds (km/h) for entry, exit, and average speeds were determined for all 65 drivers.These results are summarized in Table 2.

Table 2. Descriptive statistics for vehicle speed results for examined locations

Vehicle Location in the Tunnel	Vehicle Speeds (km/h)			
	Average	Std. Deviation	Minimum	Maximum
Entrance	98.2	24.3	52	147
Inside	104.2	30.8	40	153
Exit	100.6	28.7	42	150

Table 2 presents descriptive statistics summarizing vehicle speeds measured at three distinct locations within the highway tunnel scenario: entrance, inside, and exit. The results indicate that the average vehicle speed increased from the tunnel entrance (98.2 km/h) to the inside section (104.2 km/h) and then slightly decreased at the exit (100.6 km/h). The highest variability in vehicle speeds was observed inside the tunnel (standard deviation = 30.8 km/h), suggesting that drivers exhibited less consistent behavior in this section. The recorded speed range also indicates substantial variability, with speeds ranging from as low as 40 km/h (inside) to as high as 153 km/h (inside). Such high variations may reflect differences in individual driver perceptions or confidence levels within tunnel environments. Overall, the findings highlight notable speed fluctuations inside the tunnel, which could potentially impact safety and traffic flow efficiency.

A one-way ANOVA Test was conducted to examine the relation average speeds between the tunnel entrance, inside, and exit sections. The statistical analysis using one-way ANOVA shows an F-statistic of approximately 1.15 with a p-value of 0.318. Since the p-value exceeds the common significance level of 0.05, there is no statistically significant difference in average speeds between the tunnel entrance, inside, and exit sections. This indicates that there is no statistically significant difference between average speeds measured at these three locations in the tunnel. Therefore, based on this analysis, the slight variations observed in average vehicle speeds across different tunnel sections appear random and do not reflect meaningful differences in driver behavior or tunnel influence.

4.2. Driver characteristics

Before the driving tests, a detailed survey conducted to measure driver charactersitics of the volunteer participants. According to Fig. 7. The majority of participants hold either a Bachelor's degree or a PhD degree, indicating a generally high educational attainment among drivers in the sample. High School and Master degree holders also constitute noticeable proportions of the sample, reflecting a diverse educational range. Participants with an Associate Degree or Primary School education represent smaller segments of the overall group. This distribution suggests that the study involved a relatively educated participant pool, which could imply that participants were likely capable of adequately understanding simulator instructions and procedures. However, the relatively low representation of primary education participants should be considered when generalizing findings to broader populations.

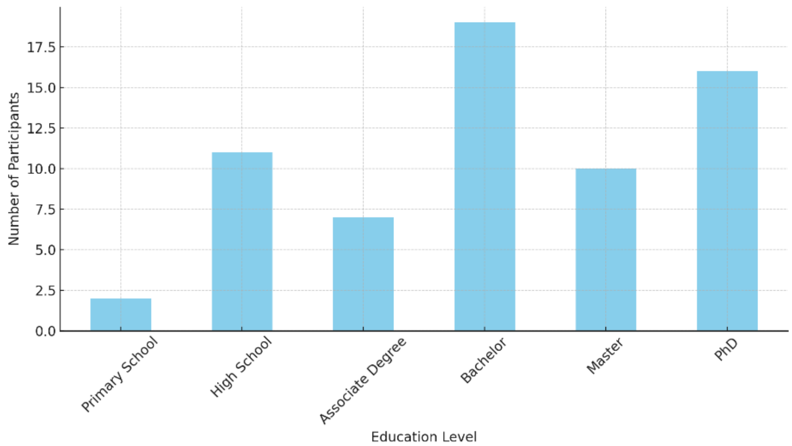

Fig. 7. Distribution of education levels

Fig. 8 also presents the distribution of job types among participants in the driving simulator study. From the Fig. 8, it can be seen that "Academicians" represent the largest job group, suggesting substantial involvement from technically-oriented professionals. Tradesmen and officers also have notable representation, indicating a diverse occupational background among participants. Groups such as Teachers, Workers, and Students appear less frequently, suggesting these occupations are underrepresented in the sample. This occupational diversity may influence the generalizability of the study findings, particularly regarding driving behavior that could be affected by occupational background and experience.

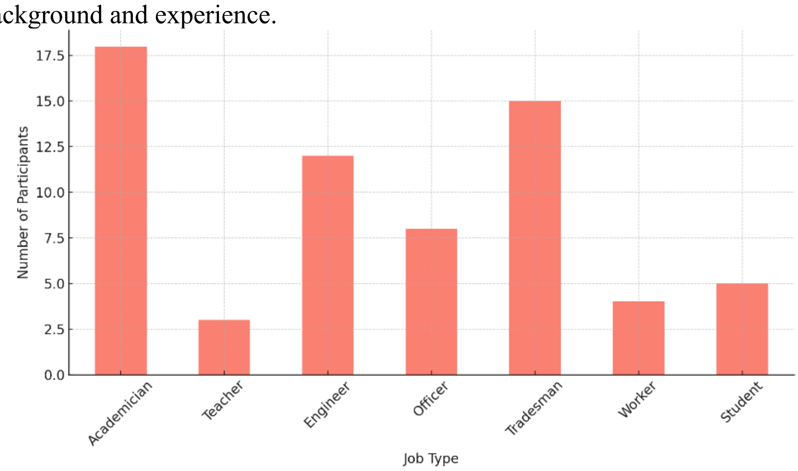

Fig. 8. Distribution of jobs among participants

Fig. 9 illustrates participants' self-reported ability to use a vehicle. The majority identify as having a professional level of ability, followed by those at the intermediate level. Very few participants classified themselves as beginners, and none reported being unable to use a vehicle. This suggests that the sample primarily consists of confident and experienced drivers, which is appropriate for a driving simulator study. However, the lack of novice drivers may limit insights into how less experienced individuals respond to tunnel environments or simulator conditions.

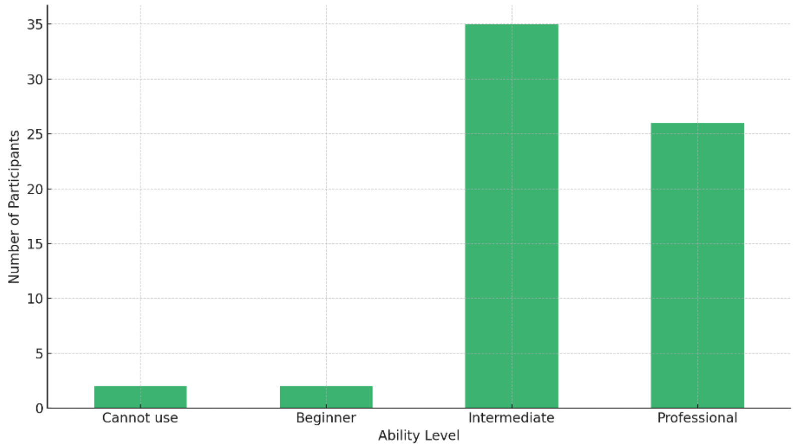

Fig. 9. Participants ability to use a vehicle

Fig. 10 also displays the distribution of driver profiles among participants. The most common profile is moderate, indicating a balanced driving style. This is followed by calm drivers, while aggressive drivers are the least represented. These results suggest that the participant group primarily exhibits controlled and composed driving behavior, which may influence how they respond to different tunnel scenarios in the driving simulator. The relatively low number of aggressive drivers may also limit insights into more risk-prone driving styles.

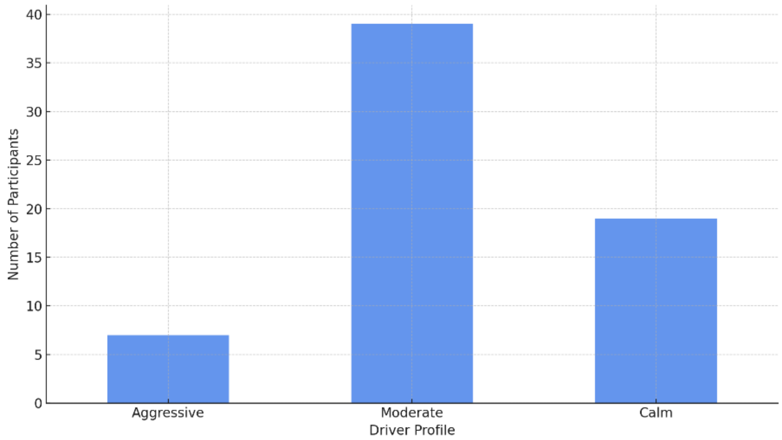

Fig. 10. Distribution of driver profiles

4.3. Driving in the Tunnel

A survey was also conducted to understand the simulator experience and feelings to drive in longer tunnels. Survey results showed that a significant majority of participants (over 80%) had never used a driving simulator before, with a small minority having prior experience or being unsure (Fig. 11a). About 21.5% of participants reported having prior knowledge about the vehicle simulator, while nearly 79% had none (Fig. 11b).

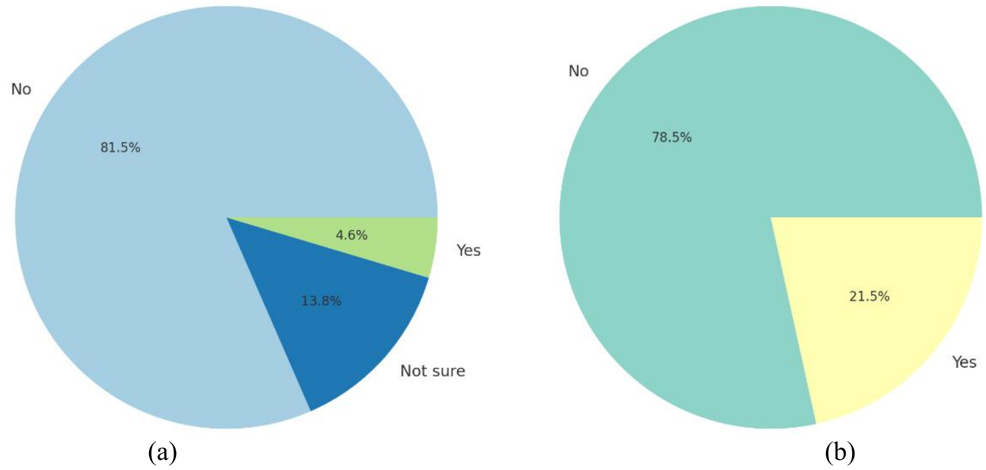

Fig. 11. (a) Driving simulator use before and (b) knowledge about driving simulator

In the survey, some special questions were also asked to particiopants to measure their opinions on driving in longer tunnel and tunnel conditions for New Zigana Tunnel. A majority of participants (~63%) responded “Not sure” about whether road tunnels are adequate in terms of traffic safety, indicating uncertainty or lack of awareness. Only a small fraction felt they were adequate (Fig. 12a). Similarly, most participants (~56%) were unsure about whether tunnels offer proper prior warnings of dangerous areas. A smaller group indicated “Sometimes”, and very few responded positively (Fig. 12b). Over 62% were uncertain if lighting conditions are sufficient, with 28% selecting “Sometimes”, reflecting overall concern or variability in lighting perception (Fig. 12c). Half of the participants (~49%) reported that driving in long tunnels is “sometimes” boring, while ~36% agreed outright, suggesting a need for visual or environmental improvements to enhance driver engagement (Fig. 12d).

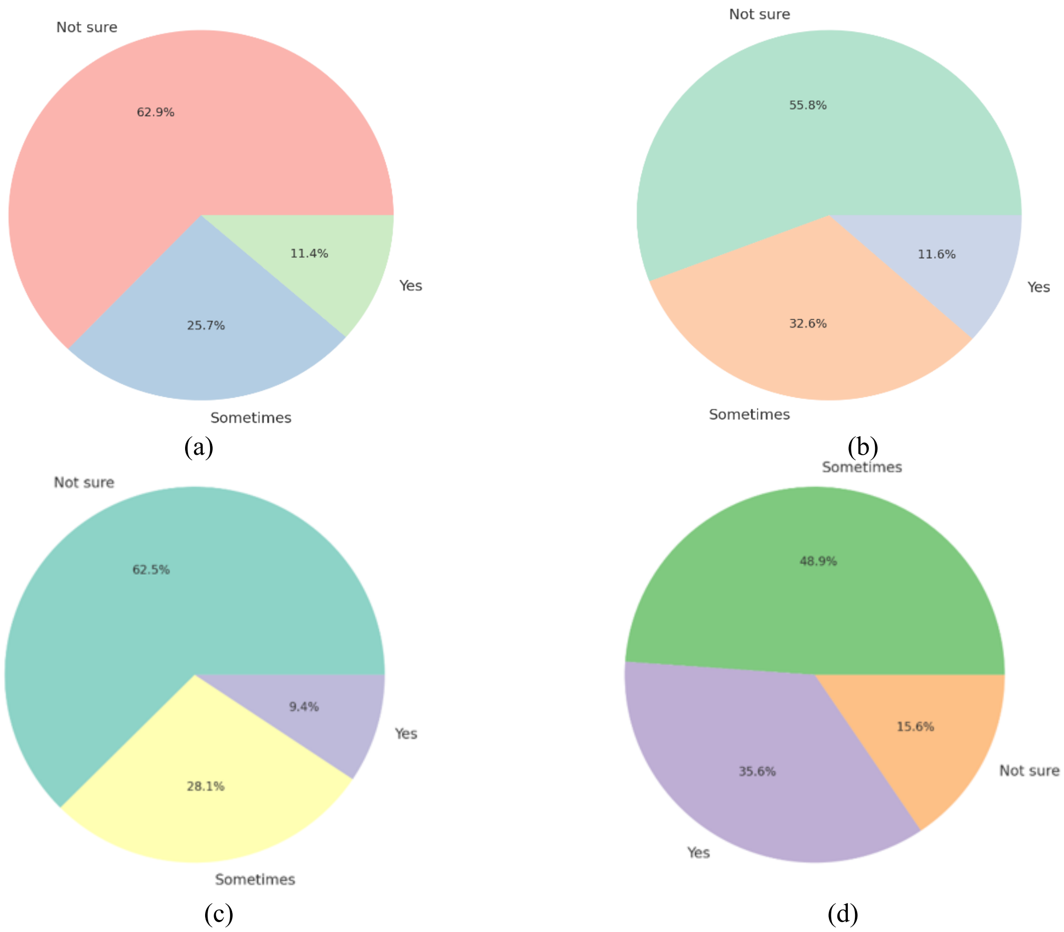

Fig. 12. Adequancy of (a) tunnel safety, (b) warnings, (c) lighting conditions and (d) weathering conditions

4.4. Behaviors and perceptions in the tunnel

A set of behavioral and perceptual questions were posed to participants using a 5-point Likert scale (1 = None, 5 = Very Much), to assess key responses in tunnel. The results are summarized below based on participants' self-reported behavior and perceptions.

Speed Adjustment to Exit the Tunnel: When asked whether they would increase speed to exit the tunnel more quickly, a majority of participants reported moderate to high agreement. Specifically, 25% selected "Much", and 3% selected "Very Much". This trend suggests that psychological factors such as discomfort or impatience may influence acceleration behaviors in longer tunnel sections (Fig. 13a).

Overtaking Heavy Vehicles Within the Tunnel: Participants were also asked if they would accelerate to overtake heavy vehicles inside the tunnel. A strong response was observed in favor of this behavior, with over 50% selecting "Very Much", indicating a substantial proportion of drivers are likely to perform overtaking maneuvers even in enclosed, confined driving conditions—potentially increasing risk if not well regulated (Fig.13b).

Speed Reduction at Tunnel Entrances and Exits for Safety: In contrast to overtaking tendencies, participants overwhelmingly reported that they do reduce speed for safety at tunnel entrance and exit points. Over 50% selected "Very Much", and 3% selected "Much", highlighting a strong adoption of cautious driving practices at critical transitional areas where visibility and reaction time can be compromised (Fig. 13c).

Impact of Digital Stimuli on Driver Attention: A significant number of participants indicated that digital stimuli within tunnels (e.g., digital signage, light strips, projections) effectively attracted their attention. The response "Very Much" was the most selected, with more than half of participants indicating a high level of engagement. This finding supports the potential utility of visual stimuli for guiding driver behavior or enhancing alertness in tunnel environments (Fig. 13d).

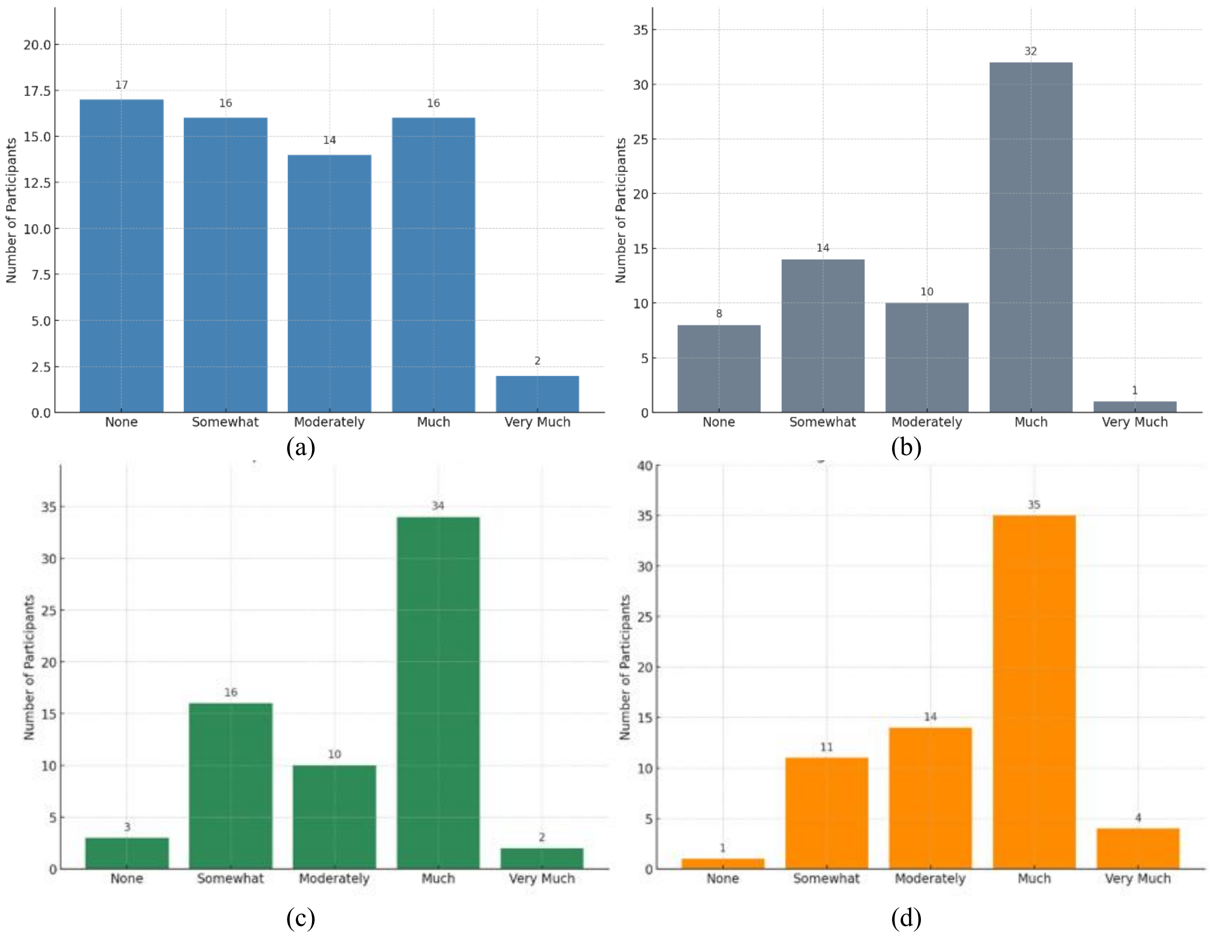

Fig. 13. (a) Increase speed to exit tunnel more faster (b) Increase speed to overtake in the tunnel, (c) Reduce speed at the tunnel entrance/exit and (d) digital stimuli impact

4.5. Awareness of chevron markings on road surfaces

As part of the driving simulator study, participants were asked whether they were familiar with chevron markings, a common road surface feature designed to help drivers maintain safe following distances on main roads. The responses were categorized as either "Yes" (aware) or "No" (not aware), and the distribution was visualized using a pie chart given in Fig. 14. The results revealed that 44% of the participants reported being aware of chevron markings, while 56 % indicated no prior knowledge of their purpose or presence. This relatively balanced distribution suggests that although more than half of the drivers recognized the markings, a significant portion of the sample lacked familiarity with this important traffic safety element. Given that chevron markings are intended to enhance road safety by visually cueing appropriate spacing between vehicles, especially at higher speeds or in complex environments like tunnels, the lack of awareness among a sizable group of drivers may reduce their effectiveness. These findings point to a need for improved public education and awareness campaigns about road safety markings. Incorporating information about chevrons into driver training programs or roadside signage could enhance their impact and support safer driving behavior.This result aligns with previous findings from the study, which highlighted mixed awareness and engagement with visual cues and digital stimuli in tunnels. As such, chevron marking, if properly understood, may serve as an additional, low-cost strategy to influence driver behavior and improve safety in confined or high-risk road environments.

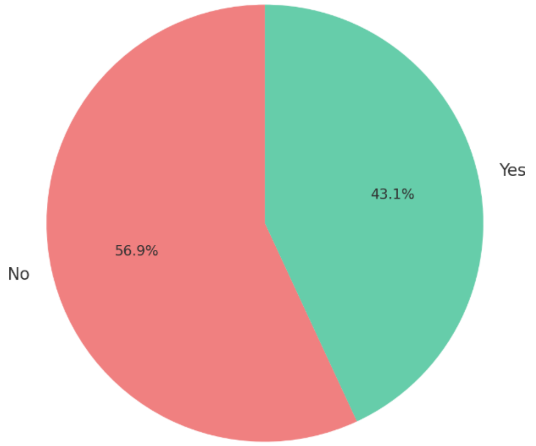

Fig. 14. Awareness of chevron markings on road surfaces in the New Zigana Tunnel

Participants were also asked to rate two statements “It is important for traffic safety to have chevrons showing the vehicle following distance in the tunnel” and “The chevron signs on the the road surface helped me to adjust the following distance.” related to the function and impact of chevron markings using a 7-point Likert scale (1 = Strongly Disagree, 7 = Strongly Agree). The responses to both statements were overwhelmingly positive. The majority of participants selected either “Agree” or “Strongly Agree”, indicating a shared perception that chevron markings are both meaningful and practical (Fig. 15). The first statement underscored the safety significance of chevrons, with participants strongly supporting their presence in tunnels. The second statement confirmed their usefulness in real-time driving behavior, as drivers found chevrons helpful for maintaining appropriate following distances. These findings suggest that chevron markings are not only recognized by many drivers but are also viewed as an effective aid in enhancing safety and spatial awareness in tunnel environments. This supports their wider implementation, particularly in road sections where driver behavior requires subtle guidance through visual means.

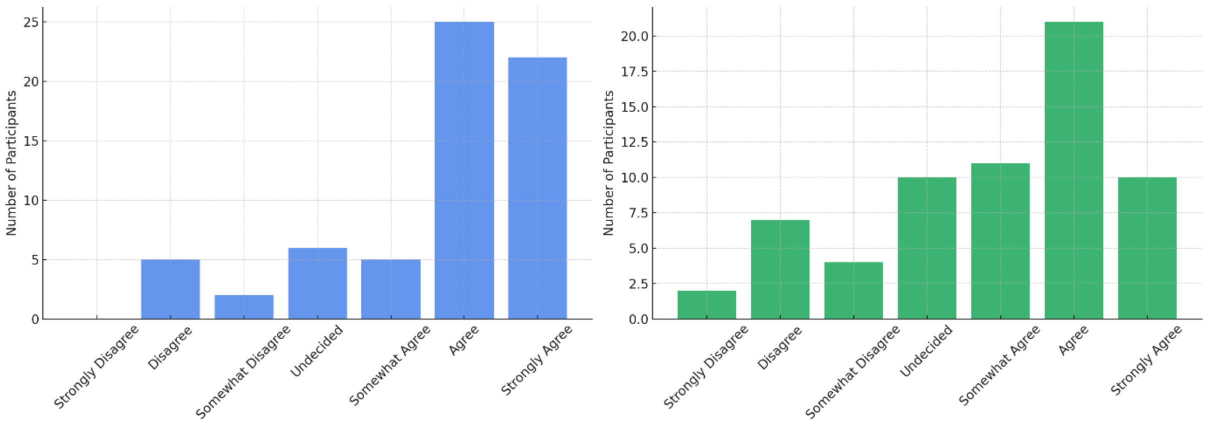

Fig. 15. Perceived effectiveness of chevron markings (a) importance of chevrons for traffic safety and (b) help of chevrons to keep vehicle following distance

5. Conclusions and suggestions

This study examined the effectiveness of chevron road markings in enhancing driving safety within tunnel environments through simulator-based experiments conducted at Erzincan Binali Yıldırım University. Results indicated that chevron markings positively influenced driver behavior by increasing driver awareness, promoting safer following distances, and contributing to speed regulation. Particularly under heavy traffic scenarios, the markings were beneficial in reducing driving stress and supporting improved decision-making. These findings underscore the practical utility of chevrons as a low-cost yet effective measure to enhance traffic safety and operational efficiency within highway tunnels.

Furthermore, survey analyses highlighted drivers' strong support for the use of chevron markings, reflecting substantial perceived benefits in maintaining appropriate following distances. However, a notable portion of participants lacked prior awareness of chevron markings, indicating a potential gap in public knowledge and driver education. This suggests a need for targeted informational campaigns and enhanced signage to maximize the effectiveness of chevron markings. Additionally, the participants' preference for visual stimuli within tunnels suggests complementary strategies such as dynamic visual alerts and enhanced illumination could further improve driver engagement and safety.

In conclusion, horizontal chevron markings demonstrate significant potential as a strategic safety intervention in tunnel environments, positively affecting driver speed, following distance, and overall safety perception. Given their low implementation cost and proven effectiveness, these markings could be widely adopted in current and future tunnel designs and integrated into broader intelligent traffic management systems. Considering the positive impact of chevron markings demonstrated in this simulator-based study, it is suggested that transportation authorities integrate chevron road markings into existing and new tunnel infrastructure, particularly in high-density traffic areas. Further studies should involve real-world trials to validate simulator findings across diverse environmental conditions and demographic groups. Additionally, awareness campaigns and educational initiatives could be implemented to enhance public understanding of chevron markings, thereby maximizing their safety benefits and ensuring drivers consistently adhere to recommended following distances within tunnels.

17-19 May 2025, Trabzon, Türkiye

Enhancing highway subbase performance with cement-stabilized recylcled concrete aggregate and fly ash

Muhammet Çelik*[1], Yavuz Abut[2], Dilara Yaşar[1]

[1] *Yalova University, Department of Civil Engineering, 77200, Yalova, Türkiye*
[2] *Yalova University, Department of Transportation Engineering, 77200, Yalova, Türkiye*

Abstract. In earthquake-prone countries like Türkiye, it is essential for the building stock to be earthquake-resistant. Therefore, the recycling of structurally compromised buildings is crucial. However, the recycling process generates demolition waste, contributing to environmental pollution, another critical issue. The reuse of demolition waste in line with sustainability principles becomes vital. There is extensive research on the reuse of demolition waste. However, gaps remain in the literature due to variations in waste properties or additives used to enhance the usability of the waste material. This study conducted California Bearing Ratio (CBR) tests to evaluate the use of demolition waste from Yalova Province as a subbase material in road construction. Existing studies often involve recycled concrete aggregate (RCA) combined with virgin aggregate or stabilized with binders like cement, which has a high carbon footprint. In this research, RCA was not mixed with other aggregates; instead, it was enhanced with fly-ash (FA) and cement. By using a low cement ratio, the primary stabilizer was intended to be FA, with cement serving as a supplementary additive. The study intevtigated whether RCA and FA, stabilized with cement, met the CBR requirements for subbase materials according to the Highway Technical Specification. Mixes containing 5%, 7%, and 10% FA and 1% or 2% cement were cured for 7, 14, and 28 days. The results indicated that a 14-day curing period was sufficient for subbase use, while the highest CBR value (216.4%) was achieved with 10% FA and 2% cement after 28 days.

Keywords: California bearing ratio; Fly ash; Highway; Recycled concrete aggregaye; Subbase

1. Introduction

In countries like Türkiye, which are located on active fault lines that can produce earthquakes, the renewal of the building stock is of great importance. Especially the renovation of buildings that have completed their economic life, that have been built without utilizing developing building technologies, without using modern workmanship and materials, and that have been built according to the old period regulations but do not comply with the current regulations is of even greater importance. In Türkiye, especially buildings that do not comply with current regulations carry a great risk. As a result of the risky building inspections of the official authorities, it has been stated that there are 28.6 million buildings in Turkey as of 2023 and approximately 6.7 million of these buildings are high-risk against earthquakes and need to be demolished urgently (ÇŞİDB, 2023).

The renovation of buildings will generate billions of tons of demolition waste. Demolition waste is a problem in many countries with similar problems like Türkiye. If waste is not planned and utilized in accordance with the principle of sustainability, it will pose a problem for the environment. In addition, storage costs constitute another problem (Lu & Tam, 2013). On the other hand, studies have shown that construction waste contains recyclable materials, and some studies have even found that 90% of construction waste can be recycled (Demir, 2009; Eren & Şen, 2023). Research shows that recycled concrete aggregate (RCA) can be used in all layers of highway pavement. Kavussi et al. showed that RCA is used in flexible pavement coating and RCA is suitable for use after a series of processes (Akbaş et al, 2023). Pasandín and Pérez in their review of previous studies on the use of RCA in bituminous hot mixes (BHM) stated that the use of RCA in BHM would be possible, but the properties of RCA would need to be developed or improved (Pasandín & Pérez, 2015). In one of the studies in the literature on the use of RCA in rigid pavements, it was observed that the flexural strength of the rigid pavement increased when rigid pavement produced with RCA reinforced with polyvinyl alcohol polymers (Yaowarat et al., 2017). In another study, Özbakkaloğlu et al. determined the results related to the substitution of different sizes of unused aggregate for the use of RCA in rigid pavements (Ozbakkaloglu et al., 2018). In highway pavements, when the layers are

*Corresponding author, E-mail: muhammet.celik@yalova.edu.tr

https://doi.org/10.31462/icearc2025_ce_tra_071

ordered from top to bottom, the highest strength properties are in the top layers. For this reason, in flexible and rigid pavements, studies have generally tried to improve on RCA or substitute it with virgin aggregates. In the base and subbase layers under the pavement, research on the use of RCA is more common. This is because the standards demand lower durability and strength in these layers than in the pavement layer. The use of RCA as a granular material in sub-base layers is very important for sustainable highway engineering (Park, 2003; Ardalan et al., 2017; Poon et al., 2004). At this point, especially the studies where CBR tests were performed are listed below.

Within the scope of the study, RCA will be examined together with fly ash, another waste material. In the literature, there is a lot of CBR test information about both the studies on subbase and base layers formed by adding RCA and the studies with other wastes. Among the studies examined in the literature, it was observed that the properties of the demolition waste, the differences in the material used as additives, and even the differences in the fly ash content changed the results. As a result of the literature review on the recycling of waste materials and the areas where fly ash is used, the following studies were found: Arulrajah et al. conducted CBR experiments in the laboratory at different time periods using RCA. They compressed the experiments with modified proctor energy at optimum water content. They kept the compressed specimens in water for four days with an additional load of 4.5 kg. The CBR values obtained as a result of the test were determined to be between 118% and 160%. The specimens were found to comply with the 80% values specified in the Australian local state road specifications (Arulrajah et al., 2012). In his master's thesis study, Yazıcı investigated the effect of fly ash on fine sand soils by CBR experiments. He prepared test specimens with different proportions of fly ash (5%, 10%, 15%, 20%, 25%) as well as a fixed proportion of cement added to the sand soil. After 7 days of curing, the CBR value obtained in pure soil was 18%, while this value increased up to 129% with the addition of cement and fly ash. The CBR value of the pure soil with a CBR value of 18% was also compared with the 28-day sample with the addition of fly ash and cement, and the CBR value of the sample increased up to 222%. As it is understood from this, the addition of fly ash as a stabilizer and cement as an activator provided a positive increase in CBR results (Yazıcı, 2023). Demir and Ok conducted CBR tests with recycled concrete aggregates consisting of demolition waste. Ok and Demir determined the optimum water content as 9.7% and also examined the CBR values of the mixtures prepared using 6% and 12% water content. While the CBR value they found with the optimum water content was 99.9%, the CBR value of the mixture with 6% water content was 50% and the CBR value of the mixture with 12% water content was 30%. Within the scope of this study, they concluded that demolition waste of reinforced concrete buildings can be an alternative to natural materials in highway embankment works (Ok & Demir 2018). Tajwar Ahmed et al. conducted CBR tests with a mixture prepared by combining concrete aggregates obtained from an old and demolished building in Hazaribag area of Dhaka with F class fly ash (5%, 10%, 15%). As a result of the experiment, they observed an increase in CBR value with the increase in the proportion of recycled concrete aggregate, while a decrease in CBR value was observed with the substitution of fly ash at certain ratios. They obtained the maximum CBR value by adding 5% fly ash (Ahmet et al., 2024).

In this study, it is planned to construct the subbase standards of the Turkish Republic Highways Technical Specifications (KTŞ) with urban recycling material. There are two different subbase types in the KTŞ (KTŞ, 2023). In the study, the subbase type with type A gradation curve was studied. In addition, fly ash, another waste material, was used in the study to increase (improve) the CBR results of RCA. In order for fly ash to play a more active role as an improver, a reinforcement improver cement additive was used. It is known that the content of fly ash varies according to the source from which it is obtained, and in some cases even differences in time can affect the content. In this study, fly ash utilization rates were selected (5%, 7%, 10%) similar to the values reported in the literature (5%, 10%, 15%). In addition, fly ash was reinforced with cement at 1% and 2% by weight. Thus, the properties of the fly ash were aimed to be activated, i.e. improved, by the cement. The activated fly ash was expected to improve the properties of another waste, RCA, in subbase behavior. The RCA used was taken from a building constructed more than 30 years ago in Yalova province.

2. Materials and methot

In this study, the improvement of RCA using fly ash (FA) for use in highway subbase was investigated. In addition, low cement addition was used for better contribution of fly ash. In the study, the comparison was made by looking at the soaked CBR values.

2.1. Materials

In this study, RCA was obtained from the demolition waste landfill of the ongoing urban transformation projects in Yalova Province. In the literature, there are studies on the improvement of RCA with cement additives and its use in highway pavements. In this study, the use of fly ash as an alternative to cement was investigated. Fly ash, which is the waste of Aksa Akrilik Kimya San.A.Ş. located in Tavşanlı Town of Yalova Province, was selected in accordance with TS EN 450-1 2013 standard (TSE, 2013). All of the FA passes through sieve number 200 and X-ray fluorescence spectrometry (XRF) results for FA are given in Table 1 (compounds with less than 1% are not shown). When the table is examined, it is understood that according to ASTM C618-23, FA is a type F due to its

CaO content (ASTM C618-23, 2023). Some properties of fly ash are also given in Table 2. CEM IV/B class cement from Bursa Beton was supplied for comparison with FA.

2.2. Method

In the study, for a gradation within the limits of the sub-base layer determined in the KTŞ, the concrete rubble provided should be separated into different sieve sizes. For this reason, since the crusher in the laboratory was not working at the desired efficiency, the rubble was crushed in a Los Angeles abrasion device. It was then separated into different sieve sizes (Fig. 1). After the crushing and sieving processes were completed, the mixture was prepared in accordance with the KTŞ 2023 subbase standards to be investigated for use in highway subbase and the (TYPE A) granulometry curve was formed as shown in Fig. 2.

Fig. 1. Crushing and Sieving Process

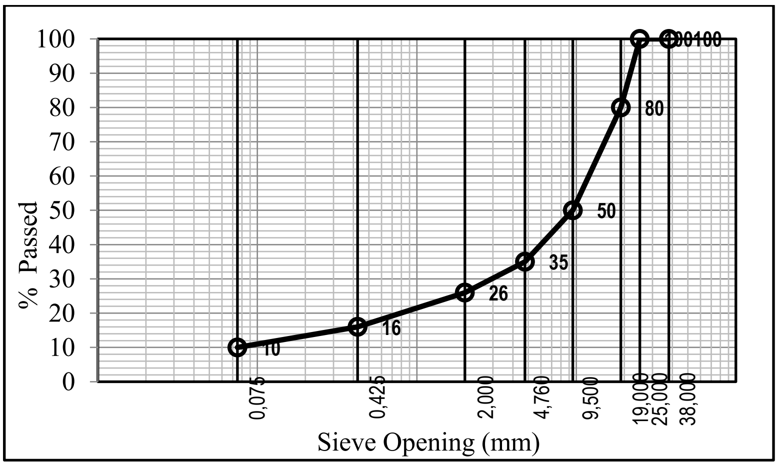

Fig. 2. Granulometric Curve in accordance with KTŞ Type A formed with sieved RCA

In the study, the use of RCA, a waste material, together with FA, another waste material, was investigated, as well as cement was added as a curing material in order to use both together. Experiments were carried out with different mixing ratios. Accordingly, the cement additive was used at 1% and 2% of the total weight of the mixture and fly ash was used at 5%, 7% and 10% of the total weight. While determining these ratios, it was planned to use the granulometric curve determined for the sub-base material in the KTŞ instead of the filler (below 0.075 mm) material. For this reason, 12% filler rate in the mixture was determined as the highest additive rate. These 6 different mixtures were evaluated according to 3 different curing times. In addition, CBR values in case only RCA was used were analyzed. Cement or fly ash was added to the mix as a substitute for the filler material.

In the experimental study, the modified Proctor test was first applied to find the optimum water contents required for the mixtures. At this point, the Modified Proctor test in accordance with TS EN 1900-1 was selected, especially due to the large grain diameter and the need for high energy for compaction (TS 1900-1, 2006). In the second part of the experimental study, soaked CBR tests were performed. CBR tests were determined according to (TS 1900-2, 2006). Three 2.27 kg weights were placed on the CBR specimens soaked in water to represent the pavement. All CBR tests were repeated at least 2 times (Table 3)

3. Result and discussion

In this study, an observational research followed by an experimental study was conducted. According to the findings obtained:

3.1. Observational research

Observational determinations were made on the RCA collected from the field and brought to the laboratory. As can be seen in Fig. 3 below, aggregates exceeding the maximum grain diameter and even reaching 10 cm in diameter were detected in the aggregate. Flat aggregates were observed in some of the specimens. It is concluded that these aggregates cause a decrease in concrete strength due to their fracture in the direction of flatness. Seashells were found in some of the aggregates. The fact that the seashell is of organic origin, can be easily broken, has a salty structure and the possibility that sea sand was used may have caused the concrete quality to be low. Smoothness was detected on the surfaces of some of the aggregates, and the inability of the cement paste to bond on smooth surfaces was evaluated within the observational findings. It was also observationally determined that some of the concrete pieces were have many voids. It is estimated that these voids are caused by both gradation defects and water/cement ratio defects. Some of the reinforcements were found to be unribbed and rusted during the inspections of the reinforced concrete elements. It was also found that the concrete quality varied between the elements. As a result of these findings, it was determined that the low strength of the concrete from which the RCA used in the experimental study was produced was one of the factors affecting the results.

Fig.3. Samples of concrete pieces collected on the storage area

3.2. Determination of optimum water content

According to TS EN 1900-1, the optimum water content and maximum dry density values obtained as a result of Modified Proctor tests were determined. Accordingly, the optimum water content and maximum dry density of RCA were determined without any additives. Subsequently, the experiment was repeated with fly ash and cement additives, but the experiments were completed by repeating the experiments separately for each fly ash and cement ratio. According to the data obtained, the optimum water content of the specimens containing only RCA was determined as 7.64% and the dry density as 22.74 kN/m³. It was determined that the optimum water level increased as the fly ash content increased, but the dry density decreased. This is an information obtained from similar studies in the literature (Totiç et al., 2019; Çelik Et al., 2024). These results are due to the pozzolanic material and light weight of the fly ash used as an additive. Table 4 shows the optimum water level and maximum dry densities obtained according to the mixture ratios.

Table 4. Results of the modified proctor experiment.

Cement	FA	Opt. Water Con. (%)	Dry Density (kN/m³)
%0	%0	7.64	22.74
%1	%5	7.82	22.58
%1	%7	8.25	22.59
%1	%10	8.33	22.34
%2	%5	8.31	22.41
%2	%7	8.68	22.19
%2	%10	9.17	21.97

3.3. California bearing ratio tests

CBR results obtained using RCA are given below. Accordingly, the specimens prepared from mixtures obtained only from urban recycling materials without any additives were kept in the water pool for 4 days (96 hours) without any curing, and the results of the CBR tests performed afterwards were 11.8%, 40.2% and 7.8%, respectively. The CBR results obtained from recycled aggregate are expected to be low. As a matter of fact, the information obtained about concrete quality in the first determinations also supports this. The reason for the differences of more than 400% between the figures is explained by the fact that aggregate breakage in the area where the CBR piston tries to sink causes low values, and relatively high values are generated when it coincides with solid durable aggregate. In the Technical Specifications of Highways, it is stated that sub-base CBR values should be 30% for Type-A and 50% for Type-B. At this point, it is seen that only one of the three different CBR tests performed exceeded the 30% limit. This shows that the aggregate obtained from recycled concrete does not have a homogeneous strength. After curing for 14 days, the results obtained from the crushing of CBR specimens kept in water for 4 days and the effect of 1% and 2% cement additives and 5,7,10% fly ash are given in Fig. 4. When the cement ratio increased, the CBR value increased approximately 2 times, which is an expected result. It is also observed in other studies that cement ratio gives similar results in highway foundation studies (Seferoğlu et al. 2018; Ai et al., 2024). In all of the results, the CBR value for subbase type A specified in the CTB was achieved, and even the mixtures with 2% cement admixture were found to meet the other foundation and subbase types.

After 28 days of curing and 4 days of soaking in water, the other specimens were subjected to CBR test and the results in Fig. 5 were obtained. When the results are analyzed, it is seen that higher CBR values were obtained compared to 14 days. It is a known fact in the literature that fly ash sets late. At this point, it is understood that the fly ash effect is more at the end of 28 days and increases the CBR results. Similar to the 14-day results, it was observed that 7% fly ash contribution gave the highest values. According to the KTŞ, it was seen that the appropriate conditions for subbase type A were met in all results, and even the desired CBR value (50%) for subbase type B was also met, while 2% cement admixture was able to meet the conditions specified for different foundation types. Fig. 6 shows the deformations of the soil specimens as a result of the test.

The results of the CBR test on the specimens placed directly in the water without curing are given in Table 5. When the results are analyzed, the importance of curing becomes apparent. It is understood that the results are inconsistent and that fly ash and cement content do not reveal a significant relationship on CBR results.

Table 5. CBR results of uncured specimens

FA%7	11.6	76.4
FA%10	6.6	16.8

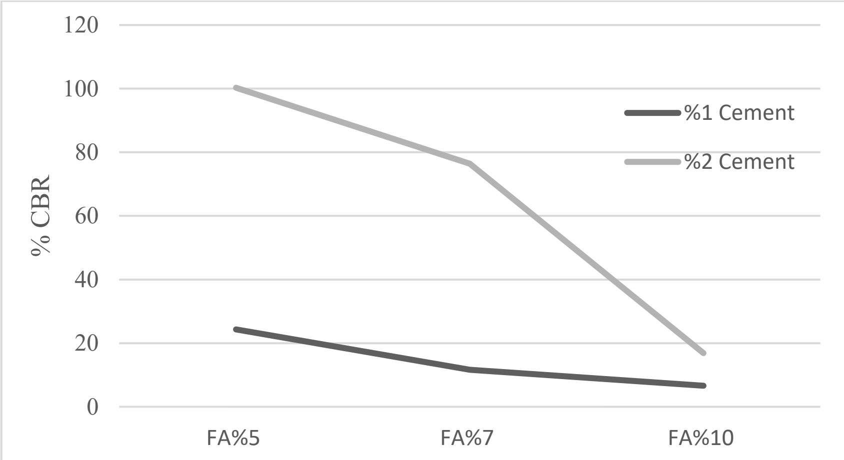

Fig.4. Samples Cured for 14 Days.

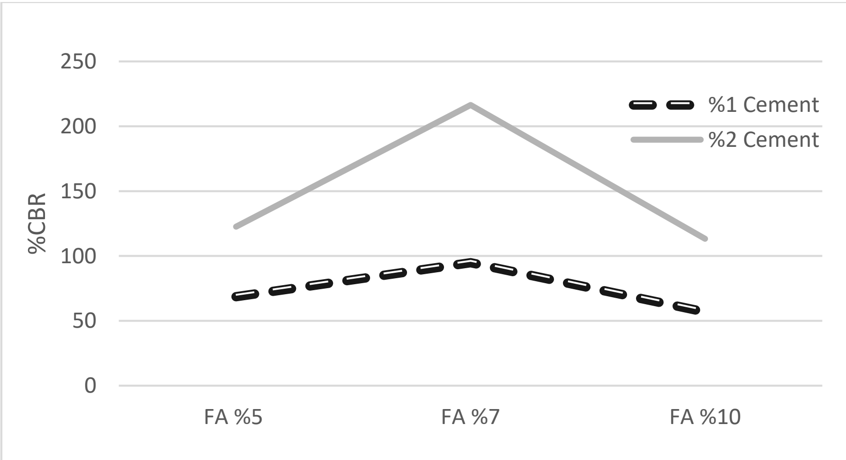

Fig.5. Samples Cured for 28 Days.

Fig.6. Deformations of the specimens after the test

4. Conclusions

As a result of the studies, observational and experimental investigations, the following points were determined:

The properties of the concrete to be used in the production of RCA are very important, and if the RCA does not show the desired properties, if improvement is to be made, the negativities it has should be eliminated. As a matter of fact, the poor quality of the concrete used in the study affected the results.

Aggregates in the range of 9.5-19.5 in the gradation are around 20% by mass. However, it was determined that some of this material obtained by crushing urban transformation waste concrete and separated through sieves is a combination of aggregate and cement paste. The fact that these joints have weak bonds due to various effects and that the CBR piston coincides with these weak bonds caused differences in the CBR test results. In addition, the concentration of coarse-grained materials (without cement paste) consisting only of pure aggregate in the mixture in the lower regions of the CBR piston is predicted as another effect that may cause an increase in the test results.

It was found that fly ash and cement additives made the results more regular, especially the curing treatment made it possible to establish a relationship between the results.

It has been observed that if a 28-day curing is applied, every mixture with fly ash and/or cement additive meets the necessary standards for the sub-base, and that the mixture with 2% cement and 7% fly ash reaches a CBR value of 216.4%

Object detection methods for vehicle counting: Comparison and optimal approach proposal

Akif Akbulut*[1],Ufuk Kirbaş[1]

[1] Ondokuz Mayıs University, Department of Civil Engineering, 55100 Samsun, Türkiye

Abstract. Object detection and recognition methods have significantly advanced in recent years thanks to developments in artificial intelligence and computer vision. These technologies provide high accuracy and efficiency, particularly in complex tasks such as vehicle counting. Determining the most suitable method for vehicle counting from video footage depends on the dataset used, environmental conditions, and application objectives. Traditional methods rely on predefined features and algorithms, whereas modern approaches, leveraging deep learning-based neural networks, offer more flexible and high-performing solutions. Notably, deep learning models such as You Only Look Once (YOLO), Faster R-CNN, and Mask R-CNN excel in both speed and accuracy for object detection and classification. These methods dynamically analyze by extracting regional features to detect and classify moving objects. During vehicle counting, challenges such as variable lighting conditions, perspective distortions, and background complexity can impact the success of the chosen algorithm. In this context, preprocessing video footage, employing data augmentation techniques, and optimizing hyperparameters for the model are critically important. Additionally, for real-time applications, factors like processing speed and hardware compatibility of the methods must be considered. By evaluating all these factors, selecting the most suitable method for vehicle counting is crucial for achieving accurate results and enhancing the overall system efficiency. This study aims to compare various object detection methods and propose the optimal approach for vehicle counting from video footage.

Keywords: Object detection; Vehicle counting; Deep learning; You Only Look Once; Computer vision

1. Introduction

Deep learning is a machine learning method that enables artificial neural networks to represent data at a higher level through nonlinear transformations and layers. Deep neural networks consist of input and output layers as well as intermediate and hidden layers, allowing the learning process to take place within a multi-layered structure. This multi-layered architecture enhances data processing and improves the model's learning accuracy (Chen et al., 2015). Advances in information technologies enable more efficient big data analysis. Although vehicle classification can be performed based on the sizes of moving objects, the accuracy level of this method is generally lower. However, the use of deep learning techniques provides more reliable and precise results in the vehicle classification process. These approaches significantly improve classification accuracy due to their ability to learn complex patterns (Krizhevsky et al., 2017). Object recognition methods are generally categorized into two main types: single-stage and two-stage approaches. Single-stage approaches prioritize processing speed, focusing on rapid data analysis. Examples of such methods include YOLO (You Only Look Once), SSD (Single Shot Multibox Detector), and RetinaNet. While these techniques offer speed advantages, their accuracy rates are often lower. On the other hand, two-stage methods aim to enhance accuracy at the expense of processing time. Models in this category include Faster R-CNN (Region-based Convolutional Neural Network), Mask R-CNN, and Cascade R-CNN. These models provide higher accuracy but may require greater computational resources (Paperswithcode, 2024). The resolution and characteristics of input images are among the key factors that directly affect the processing speed of object recognition algorithms.

1.1. Single-stage object recognition methods

Single-Stage Object Detection Methods stand out in the object detection process due to their high processing speed and low computational cost. In these methods, object classification and location prediction are performed in a single step. In contrast, traditional two-stage methods first identify potential object regions and then classify these regions, resulting in longer processing times. Single-stage methods complete all these steps at once, providing a

https://doi.org/10.31462/icearc2025_ce_tra_094

significant advantage, especially in real-time applications. The most notable feature of these methods is their simple architecture and ability to directly predict object bounding boxes and class labels. This makes them widely used in areas such as traffic monitoring in smart city systems, environmental perception in autonomous vehicles, and threat detection in surveillance systems. Additionally, their low computational requirements make them preferable for mobile devices, drones, robotic systems, and augmented reality applications. However, single-stage object detection methods have certain limitations. Compared to two-stage methods, they may suffer some accuracy loss. Performance can particularly decline in detecting small or closely located objects. One of the main reasons for this is that most single-stage methods use a grid-based approach. Dividing an image into specific cells for processing can make it difficult to adequately represent small objects. Furthermore, performing classification and location prediction simultaneously can restrict information sharing, negatively affecting accuracy. Despite these limitations, single-stage methods offer significant advantages in terms of speed, efficiency, and low computational cost. Improvements aimed at increasing their accuracy further expand their application areas, and when combined with deep learning-based approaches, they provide significant enhancements in object detection processes (Zivkovic, 2004).

1.1.1. YOLO (You Only Look Once)

YOLO (You Only Look Once) is an innovative approach that performs the object detection process using a single deep learning model. First developed in 2016 by Joseph Redmon and his team, this method works faster and more efficiently than traditional multi-stage techniques, providing an advantage in real-time applications. YOLO models divide an image into a grid and predict whether an object is present in each cell. Beginning with YOLOv1, this series has continuously improved in terms of accuracy and performance. YOLOv2 introduced anchor box usage, YOLOv3 gained multi-scale detection capability, and YOLOv4 became more efficient with CSPDarknet53 and new activation functions. Although YOLOv5, based on PyTorch, was not an official release, it was widely adopted, while YOLOv7 introduced advanced optimizations for speed and accuracy (Karadağ & Arı, 2023). YOLOv8 builds on the successes of its predecessors, offering high performance in tasks such as object detection, segmentation, tracking, and classification. Its architecture, consisting of backbone, neck, and head components, enhances detection accuracy while maintaining low resource consumption, making it suitable for real-time applications. Developed with support from Ultralytics, YOLOv8 provides various model sizes (YOLOv8n, YOLOv8m, YOLOv8l, YOLOv8x) that adapt to different hardware. The training process can be conducted on platforms like Google Colab, and extended training improves accuracy. The YOLO series has continuously evolved from YOLOv1 to the most recent version, YOLOv12 (Wang & Liao, 2024). YOLO analyzes an image by dividing it into a grid structure and determines whether an object is present in each cell. For detected objects, it simultaneously predicts class labels and bounding box coordinates, ensuring a fast and efficient detection process. Optimized with deep learning techniques and CNN architecture, the model effectively detects objects of different sizes using anchor boxes. YOLO's biggest advantage is its ability to detect multiple objects in a single operation with high speed and accuracy (Kılıç et al., 2022). YOLO is widely used in many fields that require fast and accurate object detection. Autonomous vehicles, traffic monitoring systems, security cameras, robotic systems, and augmented reality applications are among the most common areas where YOLO is preferred. Its speed and accuracy in real-time video processing and object tracking make it a crucial tool. Thanks to its high performance, YOLO has become an indispensable technology in numerous industrial applications. Each new version introduces improvements in speed, accuracy, and efficiency, significantly contributing to the advancement of object detection technology. YOLO's rapid processing time and high accuracy make it an ideal solution, especially for real-time applications. With the continuous development of deep learning techniques and ongoing optimizations, YOLO's impact in the field of object detection continues to grow.

1.1.2. SSD (Single Shot Multibox Detector)

SSD (Single Shot MultiBox Detector) is a single-stage deep learning model that performs object detection quickly and efficiently. Developed in 2016 by Wei Liu and his team, this model differs from two-stage methods like R-CNN by detecting objects directly on the image. SSD predicts objects of different sizes using predefined default boxes and can detect both small and large objects through multi-scale feature maps. This structure enables the model to provide high speed and accuracy, making it highly effective for real-time applications (Malkoçoğlu & Samli, 2023). SSD conducts object detection through a convolutional neural network (CNN)-based structure, extracting features from images and predicting object locations. The model utilizes predefined boxes at each layer to determine the presence and class of objects while optimizing coordinates to enhance the precision of bounding boxes. Being a single-stage model accelerates processing, making it suitable for real-time applications. During training, the discrepancy between predicted values and ground truth labels is minimized to improve model accuracy. SSD's holistic learning approach allows it to generate outputs directly from input data, increasing computational efficiency and enabling successful detection of objects at different scales (Liu et al., 2016). The SSD model offers significant advantages in object detection, including high speed, low computational cost, and multi-object detection capability. Its single-stage structure accelerates processing, making it ideal for real-time applications. It is effectively used in time-sensitive fields such as autonomous vehicle systems, traffic monitoring mechanisms, and security cameras. The model's ability to detect objects of varying scales, from small to large, ensures reliable performance in complex scenes. Compared to other single-stage models like YOLO, SSD achieves similar accuracy levels while requiring less computational power, making it suitable for resource-limited platforms such as embedded systems and mobile devices. SSD is widely used in real-time video processing, facial recognition, traffic monitoring, robot navigation, and augmented reality applications. Its use of multi-scale feature maps, predefined boxes for object prediction, and end-to-end training process helps maintain high accuracy while reducing computational costs. With advancements in deep learning and computer vision, future versions of SSD are expected to offer even higher performance (Liu et al., 2016).

1.1.3. RetinaNet (Retina Network)

RetinaNet was developed in 2017 by Facebook AI Research (FAIR) to optimize the balance between speed and accuracy in object detection. Addressing the class imbalance issue common in traditional single-stage models, RetinaNet achieves high success in object detection tasks. Its most significant innovation is the Focal Loss function. While previous single-stage models like YOLO and SSD excelled in speed, they struggled with detecting small or rare objects. RetinaNet mitigates this issue by assigning greater weight to low-frequency classes, allowing the model to focus more effectively on these objects. This approach enhances accuracy without sacrificing speed, effectively addressing class imbalance. Thanks to its innovative methodology, RetinaNet has become a powerful choice for real-time object detection applications (Lin et al., 2017). RetinaNet operates using a Convolutional Neural Network (CNN)-based architecture for object detection. Leveraging multi-scale feature maps, it successfully detects objects of varying sizes. The model generates predefined default boxes at each location and predicts their class labels and bounding box coordinates. Due to its single-stage nature, it eliminates the need for a separate region proposal step, significantly reducing processing time. The most crucial innovation of RetinaNet is its Focal Loss function. Traditional single-stage models struggle to detect small or rare objects due to class imbalance, but Focal Loss alleviates this problem by emphasizing misclassified examples. This enables the model to achieve high accuracy even with small datasets. Another key component enhancing RetinaNet's performance is the Feature Pyramid Network (FPN). This structure generates multi-level feature maps to better detect objects at different scales—small objects are processed in lower layers, while larger objects are handled in upper layers, ensuring scale-independent accuracy. Additionally, RetinaNet's use of default boxes (anchor boxes) allows for more efficient detection of objects with varying sizes and aspect ratios. With innovations like Focal Loss and FPN, RetinaNet stands out as a model that offers both high speed and accuracy. Its single-stage structure reduces computational cost, making it a strong candidate for real-time object detection applications. Notably, its ability to successfully detect small and rare objects distinguishes it from other single-stage models (Lin et al., 2017).

1.2. Two-stage object detection methods

Two-stage object recognition methods stand out among deep learning-based object detection approaches with high accuracy. These methods aim to achieve more precise results by performing object detection and classification in a two-step process. In the first stage, the potential object locations in the image are determined using a Region Proposal Network (RPN). Then, object classification and bounding box refinement are performed on these detected candidate regions by a second deep network. The major advantage of this method is its ability to provide object detection with high accuracy. Since the candidate regions identified in the first stage only contain parts thought to potentially include an object, the classification process in the second stage becomes more efficient and precise. Particularly in images with complex backgrounds or scenes containing objects with similar features, two-stage object recognition methods reduce false detections and produce more reliable results. This structure is commonly preferred in applications where accuracy in object detection is critical, such as security systems, medical image analysis, and autonomous driving (Türkarslan & HardalAğaç, 2022). Two-stage object recognition methods hold a significant place in the field of object detection due to their ability to achieve high accuracy. However, these models are more costly in terms of processing time due to their two-stage structure. Therefore, they are generally preferred in applications that work with large datasets and require high accuracy. The biggest disadvantage of these methods is that they require more computational power compared to single-stage models. Particularly in real-time applications, long processing times can be a limitation. Nevertheless, the advantages offered by two-stage models, especially in terms of increasing the accuracy of object candidates and enabling more precise classifications, are highly valuable. Successful models like Faster R-CNN have demonstrated that this method can be effectively applied. These models are widely used in scenarios requiring high accuracy, such as medical image analysis, autonomous vehicle systems, and security applications (Türkarslan & HardalAğaç, 2022).

1.2.1. Faster R-CNN

Faster R-CNN has been developed as a model that optimizes both speed and accuracy in object detection. In traditional two-stage methods, object regions are first determined, and then these regions are classified to predict object locations, whereas Faster R-CNN optimizes this process by using the Region Proposal Network (RPN) to make region proposals directly learnable. Previous approaches, such as R-CNN and Fast R-CNN, were inefficient either due to high computational cost or the need for an external region proposal algorithm. However, with the integration of RPN, Faster R-CNN reduces unnecessary computations, enabling end-to-end faster and more accurate object detection. The model, especially preferred in applications requiring high accuracy, has brought a significant innovation to the field of computer vision by making object detection processes more efficient (He et al., 2017). Faster R-CNN divides the object detection task into two main stages: region proposal generation (RPN) and classification and bounding box regression. The first stage, RPN, generates potential object regions for every pixel in the image. This process is carried out using Convolutional Neural Networks (CNN). A sliding window is used over the CNN feature map, associating predefined anchor boxes with each pixel. These anchor boxes provide initial predictions regarding the positions and classes of objects. The second stage involves classifying the regions proposed by RPN and refining the exact locations of each region. In this step, the Fast R-CNN classification and bounding box regression network processes the region proposals generated by RPN. Each proposed region is classified to determine which object it belongs to, and the correct location of the object is predicted through bounding box regression. Thus, Faster R-CNN presents an efficient model that integrates object classification and localization tasks (Girshick, 2015). Faster R-CNN is a model that efficiently performs object detection tasks and contains key components that contribute to its success. The first component, the Region Proposal Network (RPN), generates proposal boxes (region proposals) to detect objects in the image and makes object predictions using anchor boxes associated with each pixel. The second component is the Backbone Network, typically built using deep learning networks such as VGG16 or ResNet; these networks extract important visual features from the image. The RoI Pooling layer ensures that proposal regions of varying sizes are converted into fixed dimensions, allowing each proposal region to produce a fixed-size feature map. Finally, the Classification and Bounding Box Regression stage predicts which object each proposed region belongs to and the precise location of the object. The collaboration of these components allows Faster R-CNN to perform accurate and fast object detection. Its main advantage is significantly reducing processing time by performing object detection in an integrated manner. While traditional methods perform proposal box generation and classification independently, Faster R-CNN integrates these processes, improving both accuracy and processing speed. Additionally, by offering end-to-end training, it allows all model components to be trained simultaneously, optimizing performance. This structure makes Faster R-CNN superior to traditional methods with higher accuracy and faster processing times (Everingham et al., 2010). Faster R-CNN is used in a wide range of applications in object detection and image analysis. In autonomous driving systems, Faster R-CNN can help achieve safe driving by detecting pedestrians, vehicles, and other obstacles, enabling the vehicle to perceive its surroundings. In security systems, it can be effectively used in tasks such as theft detection, facial recognition, and intrusion detection. In industrial automation, robotic systems can use Faster R-CNN for object recognition and placement tasks on production lines. In healthcare, Faster R-CNN can be utilized for anomaly detection in medical images and disease diagnosis. By overcoming the challenges of previous object detection methods, Faster R-CNN has made significant progress in the field of object detection. The Region Proposal Network (RPN) and end-to-end training strategies enhance the model's accuracy and speed, providing a more efficient solution. This innovative model is successfully used in many applications in the field of object detection and is shaping the future of deep learning-based object recognition.

1.2.2. Mask R-CNN

Mask R-CNN is a significant advancement in the fields of object detection and image segmentation, and it is an advanced version of Faster R-CNN. Developed in 2017, this model adds pixel-level object mask prediction to the object detection process. As a result, it not only detects objects but also performs segmentation of the objects at the pixel level, providing more precise and detailed results. In addition to the core components of Faster R-CNN, such as the Region Proposal Network (RPN) and RoI Align layers, Mask R-CNN introduces a structure that predicts a mask for each detected object. This is especially advantageous in applications where accurate object boundary detection is crucial. The primary motivation behind the development of this model is that image segmentation is more complex and challenging than other tasks like object detection. Mask R-CNN improves the object detection structure of Faster R-CNN, which works in three stages, by adding an extra stage that involves classifying pixels. The first stage includes the RPN technique used in Faster R-CNN, where RPN generates potential object regions and identifies key areas. The second major innovation is RoI Align. To avoid the loss of accuracy in the RoI Pooling method, Mask R-CNN uses RoI Align, which provides more accurate feature extraction. The third stage involves the model making three predictions for each proposed region: the classification of the object, its location, and the generation of a pixel-level mask. This allows Mask R-CNN to accurately segment the pixels of each object. Mask R-CNN works with components such as the Backbone Network (using networks like ResNet or ResNeXt), RPN, RoI Align, and the Mask Generation Network. The Backbone Network extracts fundamental features from the image, while RPN detects potential object regions, RoI Align transforms each proposed region into fixed sizes, and the Mask Generation Network generates pixel-level masks for each object.

Mask R-CNN provides high precision in pixel-level accuracy and segmentation tasks and can be adapted to various applications due to its flexible structure. Additionally, the RoI Align feature eliminates sharp edge rounding issues, leading to more precise region predictions. This enhances the model's accuracy, especially in situations where accurate boundary detection of objects is required. These advantages make Mask R-CNN a powerful model in object detection and segmentation. Mask R-CNN is particularly effective in tasks that require high accuracy and reliability. In industrial applications, it is also used in processes such as object separation and classification on production lines, making manufacturing processes more efficient. With innovations added on top of Faster R-CNN, Mask R-CNN combines object detection and segmentation tasks into a powerful model. Thanks to innovations such as RoI Align and pixel-level prediction capabilities, the model offers both precise and comprehensive solutions. Since its development, Mask R-CNN has continued to achieve impressive results in many applications in the field of image analysis and segmentation (Güçlü et al., 2022).

1.2.3. Cascade R-CNN

Cascade R-CNN is a deep learning architecture developed to improve the detection of objects at various scales and complexity in the field of object detection. Traditional object detection methods often require learning both low and high-quality features simultaneously, which has specific limitations. In particular, low Intersection over Union (IoU) threshold values used during object detection can lead to false positive results and missed detections. To overcome this issue, Cascade R-CNN utilizes multiple detection stages sequentially, increasing the IoU threshold at each stage to achieve higher accuracy in object detection. Developed to overcome the limitations of popular object detection models such as Faster R-CNN, Cascade R-CNN uses a staged structure instead of a single-stage detector, offering a more precise learning process at each step. This approach allows the model to detect objects at different scales more accurately and consistently. The mechanism of the model is based on progressively improving the object detection process. Initially, the Region Proposal Network (RPN) identifies potential object regions, which serve as the foundation for subsequent object detection and classification tasks. Then, sequential detectors working with increasing IoU thresholds progressively refine the coarse detections made in the first stage, producing more accurate results. The first detector usually works with a low IoU threshold, identifying object candidates, and subsequent detectors refine these detections to produce more precise outcomes. Each stage corrects the missed or incorrect detections from the previous stage, increasing the accuracy of the model. This structure not only improves object detection but also enhances the precision of classification and bounding box regression, thereby improving the overall performance of the model. Cascade R-CNN consists of various components, including the Region Proposal Network (RPN) used to identify object candidates, Staged Object Detectors that operate with different IoU thresholds at each stage, and a Backbone Network used for feature extraction from the image. Typically, convolutional neural network (CNN)-based architectures like ResNet or ResNeXt are preferred. Additionally, a special loss function is used to optimize the learning process of the model, minimizing the error rate of each detector. One of the key advantages of this model is its ability to increase detection accuracy by working with higher IoU thresholds. The staged structure eliminates low-quality proposals early on, reducing false positive and negative rates and enhancing the reliability of the model. Moreover, the use of detectors with different IoU thresholds allows the model to successfully detect objects at different scales. Finally, the staged learning structure ensures that the model generalizes better on both small and large datasets. Considering all these features, Cascade R-CNN provides a more precise, reliable, and scalable solution in object detection tasks, standing out as an effective method for improving detection accuracy. Cascade R-CNN is effectively used in a wide range of applications. In autonomous vehicles, it helps improve driving safety by accurately detecting traffic signs, pedestrians, and other vehicles. In medical imaging, it provides high accuracy in detecting cancer cells or other anomalies, improving early diagnosis processes. In video surveillance systems, it is effective in detecting people or objects from security camera footage, thus enhancing the effectiveness of security monitoring systems. In industrial inspection, it is used to detect product defects or assembly flaws, strengthening quality control processes. In robotic systems, it enables more precise operation of robotic arms by detecting the positions of objects. Cascade R-CNN is a powerful architecture with high accuracy and generalization capabilities, increasingly gaining significance in both research and industry (Cai & Vasconcelos, 2018).

1.3. Object recognition methods and comparisons

Object recognition is the process of determining the location and type of objects in an image. Deep learning-based approaches have made significant progress in this field. These approaches are generally divided into two categories: single-stage and multi-stage methods. Both methods have certain advantages and limitations, offering features suitable for different application areas. Below, these methods are compared in detail (Aalami, 2020).

1.3.1. Properties of single layer methods

Single-stage methods are an approach that perform object detection and classification directly in a single step. In such models, the entire image is converted into feature maps, and possible objects along with their classes are predicted within the same network structure. Key features of these methods include fast operation, simple architectural structures, and high processing speed. These models are particularly suitable for real-time applications, and their less complex structures facilitate the training process and model design. Examples such as

YOLO (You Only Look Once) and SSD (Single Shot Multibox Detector) are common applications of single-stage methods. The advantages of these methods include providing time efficiency by enabling lower latency and high processing speed per image. Moreover, they are effectively used in areas that require real-time performance, such as autonomous vehicles and robotic systems. Due to their hardware-friendly nature, they can also be easily implemented on mobile devices or embedded systems. However, these methods also have limitations. The single-step process can lead to accuracy issues in detecting small objects or complex scenes. Additionally, in detections with a high IoU (Intersection over Union) threshold, they may cause sensitivity deficiencies such as an increased rate of false positives.

1.3.2. Features of double layer methods

Two-stage methods are an approach that perform object detection and classification in two separate stages. In the first stage, a Region Proposal Network (RPN) identifies potential object regions. In the second stage, these regions are processed in more detail, classified, and the bounding boxes are refined. The main feature of these methods is the analysis of different feature maps in both stages, which leads to higher accuracy. Examples of two-stage methods include models such as Faster R-CNN and Mask R-CNN. Advantages of these methods include high accuracy and improved detection and classification performance through detailed analysis. They also yield better results on small objects and complex scenes. Their flexibility makes them suitable for various applications and allows for optimization with different components. However, two-stage methods also have certain limitations. The two-step structure increases processing time, making them less suitable for real-time applications. In addition, their more complex architecture requires greater computational resources, which can increase training and deployment costs.

1.4. Comparison of single and dual layer object recognition methods

Single-stage object detection models are widely preferred in applications based on real-time image analysis due to their high processing speeds. These models can be effectively used in real-time systems that require low latency (Medium, 2024). Especially in cases such as traffic counting, where a balance between speed and accuracy is crucial, the YOLO model stands out. YOLO reduces the object recognition process to a regression problem, allowing it to simultaneously predict the positions and probabilities of bounding boxes for each class. Unlike two-stage models such as Fast R-CNN, this method enables direct detection without the need to predefine possible object locations. YOLO's ability to analyze all classes in a single operation allows for much faster determination of object positions and attributes compared to traditional methods. As a result of comprehensive research in the literature, a summary table has been created that presents a comparative analysis of single-stage and two-stage object recognition methods in terms of speed, accuracy, complexity, application areas, and hardware requirements. This table reveals that single-stage methods are preferred in real-time systems due to their high speed and low hardware requirements, whereas two-stage methods are used in procedures requiring high precision due to their accuracy and complexity (Table 1).

Table 1. Comparison of single and dual layer object recognition methods

Feature	Single Layer Methods	Double Layer Methods
Speed	High	Low
Accuracy	Middle	High
Complicacy	Low	High
Application Areas	Real Time Systems	Procedures Requiring Precision
Hardware Requirement	Little	Extra

1.5. Selection according to application areas

Single-Stage Methods: These are widely used in areas where speed is crucial, such as video surveillance, autonomous driving, and mobile applications. These methods offer low computational cost and high speed, making them effective in real-time systems. Two-Stage Methods: These are preferred in applications that require high accuracy, such as medical imaging, security analysis, and industrial control. These methods enhance object detection accuracy by performing more detailed analysis. Single-stage and two-stage object recognition methods offer complementary approaches in the field of object detection. While single-stage methods provide speed and ease of processing, two-stage methods are more advantageous in terms of accuracy and precision. Depending on the usage scenario, the strengths and weaknesses of both methods should be evaluated to select the appropriate model. In real-time applications, fast models like YOLO and SSD are preferred, whereas in cases requiring higher accuracy, methods such as Faster R-CNN or RetinaNet stand out (Tan et al., 2021). Considering the scope of real continuous object ranges, the YOLO architecture is implemented more efficiently compared to SSD. The YOLOv3 model, detailed by Redmon and Farhadi (2018), offers higher detection ranges and speed compared to SSD, providing an advantage in real-time applications. Structurally, YOLO has demonstrated better results in object detection with less programming resource usage than SSD (Redmon & Farhadi, 2018). Comprehensive reviews conducted for real-time object detection reveal that the YOLO model provides advantages in terms of both speed and accuracy. In this context, performance evaluation will be conducted using the default models of YOLO, and the model's efficiency and accuracy rates will be analyzed. The tests to be carried out will measure the detection capability of the model under different scenarios, contributing to the determination of the most suitable configuration for real-time applications.

2. Materials and methods

The materials and methods used to evaluate the performance of an object detection model include various elements such as the datasets to be analyzed, evaluation criteria, and hardware and software components employed. In this study, a comparative analysis in terms of accuracy and speed will be conducted for the latest versions of the YOLO family: YOLOv8, YOLOv9, YOLOv10, and YOLOv11. The main objective of the study is to determine how consistent the accuracy (mAP—mean Average Precision) and speed (FPS—Frames Per Second) values reported by the developers are when applied to real-world video scenarios. The datasets used in this study will consist of video data containing various objects under different environmental conditions. The video footage will include both static and dynamic scenes and will be tested at various resolutions and lighting conditions. In this context, the performance of the models under variable conditions will be evaluated. In particular, the balance between speed and accuracy in detecting moving objects will be considered an important criterion. During the evaluation process, both the accuracy and speed values reported by the developers and those obtained through experimental testing will be compared for each model. The YOLOv8 model offers higher accuracy and better overall performance compared to previous versions due to its improved architecture. YOLOv9 is optimized for enhanced performance in detecting small objects and in low-light conditions. YOLOv10 was developed to improve computational efficiency, enabling more effective operation on embedded systems and low-power devices. YOLOv11 aims to set a new standard in both speed and accuracy through deeper neural network structures and advanced data processing techniques. For model comparisons, each version will be run on the same video data, and the results will be evaluated based on specific metrics. Evaluation criteria include mAP, FPS, processing time, false positive rate, and false negative rate. Real-time tests will be conducted on the selected video sets, and each model’s object detection capability will be analyzed. Model outputs will be assessed frame-by-frame in terms of detection accuracy and timing, and cases such as missed objects and false detections will be examined in detail. Python programming language and the PyTorch deep learning library will be used as the software infrastructure. During the testing process, all models will be run in the same environment to minimize variations due to hardware differences. Through this method, the study will reveal how valid the accuracy and speed values reported by the YOLO developers are when applied to real-world video data. The specifications provided by the YOLO developers are shown in Table 2.

In this study, the real-time object detection performance of the YOLOv8, YOLOv9, YOLOv10, and YOLOv11 models will be compared using the fastest versions of each release. In real-time applications, the combined evaluation of parameters such as speed, accuracy, and processing time is of great importance. In this context, different versions of each model will be selected, specifically those optimized for speed. The fastest model in the YOLOv8 family, YOLOv8n, demonstrates highly efficient performance in terms of processing time. In the YOLOv9 series, the YOLOv9t model stands out with its faster processing capabilities, while YOLOv10 and YOLOv11 also offer strong alternatives in terms of both speed and accuracy. Smaller versions such as YOLOv10n and YOLOv11n provide faster processing times, enabling low-latency object detection. The comparison of these models will aid in selecting those that offer high efficiency, particularly for use on low-power devices or in real-time video streams. The evaluation will be based on metrics such as FPS (frames per second), processing time, and accuracy, and the efficiency of each version will be analyzed in detail. Based on the test results, the strengths and weaknesses of each model will be identified, and recommendations will be provided for selecting the most suitable model for various application scenarios. In particular, a detailed analysis will be conducted to determine which version offers the highest performance in real-time systems, and the factors that should be considered in model selection will be evaluated accordingly.

Table 2. YOLO models and their features (Ultralytics, 2025)

Model	size (pixels)	mAPval 50-95	Speed CPU ONNX (ms)	Speed T4 TensorRT10 (ms)	params (M)	FLOPs (B)
YOLOv8l	640	52,9	375,2	9,06	43,7	165,2
YOLOv8m	640	50,2	234,7	5,86	25,9	78,9
YOLOv8n	640	37,3	80,4	1,47	3,2	8,7
YOLOv8s	640	44,9	128,4	2,66	11,2	28,6
YOLOv8x	640	53,9	479,1	14,37	68,2	257,8
YOLOv9c	640	53	-	7,16	25,3	102,1
YOLOv9e	640	55,6	-	16,77	57,3	189
YOLOv9m	640	51,4	-	6,43	20	76,3
YOLOv9s	640	46,8	-	3,54	7,1	26,4
YOLOv9t	640	38,3	-	2,3	2	7,7
YOLOv10x	640	54,4	-	12,2	56,9	160,4
YOLOv10s	640	46,7	-	2,66	7,2	21,6
YOLOv10n	640	39,5	-	1,56	2,3	6,7
YOLOv10m	640	51,3	-	5,48	15,4	59,1
YOLOv10l	640	53,3	-	8,33	29,5	12,3
YOLOv10b	640	52,7	-	6,54	24,4	92
YOLO11x	640	54,7	462,8	11,3	56,9	194,9
YOLO11s	640	47	90	2,5	9,4	21,5
YOLO11n	640	39,5	56,1	1,5	2,6	6,5
YOLO11m	640	51,5	183,2	4,7	20,1	68
YOLO11l	640	53,4	238,6	6,2	25,3	86,9

3. Findings and discussion

In today's computer vision applications, object detection plays a crucial role, especially in areas such as autonomous vehicles, security cameras, and traffic analysis systems. In this context, an experiment was conducted to determine the performance differences between various versions of the YOLO (You Only Look Once) family. In the study, the models YOLOv8n, YOLOv9t, YOLOv10n, and YOLOv11n were applied to the same video footage, and their object detection accuracy and FPS values were compared. To evaluate the performance of the models, a video with a duration of 10 minutes and 20 seconds at 30 FPS was used, and the detections made by each model were examined individually. YOLO models are evolutionary deep learning networks developed to optimize both speed and accuracy in object detection. Different versions of the YOLO family offer enhanced features based on architectural optimizations and improvements. The YOLOv8n model is a relatively lightweight and optimized model suitable for real-time applications. The YOLOv9t model aims to improve accuracy rates through modifications in its deep learning architecture, while the YOLOv10n model offers a structure that requires fewer computational resources while still achieving high accuracy. The YOLOv11n model is the latest version, aiming to overcome the shortcomings of previous versions and achieve higher detection performance. As part of the experimental study, a specific video frame was selected, and the object detection performance of each YOLO model was visualized. During this evaluation, the object categories identified by the models and their detection confidence scores were analyzed. Factors such as whether the models correctly classified vehicles (car, bus, truck, etc.) and the presence of false positives and false negatives were taken into account (Fig. 1).

The image is divided into four sections, each showing a video frame analyzed by a different YOLO model. The objects detected within the same time frame and their corresponding confidence scores are displayed. The differences in object classification and the changes in confidence scores are indicated on the visual. The image includes various vehicle types in traffic, with each vehicle detected by the models at different accuracy levels. YOLOv8n model (a): This model successfully detected cars in traffic and classified a minibus as "bus," with a confidence score of 0.66. Overall, the vehicle detection accuracy is observed to be good. YOLOv9t model (b): This model also detected cars, but it misclassified the minibus as "truck," assigning a confidence score of 0.55. Therefore, this model shows some differences in object classification. YOLOv10n model (c): While generally successful in vehicle detection, this model classified the minibus as "bus" and assigned a confidence score of 0.47. The confidence scores for cars are relatively lower compared to other models, and one car was not detected. YOLOv11n model (d): This model successfully detected cars, but misclassified the minibus as "truck," with a confidence score of 0.49. The confidence scores for car detection showed variability. The analysis of the visual shows that all models were able to detect vehicles in traffic but classified the minibus differently. YOLOv8n and YOLOv10n classified the minibus as "bus," while YOLOv9t and YOLOv11n classified it as "truck." This discrepancy may be due to the dataset used during model training, the model's learning capacity, and updated algorithms. This study compares the object detection performance of different YOLO versions, focusing on accuracy rates and processing speeds for car and bus detection. The evaluation analyzes the frames-per-second (FPS) processing speeds, the number of objects detected, and their alignment with ground truth values for YOLOv8n, YOLOv9t, YOLOv10n, and YOLOv11n models running on a CPU. The detection results and speed values are shown in Table 3.

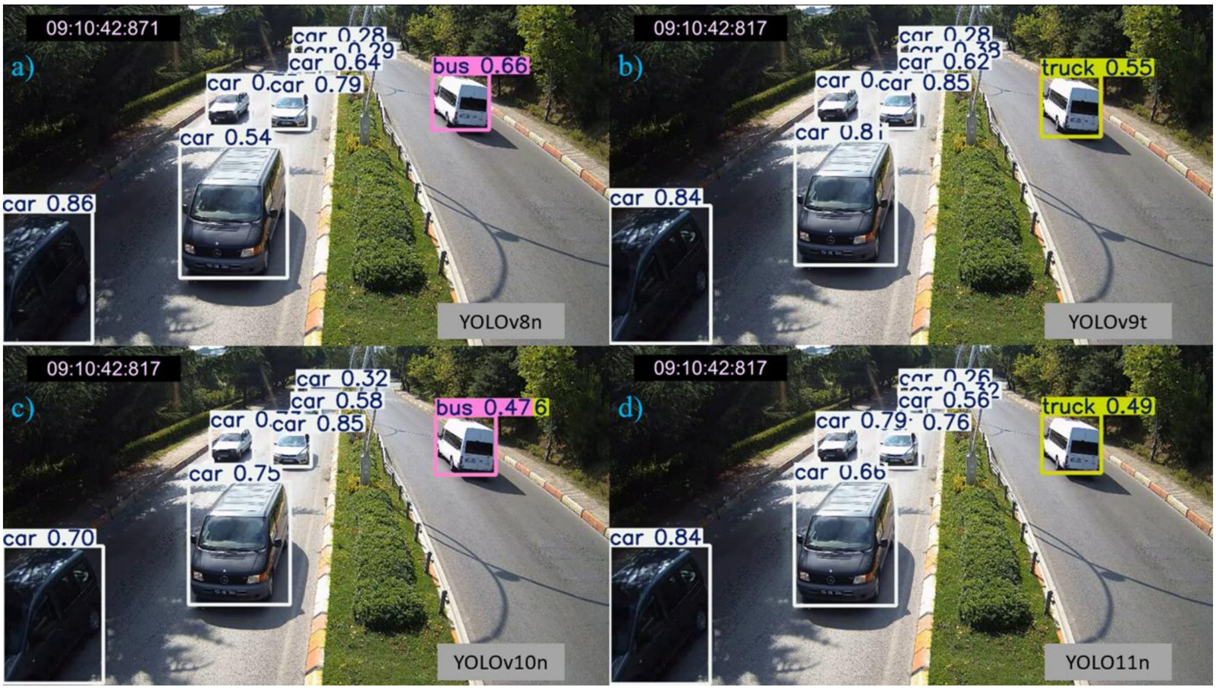

Fig. 1. Object detection confidence scores of different YOLO models within the same time frame

Table 3. YOLO models and performances

Model	FPS CPU	Car		Bus		Accuracy Rate (%)
		Detected	Real	Detected	Real	
YOLOv8n	15,81	220	256	36	36	87,67
YOLOv9t	12,87	217	256	35	36	86,30
YOLOv10n	10,68	223	256	36	36	88,69
YOLO11n	17,78	221	256	36	36	88,01

Based on the results, the model with the highest frames-per-second (FPS) is YOLOv11n, achieving 17.78 FPS. Despite this high FPS, it detected 257 vehicles. The YOLOv8n model, with a processing speed of 15.81 FPS, detected 265 vehicles and achieved an accuracy of 87.67%. The YOLOv9t model, with a lower FPS of 12.87, detected 252 vehicles and achieved an accuracy of 86.30%. The model with the lowest FPS, YOLOv10n, with 10.68 FPS, still achieved the highest accuracy of 88.69% and detected 259 vehicles. In terms of bus detection, all models performed similarly, with the exception of YOLOv9t. All models, except YOLOv9t, correctly detected 36 buses. This indicates that the models showed similar performance in distinguishing larger objects like buses. However, there were significant differences in vehicle detection. Despite its relatively lower FPS, YOLOv10n showed the highest accuracy, indicating that it provided more reliable detection. On the other hand, YOLOv11n achieved the highest FPS, offering an advantage in processing speed, but it did not deliver the best performance in terms of accuracy. These results highlight the need to balance speed and accuracy when selecting a model for object detection. Models with higher FPS may be preferred for real-time applications, while in scenarios where accuracy is critical, models that provide more reliable results with lower FPS might be more suitable. In applications like autonomous driving, traffic management, and security systems, optimizing both the processing speed and accuracy of the model is essential. YOLOv10n offers the best detection performance, while YOLOv11n stands out as the fastest option for real-time applications. Accordingly, the appropriate model should be chosen based on the specific requirements of the application.

4. Conclusion

This study presents a comparative analysis of the object detection performance of the YOLOv8, YOLOv9, YOLOv10, and YOLOv11 models on video data. A comprehensive performance evaluation was conducted by measuring detection accuracy, false positive, and false negative rates in a real-time, multi-frame data stream. The findings indicate that the YOLOv11 model has a higher overall accuracy compared to the other models. However, the YOLOv8 and YOLOv9 models exhibited lower error rates in detecting specific objects. The YOLOv10 model showed moderate accuracy but performed better than other models in certain scenes. These results demonstrate that each model has its own advantages and disadvantages depending on the use case. A more detailed analysis of model performances and testing of updated versions is recommended for future research. Additionally, testing under different angles and variable environmental conditions is crucial for assessing the models' overall detection capabilities. The findings of such studies can help determine which model should be prioritized for real-world applications. In conclusion, this study contributes to understanding the performance of object detection algorithms in video-based analysis, aiding advancements in the field. The analyses conducted are significant for understanding the evolution of object detection technologies and guiding the selection of the most effective model. In the future, it is anticipated that hybrid uses of these models or integration with advanced optimization techniques may further enhance performance.

Abstract. The thermal properties of asphalt concrete are required for understanding pavement behavior, especially regarding heat absorption, heat transfer, and the susceptibility to volumetric changes caused by temperature fluctuations throughout its service life. However, a standardized testing procedure to determine these properties has not yet been established. Although recent advancements in testing methods show promise, additional research is necessary to address limitations such as strict sample size requirements, long testing durations, and inaccuracies in test setups, which can impact the reliability and applicability of the measurements. To overcome these limitations, this study recognizes the necessity of comprehensively evaluating existing methods for measuring thermal properties, including thermal conductivity and specific heat capacity. It also systematically reviews experimental and numerical approaches from recent literature and assesses their effectiveness in understanding heat transfer mechanisms and their efficiency in practical applications. Previous studies categorized the experimental methods into steady-state and transient methods. Steady-state methods, such as the Guarded Hot Plate (GHP) and Heat Flux Meter (HFM), offer high accuracy but require significant time and careful sample preparation. In contrast, transient methods like the Transient Plane Source (TPS) and Transient Line Source (TLS) facilitate quicker measurements and greater adaptability, with innovations like the modified TPS enhancing the evaluation of various material compositions. Finally, numerical methods have become increasingly utilized as an alternative to address the limitations of experimental techniques. In summary, this study evaluates the existing methods for measuring the thermal properties of asphalt concrete and identifies their strengths, limitations, and potential for enhancement.

Keywords: Thermal properties; Asphalt concrete; Heat Transfer; Steady-state method; Transiet method

1. Introduction

Thermal changes, especially under fluctuating climatic conditions, significantly affect the long-term performance of pavement structures (El-Maaty, 2017; Tiza et al., 2022). This is mainly due to the temperature sensitivity of the asphalt binder. The viscoelastic properties of the asphalt binder change with temperature, causing permanent deformation (rutting) at high temperatures and cracking due to thermal stresses at low temperatures (Adwan et al., 2021; Li et al., 2021). These heat-induced variations directly relate to how heat is absorbed, conducted, and stored in the pavement layers. In asphalt pavements, heat is transferred by three different heat transfer modes: conduction, convection, and radiation. These modes are influenced by parameters such as surface color, roughness, and thermal properties of the asphalt mixture (Shamsaei et al., 2022). Specifically, the coefficient of thermal expansion, thermal conductivity, specific heat capacity, and thermal diffusivity of asphalt concrete are the main factors that define its thermal behaviour. These properties determine the material's capacity to undergo volumetric changes in response to temperature variations and its ability to conduct and absorb heat. Therefore, these properties need to be used as input in research on heat transfer modes in pavement engineering (Mamlouk et al., 2005; Mirzanamadi et al., 2018; Shi, 2014).

Thermal stresses and strains in asphalt concrete are intimately associated with thermal properties, as these properties directly influence the material's expansion or contraction in response to temperature variations (Zhong & Geng, 2009). Additionally, the amount of heat absorbed and retained by asphalt pavements significantly affects their environmental performance, particularly in summer when elevated surface temperatures and traffic loads lead to thermal oxidation and rutting (Abbas & Alhamdo, 2023; Khasawneh et al., 2023). Due to asphalt's dark color and low thermal conductivity, the pavement accumulates heat, increasing the surface temperature and intensifying

https://doi.org/10.31462/icearc2025_ce_tra_133

the Urban Heat Island (UHI) effect (Calkins, 2012). Thermal properties of asphalt concrete play a crucial role in predicting pavement surface temperatures, which impact not only structural performance but also frost effects in subgrades and the effectiveness of winter maintenance (Ayasrah et al., 2023; Minhoto et al., 2005). Heat-based self-healing technologies also depend on these properties to activate healing mechanisms within microcracks (Concha & Norambuena-Contreras, 2020; García et al., 2013; Liang et al., 2021). Tools like the Mechanistic-Empirical Pavement Design Guide (MEPDG) incorporate thermal properties as main inputs to simulate long-term performance in pavement design (Ceylan et al., 2009). The cooling rate of pavements during construction is fundamentally governed by their thermal properties, particularly the specific heat capacity and thermal conductivity, and thus, accurate determination of thermal properties is needed to optimize compaction processes (Highter, 1983; Timm et al., 2001). To summarize, accurately measuring the thermal properties of asphalt concrete can be defined as a key to improving pavement design practices, ensuring construction quality, and developing effective maintenance strategies, especially to hedge against urban climate changes and their challenges.

Despite its acknowledged importance, a standard test method for measuring thermal properties of asphalt concrete is still under discussion. Although recent efforts have focused on characterizing thermal behavior using current experimental approaches, further research is required to identify the main influencing parameters and to modify the test procedures. Notably, there is still no comprehensive comparative study that evaluates the suitability, accuracy, and limitations of different measurement techniques. The effect of the testing method used in obtaining the thermal properties is not yet known. Given these concerns, this study aimed to provide a comprehensive review of experimental and numerical methods used to determine the thermal properties of asphalt concrete. The study begins by reviewing commonly applied experimental methods and then presents numerical and simulation-based approaches. It then presents a comparative evaluation of these methods, attempting to reveal their practical advantages and limitations. Finally, the aim is to evaluate the applicability and effectiveness of the techniques used in determining the thermal properties of asphalt concrete, while identifying the methodological procedure and standardization opportunities.

2. Experimental methods for measuring thermal properties

There are some experimental studies in the literature on the development of test methods, the design of special equipment, and the modification of test setups to precisely measure the thermal properties of asphalt concrete. These studies primarily classify measurement techniques into two categories: steady-state and transient methods (Byzyka et al., 2021; Côté et al., 2013; Elkholy et al., 2019; Islam & Tarefder, 2014; Kuvandykova & Bateman, 2013). The following figure presents some of these experimental methods and their related test equipment, as seen in Fig.1.

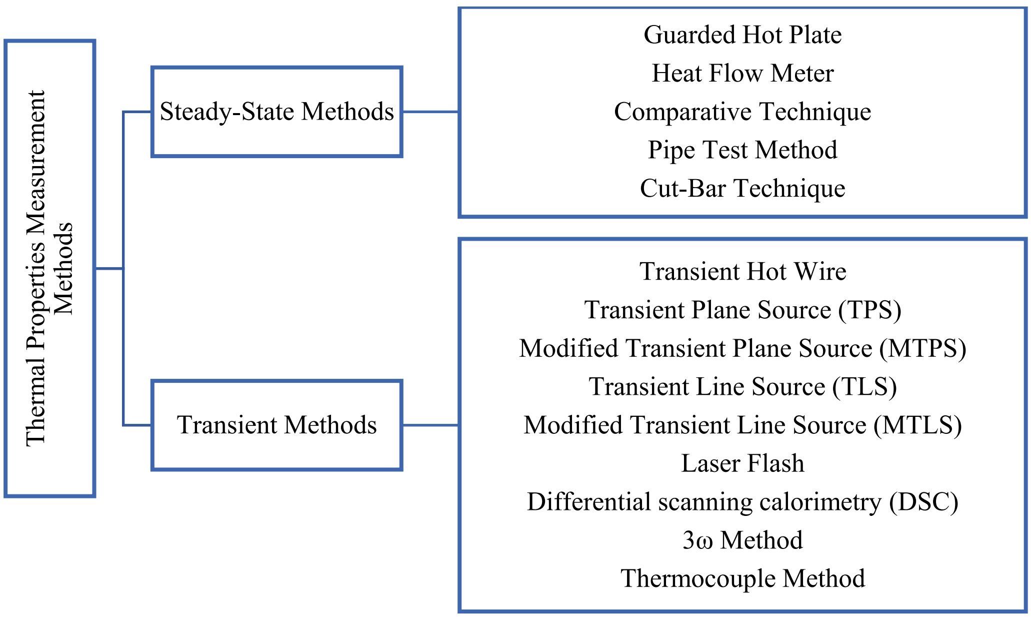

Fig. 1. Methods for measuring thermal properties (Kuvandykova & Bateman, 2013; Palacios et al., 2019)

The thermal conductivity and specific heat capacity of asphalt concrete were generally measured with the steady-state approach when the equilibrium heat flow conditions were provided in the test setup. These studies were mainly structured on one-dimensional heat transfer conditions under constant temperature changes, following Fourier's heat transfer principle (Carlson et al., 2010; Mehling & Cabeza, 2008; Tritt, 2005). Among the most widely adopted standardized procedures were the Guarded Hot Plate (GHP) and Heat Flow Meter (HFM) methods, as defined by ASTM C177-19 and ASTM C518-21, respectively (*Standard Test Method for Steady-State Heat Flux Measurements and Thermal Transmission Properties by Means of the Guarded-Hot-Plate Apparatus*, n.d.; *Standard Test Method for Steady-State Thermal Transmission Properties by Means of the Heat Flow Meter Apparatus*, n.d.). Both techniques can be considered practical approaches, particularly when working with flat and homogeneous specimens, provided that calibration and surface conditions are carefully controlled (Kim et al., 2021; Palacios et al., 2019; Richter et al., 2003). However, because asphalt concrete is a naturally heterogeneous material, applying these standard test procedures to asphalt mixtures is controversial. Nonetheless, alternative setups and modifications have been attempted to overcome the difficulties presented by traditional methods, such as long test durations and stringent sample size requirements.

Among past studies, Mrawira and Luca (2002) developed the UNB k-alpha tester, specifically designed to test small cylindrical samples, including cores extracted from pavements and lab-compacted briquettes (Mrawira & Luca, 2002). In a similar effort to address sample geometry issues, Carlson et al. (2010) developed a cylindrical heating model in which radial heat flow was generated by placing a heat source along the axis of a cylindrical sample, insulated at both ends. This method, which enabled thermal measurements within specimens typically used in mechanical tests, produced repeatable thermal conductivity results (0.896 ± 0.023 W/m·°C) (Carlson et al., 2010). On the other hand, other researchers focused on analytical modeling and enhanced instrumentation. Accordingly, Xu and Solaimanian (2010) tested asphalt concrete samples in a controlled climate chamber. They monitored transient heat transfer to validate a predictive model, eventually reaching steady-state conditions (Xu & Solaimanian, 2010). Meanwhile, Côté et al. (2013) proposed a modified test system using a thermal conductivity cell with brass disks and thermoelectric heat flux meters, as seen in Fig.2. Their study provided consistent measurements across asphalt mixtures with varying aggregate size, bitumen content, and air void ratios (Côté et al., 2013). Hassn et al. (2016a, 2016b) also made a notable contribution to this topic by using the P.A. Hilton B480 HFM system with large slab specimens (306 × 306 × 50 mm³), demonstrating that higher air void content significantly impedes heat flow due to the insulating nature of air (Hassn et al., 2016a, 2016b). In the following, Fig. 2 gives some parts of the experimental setup prepared based on the steady-state principle in the study conducted by Côté et al. (2013).

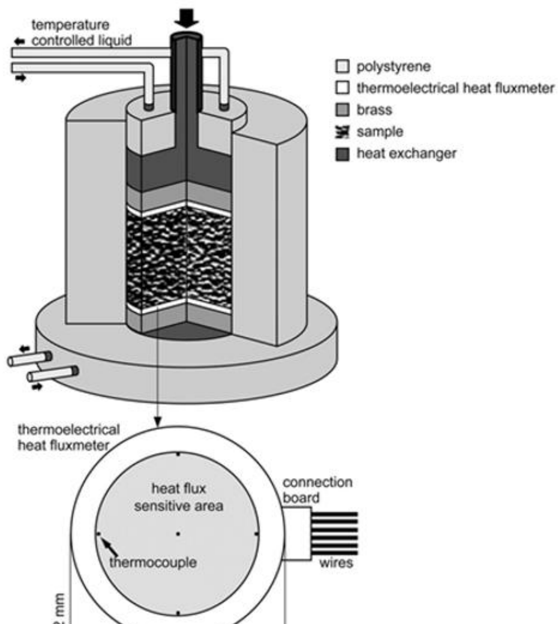

Fig. 2. Heat transfer cell adapted from Côté et al., 2013.

Some studies have also used the steady-state approach to determine specific heat capacity; however, these studies are limited. In the past, specific heat capacity was determined based on the weighted average of the constituent materials (Johnston, 1981; Jordan & Thomas, 1976). These studies were found to be unreliable due to moisture and void variations; more recent approaches are needed to provide better accuracy. Accordingly, Wolfe et al. (1980) and Islam & Tarefder (2014) studied the development of the drop calorimeter method, applying the principle of energy conservation in a steady-state setting. The latter study used a thermally insulated ice box and hot water bath to monitor temperature changes in asphalt samples (See Fig. 3c), directly calculating specific heat capacity under controlled conditions (Islam & Tarefder, 2014; Wolfe et al., 1980). Lastly, Demirtürk et al. (2023) modified the drop calorimeter method. They designed a custom calorimetry-based setup to measure the specific heat capacity of asphalt concrete samples produced in the laboratory under steady-state conditions (See Fig.3a & Fig. 3b). The system consisted of a thermally insulated steel cabinet with a water heating unit, a circulation pump, RTD sensors, and a data acquisition system. Samples pre-conditioned at a known temperature were immersed in heated water, and the temperature changes were recorded until thermal equilibrium was reached. The energy balance between the water and the asphalt specimens was then used to calculate the specific heat capacity. This setup effectively minimized lateral heat losses and allowed for precise thermal measurements in a controlled environment (Demirtürk et al., 2023).

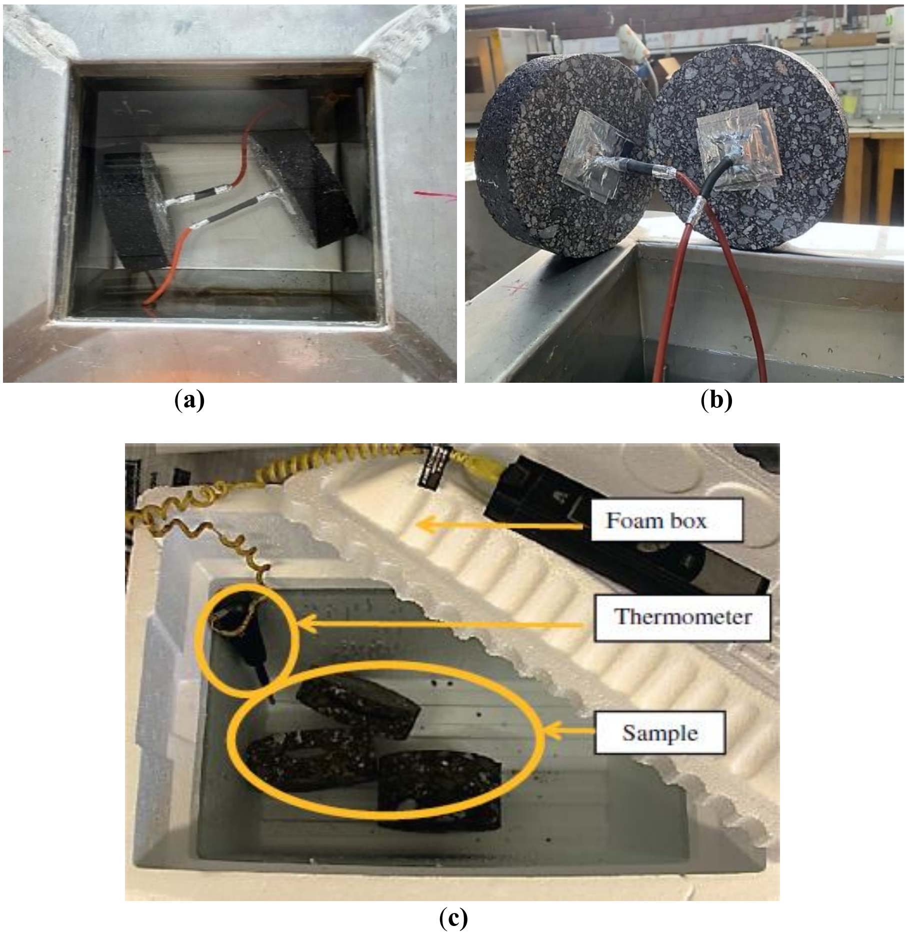

Fig.3. The main parts (a & b) of the test setup developed by Demirtürk et al. (2023) and the specific heat capacity measurement test setup (c) in asphalt concrete developed by Islam & Tarefder (2014).

Traditional one-dimensional steady-state methods may lead to inaccurate and erroneous test results (Zarr, 2010). Therefore, many researchers have tried to investigate and suggest the transient approach-based test methods, which are considered modern and rapid. The reviewed studies applied various transient methods—Transient Line Source (TLS), Transient Plane Source (TPS), and Modified Transient Plane Source (MTPS)—to measure the thermal properties of asphalt concrete. An overview of the equipment and applications related to the TLS, TPS, and MTPS methods is presented in Fig. 4. For example, Byzyka et al. (2021) applied the TLS method to find the effects of aging, temperature, and air voids on the measurement results. Their results indicated that variables, including poor needle-sample contact and drilling residue presence, can cause measurement errors, therefore affecting the reliability of the results (Byzyka et al., 2021). Mirzanamadi et al. (2018) employed the TPS method. They highlighted the importance of sensor size, heating power, and measurement time, revealing inaccuracies when the sensor diameter was too small relative to aggregate size (Mirzanamadi et al., 2018). Chen et al. (2022) and Khasawneh et al. (2023) also used TPS techniques, stressing the significance of good sensor contact (X. Chen et al., 2022; Khasawneh et al., 2023). Demirtürk et al. (2024) also found that thermal conductivity values acquired using the TPS approach were extremely location-dependent, highlighting the importance of numerous measurements to ensure acceptable results in heterogeneous materials (Demirtürk et al., 2024). Petkova-Slipets & Zlateva (2018) introduced the MTPS method, which simplifies measurements and allows field testing without needing identical samples (Petkova-Slipets & Zlateva, 2018). While accuracy depends on sensor-aggregate compatibility, it is stated that transient methods remain popular due to their speed and practicality.

In addition to thermal conductivity measurements, transient approaches have also been required to measure specific heat capacity. In this context, the MTPS method, developed by Mathis Instruments Ltd. in 2004, has emerged as one of the few applicable techniques for measuring the specific heat capacity of asphalt concrete (Petkova-Slipets & Zlateva, 2018). Besides the MTPS method, other commonly used methods include Differential Scanning Calorimetry (DSC) and Modulated Differential Scanning Calorimetry (MDSC). The DSC method provides both quantitative and qualitative data on physical and chemical changes as well as variations in heat capacity. The MDSC method, as an advanced and patent-pending version of DSC, enables the differentiation between reversible and irreversible thermal events (Reading et al., 1994). For example, Hu and Yu (2016) utilized the MDSC method to investigate the thermal behavior of thermochromic asphalt pavements. They reported a specific heat capacity range of 1475–1778 J/(kg·K) for black asphalt coating within the temperature range of –20 to 50 °C (Hu & Yu, 2016). However, a review of previous studies reveals that transient methods such as DSC and MDSC have primarily been applied to bitumen rather than asphalt mixtures. This is mainly due to the incompatibility of asphalt mixture sample sizes with the requirements of transient testing methods. Specifically, in the DSC method, the quantity of sample used in measurement pans is typically limited to around 10–20 mg (Zadshir et al., 2020). Consequently, DSC is most often employed to assess changes in the thermal properties of bitumen (Elkashef et al., 2020; Hosseinnezhad et al., 2019; Zadshir et al., 2020). Accurately measuring the specific heat capacity of asphalt concrete using transient methods remains challenging, and efforts are ongoing to discover and develop new measurement techniques.

3. Numerical approaches and simulation-based studies

Microstructural modeling should be considered as the first step in applying numerical methods to determine the thermal properties of asphalt concrete and thus, the thermal behavior of asphalt concrete. Two basic techniques are commonly used to create three-dimensional (3D) representations of asphalt mixtures: computer-aided modeling and image-based modeling (Chen et al., 2015b; Wang et al., 2018; Zhang et al., 2017). In recent years, integrated approaches combining multi-scale modeling with mathematical prediction techniques have also been studied to increase the accuracy of thermal property predictions (Ren et al., 2018)

Previous studies, such as Chen et al. (2015b), established a multi-scale 3D microstructure model of asphalt concrete and combined it with Finite Element Analysis (FEA) to improve the simulation accuracy. Asphalt concrete was modeled as a three-phase heterogeneous system in which aggregates and air voids were represented by simplified polyhedral shapes dispersed in the asphalt binder. The FEM applied in the study was based on steady-state heat transfer principles. Constant temperatures were applied to the top and bottom faces of a cubic sample, while the remaining four sides were thermally insulated, maintaining one-dimensional heat flow. The model's predictions of effective thermal conductivity showed strong agreement with experimental data, with relative errors of 4.35% and 8.92% for samples made with crushed gravel and hornfels, respectively (Chen et al., 2015b). In a related study, Chen et al. (2015a) modified the aggregate generation algorithm originally proposed by Wang et al. (1999) to create angular coarse aggregates as polygons with defined elongation ratios. Randomized aggregate distributions were generated using MATLAB and implemented into ABAQUS—the hierarchical multiscale approach for constructing the microstructure. The FEM included three-node linear heat transmission elements and relied on thermal data from Mrawira & Luca (2006) (Chen et al., 2015a; Mrawira & Luca, 2006; Wang et al., 1999). Zhang et al. (2017) used a Voronoi diagram to generate a 3D random microstructure of asphalt mixtures. This method increased modeling efficiency by preventing particle overlap. Using steady-state FEA, it was found that the shape and orientation of the aggregates affected the mixture's thermal conductivity (Zhang et al., 2017). Using a simplified modeling approach, Chu et al. (2020) examined the relationship between the volumetric composition of asphalt mixtures and their thermal conductivity. They introduced a regular row-column model, allowing a more practical simulation of mixture behavior (Chu et al., 2020). As illustrated in Fig. 5a, this 2D model used square four-node elements and assumed conduction as the sole heat transfer mechanism. Despite its simplicity, the model produced results comparable to more complex microstructure-based simulations. Zhao et al. (2020) focused on porous asphalt concrete and utilized X-ray CT scanning to capture its internal structure. A mapped meshing method was used to construct the FEM. Their study performed a transient heat transfer analysis, highlighting the role of air voids in porous mixtures, in contrast to the more uniform structure of dense-graded mixtures (Zhao et al., 2020). Lastly, current developments in numerical modeling have paved the way for inverse methods, which can be particularly useful when direct data inputs are unavailable (Telejko & Malinowski, 2004). These methods rely on known temperature fields to back-calculate thermal properties. Once an appropriate material model is established, inverse techniques can be effectively combined with commercial finite element software to determine the thermal properties of asphalt concrete.

(b)

Fig. 4. (a) 2D row-column representation of asphalt mixture (Chu et al., 2020) and (b) Image-based model development steps (Zhao et al., 2020).

4. Comparative evaluation of current methods

The main purpose of this study is to critically compare experimental and numerical approaches to measure or determine the thermal properties of asphalt concrete. It has been found that the existing methods offer different advantages and limitations. The following points summarize the main differences and practical implications associated with steady-state, transient, and computational techniques in a general framework:

- Studies with steady-state methods have found that they offer high measurement accuracy under controlled conditions but are limited by long test durations and strict sample geometry requirements, making them less practical.
- Transient methods such as TPS and MTPS are significantly faster and more flexible when testing homogeneous materials. However, their accuracy is highly sensitive to sensor-sample contact quality and surface conditions, making their use in heterogeneous materials difficult and questionable.
- While the Guarded Hot Plate (GHP) and Heat Flow Meter (HFM) techniques have been cited as reliable measurements for flat, homogeneous samples, they have often failed to accommodate the irregular geometry of asphalt samples retrieved from the field.
- Specific heat capacity measurements in steady-state setups are limited by humidity and air void variability, while calorimetry-based methods, although promising, still lack standardization and reproducibility.
- Transient methods such as DSC and MDSC are used to measure the specific heat capacity of materials, but these are mainly suitable for bitumen and not for asphalt concrete due to the limited sample volume.
- New steady-state setups, such as the UNB k-alpha tester and cylindrical heat flow systems, offer improved realism for laboratory measurement of thermal properties by increasing compatibility with laboratory-compressed briquettes and in situ cores.
- TPS and TLS methods show broader applicability and adaptability in both laboratory and field environments. However, it is underlined that for valid results, test parameters such as heating power, sensor size, and test duration are necessary for safe and reliable measurement.
- The literature introduces image-based finite element models and inverse numerical techniques as valuable alternatives that provide detailed microstructural analysis and prediction of thermal properties in asphalt concrete, where experimental methods encounter limitations. However, their reliability mostly depends on accurate experimental calibration and high-resolution input or availability of experimental data, which remain critical prerequisites for ensuring model validity.
- Despite considerable progress, existing numerical models often oversimplify material heterogeneity and heat transfer mechanisms, limiting their ability to reproduce the complex thermal reactions observed in real-world pavements accurately.

5. Conclusions

This study tries to compare the current experimental and numerical methods to determine the thermal properties of asphalt concrete. It can be concluded that steady-state and transient techniques offer certain advantages. However, their application to the inherently heterogeneous structure of asphalt mixtures remains challenging. Similarly, although numerical approaches are considered an alternative for determining the thermal properties of asphalt concrete when combined with microstructural analysis, their dependence on simplifying assumptions and the need for experimental calibration alone undermine their reliability. Thus, future research should focus on strengthening the compatibility of testing procedures with the intrinsic variability of asphalt mixtures. Steady-state procedures should be modified to reduce heat loss and improve specimen preparation consistency. Transient approaches, on the other hand, require standardisation with a larger emphasis on sensor-sample interactions and surface conditions. Furthermore, integrating numerical modelling and experimental calibration could offer a more complete understanding of heat transfer mechanisms at different levels. Accordingly, it may be beneficial for new standards to focus on the following recommendations at the first stage:

- Sensor-based measurement systems should use multi-point measurement procedures to capture local thermal property changes.
- Improved calibration protocols should be created for both steady-state and transient setups, considering sample geometry and surface conditions.
- Studies based on integrating numerical models based on microstructural information with robust experimental validation need to be increased and supported.
- Attempts should be made to combine the strengths of existing methods, such as developing hybrid methods that combine steady-state accuracy with the flexibility of transient approaches.

A Comparative analysis of bus rapid transit (BRT) systems: A framework for Sakarya

Süleyman N. A. Şahin[1], Abdurrahman Korkmaz[2], Abdulkadir Özden[1*],

[1]*Sakarya University of Applied Sciences, Department of Civil Engineering, 54050 Sakarya, Türkiye*
[2] *Giresun University, Keşap Vocational School, Department of Menagement and Organization, 28000 Giresun, Türkiye*

Abstract. This study presents a comprehensive comparative analysis of Bus Rapid Transit (BRT) systems across diverse geographic regions and cities across the world. Key performance indicators such as GDP per capita, urban population, system length, and station spacing were examined to uncover the socioeconomic and infrastructural dynamics influencing the efficiency and design of BRT networks. The findings provide a strategic framework for planning and developing BRT systems. According to these indicators, with comparative data analysis and visualization, the current status of Sakarya is shown in a wider perspective. Within this perspective for the most sustainable design for the future and transformation of urban mobility, this system will have a potential to build up the development under the human-centric paradigm. This finding highlights the crucial role of geographic and economic disparities in the design and operation of BRT systems. The significance of this study for Sakarya lies in its ability to serve as a benchmark for planning and developing the city's BRT system. The visualizations and results obtained are used to compare Sakarya with other cities from different regions with similar characteristics and identify the strengths and weaknesses of the future-planned BRT system. This allows for the development of customized BRT system design and improvement strategies for Sakarya and also for the local policy and decision makers.

Keywords: BRT system; Comparative analysis; Transformation; Sustainability; Urban mobility

---

1. Introduction

Since the early 21st century, urbanization and increasing mobility demands have prompted cities worldwide to seek cost-effective and scalable public transportation solutions (Cervero & Kang, 2011; ITDP, 2016). Bus Rapid Transit (BRT) offers a more affordable and flexible alternative to rail-based transit systems, mimicking many of Light Rail System's (LRT) advantages while maintaining lower infrastructure costs (Halimergün et al., 2024; Deng & Nelson, 2011). By incorporating dedicated lanes, traffic signal priority, and enhanced station design, BRT has gained prominence as a sustainable and efficient urban mobility solution.

The growing popularity of BRT worldwide is reflected in its rapid expansion over the past two decades. From the completion of the first BRT system in Curitiba, Brazil in 1974, BRT infrastructure remained relatively modest until the early 2000s (Prestes et al., 2022). However, as cities sought cost-effective transit solutions, BRT corridor development accelerated significantly, reaching over 5,300 km globally by 2021 (BRTDATA, 2025). Despite this growth, North America and Europe lag behind Latin America and East Asia in terms of BRT adoption, as cities in developed economies often prioritize rail-based systems (Cervero & Kang, 2011; Carrigan et al., 2019). In the North and South America, for example, BRT accounts for only 8.2% of total BRT corridor length worldwide, with many systems operating as BRT-lite, lacking dedicated right-of-way infrastructure (ITDP, 2016). This variation in BRT implementation underscores the diverse nature of BRT infrastructure, ranging from full busways with dedicated lanes to mixed-traffic operations, affecting the efficiency, reliability, and attractiveness of these systems (Deng & Nelson, 2011; Ferbrache, 2019).

Beyond mobility benefits, BRT systems have far-reaching implications for economic development, land use, and urban accessibility. Studies show that high-quality transit investments, such as LRT and BRT, can increase property values, attract new businesses, and support transit-oriented development (TOD) (Cervero & Dai, 2014). However, while the positive impact of rail-based transit on property values is well-documented, BRT's effects remain less understood, particularly in the United States and Europe (Deng & Nelson, 2011; Su, 2024). Research

*Corresponding author, Prof., E-mail: aozden@subu.edu.tr

https://doi.org/10.31462/icearc2025_ce_tra_256

in Latin America and East Asia suggests that BRT systems can generate land value premiums ranging from 5% to 10%, especially when integrated with mixed-use development and pedestrian-friendly infrastructure (Suzuki et al., 2015). However, the design and operational characteristics of BRT—such as station spacing, integration with other transport modes, and fare structures—play a crucial role in determining whether BRT can stimulate economic growth and enhance.

Given these global variations in BRT performance and effectiveness, it is essential to conduct comparative analyses that benchmark BRT systems across different geographic and economic contexts. This study aims to evaluate key performance indicators such as system length, urban population, GDP per capita, station spacing, and multimodal integration to understand the factors that drive BRT efficiency (Merkert, 2017). This study aims to clarify and provide a deeper understanding of the public transport network in Sakarya by examining the implementation of a new transit system. The system, which is still under construction, is designed as a BRT network to connect both sides of the city, contributing to the development of more inclusive and sustainable urban environments. Sakarya is a city located in the northwest of Türkiye. As of the end of 2024, its population is 1,110,735, with an annual population growth rate of 16.6 per thousand. The province covers a surface area of 4,817 km², with a population density of 228 people per km². This study was conducted in the most populated districts of Sakarya—Serdivan, Adapazarı, and Erenler—which also serve as the city's central districts (Figure 1). These districts play a significant role in the economic and social structure of Sakarya.

Fig. 1. Location map of study area

By analysing Sakarya's urban characteristics in comparison with global BRT systems, this study aims to uncover both opportunities and challenges in developing a locally adapted BRT strategy that aligns with the city's socioeconomic dynamics and sustainability objectives. The findings offer a strategic roadmap for BRT implementation in Sakarya, providing valuable insights for local policymakers, urban planners, and transit authorities. The discussion delves into how Sakarya's urban mobility strategy can be enhanced by integrating global BRT best practices, culminating in policy recommendations for effective implementation. This paper serves as a strategic background for the planning and development of Sakarya's BRT system, using global benchmarks to inform region-specific solutions.

2. Methodology

BRT systems serve as one of the best examples of urban transportation systems implemented in all continents of the world. In particular, the data of the cities with BRT systems in all continents, especially in this field, are also kept on the web address www.brtdata.org (BRTDATA, 2025). This website, which also has an interactive user interface, is a very useful website for the necessary comparisons and current situation analysis as well as presenting data.

In this study, the data sets of all cities available on this website (Fig. 2) were collected. Infrastructure data for a total of 192 cities were extracted and listed. The data for 191 cities were collected considering basic variables such as GDP, population city, population density by metropolitan area, integration terminals, system length, station spacing and standard fare. In the light of the collected data, it was observed that some cities lacked data in these categories, and for this reason, the number of data to be subjected to analysis was reduced to 151 cities by cleaning the data.

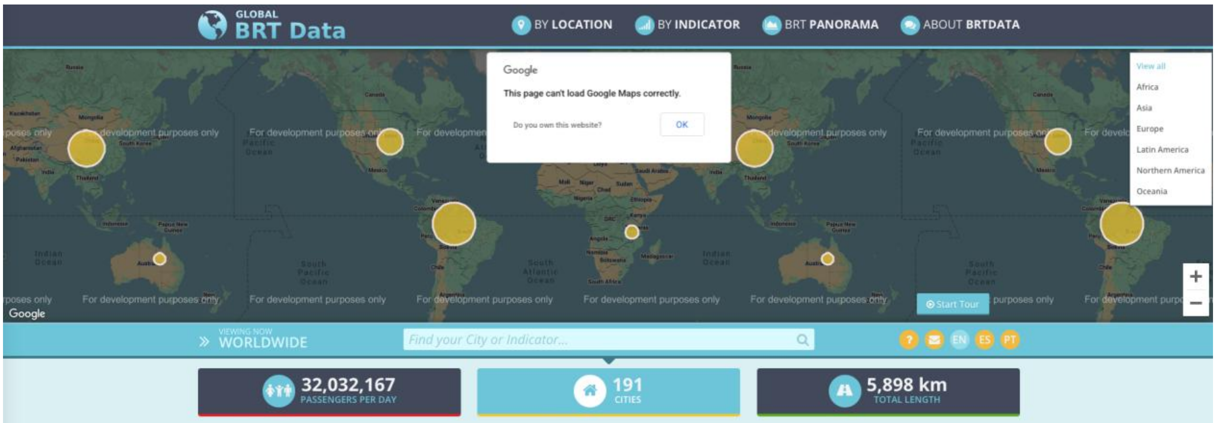

Fig. 2. The general view of www.brtdata.org

However, the data for cities in all these categories are compared using comparative analyses across continents. Since Sakarya will be the second metrobus city in Turkey (Fig. 3), the system length, station spacing and standard fare planned by the metropolitan municipality were added to this dataset and a comparison was made between 152 cities. It should be taken into account that some of the data sets we receive from BRT (www.brtdata.org) are outdated and may produce different results when compared with today's values. The integration terminals and population city categories, which were not found to contribute to the continent-specific comparisons of all these cities, were not included in the analysis. Sakarya data sets are presented in Table 1.

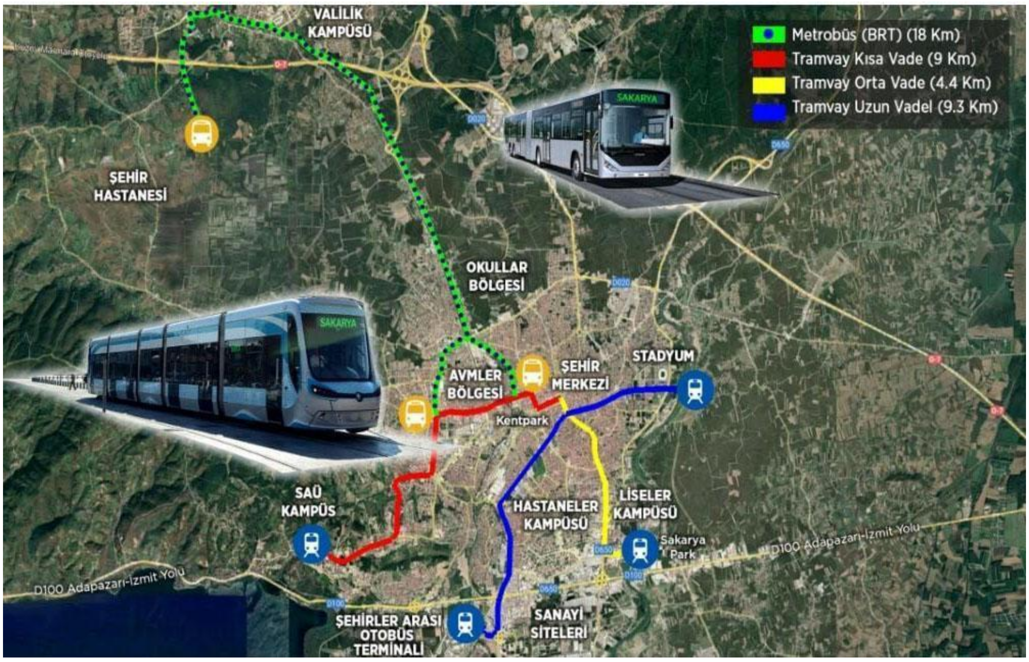

Fig. 3. The general view of www.brtdata.org

These analyses and comparisons have been tested with the current state of the data on www.brtdata. org and have enabled us to see the current status of the BRT system planned to be implemented in Sakarya with all other continents and its current position resulting from the comparisons. It was evaluated in this way that the planned system is at a level that can compete with both Europe and all other continents and that this sustainable public transportation system will come to this city.

Table 1. Sakarya city datasets

Region	Country	City	GDP per capita (US$)	Population density	Standard fare (US$)	System length (km)	Station spacing (m)
Europe	Türkiye	Sakarya	8.171	907	0,31	16	1.300

3. Results

This comparative analysis of BRT systems highlights the critical interplay between economic, demographic, and infrastructural factors. The insights provide valuable guidance for designing equitable and efficient transit systems, emphasizing the importance of context-sensitive approaches in global BRT planning.

The heatmap highlights global disparities in GDP per capita in Figure 4, with economically advanced nations (e.g., North America and Western Europe) exhibiting higher values compared to regions such as Africa and parts of Asia. Turkey's GDP per capita is positioned in the middle range, reflecting its developing economy status. These economic variations have significant implications for the development and sustainability of BRT systems, particularly in funding and affordability

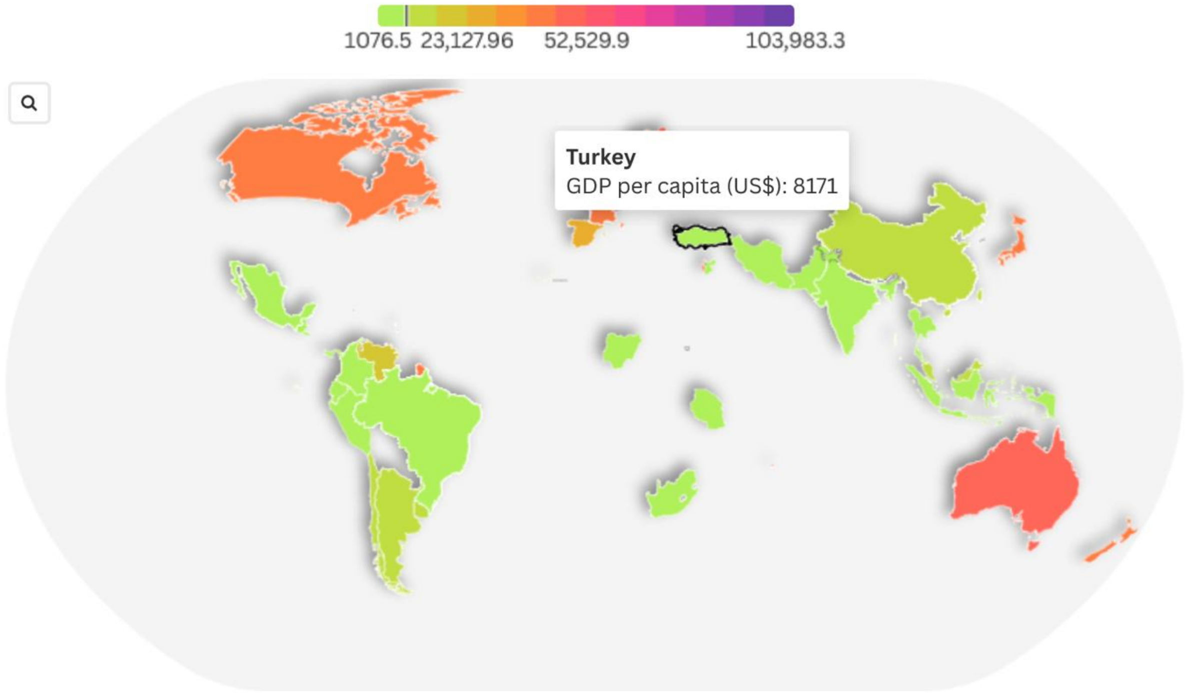

Fig. 4. The global distribution heatmap of GDP (BRTDATA, 2025)

The circular bar chart demonstrates in Figure 5 stark differences in population density across regions. Highly urbanized countries such as India and China showcase significantly higher densities, indicating greater reliance on public transport solutions like BRT systems. In contrast, lower-density regions like Australia suggest a reduced demand for such infrastructure. This underscores the necessity of tailoring BRT designs to the unique urban fabric of each region.

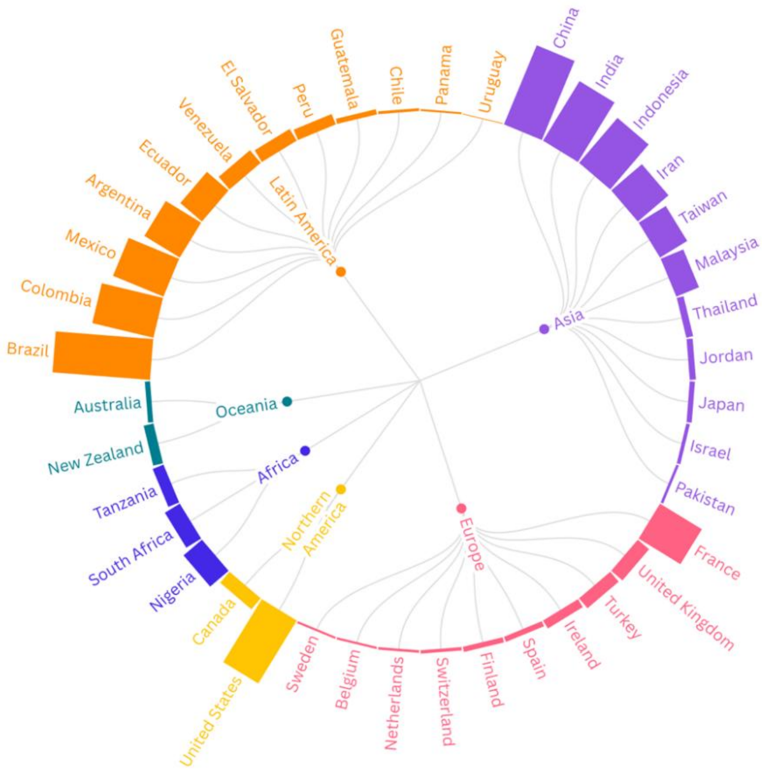

Fig. 5. The population density in metropolitan areas (BRTDATA, 2025)

The visualization of standard fare distribution in Figure 6 reveals considerable variability, with lower fares in developing regions and higher fares in developed economies. This disparity reflects not only differences in economic capacity but also the degree of subsidies provided by governments. The equitable balance between affordability and system sustainability emerges as a key consideration for policymakers.

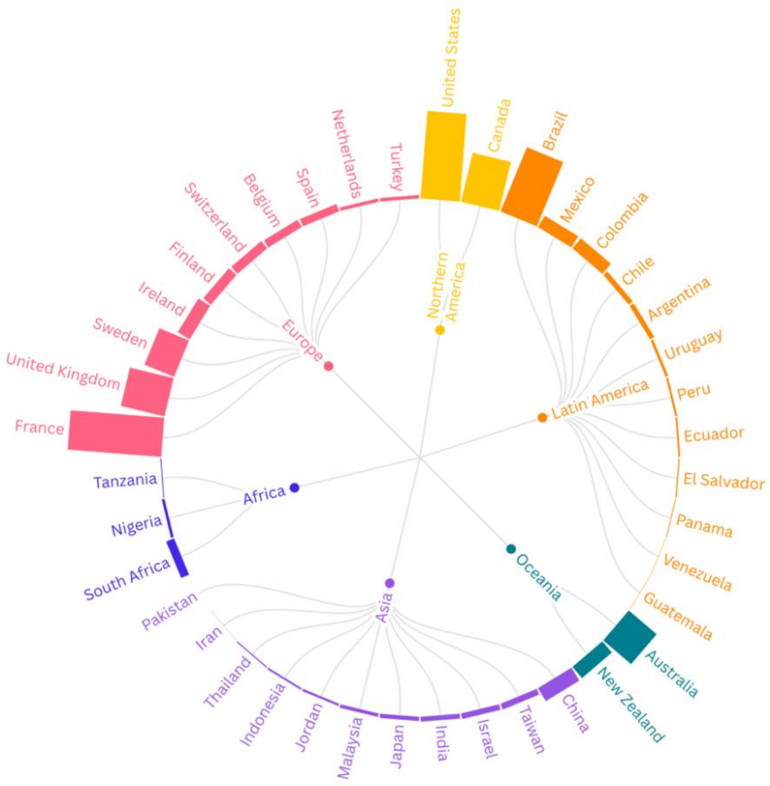

Fig. 6. The standard fare analysis (BRTDATA, 2025)

The scatter plot in Figure 7 reveals a strong correlation between GDP per capita and standard fare, with higher-income regions typically charging higher fares. Sakarya, located within a moderate GDP per capita range, demonstrates a fare structure that aligns with regional norms for affordability. This observation underscores how mid-income regions prioritize public transport affordability to encourage ridership and accessibility. However, notable outliers in the scatter plot highlight the role of subsidies and operational efficiencies in determining fares, suggesting areas for policy innovation in Sakarya's BRT development.

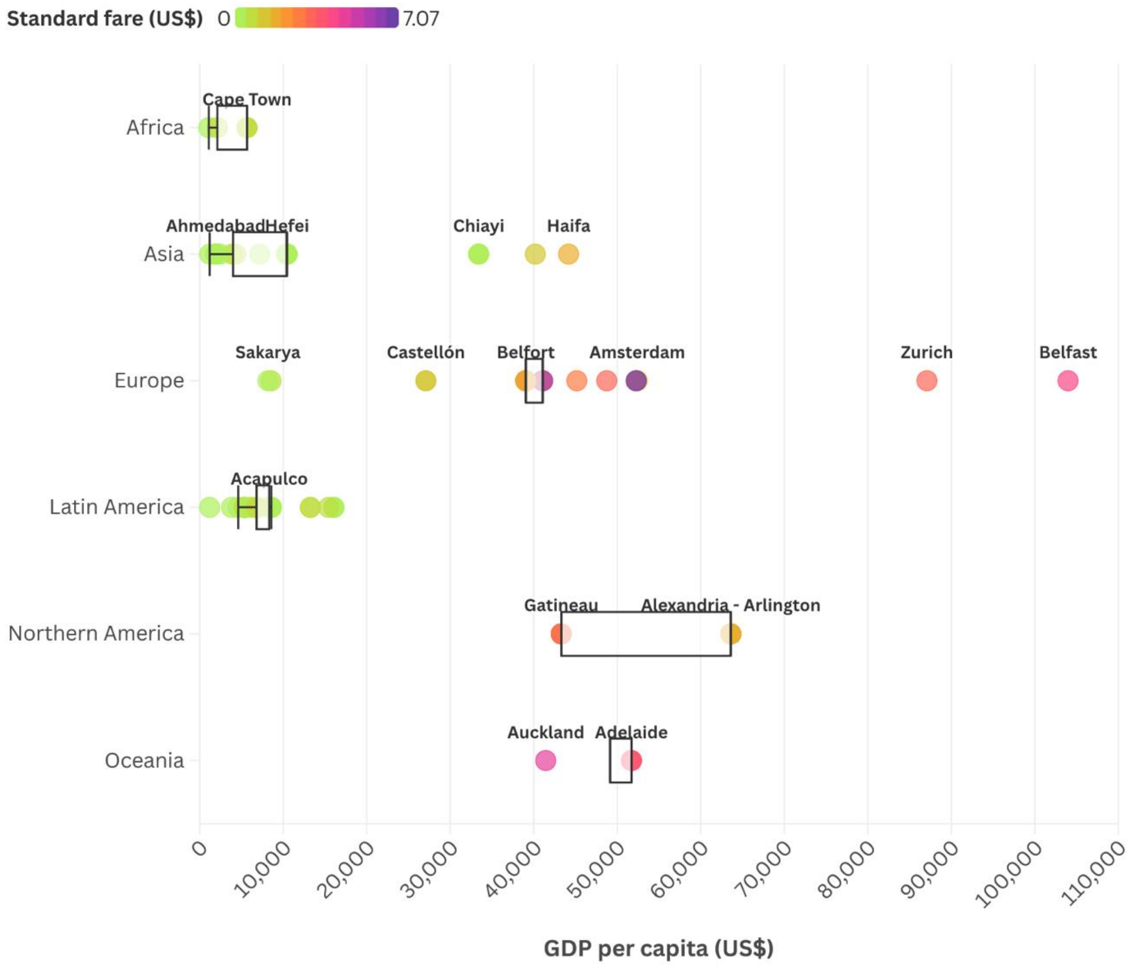

Fig. 7. The GDP per capita vs. standard fare (BRTDATA, 2025)

The relationship between station spacing and population density in Figure 8 indicates divergent strategies across regions, with developed areas favouring longer spacings to enhance travel speed and high-density regions prioritizing shorter distances for accessibility. Sakarya's station spacing aligns with regional averages for Europe, reflecting its focus on balancing commuter convenience and network efficiency. This suggests that Sakarya has adopted a scalable design suitable for its urban density, aligning with broader trends observed in similarly populated regions.

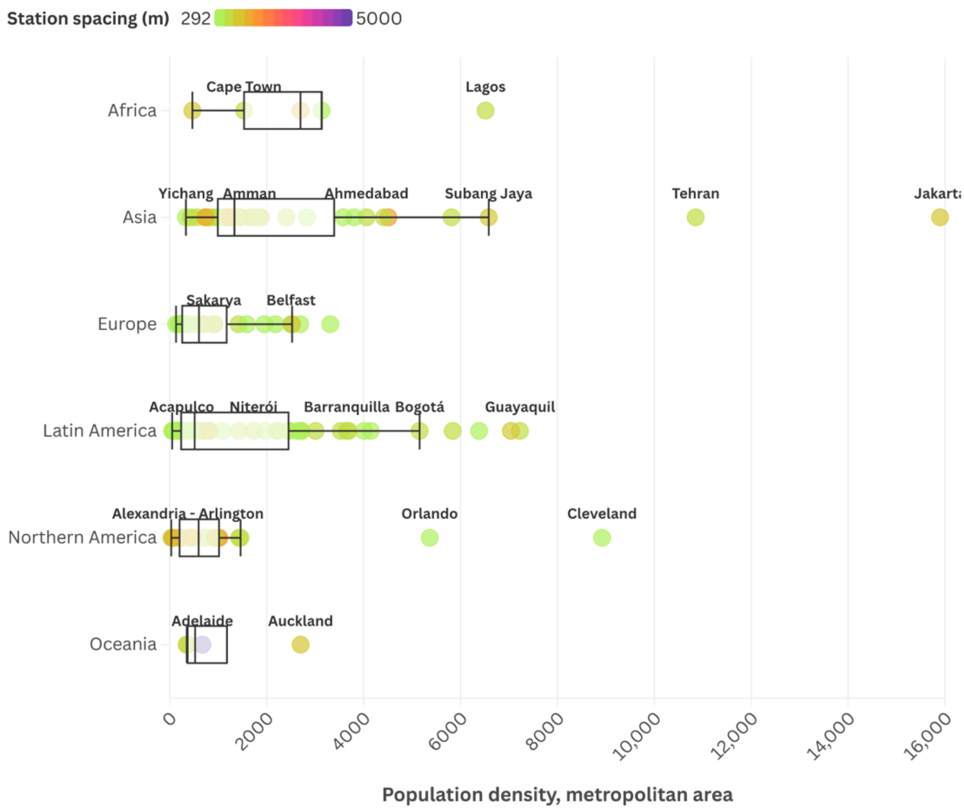

Fig. 8. The station spacing vs. population density (BRTDATA, 2025)

System length varies widely with population density, highlighting the influence of urban sprawl and transit policy on network design. Sakarya represents a developing urban area with a shorter system length, consistent with cities that emphasize efficient coverage in smaller geographic footprints. This design strategy aligns with the global trend of tailoring transit solutions to local urban characteristics, particularly in growing metropolitan areas where system expansion is incremental (Figure 9).

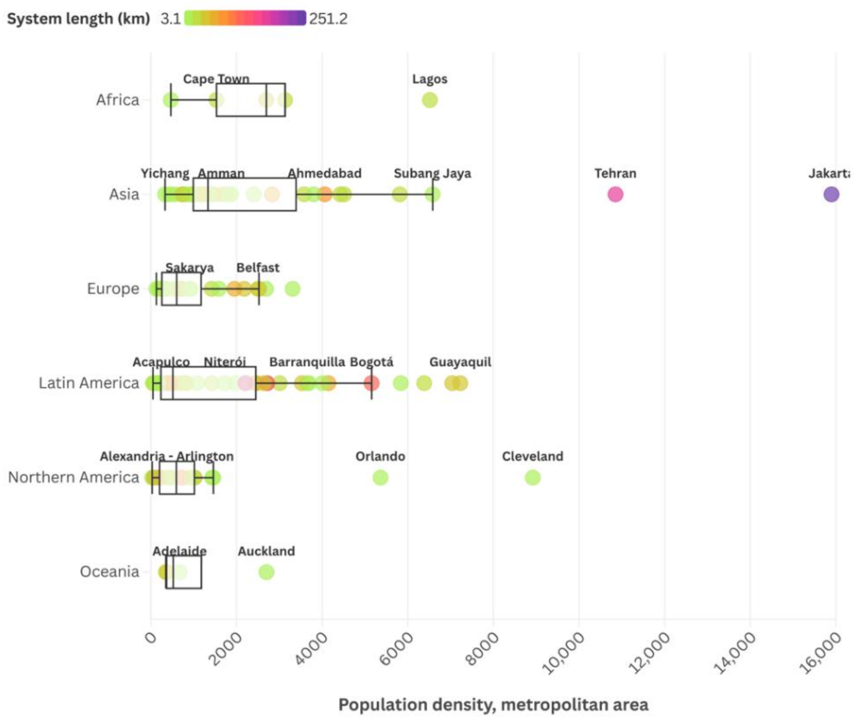

Fig. 9. The system length vs. population density (BRTDATA, 2025)

The violin plot demonstrates in Figure 10, the variability in station spacing across different system lengths. Sakarya lies within a cluster of cities that maintain moderate station spacings relative to their system length, suggesting a balanced approach to network design. By situating itself within the broader Asian and European trend of compact yet effective networks, Sakarya's BRT system appears well-suited to its urban and commuter needs, emphasizing accessibility without compromising operational speed.

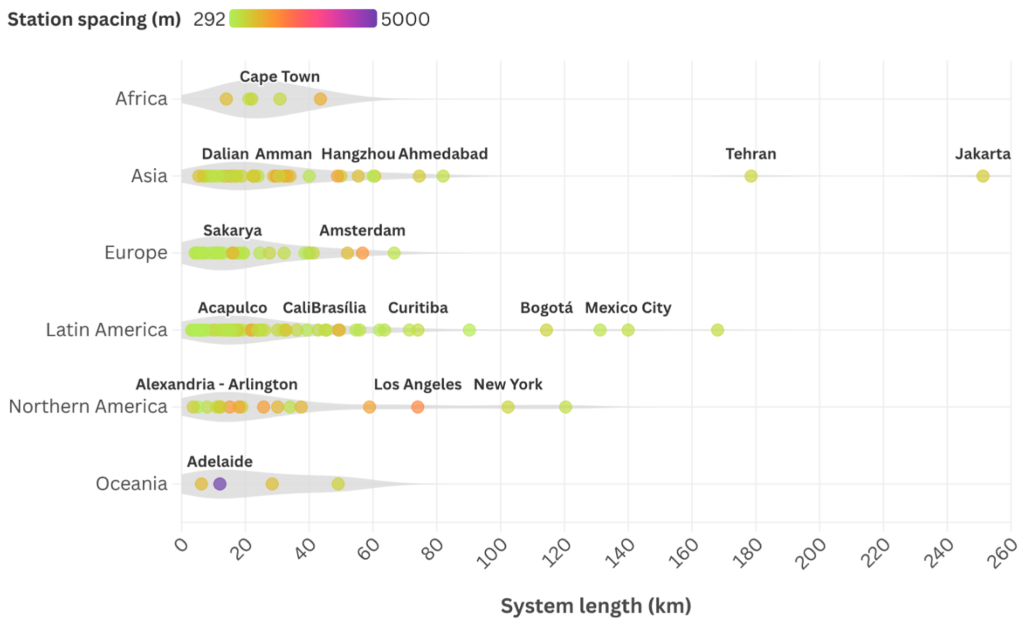

Fig. 10. The station spacing vs system length (BRTDATA, 2025)

The violin plot in Figure 11 examining the trade-off between system length and station spacing highlights distinct regional patterns. Asia and Europe exhibit standardized clustering, with Sakarya fitting neatly into the European cluster. Its positioning reflects a focus on optimizing station distribution to ensure efficient transit coverage within its compact network. This finding reinforces Sakarya's adherence to regional best practices while accommodating the unique demands of its urban landscape.

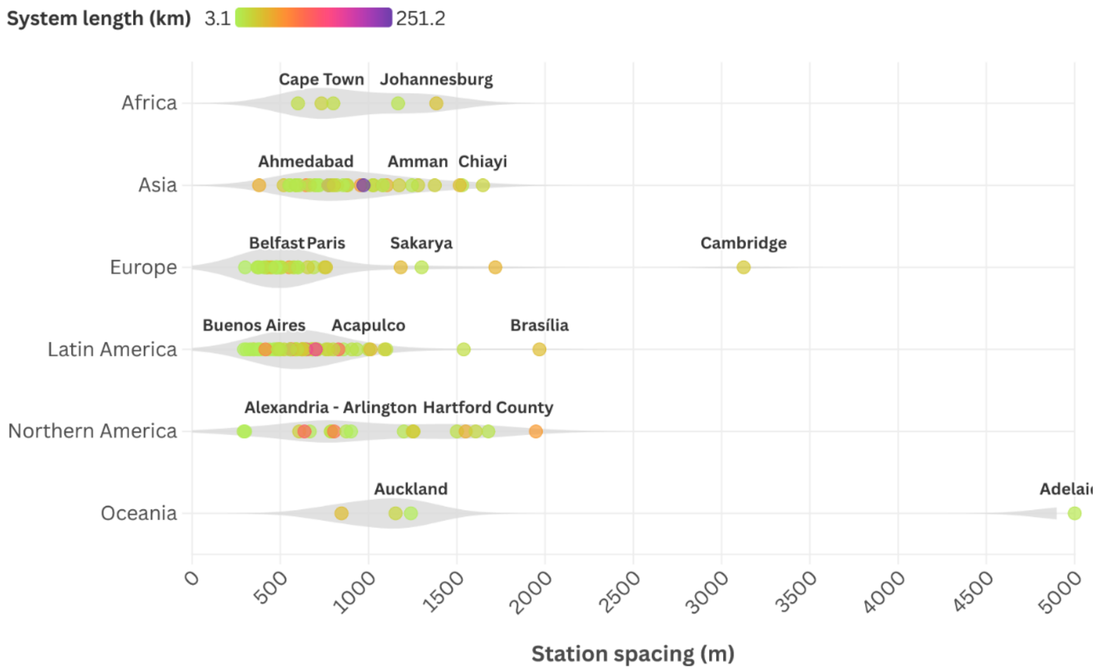

Fig. 11. The system length vs. station spacing (BRTDATA, 2025)

Incorporating Sakarya into the comparative analysis reveals that its BRT system aligns closely with global and regional patterns observed in similar economic and urban contexts. The city exhibits a balanced approach to station spacing and system length, prioritizing accessibility and efficiency in a developing urban environment. By adhering to regional norms while identifying opportunities for innovation, Sakarya's BRT system can serve as a model for scalable, context-sensitive transit solutions in mid-income, high-density areas. This analysis highlights the potential for further aligning local transit policies with global best practices to enhance system performance and sustainability.

4. Conclusions

This comparative analysis of BRT systems provides critical insights into the socioeconomic and infrastructural factors influencing transit system efficiency and accessibility across diverse geographic contexts. By benchmarking Sakarya's planned BRT system against global best practices, this study offers valuable recommendations for its development and operational optimization.

Sakarya's BRT design reflects a tailored alignment with its socioeconomic profile, particularly within the middle GDP per capita range. This ensures affordability for public transport users, a critical factor in fostering accessibility and widespread adoption. Additionally, the city's moderate station spacing and system length highlight a balanced approach that effectively integrates operational efficiency with commuter accessibility. These characteristics are consistent with regional practices observed in Asia, demonstrating Sakarya's adherence to global benchmarks and its commitment to efficient urban mobility. The study also reveals significant regional variations in BRT characteristics. Developed regions prioritize travel speed through longer station spacings, while high-density urban areas focus on shorter spacings to enhance accessibility. Sakarya's station spacing and system length align with European trends, emphasizing a compact and efficient network tailored to its urban density. Furthermore, global insights indicate that financial sustainability and fare affordability are crucial for mid-income cities. Innovative approaches, such as integrating multimodal transit options and optimizing network expansion, are essential for ensuring long-term operational efficiency and resilience.

The most important perspective emerging from this analysis is the necessity of adopting a context-sensitive approach. Sakarya must prioritize strategies that account for its unique urban density, economic constraints, and mobility needs. For example, Adapazarı, as the administrative and commercial center, experiences high daily commuting volumes, requiring efficient transit connections to reduce congestion. Serdivan, home to Sakarya University and a growing student population, demands accessible and affordable public transport solutions, particularly during peak hours. Meanwhile, Erenler, with its expanding residential areas and industrial zones, needs a well-integrated transit network to support both workers and residents. Addressing these specific dynamics involves conducting detailed assessments of local commuting patterns, spatial constraints, and demographic trends to design a sustainable and equitable transit system tailored to Sakarya's needs.

However, there are areas for improvement that could enhance Sakarya's BRT system. Integration with multimodal transit options, such as minibuses, cycling infrastructure, and pedestrian pathways, should be emphasized to ensure seamless connectivity. Investments in digital tools, such as real-time tracking and integrated ticketing systems, would significantly enhance user experience and operational efficiency. Moreover, exploring green energy solutions, such as electric or hybrid buses, could reduce environmental impacts and align with global sustainability goals. Dynamic pricing models and targeted subsidies could further improve fare equity while maintaining financial sustainability. Leveraging urban mobility data and advanced modelling tools would provide valuable insights into optimizing station placement, route design, and frequency management. Regular evaluations of system performance would allow for adaptive improvements and scalability in response to evolving urban demands.

Ultimately, Sakarya's planned BRT system demonstrates the potential to serve as a benchmark for mid-income, high-density cities seeking scalable and sustainable transit solutions. By aligning its policies with global best practices, enhancing integration with multimodal systems, and investing in sustainability and innovation, the city can position itself as a leader in urban mobility. Addressing the identified improvable aspects through a scientific, evidence-based approach will ensure long-term efficiency, equity, and resilience in its transit network.

Renovating transportation infrastructure in emerging economies: Transforming systems for a sustainable future

Ilgin Gokasar*[1], Ali E. Karaismailoglu[1]

[1] Bogazici University, Department of Civil Engineering, 34342, Istanbul, Turkiye

Abstract. Both industrialized and developing nations have realized in recent years that there are important indicators that infrastructure needs to be updated, especially in urban areas where the need for strong infrastructure is much greater than in less populated areas. At the same time, there are many environmental problems facing the planet, and one of the most urgent ones is global climate change. To address the underlying causes of climate change, almost every country has responded by committing to international accords aimed at modernizing and enhancing infrastructure with eco-friendly solutions. The transportation industry and its infrastructure are a major cause of this problem. In order to build a more resilient and environmentally friendly future, this article looks at the best infrastructure renovation options for the transportation sector in emerging nations that are in line with sustainable development objectives.

Keywords: Sustainability; Transportation infrastructure; Renovation; Emerging economies

1. Introduction

The foundation of human mobility, economic competitiveness, and urban functionality is transportation infrastructure. Emerging countries are battling an unparalleled confluence of environmental deterioration, urban population growth, and the need for mobility in the twenty-first century (World Bank, 2021). Urbanization increases inequality, pollution, and traffic while also putting a burden on the infrastructure that already exists. Older roads, overworked buses, and congested streets are signs of more serious systemic issues in cities throughout Asia, Africa, and Latin America (United Nations Human Settlements Programme, 2020). These challenges are compounded by rising emissions, extreme weather events, and unsustainable fossil fuel dependence (International Energy Agency, 2023).

Amid this context, the transition to sustainable transportation systems has become an international imperative. The United Nations Sustainable Development Goals, especially Goal 11 on sustainable cities and Goal 13 on climate action, frame transportation not just as a logistical concern but as a lever for environmental and social transformation (United Nations, 2015). One of the most viable solutions emerging from global best practices is the widespread deployment of mass rapid transit systems, particularly metro networks and urban rail lines, which have proven to reduce urban emissions, improve commuter safety, and provide equitable access to economic centers (Litman, 2020).

In particular, metro systems provide long-term resilience against climate threats and energy shocks. Metros may transport hundreds of thousands of people every day with little energy intensity and land use, in contrast to road-based alternatives that frequently promote private vehicle ownership or dispersed informal transit (Guerra & Cervero, 2011). A move away from carbon-intensive growth and toward an inclusive, dependable, and environmentally sustainable urbanization vision is reflected in their incorporation into national infrastructure plans (International Renewable Energy Agency, 2022).

Additionally, the growing interdependence of economic systems across continents has elevated the role of urban transportation networks in ensuring the fluidity of trade, employment access, and service delivery. Transport bottlenecks in megacities directly impact GDP by increasing operational costs, hindering logistics, and causing labor inefficiencies (World Bank, 2021). The consequences of inaction are not just economic but also social and environmental, as congestion exacerbates greenhouse gas emissions and reduces productivity (Intergovernmental Panel on Climate Change, 2023).

Therefore, policymakers in emerging economies need to view transportation as a complex socio-technical system with environmental implications rather than just an engineering problem. A new planning paradigm focused on mass public transportation is required due to the pressing need for decarbonization, energy resilience,

* Corresponding author, E-mail: ilgin.gokasar@bogazici.edu.tr

https://doi.org/10.31462/icearc2025_ce_tra_262

and equal access. In this regard, metro systems are a fundamental resource. They are essential to any national sustainability strategy because of their capacity to operate on renewable energy, integrate with land use planning, and lower per capita emissions (United Nations Economic and Social Commission for Asia and the Pacific, 2021).

2. Methodology

This research employs a multidisciplinary approach that combines policy evaluation, energy systems analysis, and literature review. Publications from the Intergovernmental Panel on Climate Change, the World Bank, the United Nations, and the International Energy Agency are cited. Regional insights are provided by case studies from Kenya, India, and Turkiye. In addition to examining sectoral integration with national energy planning and urban development objectives, comparative analysis is employed to identify common difficulties and best practices.

3. Global transportation energy landscape

The use of fossil fuels continues to dominate the global transportation industry. Oil-based energy sources are essential to shipping, aviation, and road transportation. Nearly 77% of all transport energy was used for road transportation as of 2022, with aviation and maritime shipping accounting for a large portion of emissions (International Energy Agency, 2022). Nearly 25% of global CO_2 emissions are caused by this reliance on fossil fuels, which has direct effects on the climate (Intergovernmental Panel on Climate Change, 2023).

Vehicle production systems, port terminals, and gasoline distribution networks are important infrastructure elements. Without major financial investment and policy reform, these systems' inertia makes transformations challenging. However, by adopting sustainable transport models early on, rising economies can also avoid the expensive effects of stranded infrastructure.

4. The case for energy system transformation in transport

Among the most ecological and energy-efficient modes of urban transportation are electrified mass transit systems, especially light rail and metros. These systems provide a zero-emission solution for urban transportation demands when they are fueled by renewable electricity (International Energy Agency, 2022). The utilization of solar and wind energy to power whole transit lines is demonstrated by international examples like the Delhi Metro and Santiago Metro (Delhi Metro Rail Corporation, 2021).

Compared to diesel or compressed natural gas systems, electrified mass transit systems offer long-term operational cost savings in addition to lowering direct emissions. Furthermore, metro systems that run on renewable energy offer a dual climate answer by reducing transportation-related emissions and increasing grid flexibility at the same time. Hybrid strategies that combine modular hydrogen fuel cells, solar photovoltaic microgrids, and battery storage are becoming popular decentralized options for areas where grid dependability is still an issue (Asian Development Bank, 2022).

5. Transportation infrastructure in emerging economies

Existing transportation networks are under tremendous strain as a result of the exponential urbanization occurring in emerging economies. Over the last three decades, the population of cities like Lagos, Jakarta, and Dhaka has more than doubled, but there hasn't been a commensurate increase in transportation infrastructure (World Bank, 2021). The ensuing imbalance between capacity and demand shows up as heavy traffic, protracted commutes, and high transportation expenses. These areas frequently have disjointed and inadequately linked public transportation networks that mostly rely on unofficial minibuses or antiquated diesel bus fleets. These systems lack fare unification, uniform ticketing systems, and coordinated route planning in addition to having scheduling and reliability issues. Consequently, metro infrastructure—despite its efficiency and scalability—remains underfunded, largely due to high initial capital costs, political short-termism, and limited technical capacity at municipal levels.

Rapid motorization is a characteristic that exacerbates this difficulty. Car ownership is rising in emerging economies due to urban development and increased affluence. The use of private vehicles is expected to increase in the absence of robust public transportation options, particularly in middle-class urban areas. The Intergovernmental Panel on Climate Change (2023) estimates that if current trends continue unchecked, transportation-related emissions could triple by 2050. In addition to its effects on the climate, this trend presents serious concerns to public health, air quality, and urban livability, especially in megacities like Delhi, Cairo, and Manila that already have high pollution levels.

Reform initiatives are made more difficult by the institutional environment. In many cities, several entities with conflicting agendas and overlapping powers share responsibility for transportation planning, funding, and operations. This institutional fragmentation leads to delays, redundancy, and suboptimal project outcomes. Furthermore, ineffective budgetary allocations, a lack of procurement openness, and susceptibility to political cycles are frequently the outcomes of inadequate governance structures (United Nations Economic and Social Commission for Asia and the Pacific, 2021).

To achieve meaningful progress, emerging economies must pursue integrated urban planning, wherein transportation is coordinated with housing, land use, and environmental strategies. Successful examples can be found in Curitiba (Brazil) and Ahmedabad (India), where transit-oriented development (TOD) has helped synchronize metro expansion with high-density zoning and walkable neighborhoods. Moreover, sustainable financing mechanisms such as land value capture, congestion pricing, and public-private partnerships can provide stable funding streams for metro investments while promoting equitable cost distribution.

Equally crucial is the emphasis on inclusive design. Vulnerable populations—particularly women, elderly citizens, and persons with disabilities—face disproportionate barriers to mobility. Features such as level boarding, tactile guidance, well-lit stations, and gender-segregated compartments significantly enhance access and safety (United Nations, 2015). When combined with fare affordability programs, these measures can dramatically improve labor force participation and access to essential services like education and healthcare. In this way, well-designed metro systems function not only as infrastructure but as enablers of social equity, economic opportunity, and environmental sustainability.

6. Comparative global case studies

India's Smart Cities Mission advocates for solar-powered electrified metro systems. The metropolises of Bengaluru, Pune, and Delhi have implemented energy recovery and rooftop solar systems (International Renewable Energy Agency, 2022).

The integrated urban rail architecture of Turkey is demonstrated by the Marmaray, Başkentray, and Gaziray projects, which provide dependable substitutes for driving and lower emissions (Republic of Türkiye Ministry of Transport and Infrastructure, 2022).

Kenya's mobility initiatives tackle energy and equality issues by combining solar mini-grids, fare digitization, and indigenous technical capabilities (World Bank, 2021). Rail may service informal settlements, as demonstrated by Medellín's cable metro and hillside access (United Nations Human Settlements Programme, 2020).

7. Conclusion

Expanding electrified metro systems with renewable energy infrastructure must be a strategic priority for rising countries in order to address both the pressing demands of growing urbanization and climate mitigation goals. Metro systems have the twin benefits of high-capacity urban transit and much reduced per capita emissions, in contrast to private vehicle-based options. They offer a scalable and sustainable route to decarbonization when driven by clean electricity, such as that produced by solar, wind, or hydropower. Additionally, urban areas reduce traffic, enhance air quality, and open doors for fair access to services, jobs, and education. In light of the Intergovernmental Panel on Climate Change's (2023) warnings about rising emissions trends, electrifying public transit becomes imperative rather than optional. Additionally, governments can lessen urban sprawl and encourage compact, efficient communities by planning rail corridors in accordance with land use plans and urban density.

But more than just the deployment of infrastructure is required to make this vision a reality. It necessitates long-term institutional transformation, coordinated multi-level governance, and creative financing techniques that can raise both public and private funds. Governments must support regulatory frameworks that facilitate the integration of sustainable energy, promote transit-oriented development, and expedite project approval procedures. By bridging the silos between energy, transportation, and urban development, national urban transport agencies and metropolitan transit authorities can overcome institutional fragmentation, which is frequently a significant obstacle. Meanwhile, the funds required for long-term metro expansion can be unlocked through sustainable financing options including land value capture, green bonds, and performance-based public-private partnerships. In the end, making the switch to sustainable, electrified transportation systems is not only possible, but essential to creating resilient, inclusive, and climate-aligned urban futures.

Abstract. With the increasing population and traffic volume, the demand for high-performance pavement materials has become necessary. This necessity has encouraged researchers to explore novel additives and materials to enhance bitumen performance. Although various additives have been investigated over the years, recent studies have increasingly focused on sustainable, environmentally friendly, and cost-effective solutions for bitumen modification. Consequently, research on incorporating waste and sustainable materials in bitumen modification has been steadily expanding. This study investigates the applicability of T-Flex, a product of the Tayraş Refinery, for bitumen modification and its effects on physical properties. Accordingly, modified bitumen samples were prepared by adding T-Flex at 5% and 10% by weight of the bitumen, followed by penetration, softening point and rotational viscosity tests. The experimental results revealed that T-Flex addition increased the penetration values and decreased the softening point and penetration index, indicating a softening effect and increased temperature susceptibility of the bitumen. Furthermore, T-Flex significantly reduced the rotational viscosity, improving the workability of the bitumen at mixing and compaction temperatures. These findings suggest that T-Flex can effectively enhance the flexibility and workability of bitumen. However, its use should be optimized depending on application requirements, considering the mechanical performance.

Keywords: Bitumen; Bitumen modification; T-Flex; Penetration; Softening point; Rotational viscosity

1. Introduction

In recent years, increasing environmental awareness has highlighted the importance of utilizing waste materials across various industries. The construction sector has become one of the prominent fields where the use of waste materials has attracted attention. Today, besides being used as building materials, different types of waste materials are also being explored for bitumen modification (Fode et al., 2025; Hu et al., 2025; Minhajuddin & Saha, 2025; Yegane et al., 2025). Researchers have investigated the use of waste plastics (Deb et al., 2025; Javadi et al., 2024), waste rubbers (Blab et al., 2024; Obukhova et al., 2024), other waste polymers (Rashid et al., 2024), waste oils (Çavdar et al., 2024; Kumandaş et al., 2022; Kumandaş et al., 2024), and many other waste materials to modify bitumen, the binder in asphalt pavements.

Waste oils encompass a broad range of materials, including waste cooking oils derived from vegetable oils such as soybean, corn, and cottonseed oils, as well as waste engine oils generated by industries such as chemical manufacturing, production, and automotive sectors. Studies have generally shown that waste oils can effectively improve the workability of bitumen, enhance its low-temperature cracking resistance, increase fatigue resistance, and positively affect aging resistance (Kumandaş et al., 2022; Xu et al., 2023).

Each year, approximately 40 million tons of waste engine oil are produced worldwide (Guo et al., 2025). About 70–80% of this amount is recycled into products like lubricants through centrifugation and distillation processes (Guo et al., 2025). However, 20–30% of waste engine oil cannot be recycled and is known as Re-refined Engine Oil Bottoms (REOB) (Guo et al., 2025). In other words, REOB refers to the residue from refining processes after the removal of metal particles and light compounds, and it has a wide range of sources (Xu et al., 2025).

Although the use of REOB in bitumen modification dates back almost thirty years, its effects on bituminous binder properties have been examined in only a limited number of studies (Karki & Zhou, 2019). Furthermore, the findings reported in the literature are inconsistent, making it difficult to draw a definitive conclusion regarding the

* Corresponding author, E-mail: ermancavdar@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_tra_388

influence of REOB on bitumen. While one study (Li et al., 2023) reported that REOB improved the high-temperature performance of bitumen, other studies (Karki & Zhou, 2019; Xu et al., 2021; You et al., 2018) observed the opposite effect. Similarly, one study (You et al., 2018) found that REOB increased the low-temperature cracking susceptibility of bitumen, whereas other studies (Fried & and Castorena, 2024; Karki & Zhou, 2019) indicated that although REOB softened bitumen, its impact on low-temperature performance was not significant. Additionally, while one study (Xu et al., 2021) reported that REOB improved the fatigue life of bitumen, another study (Li et al., 2017) suggested that the addition of small amounts of REOB enhanced the fatigue resistance of bitumen, whereas higher amounts significantly reduced it.

In light of the above, there is a need to further investigate the effects of REOB on bitumen properties. This study aims to examine the impact of REOB on bitumen through experimental methods. For this purpose, a type of REOB known as T-Flex, supplied by Tayraş Company, was incorporated into 50/70 penetration grade bitumen at 5% and 10% by weight to produce modified binders. Subsequently, the properties of both the unmodified and modified bitumens were evaluated through penetration, softening point, and rotational viscosity (RV) tests.

2. Materials and methods

2.1. Materials

2.1.1. Bitumen

The base bitumen used in this study was supplied by the 10th Regional Directorate of the General Directorate of Highways of the Republic of Türkiye and belongs to the 50/70 penetration grade. This grade was selected due to its widespread use across the country and its frequent reference in previous academic studies.

2.1.2. T-Flex

The T-Flex product, supplied by the company Tayraş to the Transportation Laboratory of Karadeniz Technical University (KTU), is recommended in the product information sheet as a bitumen modifier for use in asphalt and roofing applications. Considering its production process, the material is believed to be similar to waste oil products referred to in the literature as "Re-refined Engine Oil Bottom (REOB)." Several properties of the material were identified through tests conducted at the Tayraş refinery and were included in the product information sheet. These properties are presented in Table 1.

Table 1. Properties of T-Flex

Property	Test Method	Value
Appearance	ASTM D4126	Dark Coloured Viscous Liquid
Viscosity @50 °C, cSt	ASTM D4052	<10000
Density @15 °C, kg/lt	ASTM D7042	0.93
Flash Point, °C	ASTM D3278	Min. 200
Pour Point, °C	ASTM D97	-3
Water Content, %	ASTM D95	Max. 0.2
Sulfur Content, %	ICP-OES	1.0

2.1.3. Preparation of T-Flex modified bitumen

In order to produce modified bitumen, certain process parameters must be defined in advance. These include the type of mixer, mixing speed, temperature, duration, and additive dosage. In the literature, studies on the production of REOB-modified bitumen commonly involve manual mixing at approximately 150 °C for a duration of 5 to 15 minutes (Karki & Zhou, 2019; Omari et al., 2016). However, due to the limitations of manual mixing methods, our previous experimental experience has led us to adopt more controlled processing conditions in our own studies (Çavdar et al., 2024; Kumandaş et al., 2022; Kumandaş et al., 2024). The parameters applied in this study are summarized in Table 2.

Table 2. Preparation parameters for T-Flex modified bitumen

Parameter	Value
Type of Mixer	Four-blade mechanical mixer
Mixing Speed	1500 rpm
Mixing Temperature	135±2 °C
Mixing Duration	30 minutes
Additive Dosage	5% and 10%

The liquefied bitumen was transferred into 600 mL beakers and placed on a temperature-controlled hot plate. The temperature of the plate was adjusted to maintain the bitumen at 135±2 °C. Once this target temperature was reached, T-Flex was added at dosages of 5% and 10% by weight. The mixing process was carried out at a constant speed of 1500 rpm for 30 minutes. At the end of this period, the T-Flex modified bitumen samples were prepared and made ready for further analysis. To ensure systematic identification during the experimental process, a sample coding scheme was employed, as presented in Table 3.

Table 3. Description and coding of the tested samples.

Description	Sample Details	Code
Base bitumen	Base Bitumen (Pen 50/70)	B
Control bitumen (base bitumen mixed without T-Flex addition)	Base Bitumen (Pen 50/70) mixed at 135 °C and 1500 rpm, for 30 minutes	CB
5% T-Flex modified bitumen	Base Bitumen (Pen 50/70) + 5% T-Flex: mixed at 135 °C and 1500 rpm, for 30 minutes	T5
10% T-Flex modified bitumen	Base Bitumen (Pen 50/70) + 10% T-Flex: mixed at 135 °C and 1500 rpm, for 30 minutes	T10

2.2. Methods

2.2.1. Penetration test

The penetration test is one of the fundamental methods used to assess the consistency, or in other words, the hardness of bitumen. In this study, the procedure was conducted in accordance with the TS EN 1426 (2025) standard. During the test, a standard needle of specified dimensions is allowed to penetrate the bitumen sample for 5 seconds under a load of 100 grams at a temperature of 25 °C. The depth of penetration, measured in tenths of a millimeter (dmm), represents the penetration value of the sample. This value is widely employed in the classification of bituminous binders, where a higher penetration value indicates a softer material, whereas a lower value reflects a harder consistency.

The needle on the device is carefully aligned with the surface of the bitumen sample and then fixed in position. Subsequently, the needle is released, initiating a 5-second penetration period. The depth of penetration is recorded at the end of this duration. For each sample, three individual measurements are performed, and the average of these values is taken as the final test result. The variation between the individual measurements must remain within the limits specified by the relevant standard.

2.2.2. Softening point test

The softening point test is a method used to evaluate the temperature-dependent viscosity behavior of bitumen. In this study, the procedures were carried out in accordance with the TS EN 1427 (2015) standard. The principle of the test is based on recording the temperature at which a metal ball, placed on a bitumen specimen, travels a specified distance under conditions of steadily increasing temperature. The temperature at which this occurs is defined as the softening point of the bitumen.

In the application of the test, the bitumen sample is first heated until it becomes fluid, then poured into metal rings whose inner surfaces have been coated with a release agent (e.g., petroleum jelly). Once the sample reaches room temperature, any excess bitumen on the edges of the rings is trimmed using a heated spatula. The prepared rings are then placed into the test apparatus, and steel balls are positioned on top of the bitumen samples.

During the test, the apparatus is immersed in a 600 mL beaker filled with distilled water, and the heating rate is adjusted to 5 °C per minute. As the temperature rises, the steel balls gradually push the bitumen downward. The temperature at which each ball reaches the bottom plate is recorded. The test is considered valid only if the difference between the two recorded temperatures does not exceed 1 °C. If the difference exceeds this limit, the test must be repeated. When valid results are obtained, the average of the two temperatures is calculated and reported as the softening point of the bitumen sample.

2.2.3. Penetration index (*PI*)

The penetration index (*PI*) is calculated to assess the temperature susceptibility of bitumen. This parameter is derived using the softening point and the penetration value measured at 25 °C, according to the Equation (1):

$$PI=\frac{1952\text{-}500\times \log Pen25\text{ -}20\times SP}{50\times \log Pen25\text{ -}SP\text{-}120} \tag{1}$$

In this formula, *SP* represents the softening point in °C, while *Pen25* denotes the penetration value measured at 25 °C, expressed in tenths of a millimeter (dmm). As the *PI* value increases, the bitumen is considered to exhibit lower sensitivity to temperature fluctuations, indicating enhanced resistance to rutting at high temperatures and cracking at low temperatures.

2.2.4. Rotational viscosity test

The rotational viscosity of the base and modified bitumen samples was determined using a Brookfield rotational viscometer, in accordance with the TS EN 13302 (2018) standard. The purpose of this test was to evaluate the flow behavior of the samples at elevated temperatures, which are critical for mixing and compaction processes during asphalt pavement construction.

Approximately 8-10 grams of each bitumen sample was carefully poured into aluminum sample chambers. Prior to testing, the samples were heated in an oven at the target test temperatures to ensure thermal equilibrium without causing thermal degradation. The measurements were conducted at five different temperatures: 120 °C, 135 °C, 150 °C, 165 °C, and 180 °C. A spindle (No.21) was used for the measurements, operating at a constant rotational speed of 20 rpm. The viscosity values (in centipoise, cP) were recorded once the system achieved stable torque readings, indicating steady-state conditions. The obtained viscosity data were used to assess the effect of T-Flex addition on the workability of the bitumen samples, especially at typical asphalt mixing and compaction temperatures.

3. Results and discussion

3.1. Penetration test results

Fig. 1 illustrates the penetration values of the base bitumen (B), control bitumen (CB), and T-Flex modified bitumens (T5 and T10). It is observed that the B exhibits a penetration value of 59.8 dmm. After mixing under the specified conditions (135 °C, 1500 rpm, 30 minutes), the CB shows a slight reduction in penetration, suggesting that the mixing process alone leads to a minor hardening of the bitumen.

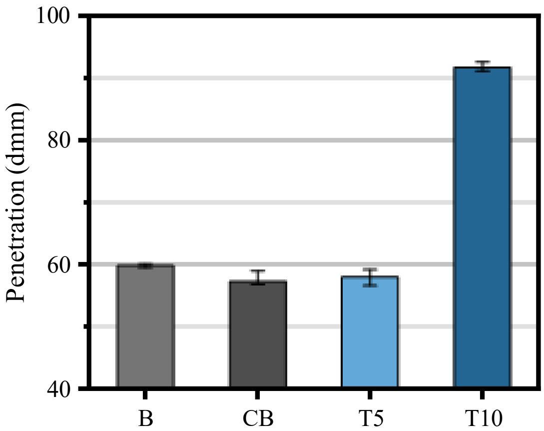

Fig. 1. Penetration test results.

Upon the addition of 5% T-Flex (T5), a marginal increase in penetration is observed compared to the control bitumen, although the value remains close to that of the base bitumen. This indicates that low levels of T-Flex addition have a limited softening effect on bitumen. However, when the T-Flex content is increased to 10% (T10), the penetration value significantly rises, reaching 91.7 dmm. This substantial increase demonstrates that higher T-Flex dosages effectively soften the bitumen, resulting in a material with lower consistency and higher deformability under loading.

3.2. Softening point test results

Fig. 2 presents the softening point values of the B, CB, T5, and T10. The base bitumen exhibits a softening point of 50.3 °C. Following the mixing process (135 °C, 1500 rpm, 30 minutes), the CB shows a slight increase in softening point compared to the base bitumen, indicating a minor hardening effect attributed to mixing.

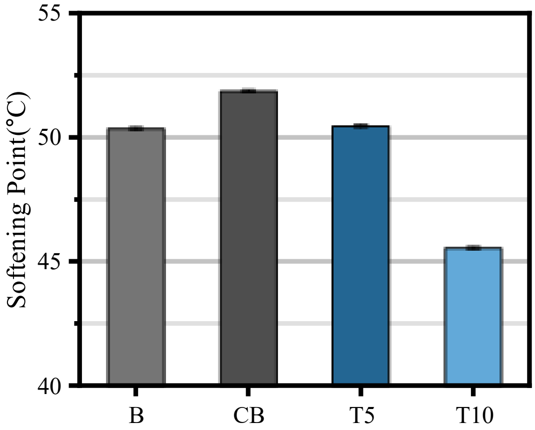

Fig. 2. Softening point test results.

Upon the addition of 5% T-Flex (T5), a slight decrease in the softening point is observed relative to the control sample, suggesting that low levels of T-Flex have a limited softening influence on the bitumen. Nevertheless, the softening point remains relatively close to that of the base bitumen. A significant reduction in the softening point is noted when 10% T-Flex (T10) is incorporated, with the value dropping to 45.5 °C. This substantial decrease confirms that higher T-Flex content significantly lowers the softening point of bitumen, reflecting a considerable reduction in the material's thermal stability at elevated temperatures.

3.3. Penetration index results

Fig. 3 displays the penetration index (PI) values of the B, CB, T5, and T10. The PI is an important indicator reflecting the temperature susceptibility of bituminous binders; lower PI values generally denote higher sensitivity to temperature changes.

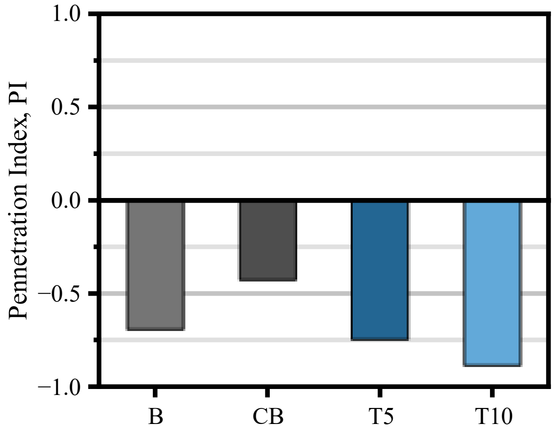

Fig. 3. Penetration indexes.

The B shows a PI value of -0.7, indicating moderate temperature sensitivity. The CB, produced by mixing without T-Flex addition, exhibits a slightly higher PI compared to the base bitumen, suggesting a marginal improvement in temperature resistance due to the mixing process.

In contrast, with the addition of 5% T-Flex (T5), the PI value decreases, indicating that T-Flex addition slightly increases the temperature susceptibility of the bitumen. This trend becomes even more pronounced with the addition of 10% T-Flex (T10), where the PI value drops to -0.88. Such a decrease implies that higher T-Flex content significantly worsens the thermal stability of the bitumen, making it more sensitive to temperature variations.

3.4. Rotational viscosity test results

Fig. 4 shows the rotational viscosity values of the base bitumen (B), control bitumen (CB), and T-Flex modified bitumens (T5 and T10) measured at different temperatures ranging from 120 °C to 180 °C. As expected, the viscosity of all samples decreases with increasing temperature, reflecting the typical thermorheological behavior of bituminous binders.

At 120 °C, the control bitumen (CB) exhibits a slightly higher viscosity compared to the base bitumen (B), indicating that the mixing process without T-Flex addition induces a minor increase in stiffness. However, upon T-Flex modification, especially at 10% addition (T10), a considerable reduction in viscosity is observed at 120 °C compared to both the base and control samples. The T5 sample also shows a viscosity decrease but to a lesser extent than T10.

This viscosity-lowering trend persists across all tested temperatures. At higher temperatures (150 °C, 165 °C, and 180 °C), the viscosity differences among the samples become less pronounced; nonetheless, T10 consistently maintains the lowest viscosity values.

The observed reduction in rotational viscosity due to T-Flex addition, particularly at lower temperatures, confirms the softening effect of T-Flex. Lower viscosities at mixing and compaction temperatures (typically 135–165 °C) are generally beneficial for workability during asphalt production and paving operations. However, excessively low viscosities may raise concerns about the rutting resistance of the final asphalt mixture.

In summary, the addition of T-Flex significantly improves the workability of bitumen by reducing its viscosity, with the magnitude of reduction increasing with higher T-Flex content.

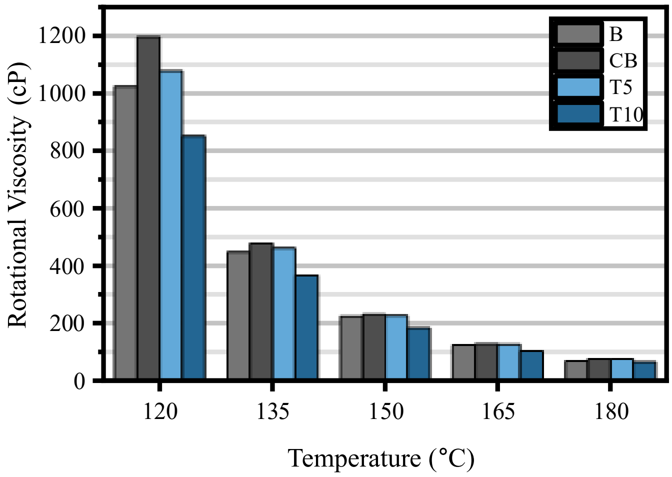

Fig. 4. Rotational viscosity test results.

The experimental findings revealed that the addition of T-Flex, a REOB-derived material, significantly altered the physical and rheological properties of bitumen. The comparison among B, CB, T5, and T10 samples showed that the mixing process alone (CB) resulted in a slight hardening of the bitumen, evidenced by minor changes in penetration and softening point values. However, the incorporation of T-Flex at 5% and 10% (T5 and T10) led to increased penetration values, reduced softening points, and lower penetration indexes, indicating a softening effect and increased temperature susceptibility.

Furthermore, rotational viscosity tests demonstrated a substantial reduction in viscosity with T-Flex addition, particularly at higher temperatures, enhancing the workability of the bitumen during mixing and compaction operations. Among the modified samples, T10 exhibited the most pronounced changes across all measured properties. Overall, the results suggest that REOB-based additives like T-Flex can effectively improve bitumen flexibility and workability but require careful optimization to balance thermal stability and mechanical performance for practical applications.

4. Conclusions

This study investigated the effects of Recycled Engine Oil Bottoms (REOB), commercially known as T-Flex, on the physical and rheological properties of 50/70 penetration grade bitumen. Modified binders were prepared by incorporating T-Flex at 5% and 10% by weight, and their performance was evaluated through penetration, softening point, penetration index (PI), and rotational viscosity tests.

The main findings of the study are as follows:

- The addition of T-Flex increased the penetration values of bitumen, especially at higher contents, indicating a softening effect.
- The softening point of the bitumen decreased with increasing T-Flex content, suggesting reduced thermal stability at elevated temperatures.

- Penetration index (PI) values decreased with T-Flex addition, highlighting an increase in temperature susceptibility, particularly at 10% T-Flex content.
- Rotational viscosity values significantly dropped across all tested temperatures with T-Flex modification, improving the workability of bitumen during mixing and compaction.

Although the use of T-Flex improved the flexibility and workability of bitumen, it also led to increased temperature susceptibility and reduced high-temperature performance. Future research should focus on optimizing the dosage of T-Flex to achieve a balance between workability, flexibility, and thermal stability, as well as investigating the long-term aging behavior and field performance of T-Flex-modified bitumens under various climatic and traffic conditions.

Acknowledgments

The authors would like to sincerely thank Mr. Hakan İMRE for his valuable support in supplying the T-Flex material used in this study. His contribution was essential for the successful completion of the experimental work.

Sustainable concrete pavements using pb-zn-cu mining waste and recycled tire steel fibers

Mehmet T. Seferoğlu*[1]

[1] Gümüşhane University, Department of Civil Engineering, 29100 Gümüşhane, Türkiye

Abstract. This study explores the combined use of lead-zinc-copper (Pb-Zn-Cu) mining waste and recycled steel fibers (SF) from waste vehicle tires in concrete pavement mixtures to enhance sustainability and mechanical performance. Traditional concrete pavement samples were prepared using three aggregate sizes (0–5 mm, 5–12 mm, 12–36 mm), with the 0–5 mm portion subsequently replaced by mining waste. Additionally, SFs were incorporated at 0.2%, 0.4%, and 0.6% by volume. Physical tests indicated that porosity and water absorption remained largely unaffected, though slight reductions in porosity were noted with 0.4% and 0.6% SF additions. A strong correlation between porosity and water absorption was observed, particularly at early curing stages. Mechanically, the inclusion of SFs improved compressive and splitting tensile strengths, with the highest compressive strength increase (18.2%) recorded at 0.6% SF after 28 days. The use of mining waste alone decreased strength, whereas the addition of 0.2% SF enhanced the modulus of elasticity by 25% at 7 days and 60% at 28 days. Higher SF contents reduced elasticity, and variations in Poisson's ratio indicated changes in microstructural deformation. The results suggest that combining mine waste with low levels of recycled SF (especially 0.2%) enhances concrete's mechanical and elastic properties without compromising its physical durability. This approach supports the reuse of industrial waste materials and offers an environmentally sustainable solution for concrete pavement applications.

Keywords: Concrete pavement; Mining waste; Recycled vehicle tires; Mechanical properties; Sustainability.

1. Introduction

In recent years, concrete pavement has been widely preferred due to its durability and long service life. However, the conventional materials used in its production pose significant challenges in terms of environmental sustainability. For this reason, the incorporation of waste materials into concrete production has gained importance both to reduce environmental impacts and to promote the efficient use of natural resources. In line with the goals of minimizing environmental impacts and enhancing sustainability in the construction sector, the reuse of waste materials is becoming increasingly critical. The utilization of recyclable industrial and manufacturing wastes in construction materials such as concrete not only reduces the consumption of natural resources but also offers both economic and environmental benefits in terms of waste management.

The uncontrolled disposal of mining wastes into the environment can lead to severe environmental issues such as heavy metal leaching, soil contamination, and water pollution. Furthermore, the disposal of these wastes typically involves high-cost processes. In this context, the use of wastes derived from lead, zinc, and copper mining as alternative binders or aggregates in concrete pavements presents significant potential for sustainable infrastructure solutions. However, the direct utilization of mining wastes in concrete pavement applications has been explored in only a limited number of studies.

Studies on the use of metallic wastes such as lead-zinc-copper (Pb-Zn-Cu) residues in concrete production have shown that these materials can positively affect the mechanical properties of concrete. For example, the partial replacement of conventional materials with up to 50% Pb-Zn slag has led to improvements in both durability and radiological performance. Additionally, these types of wastes have been found to enhance the sulfate resistance of concrete (Kanneboina et al., 2023).

Çullu (2018) reported that replacing limestone aggregate with Pb-Zn mining waste in concrete mixtures—at substitution rates of up to 75%—resulted in reduced porosity and water absorption, increased density, and consequently, improved mechanical performance. Öztürk (2018) incorporated granulated Zn ore slag into concrete by classifying it into two particle size ranges: 5–15 mm and 0–5 mm. Compressive strength tests conducted at 7, 14, and 28 days of curing revealed that the 28-day compressive strength was comparable to that of the reference

* Corresponding author, E-mail: mtseferoglu@gmail.com

https://doi.org/10.31462/icearc2025_ce_tra_397

concrete, while the resulting concrete was lighter in weight. These findings indicate that Zn ore slag can serve as a viable aggregate replacement for producing lightweight concrete without compromising compressive strength. El Machi et al. (2024) investigated the inclusion of Au (gold), Cu, and Fe (iron) ore wastes in concrete mixtures at rates ranging from 10% to 30%. They reported that a 20% substitution with Cu waste resulted in a 12% increase in compressive strength, whereas a 30% replacement with Fe waste led to a 9% decrease in strength.

Nandi et al. (2022) evaluated jarosite, a byproduct of Zn production, for its potential to reduce cement consumption in road construction. Their study concluded that jarosite enhances concrete strength and provides environmental benefits. Similarly, Amrani et al. (2022) used Pb and Zn mining wastes as aggregate replacements in low-traffic pavement applications. A 25% inclusion of these wastes led to an 18% reduction in cost, a 22% decrease in CO_2 emissions, and surface strength that met standard requirements.

Wu et al. (2024) conducted an experimental study on the preparation of cementitious materials using activated Pb-Zn wastes. The study evaluated both the usability and environmental impact of these wastes in cement-based materials. According to the results of the Toxicity Characteristic Leaching Procedure (TCLP) applied to the samples, the leaching of Pb remained well below the Chinese Hazardous Waste Standard limit of 5.0 mg/L, indicating that these materials can be used in an environmentally safe manner. Similarly, Vahdat et al. (2024) demonstrated that Pb-Zn mining wastes can be used as an alternative to aggregates in mortar mixtures, with minimal environmental impact. The findings suggest that the use of such wastes contributes to both environmental sustainability and effective waste management.

In studies specifically focusing on Zn slag, Kotan et al. (2023) reported that replacing cement with 5%, 7.5%, and 10% of Zn slag powder in self-compacting concrete (SCC) mixtures resulted in improved fresh and hardened concrete properties, particularly at the 5% replacement level. The compressive strength was found to be comparable to that of the control mixture. The study confirmed that Zn slag powder enhanced the workability of fresh SCC and achieved compressive strengths equivalent to those of conventional concretes at 28 days.

Today, industrially manufactured steel fibers (SF) are widely used to improve the strength and durability of reinforced concrete structures. These fibers enhance the tensile strain capacity and ductility of concrete, while also preventing crack propagation and positively affecting post-cracking behavior (Su et al., 2023). Although the use of SF increases tensile strength and toughness, some reduction in workability has been observed (Samindi et al., 2019). Recent research has highlighted that steel fibers recovered from waste vehicle tires (RF) can serve as an environmentally friendly and cost-effective alternative to conventional SF.

Şimşek et al. (2021) observed that the addition of fibers reduced the workability and air content of fresh concrete. In hardened concrete, particularly with the inclusion of 80/60 type SF at a dosage of 0.10%, the best performance was achieved in terms of compressive strength, flexural strength, and abrasion resistance. Although increasing the fiber dosage led to improvements in certain mechanical properties, exceeding the optimum level resulted in significant losses in workability. Therefore, the study emphasized the critical importance of selecting the appropriate fiber shape and content to optimize concrete performance.

Waris et al. (2022) reported that a combination of 0.2% SF and 2% rubber fiber resulted in higher compressive and flexural strength compared to concrete containing only rubber fibers. Awal et al. (2018) stated that while strength improved with increasing fiber content, workability decreased. Centonze et al. (2012) emphasized that concrete reinforced with recycled SFs exhibited post-cracking energy absorption and residual strength performance comparable to that of concrete reinforced with industrial SFs. Zeybek et al. (2022) reported that incorporating 1% recycled SFs from waste vehicle tires led to a 25% increase in flexural strength and a 20% increase in tensile strength.

Amin et al. (2023) reported that the addition of 0.75% waste SF increased compressive strength by 13%, flexural strength by 18%, and tensile strength by 20%. Şengül (2016) indicated that the use of 0.75% recycled SF increased compressive strength from 39 MPa to 42 MPa (7.7%) and flexural strength from 5.2 MPa to 6.6 MPa (26.9%). Furthermore, it was found that these fibers significantly enhanced ductility while maintaining post-cracking strength. Domski et al. (2017) reported that waste SFs exhibited 10–20% lower tensile strength performance compared to engineered fibers but showed similar levels of flexural strength. They emphasized that with proper mix design, waste fibers could be effectively utilized. Altun et al. (2007) observed increases in both compressive and tensile strengths with increasing SF content, with a 3% fiber addition resulting in an 18% increase in compressive strength and a 40% increase in tensile strength. However, they also noted that higher fiber dosages negatively impacted workability. Ayhan et al. (2024) used waste SFs as a replacement for aggregates in concrete at volumes of 0.4% and 0.8%. Experimental studies included the production of cylindrical samples (150×300 mm) and beam samples (150×150×600 mm), with tests on compressive strength, flexural strength, and ultrasonic pulse velocity (UPV). The results indicated that the addition of waste vehicle tire steel had no significant effect on compressive strength but improved flexural strength. Moreover, there was a parallel relationship between concrete compressive strength and UPV.

These studies suggest that the use of waste SF in concrete mixtures, with appropriate proportions and distribution, can lead to significant improvements in mechanical properties while also providing an environmentally sustainable contribution. However, there are limited studies in the existing literature on the combined use of Pb-Zn-Cu waste and waste tire SF in concrete mixtures.

In this study, traditional concrete mortar samples will first be prepared. Three different aggregate particle sizes will be used in these samples: 0-5 mm, 5-12 mm, and 12-25 mm. These aggregates will be included in the mixture in specific proportions to examine their effect on the mechanical properties of concrete. This mixture will be considered as the control sample. In the next phase, the 0-5 mm filler portion of the concrete mix will be replaced with Pb-Cu-Zn waste materials. These waste materials will be used in place of traditional filler materials and will be incorporated into the concrete mix. Finally, SF from waste vehicle tires will be added to the concrete mix at volumetric ratios of 2%, 4%, and 6% to prepare samples. The effects of adding these SF on the mechanical behavior of concrete will be investigated. This approach aims to contribute to environmental sustainability while improving the performance of the concrete pavement.

2. Materials and methods

2.1. Materials

2.1.1. Concrete

In this study, CEM I 42.5 R type Portland cement was used. Aggregates with particle sizes of 0-5 mm, 5-12 mm, and 12-25 mm were utilized. The aggregates were sourced from basalt aggregates obtained from a quarry. The concrete mixtures were prepared according to the TS802 standard. Since waste steel fibers were used in the study, the largest aggregate size was ensured to be 22.40 mm according to the TS 10514 (mix proportions and production of fiber-reinforced concrete) standard based on the selected fiber content. For mixtures with a maximum aggregate size of 22.4 mm, the TS 10514 standard recommends a water/cement ratio between 0.35 and 0.50. In this study, the water/cement ratio was set at 0.5 to ensure good mechanical strength and adequate workability of the mixtures.

Plasticizer additive, modified polycarboxylate (PCE) is polymer based and has the appearance of light brown liquid. PCE is a liquid with a density of 1.10+0.02 kg/l and is a highly water-reducing/super plasticizing admixture developed for the ready-mixed concrete and precast industry, where early and final high strength and durability are required, to achieve excellent surface appearance.

2.1.2. Pb-Zn-Cu waste materials

Gümüştaş Pb-Zn-Cu mineralisation located in Süleymaniye Quarter of Gümüşhane province is located in 1/25.000-scale H42-b2 map, and the area consists of Palaeozoic quartz porphyry, Permocarboniferous Gümüşhane Granite (Çoğulu, 1970), Jurassic-Liassic volcanotortulae series (Kandemir, 2004), Lower Cretaceous (Dogger-Malm) massive and stratified limestones (Pelin, 1977) and Upper Cretaceous phyllites and andesitic tuffs, Eocene andesite and basalt lavas and pyroclasts (Tokel, 1972) are surfaced. Mineralisation is observed in the form of veins within the Jurassic-Liassic volcanotortulae series and Lower Cretaceous limestones. The 0-5 mm size range of the waste material used in this study consists mostly of pyrite-bearing limestone and volcanotorture rocks. The maximum aggregate diameter of 30 mm was taken from the mine site and brought to the laboratory and then this material was sieved through a 5 mm sieve and the part between 0-5 mm was used as fine aggregate in the study (Fig. 1).

Fig. 1. The Pb-Zn-Cu mine wastes

2.1.3. Steel fibre from recycled tire

The SFs used in this study were obtained through a mechanical shredding process of waste tires. The diameters of the fibers were measured using an electronic caliper. Since the lengths of the SFs vary due to the mechanical fragmentation process, the lengths are presented as measurement ranges. The aspect ratio of the fibers was calculated by dividing their lengths by their diameters. The images of the SFs are shown in Fig. 1, and physical properties are provided in Table 1. As can be seen in Fig. 2, the SFs have a curled structure and vary in length and diameter.

Fig. 2. The SFs

Table 1. The physical properties of the SFs

	Diameter, mm	Length, mm	Aspect ratio	By weight ratio, %
SF	0,10-0,15	15-35	110-180	40-60

2.1.4. Concrete mix and preparation of test specimens

As the reference sample, a standard concrete mix composed entirely of basalt aggregates, with three different particle size ranges of 0-5 mm, 5-12 mm, and 12-25 mm, was prepared. This control sample was labeled as 'N.' In the control mix, the natural aggregates with a 0-5 mm particle size were replaced with Pb-Zn-Cu mine wastes of the same size. This mix was labeled as "W." By substituting only, the filler-sized aggregates, approximately 45% of the total mix weight was made up of recycled materials.

The recycled SFs were added to the fresh concrete mix to determine their applicability as reinforcement in concrete. Recycled SFs obtained from waste vehicle tires were added to the W mix at volumetric rates of 0.2%, 0.4%, and 0.6%, and the samples were labeled as W-2, W-4 and W-6, respectively. Thus, recycled-based concrete mixes containing both mine wastes and steel fiber additions were obtained.

For each mix, a total of 12 cylindrical samples, six each for 7-day and 28-day curing periods, were prepared. In total, 60 cylindrical concrete samples were produced (Fig. 3) for the N, W, W-2, W-4 and W-6 mixes, and cured in water until the day of testing.

Fig. 3. Concrete samples used in the study

Table 2. Mix design of recycled SF reinforced concrete

Mixture code	Cement, kg/m^3	Water, L/m^3	Aggregate, kg/m^3	SP, kg/m^3	Pb-Zn-Cu wastes (0-5 mm), kg/m^3	SF, %	SF, kg/m^3
N					-	-	-
W						-	-
W-2	350	175	1,744.03	5.25	784.81	2	15.7
W-4						4	31.4
W-6						6	47.1

For each mix, three of the six cylindrical samples underwent non-destructive physical property tests, such as porosity and void ratio. Following these tests, splitting tensile strength tests were performed on the same samples. The remaining three samples were subjected to compressive strength tests, thereby determining mechanical properties such as compressive strength, elastic modulus, and Poisson's ratio. All experimental data obtained were evaluated by calculating the average of the three samples for each test group. The mix proportion of recycled SF reinforced concrete is shown in Table 2.

2.2. Test methods

2.2.1. Physical characteristics

Three samples were taken from each concrete group made with different fiber ratios, and their physical properties were evaluated according to TS EN 12390-7 standard. First, the samples were soaked in water at 23±2 °C until they were fully saturated. Then, the samples were removed from the water, and procedures were carried out to clean the free water on their surfaces and determine their mass in the air. In the next step, the mass of the samples in water was measured using an Archimedean balance. Finally, the samples were dried in an oven at 105°C and left to cool to room temperature. During this process, the mass of the samples in their oven-dried state was determined.

2.2.2. Compressive strength tests

The compressive strength of the concrete samples cured for 7 and 28 days was tested according to BS EN 12390-3. The compressive strengths of both control and fiber-reinforced samples were determined using a uniaxial compressive strength test conducted on standard cylindrical specimens in accordance with BS EN 12390-3. The cylinder samples were prepared with dimensions of 102 × 204 mm. The tests were performed with a loading rate of 0.22 MPa/s, and the average compressive strength was determined by testing three samples for each group.

The determination of the modulus of elasticity and Poisson's ratio was carried out according to ASTM C39. The axial and lateral unit deformations of the specimens were recorded using extensometers on a gauge measuring the change in length and diameter. Poisson's ratio was determined by the ratio of lateral unit deformation to axial unit deformation.

2.2.3. Splitting tensile strength tests

According to ASTM C496 Standard, the splitting tensile strength was tested for each type of sample at 7 and 28 curing days to investigate the effect of fibers on the tensile strength of concrete. The tests were conducted on cylindrical samples of the same size as those used in the compression test, using a material testing system and strain control method. The loading rate was kept constant at 0.04 – 0.06 $N/mm^2.s$, and the peak load was recorded during the test. The splitting tensile strength was calculated using Equation (1), and the tensile strength of each type of concrete was determined by averaging the results of three samples. The splitting tensile strength was calculated as follows:

$$T = \frac{2P}{\pi DL} \tag{1}$$

Where, T = Splitting tensile strength, MPa; P = Peak load at failure point, N; D = Diameter of the cylinder, mm; L = Length of the cylinder, mm.

3. Results and discussion

3.1. Physical properties

When the porosity (v%) and water absorption (m%) results of the 7 and 28-day samples given in Fig. 4 and Fig. 5 are examined, it is observed that the use of mine waste and the addition of waste tyre wire did not cause a significant change in porosity and water absorption values compared to the control sample (N) at both curing times. In 7-day samples, porosity values in W group series showed a slight increase compared to N sample, while no significant difference was detected in water absorption rates. Similarly, although small fluctuations were observed in porosity values in 28-day samples, water absorption values followed a fairly constant course. In particular, the addition of 0.4% and 0.6% waste tyre wire (W-4 and W-6) did not affect the porosity and water absorption performance negatively in both 7 and 28 day samples, and even showed a slight decrease in porosity. These results indicate that the use of mine waste and waste tyre wire does not have a negative effect on the permeability properties of the concrete and microstructural improvements continue at later curing times.

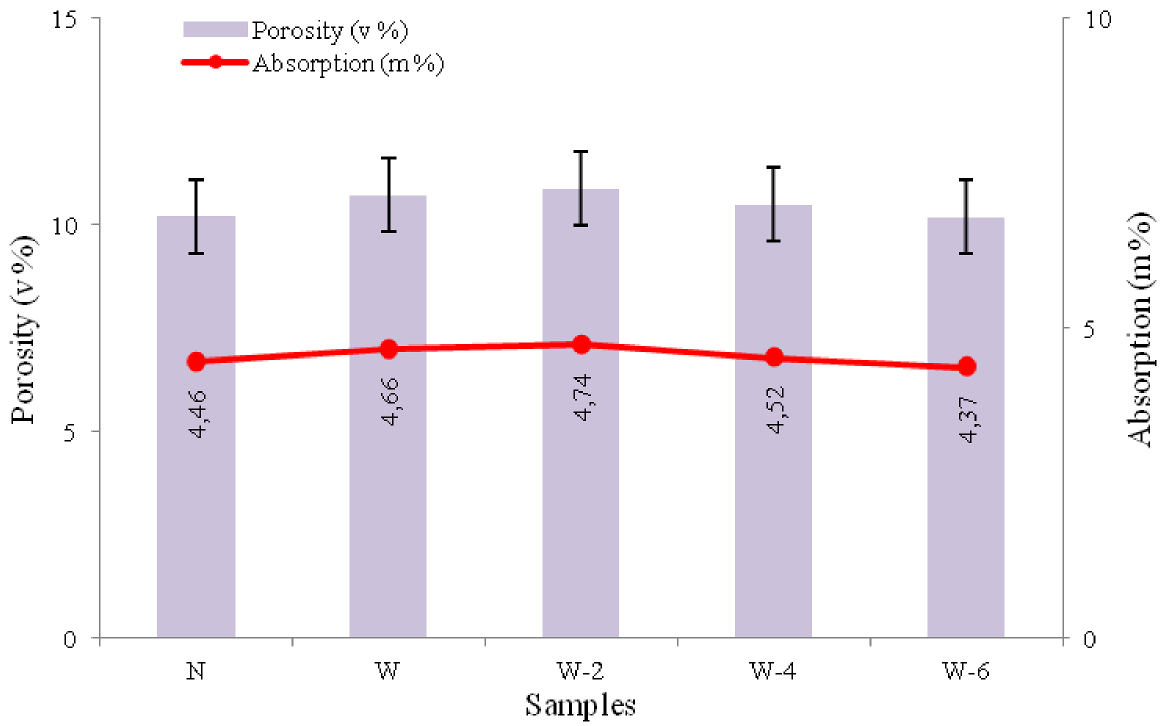

Fig. 4. Physical properties of fibre reinforced concrete with witness and mine waste admixture (7 days)

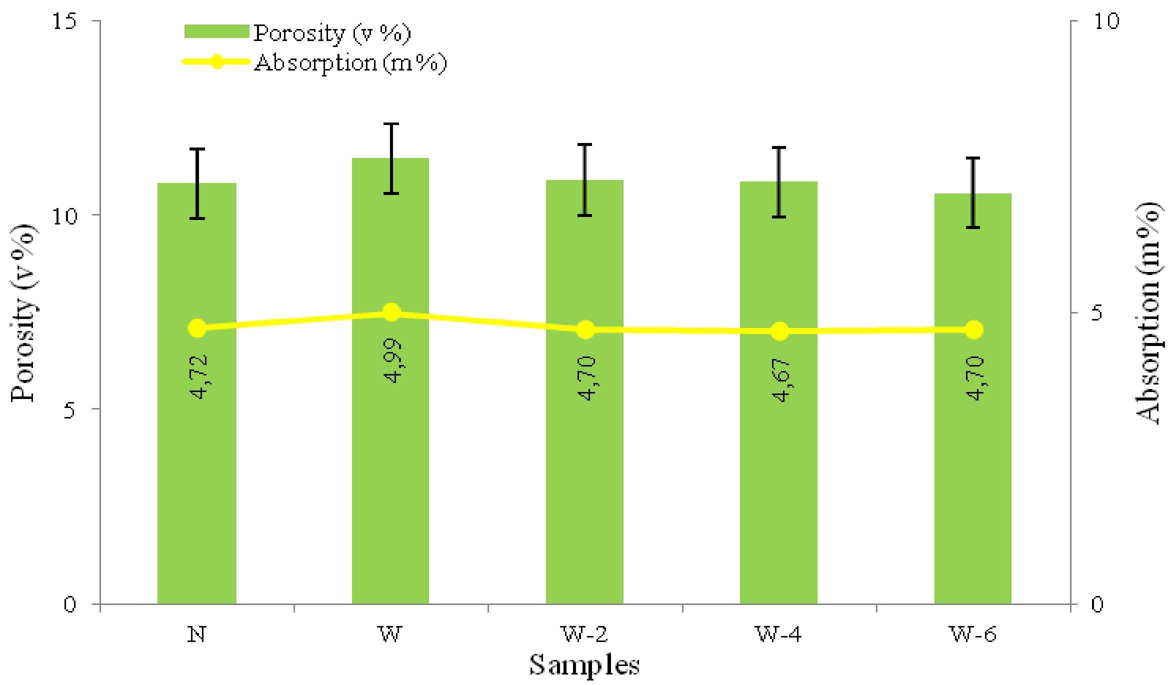

Fig. 5. Physical properties of fibre reinforced concrete with witness and mine waste admixture (28 days)

When the relationship between water absorption (m%) and porosity (v%) given in Fig. 6 and Fig. 7 is analysed, it is seen that there is a positive correlation for both curing times. According to the regression equation (y = 2.0064x

+ 1.3755) determined in the correlation graph of 7-day samples (Fig. 6), the R^2 value is 0.954 and it is understood that there is a very strong linear relationship between water absorption and porosity. This high correlation coefficient indicates that microstructural voids directly affect the water absorption capacity during the early curing period. In the correlation graph of 28-day samples (Fig. 7), the regression equation (y = 2.2611x + 0.1606) and R^2 value was found as 0.8192. This value shows that the correlation has weakened slightly compared to the 7-day samples, but there is still a strong relationship. After 28 days of curing, it can be said that the direct relationship between water absorption and porosity has decreased slightly due to the microstructural development of the specimens and the effect of the organisation of the void structure. In general, it was determined that porosity increased as the water absorption rate increased in both 7 and 28 day samples; therefore, the two parameters are closely related to each other in the evaluation of permeability and durability properties of concrete. The control of porosity, especially at early ages, is critical for the long-term durability of concrete.

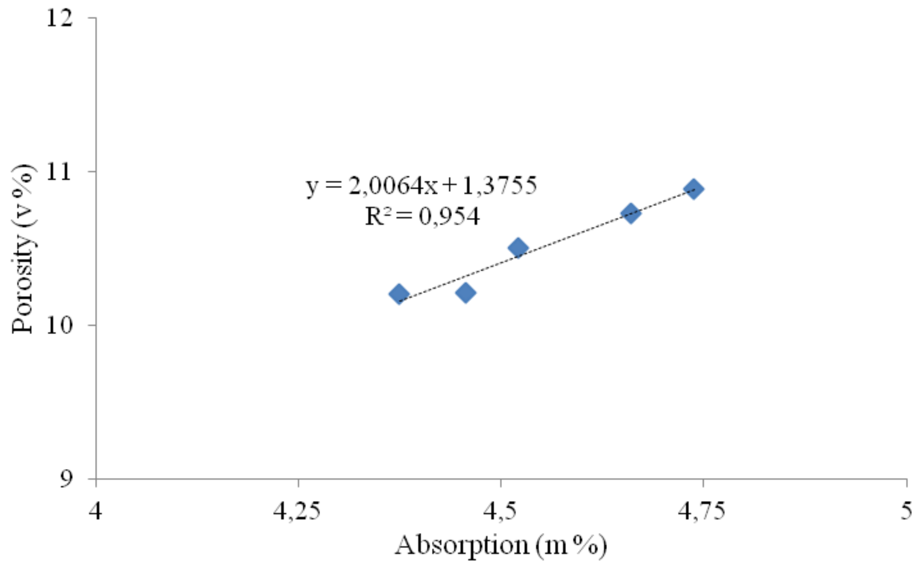

Fig. 6. Porosity-water absorption relationship of fibre concrete with witness and mine waste admixture (7 days)

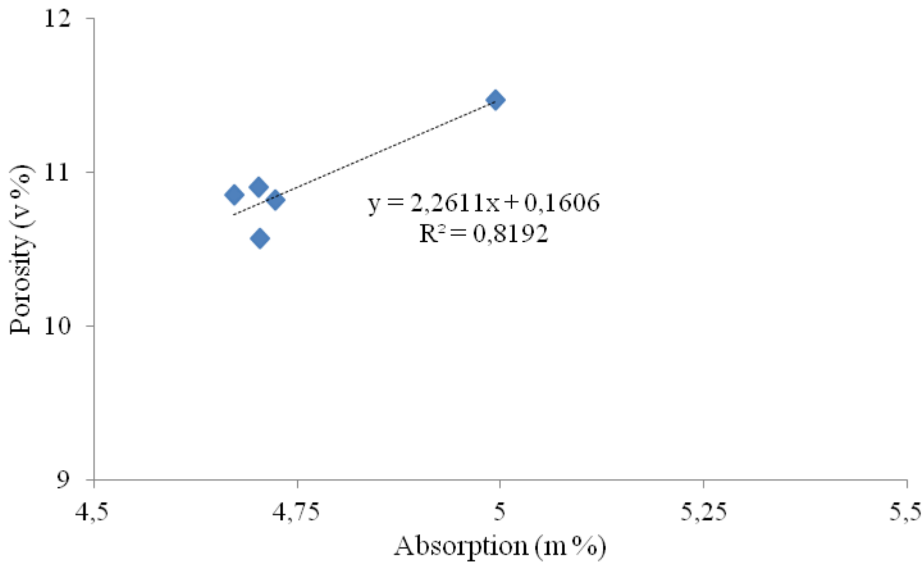

Fig. 7. Porosity-water absorption relationship of fibre concrete with witness and mine waste admixture (28 days)

3.2. Mechanical properties

According to the results presented in Fig. 8 and Fig. 9, the normal concrete (N) specimen exhibited a compressive strength of 18.88 MPa and a splitting tensile strength of 2.92 MPa at 7 days curing time. These values decreased by 20.2% and 5.8% to 15.08 MPa and 2.75 MPa, respectively, for the W specimen using mine waste. On the other hand, the compressive strength increased by 13.7% to 21.47 MPa and the splitting tensile strength increased by 4.1% to 3.04 MPa in specimen W-2 to which 0.2% waste tyre wire was added. The increasing trend continued in W-4 and W-6 specimens; the compressive strength of W-4 specimen was 22.96 MPa (21.6% increase) and W-6 specimen was 22.44 MPa (18.9% increase). At 28 days curing time, the compressive strength of N specimen was 21.99 MPa and the splitting tensile strength was 2.87 MPa. In W specimen, the compressive strength decreased by 18.1% to 18.00 MPa and the splitting tensile strength decreased by 8.4% to 2.63 MPa. However, W-2, W-4 and W-6 specimens increased by 4.0%, 10.1% and 18.2% respectively and reached compressive strength values of 22.87 MPa, 24.21 MPa and 26.00 MPa. The splitting tensile strengths ranged between 2.58-2.83 MPa and the W-6 specimen obtained the highest value of 2.83 MPa with an increase of 2.1%. These findings show that the addition of low proportions (0.2%-0.6%) of waste tyre wire significantly increased the compressive and tensile strengths both at early age and at later curing times, whereas the use of only mine waste decreased the mechanical performance. In particular, 0.6% tyre wire admixture provided 18.2% higher compressive strength compared to normal concrete after 28 days.

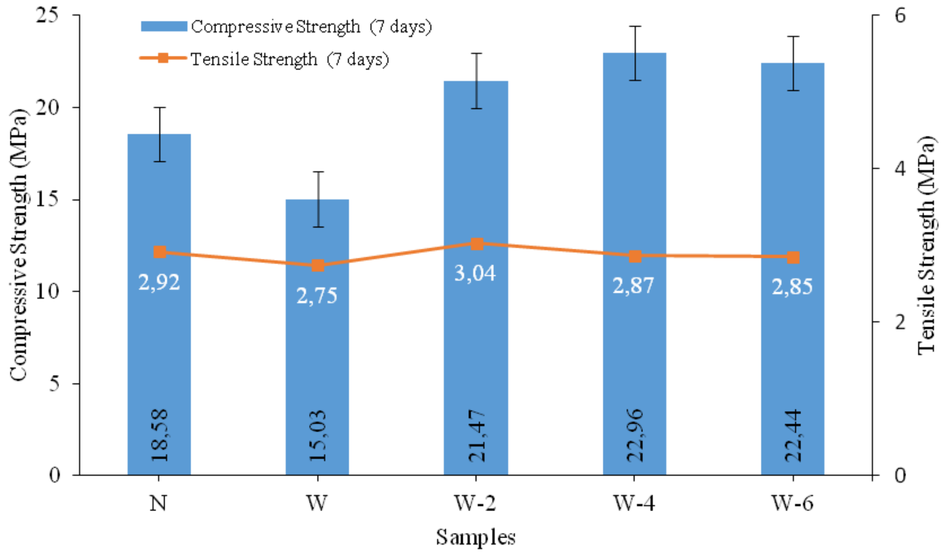

Fig. 8. 7-days compressive and splitting tensile strength of mine waste and waste tyre wire at different replacement ratios (0.2%; 0.4% and 0.6%)

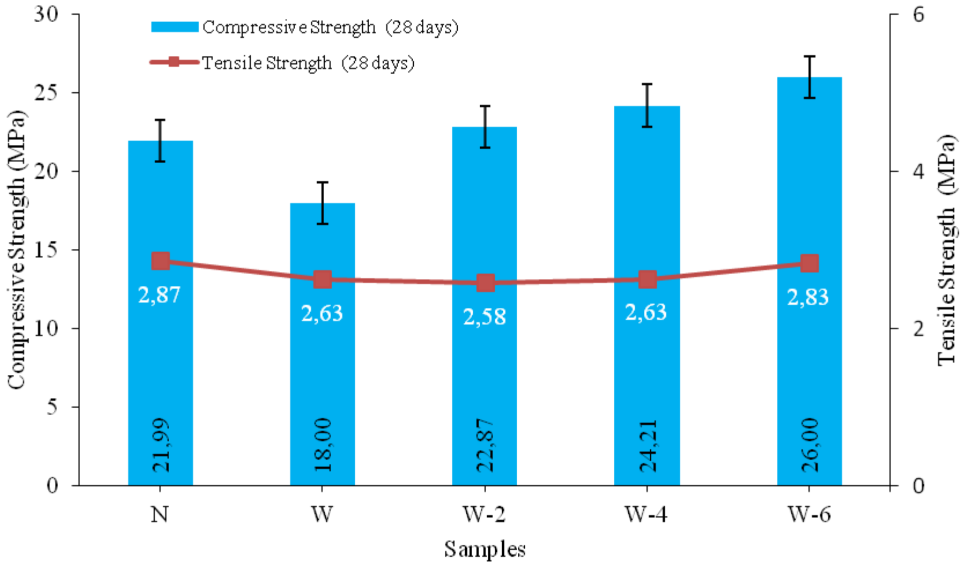

Fig. 9. 28-days compressive and splitting tensile strength of mine waste and waste tyre wire at different replacement ratios (0.2%; 0.4% and 0.6%)

According to the modulus of elasticity and Poisson's ratio results given in Fig. 10 and Fig. 11, the modulus of elasticity of the normal concrete (N) sample was determined as approximately 30 GPa and Poisson's ratio was 0.015 at the end of 7 days of curing. The modulus of elasticity increased by 6.7% to approximately 32 GPa and the Poisson's ratio doubled to 0.03 for specimen W. The modulus of elasticity increased by 25.0% to approximately 40 GPa and the Poisson's ratio increased to 1.3 for specimen W-2 to which 0.2% waste tyre wire was added. In specimens W-4 and W-6, the modulus of elasticity was approximately 32 GPa and 34 GPa, respectively, and the Poisson's ratio was 1.12 and 1.73. At 28 days curing time, a general increase in the modulus of elasticity values was observed. While the modulus of elasticity increased to 50 GPa in sample N, it reached approximately 55 GPa in sample W with a 10% increase. In specimen W-2, the modulus of elasticity increased to approximately 80 GPa, which is a 60% increase compared to normal concrete. Poisson's ratio was determined as 1.81 in this specimen. In specimens W-4 and W-6, the modulus of elasticity was measured at approximately 35 GPa and 38 GPa, respectively, showing a decrease of 30% and 24%, respectively, compared to specimen N. Poisson's ratio decreased to 0.8 in W-4 and increased to 1.03 in W-6. These findings indicate that the addition of 0.2% waste tyre wire significantly increases the modulus of elasticity of concrete with mine waste, whereas higher additions lead to a decrease in the modulus of elasticity. In addition, changes in Poisson's ratio indicate changes in microstructural deformation characteristics within the specimen.

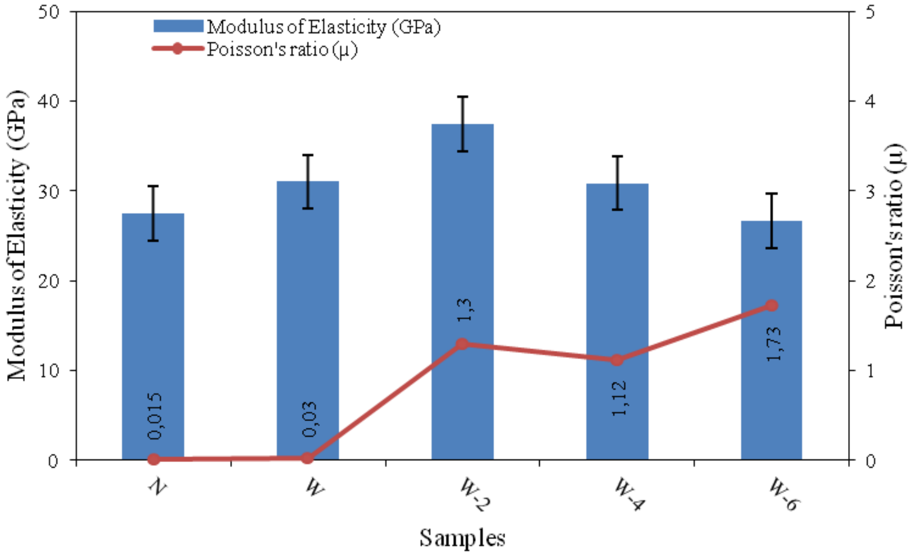

Fig. 10. Elasticity-Poisson relationship of mine waste and waste tyre wire substituted concretes (7 days)

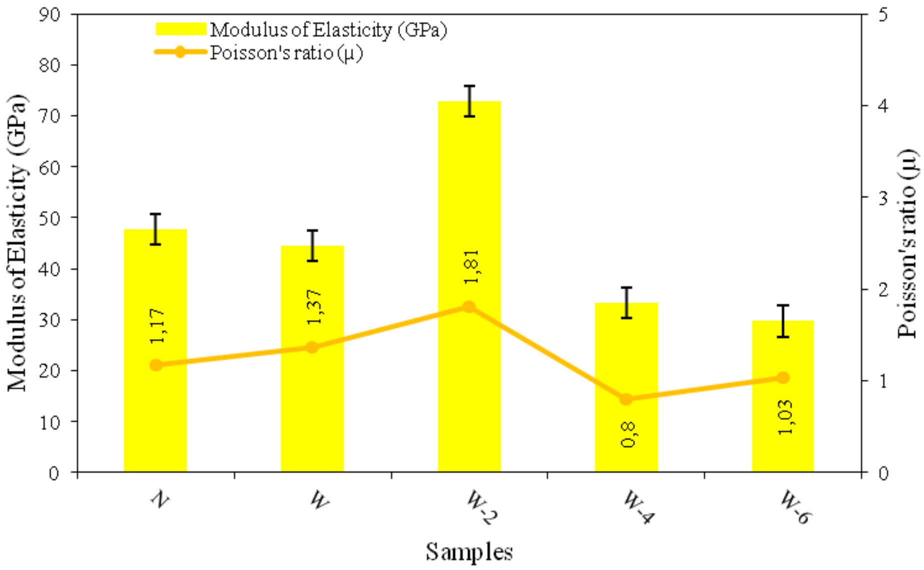

Fig. 11. Elasticity-Poisson relationship of mine waste and waste tyre wire substituted concretes (28 days)

3.3. Discussion

Several studies in the literature have indicated that the incorporation of SFs can enhance the compressive strength of concrete (Li & Li., 2017; Abbas et al., 2018). However, contrasting findings have also been reported, with some researchers concluding that SFs have little to no impact on compressive strength (Papakonstantinou & Tobolski, 2006; Doğruyol et al., 2024). In this study, the physical and mechanical properties of concretes produced using mine waste and waste tyre wire at different ratios (0.2%, 0.4% and 0.6%) were evaluated. In terms of physical properties, it was observed that the addition of mine waste and waste tyre wire at both curing times (7 and 28 days) did not cause a significant change in porosity and water absorption rates compared to the control sample. In particular, it was determined that the addition of 0.4% and 0.6% wire decreased the porosity to a limited extent and did not adversely affect the water absorption performance. The strong positive correlation between water absorption and porosity (R^2 = 0.954 for 7 days, R^2 = 0.8192 for 28 days) was found to be effective on microstructural permeability especially at early ages. In terms of mechanical performance, the addition of 0.2%-0.6% waste tyre wire had an increasing effect on both compressive and splitting tensile strengths. At 7 days curing time, compressive strength of 0.2% wire added specimen increased by 13.7% and at 28 days curing time, compressive strength of 0.6% wire added specimen increased by 18.2%. A decrease in mechanical strength was observed in the specimens where only mine waste was used. In addition, in the modulus of elasticity evaluations, it was determined that the addition of 0.2% wire increased the modulus of elasticity by 25.0% in 7 days and 60% in 28 days; decreases in the modulus of elasticity were recorded at higher wire ratios. The changes in Poisson's ratio values indicate the differentiation in microstructural deformation mechanisms. In general, the use of mine waste and low levels of waste tyre wire has the potential to improve the mechanical performance and modulus of elasticity of concrete while maintaining its physical integrity. In particular, 0.2% tyre wire admixture provided optimum performance enhancement at both early and later curing times, and in this context, made a significant contribution to the sustainable utilisation of environmental wastes in the concrete road industry.

4. Conclusions

This study investigated the physical and mechanical properties of concrete incorporating mine waste and varying proportions (0.2%, 0.4%, and 0.6%) of waste tyre wire. The findings suggest that the inclusion of these materials can contribute to both performance enhancement and sustainable waste utilization in the concrete pavement industry. Physically, the addition of mine waste and tyre wire did not significantly alter porosity or water absorption rates compared to the control specimens at both 7 and 28 days of curing. Notably, wire additions at 0.4% and 0.6% slightly reduced porosity without negatively impacting water absorption. A strong positive correlation between water absorption and porosity was observed, particularly at early curing stages, indicating an influence on microstructural permeability. Mechanically, the incorporation of waste tyre wire enhanced both compressive and splitting tensile strengths, with the most notable increase in compressive strength (18.2%) recorded at 0.6% wire addition after 28 days. Conversely, the use of mine waste alone resulted in decreased strength. The addition of 0.2% wire significantly improved the modulus of elasticity by 25.0% at 7 days and 60% at 28 days while higher wire ratios led to reductions. Variations in Poisson's ratio further reflected changes in microstructural deformation behavior. Overall, the results indicate that the use of mine waste in combination with low levels of waste tyre wire, particularly at 0.2%, can enhance mechanical properties and elastic behavior without compromising physical durability. This approach not only improves concrete performance but also offers a promising pathway for the sustainable reuse of industrial and environmental waste materials in infrastructure applications such as concrete pavements.

Abstract. The rapid growth of urban populations has raised the imperative of efficient mass transit systems, and subway lines have emerged as an integral part thereof. Over the years, subway stations have evolved from solely functional transport endpoints to diversified multi-use complexes involving heterogeneous services and facilities and promoting Transit-Oriented Development (TOD). This is an evaluation of the effects on land use caused by central urban multi-purpose transit nodes, which includes how these nodes influence interactions between metro/subway crossing nodes and bus/BRT routes and the growth of private small convenience stores and nearby local taxi fleets. A range of indicators, measures, and variables were isolated to construct an ordered questionnaire whose reliability was guaranteed by Cronbach's alpha. Testing of hypotheses was conducted based on Pearson's correlation coefficient. The results confirm that the integration of mixed-use developments and a range of services within and in the areas of transport hubs significantly enhances their attractiveness, elevates the extent of citizens' involvement, and renders the complexes more utilized. Furthermore, the study highlights the importance of such terminals in spurring localized economic activities, including the growth of private small markets and taxi businesses, thereby promoting the sustainable urban space development. Such observations call for an adoption of a TOD strategy to ensure urban transportation centers maximize functionality and socio-economic impacts.

Keywords: Private transportation system; Socio-economic impacts; Heterogeneous services; Urban land use; TOD

1. Introduction

This urban transportation challenges linked to rapid urbanization and proposes solutions like Transit-Oriented Development (TOD). Integrating transport and land use planning helps cities become more sustainable, efficient, and liveable. Urban population growth has exacerbated traffic congestion and pollution. Traditional public transportation has become inadequate, necessitating sustainable urban transport solutions including metro systems and TOD principles (Curtis & Scheurer, 2021).

Sustainable transport aims to reduce reliance on private vehicles, minimize environmental impacts, and improve accessibility. Strategies include promoting public transport, walking, and cycling, and encouraging compact, mixed-use development (Curtis & Scheurer, 2021)

Metro systems provide fast, clean, and high-capacity transport, reducing dependence on private cars. TOD encourages dense, walkable, mixed-use developments around transit stations, improving urban quality (Calthorpe, 2017). High-quality urban spaces are accessible, attractive, safe, and multifunctional. These spaces promote social interaction, encourage public transport use, and contribute to urban sustainability (Gehl, 2019). Sustainable transport and TOD principles offer a viable pathway for developing resilient cities. Proper integration of transport systems and land-use planning is essential to achieve liveable urban environments (Bertolini, 2020).

Table 1. Comparison of urban transport modes based on speed, capacity, and pollution

Transport Mode	Speed	Capacity	Pollution Level
Bus	Low	Medium	Low
Tram	Medium	Medium-High	Very Low
Metro	High	High	High

With the rapid growth of urbanization, public transportation systems, especially metro networks, have gained increasing importance in organizing urban land use.

Transit-Oriented Development (TOD) focuses on increasing density, mixed land use, and enhancing pedestrian accessibility to public transport stations. This study analyses the impact of metro station complexes on land use patterns, emphasizing the case study of Mirdamad Metro Station. Urban rail transport is now recognized as a key tool for sustainable urban development (Cervero, 2016).

Establishing metro station complexes with commercial, residential, administrative, and cultural land uses not only improves the environmental quality of surrounding areas but also reduces energy consumption and reliance on private vehicles (Curtis, 2020). Studies in London (Broadgate and King's Cross stations) show that station complexes integrating commercial spaces and green areas have significantly enhanced land value and environmental quality (Mior, 2002).

In Seoul (Samsung station), the development of administrative and recreational spaces attracted private investment and increased pedestrian traffic around the station (Jamshidzadeh, 1999). Similarly, Stockholm and Paris offer successful examples of connecting transport networks with commercial and leisure centers (Loukaitou-Sideris, 2022).

The TOD approach emphasizes high-density development, mixed land use, improved walkability, and reduced dependence on private vehicles (Newman & Kenworthy, 2021) .Building multifunctional complexes around metro stations attracts investments in residential, commercial, administrative, and recreational projects due to improved accessibility (Knowles, 2022) .In the case of Mirdamad Metro Station in Tehran, developing station complexes can lead to:

- Increased population and economic density around the station
- Improved pedestrian access and service availability
- Reduced local traffic congestion
- Enhanced urban environmental quality

Mirdamad Station, located strategically in northern Tehran, holds high potential for TOD-based development. Creating commercial, administrative, and public spaces in this area can significantly transform surrounding land uses and promote sustainable urban development. International examples such as Ploshchad Metro in Moscow and La Defence Metro Station in Paris have demonstrated how station complexes can effectively revitalize local economies and enhance urban living standards. Developing station complexes around Mirdamad Metro based on TOD principles can significantly improve surrounding land use patterns. Proper integration of commercial, administrative, residential, and cultural spaces will enhance environmental quality and encourage public transportation use. Global experiences demonstrate that with proper planning, station complexes can foster economic and social growth alongside improved urban mobility.

2. Methodology

This study employed a descriptive-analytical research methodology to assess the impacts of metro station complexes on surrounding land use, adopting a Transit-Oriented Development (TOD) framework. The research included two segments: theoretical studies (reviewing global TOD practices and station complexes) and fieldwork (direct observations, data collection, and surveys). The methodology integrated qualitative insights and quantitative analysis to evaluate the spatial impacts of Mirdamad Metro Station. Primary data was collected through direct surveys with 120 randomly selected passengers at Mirdamad Metro Station, authorized by Tehran Metro Co. Secondary data included document reviews and internet searches (Bertolini, 2012).

Key dimensions assessed in three items as following (Table 2):

- Attractiveness and aesthetics
- Activity and functionality
- Security and comfort

Descriptive statistics, correlation analysis (using Pearson coefficients), and regression modelling were applied. Reliability of the questionnaire was assessed through Cronbach's Alpha ($\alpha > 0.7$).

Table 2. Key indicators assessed

Dimension	Indicators	Examples
Attractiveness	Cleanliness, Visual Quality	Public Space Aesthetics
Functionality	Activity Diversity	Restaurants, Shops, Cultural Centers
Security	Lighting, Surveillance	CCTV Cameras, Police Presence

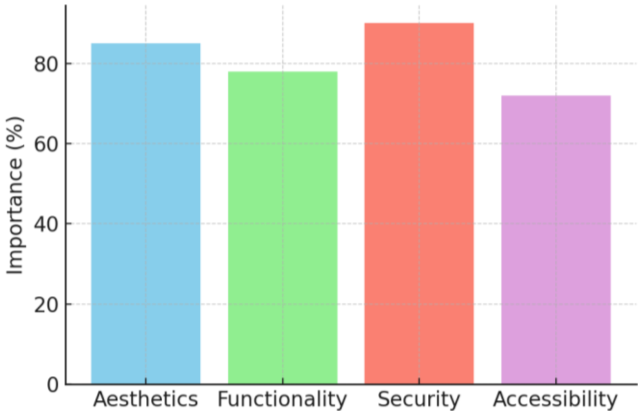

Fig. 1. Respondents' prioritized preferences

The questionnaire covered two sections: current station conditions and user improvement preferences. Sample questions evaluated aspects such as aesthetics, cultural activity presence, and public safety (Cervero, 2021).

After refinement, the Cronbach's Alpha coefficient exceeded 0.7, validating the internal consistency of the survey instrument (Zhang & Xu, 2022).

The analysis revealed strong user preference for diversified amenities (Table 3), enhanced aesthetics, and secure environments around Mirdamad Station, consistent with TOD principles [17]. Regression analysis confirmed that improvements in station complexes significantly influenced surrounding land use changes (Tehran Urban & Suburban Railway Co., 2023).

3. Results and discussion

The study revealed several significant outcomes, summarized in Table 3. Transit-Oriented Development (TOD) focuses on creating vibrant, liveable urban spaces around high-quality public transport stations. Metro stations like Mirdamad in Tehran act as significant catalysts for influencing surrounding land uses (Cervero, 2021). Data was collected via a structured 29-question survey filled by 120 participants, analysed using SPSS software. Both descriptive and inferential statistics were employed.

Table 3. Change in land use indicators after TOD implementation

Indicator	Before TOD (%)	After TOD (%)
Small Commercial Establishments	25	67
Private Vehicle Usage	80	43
Local Taxi Fleet Size	10	41
Pedestrian Traffic	30	78

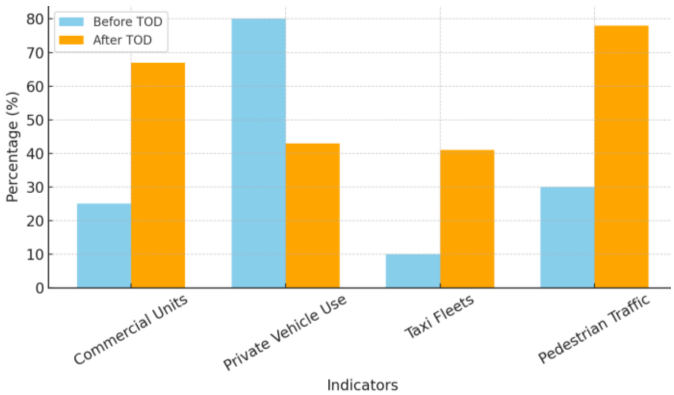

Fig. 2. Comparison of urban indicators before and after TOD

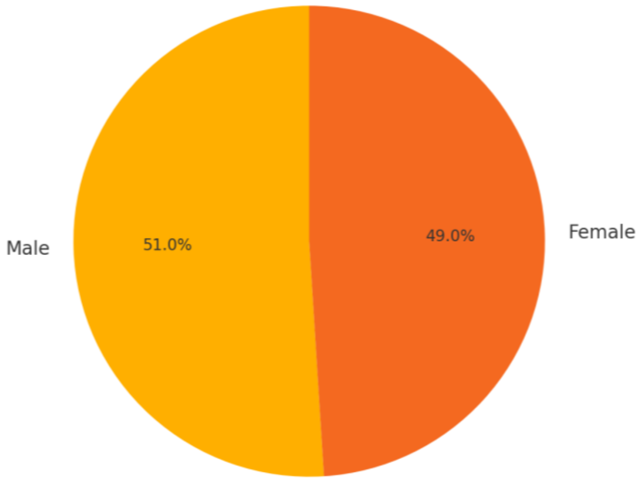

Fig. 3. Gender distribution among participants

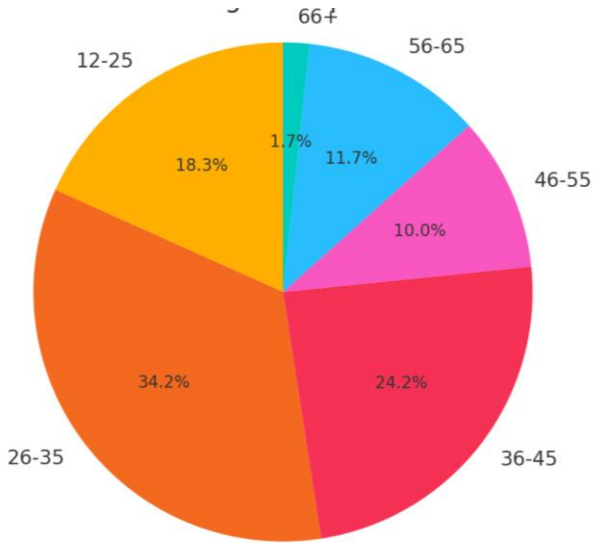

Fig.4. Age group distribution among participants

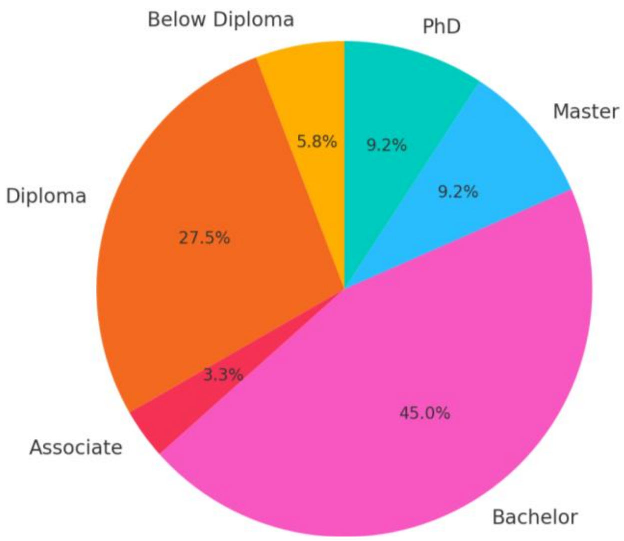

Fig. 5. Education level of participants

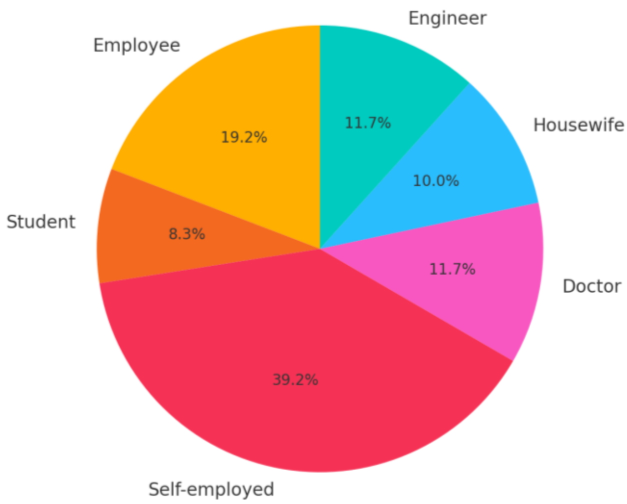

Fig. 6. Occupation of participants

Overall, the majority of respondents were young, educated, and professionally active, which enhances the credibility of the survey results. Survey results indicated positive satisfaction levels regarding cleanliness, lighting, accessibility, and safety measures around the metro station.

The Pearson correlation coefficient ($r=0.611$, $p<0.001$) showed a significant positive relationship between the availability of diverse land uses and station efficiency (Zhang & Xu, 2022). Further analysis indicated strong links between the presence of services and perceived security and attractiveness (Pojani & Stead, 2021).

4. Conclusion

Centralized multi-purpose transit stations are pivotal for modern urban development. Their ability to integrate transportation functions with commercial and social activities promotes sustainable land use, enhances local economies, and contributes to reducing urban sprawl. Policymakers and planners should prioritize TOD strategies to optimize the utility of transportation hubs and foster resilient urban growth. The Mirdamad Metro Station demonstrates that integrated TOD principles can successfully influence urban growth patterns. Authorities are recommended to plan future urban expansions with TOD models in mind (Newman & Kenworthy, 2020).

Abstract. The presence of water, snow, or ice on road surfaces poses a significant threat to road safety. These adverse conditions substantially reduce the friction coefficient between the tires and the road surface. Therefore, prompt measures are necessary to mitigate such risks. To melt ice and snow on pavement surfaces, chemicals such as NaCl, $MgCl_2$, and $CaCl_2$ are often applied. However, these methods carry risks of negatively impacting asphalt pavement performance, vehicles, and infrastructure such as bridges, as well as causing long-term environmental issues. Current literature indicates that the application of superhydrophobic pavements can significantly enhance road safety. In this context, the use of fluoropolymer-based materials containing PTFE, TiO_2, ZnO, SiO_2, Mg-Al LDHs, and nano-CaO has been proposed for incorporation into asphalt mixtures to improve road safety. Superhydrophobic surfaces offer a wide range of functionalities, including water resistance, ice prevention, antibacterial properties, dirt repellence, self-cleaning capabilities, and corrosion resistance. Superhydrophobic pavements are a special type of surface treatment characterized by unique wettability properties, with a water contact angle greater than 150° and a roll-off angle of less than 10°. These surfaces are typically designed by applying low-surface-energy treatments or creating rough surface textures. When applied to road pavements, these features provide significant advantages, such as reduced water accumulation, minimized ice formation, and less damage to the pavement compared to conventional methods. This study provides an overview of superhydrophobic pavement applications and their potential benefits for enhancing road safety.

Keywords: Superhydrophobic pavements; Road safety; Anti-icing agent; De-icing agent.

1. Introduction

The accumulation of water, snow, and ice on pavement surfaces leads to time loss, economic damage, environmental pollution, compromised passenger safety and increased traffic congestion (Segundo et al., 2020). Furthermore, the formation of ice or snow on airport runways often results in flight cancellations, causing personal inconvenience for passengers and financial losses amounting to millions for airline companies and airport operators (Arabzadeh et al., 2016).

The conventional method for removing ice and snow from pavement surfaces involves the application of salts (primarily chloride-based salts such as sodium chloride (NaCl) and calcium chloride ($CaCl_2$) etc.) and chemical compounds. It can deteriorate asphalt pavement performance, accelerate the corrosion of vehicles and critical infrastructure (e.g., bridges) and contribute to significant long-term environmental degradation (Peng et al., 2018). For field applications, deicers are selected based on their effectiveness at freezing temperatures, cost, availability and ease of application on the pavement surface. Their effectiveness in melting ice and snow is defined by the effective temperature, which is the lowest practical temperature at which the deicer can be used; this temperature is relevant for ice melting, anti-icing and other applications. In road deicing and anti-icing operations, chloride-based deicers are commonly used. This is because their costs are lower and they can be obtained easily. Among chloride-based deicers used on roads, NaCl is the most commonly used. The effective temperature for NaCl is 15°F (Nilssen et al., 2018). Below this temperature, NaCl is unable to melt snow and therefore becomes ineffective at extremely low freezing temperatures. However, to enable its use across a wide range of conditions, it is often mixed with other deicers and corrosion inhibitors (Sajid et al., 2021; Abbas et al., 2021). On the other hand, calcium

https://doi.org/10.31462/icearc2025_ce_tra_564

chloride is another chloride-based deicer that remains effective at temperatures as low as -25°F, making it suitable for regions experiencing severe winter conditions. It is considered relatively harmless to the environment. However, it has been shown to cause significant deterioration of pavement materials (Wang et al., 2006; Sutter et al., 2006) and is more expensive compared to sodium chloride (Nixon, 2008).

Magnesium chloride is another chloride-based deicer effective at relatively low temperatures (approximately -10°F), and it is widely used for deicing highways and parking lots (Shi et al., 2009). However, it has also been found to be corrosive, cause severe pavement deterioration, and contribute to environmental pollution (Fay & Shi, 2012).

Calcium magnesium acetate (CMA) deicer is less corrosive compared to chloride-based deicers (Peterson, 1995). It is also biodegradable, which makes it somewhat environmentally friendly. However, CMA is not as cost-effective as chloride-based deicers. Moreover, its effectiveness is limited to moderately cold temperatures. Potassium acetate is another acetate-based deicer that works at very low temperatures (-15°F) (Western Transportation Institute, 2017). Like CMA, it is a less corrosive and more environmentally friendly option. For this reason, it is mostly used on airport runways (Shi et al., 2009). The selection of deicers is an important part of the experimental methods adopted in the literature. Different deicers have different properties, which result in varying rates of concrete deterioration.

Due to its high efficiency and low environmental impact, superhydrophobic deicing coating material holds great promise for road pavement applications. Therefore, it is necessary to explore reliable and cost-effective deicing methods to ensure safe driving on pavements under severe weather conditions (Huang et al., 2021). Commonly used deicing methods include the application of chemical products, heating, and the use of superhydrophobic materials. The mechanisms of road deicing methods are generally categorized into passive and active deicing approaches (Cao et al., 2018). Passive deicing methods (e.g., the use of chemical products) are simple and relatively low-cost. However, they tend to be less efficient and often require labor and material-intensive. In addition, they can cause significant damage to the pavement structure. In contrast, active deicing methods offer high efficiency and cause less harm to road structures. However, current active deicing methods used in the market (e.g., heating) are often expensive. The use of superhydrophobic materials as another potential active deicing option is attracting increasing interest due to their simple preparation, cost-effectiveness, and pollution-free properties (Cao et al., 2018). Therefore, utilizing superhydrophobic materials as an anti-icing technology in road pavements is considered an ideal solution due to their numerous advantages (Huang et al., 2021).

In engineering, superhydrophobic coatings are temporarily applied to critical and ice-prone areas, such as intersections and bridge decks, to maintain their anti-icing properties for at least one year before winter. However, the strategies for preparing superhydrophobic coating materials and the testing methods are diverse, and there is a lack of a unified understanding of the anti-icing mechanisms and the performance characteristics of these materials. All of these factors limit the further development of this new anti-icing approach (Li et al., 2023).

2. Superhydrophobic coatings

One of the most common methods for deicing pavements is the use of salts and chemicals. However, these methods have become outdated and insufficient in contemporary practice. Numerous studies have shown that these chemicals significantly affect the performance of asphalt pavement. Furthermore, they contribute to the corrosion of vehicles and deck bridge deck, leading to long-term environmental damage (Munck et al., 2010). In recent years, thermal melting technologies (including liquid heating) (Chen et al., 2011), microwave heating (Tang et al., 2008), thermal cables (Zhou et al., 2011) and electrically conductive roads (Hou et al., 2010) have been widely utilized to prevent the formation of ice layers on road surfaces. However, the high energy consumption of these technologies and their economic inefficiency have limited their development and application (Li et al., 2012). Research indicates that low free energy levels are indicative of a superhydrophobic surface, which reduces the adhesion of ice to the surface (Lin et al., 2013).

Objects with superhydrophobic surfaces were first discovered through the investigation of the lotus leaf's ability to remain clean. The leaf surface is covered with a substance that has low free surface energy and also features a rough structure at the nanoscale. The combination of these two properties has been found to give the lotus leaf surface its superhydrophobic characteristics. As a result, the liquid droplet on the surface makes minimal contact with the surface, as it is trapped in the nanoscale cavities, with air occupying the space. This allows the droplet to remain on the surface with a high contact angle, closely resembling a spherical shape due to surface tension. Additionally, the liquid droplet can roll off the surface at a slight slope. As it rolls, it picks up dirt and dust from the surface, thereby cleaning it. Due to these properties, superhydrophobic/hydrophobic surfaces have the potential for use in a wide range of applications, including self-cleaning, anti-icing, corrosion prevention, anti-fogging, and reducing drag resistance (Kibar, 2016).

The self-cleaning ability of lotus (Nymphaea) leaves was discovered by W. Barthlott et al. in 1997 during their study of the surface structure of lotus leaves, which possess superhydrophobic properties (Barthlott & Neinhuis, 1997).

Various studies have been conducted to investigate the adhesion mechanism of ice on superhydrophobic surfaces (Zhang et al., 2017; Chen et al., 2017). Superhydrophobic coatings can reduce the ice formation area, prevent the development of ice layers, and weaken the adhesive force of ice to surfaces. Additionally, these coatings possess self-cleaning properties and can protect the underlying substrate. Such coatings have been successfully applied in fields such as aerospace (Huang et al., 2019), energy transmission (Peng et al., 2018), marine environments (Ferrari & Benedetti, 2015), and medical applications (Falde et al., 2016). However, the use of superhydrophobic coatings for road surface anti-icing is still in the exploratory stage, and there are limited reports on their applications in road anti-icing engineering (Cui et al., 2024).

Several potential applications of superhydrophobic surfaces, including anti-freezing, anti-corrosion, anti-frosting, anti-icing for photovoltaic cells, power lines, airplanes, ships, anti-friction for submarines, self-cleaning of solar panels and glass windows etc. are illustrated in Fig. 1 (Zhang & Lv, 2015).

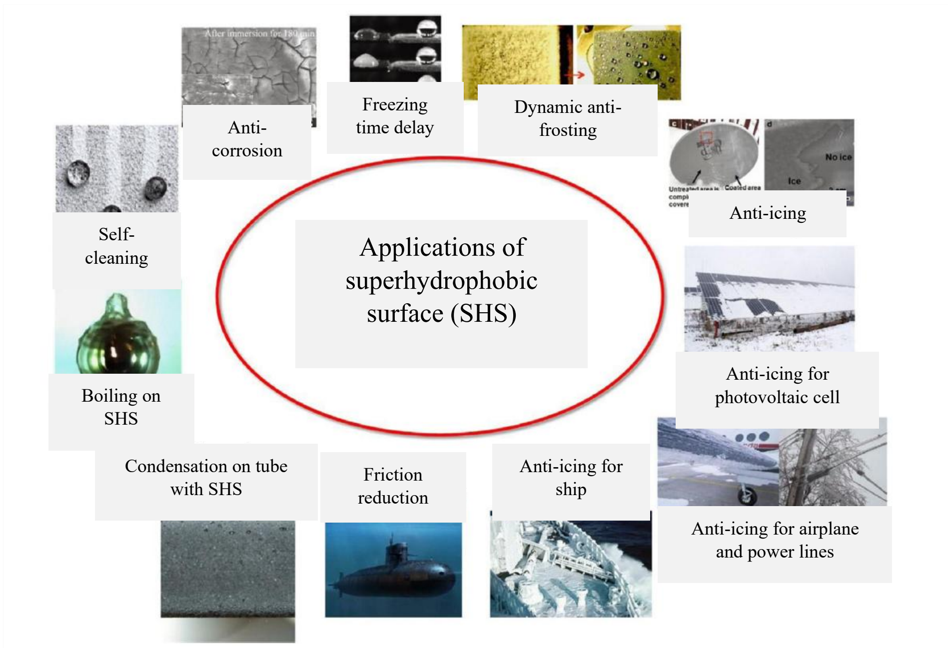

Fig. 1. The potential applications of superhydrophobic surfaces (Hooda et al., 2020).

Asphalt mixtures with photocatalytic properties support air purification through the application of semiconductor materials. Photocatalytic asphalt pavements, when exposed to sunlight in the presence of water and oxygen, degrade organic pollutants as well as SO_2 and NO_x. This effect contributes to both air and surface cleanliness, particularly when oils and greases are adsorbed onto the asphalt surface. Another functionalization process involves enhancing the superhydrophobic capacity. A superhydrophobic asphalt mixture possesses the ability to repel water and prevent ice formation on the surface, which can improve road safety. The self-cleaning capacity associated with superhydrophobicity is based on the fact that water droplets maintain a spherical shape and can easily roll over the surface, carrying away dirt particles (da Rocha Segundo, 2021). A long-term superhydrophobic self-cleaning coating was first developed through the simple mixing of TiO_2 nanoparticles with a fluorinated polysiloxane binder that cures under ambient conditions (Ding et al., 2011).

The superhydrophobic property is achieved when the contact angle is greater than 150° (Zhu et al., 2014). Superhydrophobic coating is a type of coating with special surface wetting properties; the water contact angle is greater than 150° and the rolling angle is less than 10° (Barthlott & Neinhuis, 1997; Pan et al., 2017).

Surfaces with a water contact angle less than 90° are considered hydrophilic, whereas those with a contact angle greater than 90° are defined as hydrophobic. The contact angles of a water droplet on a hydrophilic, hydrophobic and superhydrophobic surfaces are shown in Fig. 2 (Khan et al., 2022).

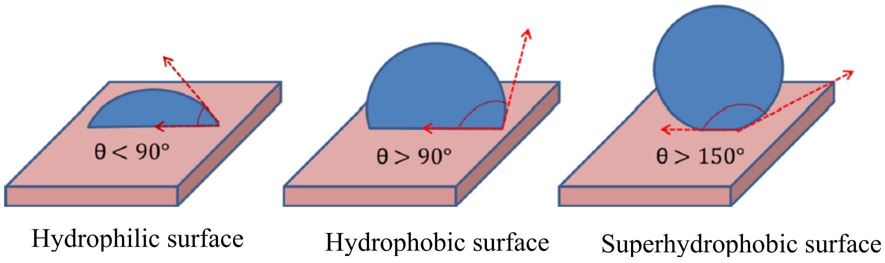

Fig. 2. Schematic illustration of the wettability of surfaces with different water contact angles.

Superhydrophobic properties are typically evaluated using optical and electron-based analyses. The primary method involves measuring the contact angle between water and the surface. As the surface must be rough, the analysis of the microtopography of the surface is important in this respect. Surface roughness is often examined through optical methods, such as optical triangulation-based microtopography. In this case, characterization can be done by evaluating the surface parameters and comparing the materials and processes. In addition, the images obtained with the Scanning Electron Microscope (SEM) are important to understand the microtopographic structure of the surface (Segundo et al., 2020).

One of the factors influencing the hydrophobic treatment is the curing time. In one study, all hydrophobic materials with a curing time of 24 hours exhibited larger contact angles compared to those cured for only 2 hours. Therefore, it can be concluded that curing time has a significant impact on the formation of hydrophobic coatings on asphalt surfaces. On average, longer curing times increased the contact angles by 20 degrees (approximately 18%) (Zakerzadeh et al., 2018).

3. Superhydrophobic coatings preparation methods

Superhydrophobic surfaces are not wetted by water and exhibit low surface energy. These surfaces are typically designed either by applying surface treatments that lower surface energy or by creating a rough surface texture (Segundo et al., 2020).

Superhydrophobicity is generally achieved in two ways: by increasing the roughness of low surface energy materials or by reducing the surface energy of micro- and nano-structured rough surfaces (Li et al., 2023). To describe the wettability of rough surfaces, two main models are commonly used: the Wenzel model (Wenzel, 1936) and the Cassie–Baxter model (Cassie & Baxter, 1944). Fig. 3 presents both the Wenzel and Cassie–Baxter models. The Wenzel model assumes that the liquid completely fills the grooves in the rough surface. In this case, by increasing the roughness of the object, the surface of an initially hydrophilic object becomes more hydrophilic, while the surface of an initially hydrophobic object becomes more hydrophobic. However, the Wenzel model has a shortcoming; it can only be applied to surfaces with uniform chemical composition. Asphalt and various asphalt mixtures are not suitable for this condition. Cassie and Baxter proposed a drop contact model to describe surfaces composed of composites. In this model, it is assumed that the droplets do not fully wet the solid surface, and the rough structure of the surface traps air, thus the droplets remain at the composite phase interface, consisting of solid-liquid and solid-gas phases. This situation aligns with the Cassie-Baxter model (Lafuma & Quéré, 2003).

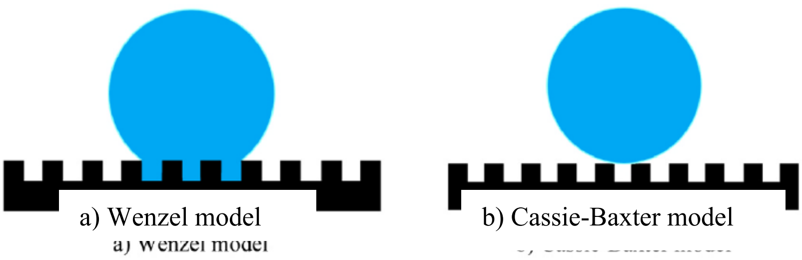

Fig. 3. Wenzel and Cassie-Baxter model

In general, the contact angle and rolling angle are used to evaluate the superhydrophobic capacity of a material (Yao et al., 2010). In order to enhance the performance and service life of the pavement, a nano-TiO_2 superhydrophobic coating (PSC) was prepared on asphalt pavement using waterborne polyurethane and stearic acid-modified nano-TiO_2. The SEM image indicate that the superhydrophobic coating has a rough surface structure. In the contact angle test, the contact angle of the PSC was measured to be 153.5° and the rolling angle was 4.7°. The results indicate that the surface superhydrophobic coating can effectively reduce water damage on asphalt pavement and has a significant impact (Li et al., 2021).

Water-repellent surfaces are typically recognized by their micro or nano roughness and complex morphologies. Another important feature is the replication of the micro-level morphology into what are called nano projections, creating multi-scale roughness. Therefore, the following fabrication techniques are employed to develop the specified characteristics on pseudo-surfaces (Hooda et al., 2020).

- Electrochemical deposition
- Electro-spinning and electro-spraying
- Chemical vapour deposition (CVD)
- Layer-by-layer (LBL) deposition
- Wet-chemical method
- Phase separation technique
- Imprinting technique
- Lithography technique
- Templating technique
- Hydrothermal method
- Sol-gel route
- Mussel-inspired chemistry

The sol-gel, wet chemical, electrochemical deposition, and Mussel-inspired chemistry are recognized as the most efficient, cost-effective, and industrially viable methods for producing superhydrophobic coatings. Therefore, there is a significant need to optimize the control parameters of these techniques in order to develop advanced superhydrophobic coatings for various applications (Hooda et al., 2020).

The superhydrophobic coating fabrication process consists of two steps: synthesis and coating. Commonly used synthesis techniques include etching, isoelectric precipitation, phase separation and the sol-gel method. For road superhydrophobic coatings, the sol-gel method is primarily used, as it meets the cost-effective and large-scale production requirements. On the other hand, the coating process should ensure uniformity and good adhesion to the coating surface. In addition to traditional brush and spray methods, the layer-by-layer (LBL) technique is primarily employed (Li et al., 2023).

The original contact angle of asphalt binder is approximately 100°, which decreases to about 70° after oxidation by thermal treatment. After spraying a superhydrophobic coating on the road surface, it will restore its hydrophobicity. Researchers commonly investigate material selection, material modification and production processes. Polytetrafluoroethylene (PTFE) is a widely used super anti-ice and waterproof material due to its low surface energy properties. PTFE waterproof coatings can enhance the waterproofing and anti-icing properties of airport runways, standard asphalt road surfaces and ordinary cement concrete road surfaces (Cui et al., 2024). Some studies have shown that under optimum spray conditions, PTFE coatings applied using layer-by-layer (LBL) techniques impart remarkable hydrophobic properties, achieving high contact angles of up to 155° (Arabzadeh et al., 2017).

In order to functionalize asphalt mixtures used in road pavements, nano/micro materials such as polytetrafluoroethylene (PTFE), TiO_2 and SiO_2 among others, have been applied to the pavement by spraying. The mixtures are typically characterized by their water contact angle and surface roughness is usually evaluated using optical and electron analysis (Segundo et al., 2020).

A study has proposed a heterogeneous nucleation ice crystal growth model, focusing specifically on the effects of surface roughness and contact angle. The mechanism of ice retention by superhydrophobic materials has been determined using this model and experimentally validated. Experimental results from water contact angle and sliding resistance tests showed that the prepared TiO_2–stearic acid coating material exhibited a contact angle greater than 150° and good sliding resistance. Superhydrophobic coatings are typically prepared with materials that have good inhibitor performance. In this study, superhydrophobic materials were prepared using a hydrothermal method. The reaction between nano-sized titanium dioxide (TiO_2) and stearic acid was synthesized in an anhydrous ethanol environment. Titanium dioxide has a purity of 99.8% and a particle size of 60 nm, with a rutile structure. Stearic acid and anhydrous ethanol are analytical reagents. To prepare the TiO_2–octadecanoic acid composite material, nano TiO_2 powder was first dispersed in pure ethanol by sonication for 1 hour. Then, octadecanoic acid was added to the previous solution. The mixture was homogenized by sonication for 3 hours. The final solution was obtained by stirring with a magnetic stirrer at 70°C for 6 to 12 hours. After that, an additional 60 mL of ethanol was added at 25°C, and the solution was centrifuged for 20 minutes to remove the supernatant. Finally, the TiO_2-OA sample was obtained after being dried at 120°C for 1 hour. The resulting superhydrophobic materials were then applied to asphalt or concrete surfaces by manual brushing or spray method (Huang et al., 2021).

In this study, spraying, dipping and brushing methods were used to determine the optimum preparation method for hydrophobic coatings. In this work, Nano-ZnO, TiO_2 and SiO_2 particles were converted into hydrophobicity with stearic acid. The optimum preparation method for the nanoparticle/epoxy coating was determined to be ultrasonic dispersion and layered spraying. The mass ratio of nanoparticles to stearic acid and the nanoparticle dosage were found to have a significant impact on the contact angle of the hydrophobic coating. If the amount of stearic acid exceeds the optimum value, the hydrophilic carboxyl group of the unreacted stearic acid and the hydrophobic interactions of stearic acid reduce the hydrophobicity of the coating. Furthermore, as the nanoparticle content increases, the aggregation of nanoparticles becomes more pronounced, which complicates the dispersion of nanoparticles and negatively affects the rate of hydrophobicity increase of the coating (Liu et al., 2024).

In a study where modified nano-TiO_2 and waterborne polyurethane were used as the main materials, the spraying method was employed to create a superhydrophobic surface. Compared to the sol-gel method, vapor deposition method, electrochemical method, template method, etc., the coating offers a simple preparation process, low cost, excellent superhydrophobic properties and some wear resistance. Test results demonstrate that it can effectively enhance the road surface's resistance to water damage and extend its service life (Li et al., 2021).

The production of superhydrophobic coatings using the spray coating method has become the subject of many studies due to several advantages, including the ability to be applied to surfaces with different chemical structures, large and irregular surfaces, low production and application costs, the fact that the spray coating method is already used in the coating industry, simplicity of application, not requiring special and high-cost equipment, the ability to be prepared and applied in a short period, ease of application, no need for specially trained personnel, allowing the production of translucent coatings and being user-friendly from the end-user's perspective (Güneş & Fidan, 2022).

One of the major issues encountered in road safety is the slipperiness of the road surface during rain. The presence of water on the road reduces friction on the surface of the pavement. When there is insufficient friction, accidents caused by sliding become inevitable. A common phenomenon during rain is hydroplaning, which refers to the reduction of contact on wet surfaces, leading to the loss of traction. Hydroplaning characteristics are influenced by factors such as water film thickness, tire inflation pressure, pavement texture depth, surface hydraulic properties, and tire tread depth (Zakerzadeh et al., 2021).

In a study investigating the effects of octafluoropentyl methacrylate superhydrophobic coating on hydroplaning risk and water film thickness on asphalt roads, a device simulating rainy conditions on asphalt roads was designed. The water flow rate was measured on coated and uncoated asphalt surfaces with varying degrees of superhydrophobic coating and the hydroplaning speed was calculated. According to the results, the average hydroplaning speeds of vehicles on coated asphalt samples were found to be approximately 1.33 times higher compared to uncoated asphalt samples. Additionally, the results suggest that superhydrophobic coatings could be an innovative method to reduce the hydroplaning risk and decrease the water film thickness on asphalt roads (Zakerzadeh et al., 2021).

One of the main factors for surface superhydrophobicity is the amount of material sprayed. To determine the optimum consumption of superhydrophobic material, the amount sprayed on asphalt samples was experimentally chosen as 50, 100, 150, 200 and 250 grams; this amount was determined for a 0.5 m^2 (0.5 m × 1 m) asphalt surface. In this part of the experiment, the slope was set to 3% and the flow rate was set to 3 lit/min. The surfaces coated with superhydrophobic material need to remain free from contact with any substances for 24 hours to allow the chemical bond between the coating and the asphalt surface to form. The results show that increasing the consumption rate from 50 g to 100 g strongly increases the hydroplaning speed; however, when the consumption rate exceeds 100 g, the hydroplaning speed remains almost constant (Zakerzadeh et al., 2021).

A superhydrophobic coating material typically consists of two main components: a superhydrophobic agent and a coating base (Li et al., 2023). On one hand, an effective and stable superhydrophobic material can be achieved by combining a micro-rough surface (approximately 1 nm to 10^2 nm) (Lin et al., 2013) with a low surface energy (SFE) material (Oliveira et al., 2013), which is considered a key factor in anti-icing strategies (Mahadik et al., 2010). There are two principal fabrication strategies: roughening low-SFE materials, such as by producing polytetrafluoroethylene (PTFE) nanoparticles (Nahvi et al., 2019) or forming a micro-rough surface via hydrolysis and condensation of polymethylhydrosiloxane (PMHS) (Zhang et al., 2021); and using nanomaterials modified with low-SFE substances to generate micro-rough surfaces. Among the successful applications of nanomaterials, nano-SiO_2, which offers high cost-effectiveness, is considered the most suitable option for large-scale highway engineering (Peng et al., 2018; Gao et al., 2018; Soleimani et al., 2021). Additionally, nano-TiO_2, known for its photocatalytic degradation properties, has also attracted significant research interest (Segundo et al., 2022; Huang et al., 2021; Li et al., 2021).

Nanostructures are considered an attractive option for creating nanoscale roughness on solid surfaces, as nanomaterials typically have dimensions in the range of 1–100 nm, allowing them to deposit as layers on surfaces (Goyat et al., 2011). The small size of nanostructures enables them to exhibit unique physical and chemical properties, particularly due to their high specific surface area-to-volume ratios (Goyat et al., 2011). The surface energy of solid surfaces can be reduced by incorporating low surface energy materials onto the surface. This can be achieved in two ways. In the first approach, low surface energy materials are either directly coated onto the surface or first attached to nanostructures, which are then deposited onto the solid surface. In the second approach, both low surface energy and nanoscale roughness are combined, which is particularly beneficial for the development of superhydrophobic surfaces (Chen & Carroll, 2002). It is a well-known concept that rough surfaces exhibit superior hydrophobic properties compared to smooth surfaces (Burkarter et al., 2007).

4. Shortcomings of superhydrophobic coating

There are two major challenges associated with achieving superhydrophobicity on asphalt surfaces. First, the hydrophobic nature of the surface alone is not sufficient to prevent ice adhesion; instead, a truly superhydrophobic surface is required (Arabzadeh et al., 2016). Therefore, it is essential to use a material that is not only compatible with asphalt surfaces (due to the presence of bitumen) but also capable of forming a superhydrophobic layer (Zakerzadeh et al., 2018). The second issue is the high cost of superhydrophobic materials, which makes some of them economically unfeasible for use with asphalt surfaces (Zakerzadeh et al., 2018).

In the development of superhydrophobic surfaces and films, several limitations are encountered, such as the high cost of superhydrophobic materials, the durability of nanostructures, coating stability, issues related to precipitation/condensation, interaction problems and emulsifier/oil wetting issues (Hooda et al., 2020).

To obtain an extraordinary superhydrophobic coating, a high water contact angle is required. Therefore, it is important to have a low-energy surface with water-repellent chemistry and durable micro- and nanoscale topographical features. Typically, achieving all of these challenging experimental parameters simultaneously can be somewhat difficult. For example, some polymers at the nanoscale have nano-textural properties and behave like 'wet noodles'. These polymer strands or 'wet noodles', easily mix and as a result, they stop behaving like a superhydrophobic surface (Bhushan & Jung, 2011).

Current studies show that improving the hydrophobicity of the coating and the adhesion between the coating and the road surface can provide good de-icing performance and durability. However, existing research on the application of hydrophobic materials for road anti-icing is generally limited to laboratory experiments and only a few coating technologies are used, recognized or promoted in physical engineering. The reason for this is that superhydrophobic coating materials are fragile and wear-sensitive, have poor adhesion to the road surface, easily peel off and have poor surface stability, which leads to insufficient durability of their ice and snow melting function (Wu & Chen, 2018); (Zhuo, et al., 2018).

Future studies on superhydrophobic surfaces should focus on improving the durability and stability of superhydrophobic surfaces. In the future, more research is needed on precisely controlling the surface roughness and structure at both small and large scales (Khan et al., 2022).

5. Conclusions

This study aims to examine superhydrophobic coatings, their production methods and general properties. Adverse weather conditions in terms of road safety occur when there is water, snow or ice on the road surface. The presence of these adverse weather conditions significantly reduces the friction coefficient on the road surface. Therefore, it is important to remove them quickly. The application of superhydrophobic coatings, removal of water droplets from the surface or prevention of ice/snow formation makes roads safer. In addition to their water-proof and anti-icing properties, superhydrophobic coatings also provide various benefits such as antibacterial, dirt-repellent, self-cleaning and corrosion protection.

- The ability of coatings to repel water varies depending on the properties of the materials used and the application methods. Superhydrophobic coatings containing PTFE, TiO_2, SiO_2, Mg-Al LDHs and nano-CaO nano/microparticle fluorine polymers have been applied on asphalt mixtures to increase road safety. The relevant literature results show that superhydrophobic asphalt mixtures can significantly increase road safety.
- Although superhydrophobic surfaces have attracted widespread attention in industrial areas, there are some limitations in the development of superhydrophobic coatings. These are; the cost of superhydrophobic materials, durability of nano-features, coating stability, precipitation/condensation problem and interaction problem.

As a result, superhydrophobic coatings are one of the effective methods to reduce the effects of water on road surfaces and there is a need for increased research in this area. Future studies should focus on improving the durability and stability of superhydrophobic surfaces.

Balancing costs and commuter comfort to enhance urban rail transit performance

Emre Demir*[1]

[1] Antalya Bilim University, Department of Civil Engineering, 07190 Antalya, Türkiye

Abstract. In civil engineering, designing effective public transportation (PT) lines in urban settings necessitates a strategy that takes into account both technological and human-centric aspects. This study measures the effectiveness of new rail transit (RT) stations in a large urban area, focusing on a balanced assessment of costs and benefits. Alongside structural costs and traditional benefits like travel demand and service frequency, this study adds two dimensions: commuter comfort in terms of food accessibility near the stations and the impact of terrain slope, including the amount of stairs around each station. As a case study, a lot of new stations on an RT line are examined in Antalya, Türkiye using a multi-criteria decision-making (MCDM) method. Thus, building costs and the operations to constitute station surroundings, such as cutting slopes and generating steps, are seen as significant cost factors. On the other hand, benefits include higher peak-hour trip volumes, faster average speed of the RT line, more frequent service, and the availability of food options nearby, which improve commuter satisfaction. The results reveal significant differences in station efficiency, demonstrating how design and location considerations influence both operational performance and user comfort. In addition, RT stations with better access to food services and fewer physical barriers have higher scores in efficiency. As a result, this study aims to support the construction of PT systems in developing regions by addressing human-centric concerns with cost-efficiency by implementing an MCDM technique.

Keywords: Public transportation; Rail transit efficiency; Multi-criteria decision-making; Commuter comfort

1. Introduction

Rail transit (RT) systems in urbanized areas serve as essential components of public transportation (PT) networks, significantly contributing to urban accessibility, sustainability, and overall quality of life. In this manner, the planning and effective operation of RT stations are crucial for the success of PT systems in developing areas where transportation demand rises. Therefore, efficient PT planning requires a balance between structural costs and societal benefits which needs an integrated assessment considering both technical performance and human-centric issues together.

While traditional assessments of RT stations often include metrics such as travel demand and structural costs, emerging urban planning patterns emphasize the need to integrate commuter experience into evaluation frameworks. Sustainable and accessible PT systems not only depend on operational efficiency but also on the extent to which they meet the comfort and convenience needs of the road users. In this way, human-centric factors become important in shaping user satisfaction and PT adoption rates. Despite this growing recognition, systematic evaluations that holistically address both cost-efficiency and commuter-centric benefits remain relatively limited. Decision-making processes for station planning and optimization often lack structured, multi-dimensional methodologies. Consequently, there is a critical need for comprehensive assessment frameworks that can guide the design and operation of RT stations in a way that balances technical, financial, and human factors.

This study proposes an evaluative approach that applies the technique for order of preference by similarity to ideal solution (TOPSIS) that is a multi-criteria decision-making (MCDM) methodology, for assessing the performance of newly developed tram stations in Antalya, Türkiye. The research examines 20 tram stations, utilizing six key evaluation criteria: platform type, maximum daily trips during peak hours, average vehicle speed near the station, service frequency, commuter comfort in terms of food accessibility, and the terrain slope around each station. By including commuter comfort indicators (specifically food accessibility and terrain slope) in the evaluation, this study extends beyond traditional infrastructure assessments. Station surroundings, such as the proximity of food services, are treated as important elements influencing user experience. On the cost side, building efforts such as constructions are considered that reflect construction and maintenance challenges.

The research findings reveal the variations in station efficiency which illustrate how infrastructural design and locational attributes impact functional performance and user satisfaction. For instance, stations with fewer physical barriers and greater food accessibility tend to achieve higher efficiency scores. Therefore, this study contributes to the field of urban transportation planning by offering a balanced and systematic evaluation framework.

A number of studies have looked at factors that influence passenger comfort in urban RT systems. For example, Nordin et al. (2016) investigate noise, vibration, and coach design. They collect input from RT commuters across various rail routes. A methodology for measuring comfort degrees throughout RT rides is presented (Mohammadi et al., 2020), whereas longitudinal acceleration numbers and traveler input are used to estimate traveling comfort in a big metropolitan subway (Ma et al., 2020). Also, a configuration is offered for en route comfort degree based on passenger counts and vehicle position statistics (Roncoli et al., 2023). Several scholars use MCDM approaches to examine the transformation of urban PT systems (Demir, 2024; Kiciński & Solecka, 2018; Li et al., 2019; Görçün, 2021; Zhang et al., 2020). These pieces of art use a variety of factors, including comfort, to assess various settings. Nevertheless, none of these works expressly address comfort at RT stops, especially with regard to nearby services or amenities. Therefore, this study gap in the literature highlights the requirement for more research into the comfort aspects during RT stops.

This study employs the TOPSIS method because the method's ability to handle complex decision-making environments by integrating multiple criteria has made it a popular tool across various areas such as engineering (Celik et al., 2012). The method of TOPSIS was developed as a reliable method within the field of MCDM (Tzeng & Huang, 2011). TOPSIS is based on the notion that the most desired option should be the smallest geometric distance from an ideal solution while remaining the farthest away from a negative-ideal solution. In the context of urban PT systems, TOPSIS has been utilized to evaluate many infrastructural and operational elements (Awasthi et al., 2011; Zhang et al., 2018). Studies apply TOPSIS to select optimal PT routes by considering factors such as travel time, passenger load capacity, operating costs, and environmental impact. Moreover, TOPSIS is a reliable method to address urban mobility challenges by aiding in the selection of optimal locations for transportation infrastructure, through the consideration of different criteria like accessibility, safety, cost, and social equity (de Aquino et al., 2019; Tsao et al., 2025). Recent studies recognize that focusing solely on technical and economic indicators is insufficient for promoting sustainable urban PT. Incorporating variables like food accessibility and physical accessibility (e.g., terrain slope) allows for a more comprehensive understanding of PT performance from a user perspective.

2. Materials and method

The study offers a systematic and holistic approach to assess the performance of RT stations in Antalya, Türkiye. Additionally, the study integrates operational, design, and commuter-centric service dimensions. The analysis uses the TOPSIS method, a widely recognized MCDM technique. The section below elaborates on the steps involved in the TOPSIS methodology, the evaluation criteria employed, and the specific characteristics of the study area.

2.1 TOPSIS methodology

The TOPSIS method is designed to rank alternatives based on their proximity to an ideal solution (Tzeng & Huang, 2011). The key assumption underlying TOPSIS is that the optimal alternative should have the shortest distance to the positive ideal solution and the farthest distance from the negative ideal solution. The method systematically proceeds through six algorithmic steps, each described in detail below:

- Step 1 is to create a decision matrix. The decision matrix is an n x m dimensional matrix produced by the decision maker after identifying the alternatives and assessment criteria. Here, n and m are the numbers of choice options and evaluation measures, respectively.
- Step 2 forms the standard decision matrix which is normalized or regulated. The standard decision matrix is obtained by taking the square root of the sum of squares of the values of each measure in the decision matrix (sum of squares of column values) and dividing the relevant component of the column by this value. If any member of the choice matrix has a value of zero, the corresponding part of the conventional decision matrix has the same value.
- Step 3 is to establish a weighted standard decision matrix. Initially, the weight standards for the assessment criteria are determined. Here, the sum of all weights must be the value of 1. This weighting approach exposes the subjective characteristic of the TOPSIS in decision-making since the weighting process is based on the importance or significance of the criteria. The components of the standard decision matrix are multiplied by their respective weight values to form a matrix called weighted standard decision matrix.
- Step 4 obtains positive ideal and negative ideal or optimum solution values. By means of the weighted standard decision matrix, the sets of positive ideal and negative ideal solutions are obtained for each criterion consistent with the objective of the evaluation criterion of interest. If the evaluation criteria are in terms of benefits, the positive ideal solution is the largest value of the columns of the weighted standard decision matrix, and the negative ideal solution is the smallest value of the columns of the weighted standard decision matrix. If the appraisal criteria are in terms of costs, the positive ideal outcome is the smallest

value of columns of weighted standard decision matrix, and the negative ideal answer is the largest value of columns of standard decision matrix weighted.

- In step 5, the distances to the positive ideal and negative ideal solutions are acquired. The Euclidean methodology is utilized to discover deviations of evaluation criteria for each decision alternative from the positive ideal and negative ideal solution values. Accordingly, distances or distance values are computed for the number of decision options.
- Finally, step 6 calculates the relative closeness coefficients to the optimum or ideal solution. The distances from the positive ideal and the negative ideal answers are accepted to estimate the relative closeness constants of each decision possibility to the ideal result. Relative closeness values are found for each decision option. Further, the share of distance to the negative ideal answer in the entire distance is calculated. Consequently, options of decision are prioritized as close to the value of 1.

2.2 Evaluation criteria

In line with the holistic aim of the study, six evaluation criteria were selected to comprehensively assess RT station performance, which are in the following. Evaluation criterion 1 (EC1) is platform type (PLT), capturing the influence of platform design choices on both construction and long-term maintenance costs. For instance, simple platforms are generally less costly, while elevated or underground structures entail higher financial demands. Secondly, evaluation criterion 2 (EC2) is maximum daily trips at peak hours (MDT), reflecting the level of passenger demand. In this case, higher values are associated with greater station utility and network significance. Thirdly, evaluation criterion 3 (EC3) is average speed of vehicles near the station (ASV), which is an operational indicator reflecting the smoothness of service near each station. For example, higher average speeds suggest efficient operations and minimal congestion, enhancing overall network performance. Then, the fourth evaluation criterion (EC4) is service frequency (SFR), indicating the intervals between successive tram arrivals. Hence, higher frequencies are associated with improved commuter satisfaction and reduced wait times. Moreover, the fifth evaluation criterion (EC5) is commuter comfort for food accessibility (CFA), recognizing the importance of station surroundings. CFA measures the proximity and availability of food options. Therefore, stations with better food access improve commuter comfort and satisfaction. Lastly, evaluation criterion 6 (EC6) is terrain slope around the stations (TSS) because the physical accessibility of a station is influenced by its surrounding terrain. Stations located in areas with steep slopes present challenges for road users with mobility difficulties.

2.3 Study area and data collection

The case study focuses on 20 tram stations located along the recently expanded tram line in Antalya, Türkiye, as of February 2024. The stations include Kadınlar Plajı (D1), Sarısu (D2), Liman (D3), Serbest Bölge (D4), Akdeniz Blv (D5), Konyaaltı (D6), Boğaçay (D7), Gürsu (D8), Altınkum (D9), Konyaaltı Bld (D10), Tıp Merkezi (D11), İl Sağlık Müd. (D12), AVM (D13), Stadyum Piramit (D14), Meltem Defterdarlık (D15), Güllük 100 Yıl (D16), Muratpaşa Cami (D17), Büyükşehir Bld (D18), Yeşilırmak (D19), and Kepez Bld (D20).

Data for each evaluation criterion were collected from available sources provided by the Antalya's available web sources and field observations. Physical site inspections were conducted to assess food accessibility and terrain slope conditions around each station. Moreover, operational data, including MDT, ASV, and SFR, were obtained from the Antalya's available internet sources. Thus, the final decision matrix comprised 20 alternatives which are the stations in this case and six criteria, with standardized and weighted values prepared for TOPSIS analysis created by the decision makers (Table 1). Accordingly, a representative portion of the decision or determination matrix's normalized form and the related main criteria weights obtained are seen in Table 2 and Table 3 respectively. Experts with relevant expertise and knowledge in the related field assign weights to each criterion based on their subjective judgment.

Table 1. A sample of the decision matrix

Station ID	PLT	MDT	ASV	SFR	CFA	TSS
D13	2	4.871	30	8	10	1.5
D14	2	4.988	30	8	1	2.5
D15	6	6.086	30	8	3	1.5
D16	6	6.635	35	12	27	0.5

3. Results and discussion

The application of the TOPSIS method to evaluate the 20 tram stations in Antalya yielded a ranking of their relative efficiency scores (P-scores) in Table 4. The results demonstrate a differentiation among the stations based on the six evaluation criteria showing the holistic approach of this study.

Table 4. Stations ranking

Station ID	P_score	Rank	Station ID	P_score	Rank
D16	0.68595	1	D6	0.41613	11
D9	0.64930	2	D12	0.41367	12
D17	0.63364	3	D7	0.39514	13
D20	0.63176	4	D14	0.39508	14
D13	0.52305	5	D2	0.35505	15
D11	0.51439	6	D5	0.34287	16
D19	0.48818	7	D1	0.33840	17
D10	0.44313	8	D15	0.31862	18
D8	0.43643	9	D4	0.30462	19
D18	0.42053	10	D3	0.30011	20

The top-performing stations are identified as D16 (Güllük 100. Yıl), D9 (Altınkum), D17 (Muratpaşa Cami), D20 (Kepez Bld), and D13 (AVM), with D16 achieving the highest P-score of 0.68595. These stations not only exhibit operational advantages such as high peak-hour trip volumes and favorable service frequencies but also excel in human-centric aspects such as accessibility to food services and convenient terrain conditions. Therefore, higher performance of those stations demonstrates the importance of designing station environments that are both operationally efficient and user-friendly. Furthermore, only four stations (D16, D9, D17, and D20) achieved a P-score between 0.6 and 0.7 indicating a relatively high level of efficiency within the RT network (Fig. 1). In other words, a limited number of stations optimize the balance between structural investments and commuter satisfaction.

On the other hand, the majority of the stations scored between 0.3 and 0.5 showing substantial room for improvement (Fig. 2). For example, the stations like D3 (Liman), D4 (Serbest Bölge) and D15 (Meltem Defterdarlık), which occupy the lower end of the ranking, may suffer from design inefficiencies, insufficient service frequencies, challenging topographical conditions, or limited access to food amenities. Such deficiencies can adversely affect the utility of many stations. Therefore, some interventions are necessary to elevate the performance of low score stations.

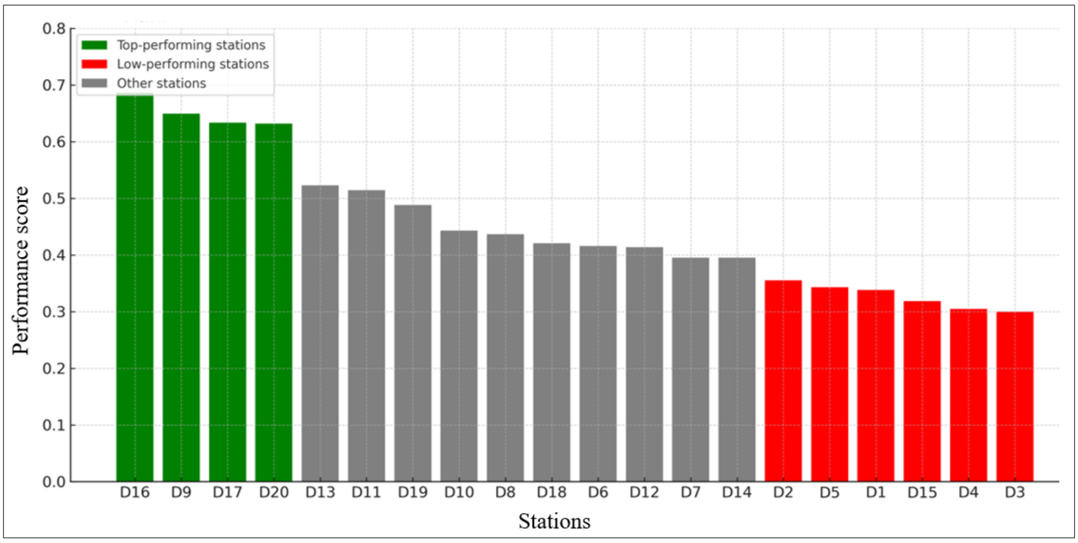

Fig. 1. Performance scores of 20 tram stations assessed, highlighting variations based on operational efficiency and commuter-centric factors

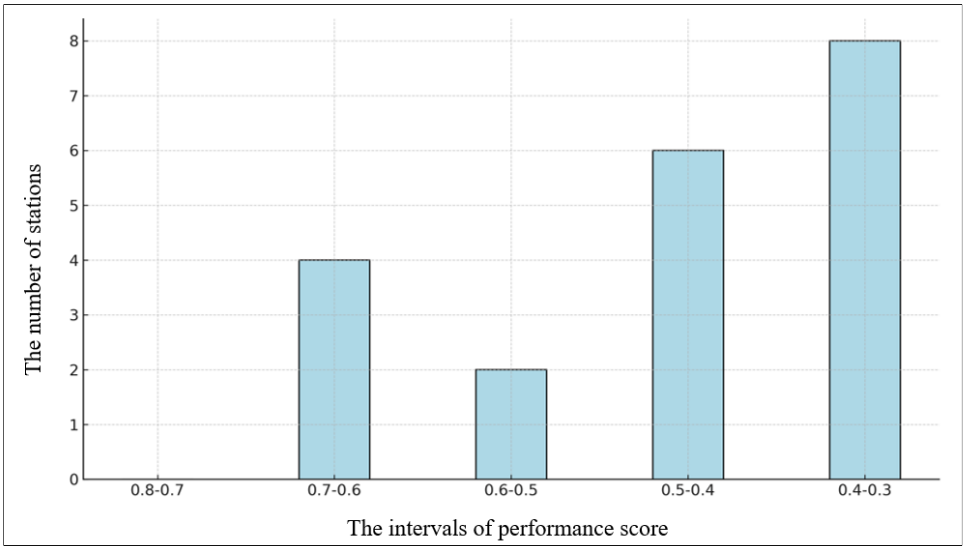

Fig. 2. Distribution of P-score values among the stations

The overall distribution of scores suggests that while a few stations are setting a benchmark for efficiency, there is a general need for network-wide improvements, especially in addressing the human-centric factors that are emphasized in this study. Additionally, the findings in this study validate the significance of integrating both technical and commuter-oriented parameters into RT station performance evaluations. Therefore, the multi-criteria framework provides valuable insights for decision makers aiming to enhance the functionality and attractiveness of urban RT systems, especially in developing cities like Antalya.

4. Conclusions

This study provides actionable insights for optimizing RT systems by aiming to enhance urban livability and promote transportation equity, particularly in developing urban environments. Through the application of the TOPSIS method, a systematic and structured evaluation of 20 tram stations in Antalya, Türkiye, was conducted, offering a replicable framework for improving PT systems in similar contexts.

The analysis reveals that stations D16 and D17 excel due to their high accessibility to food facilities, efficient operations, high service frequencies, and elevated average speeds, although they incur relatively higher platform construction costs. In contrast, RT stations D9, D20, and D13 perform strongly because of their low platform costs, efficient operational metrics, and frequent services. Also, the majority of stations scored between 0.4 and 0.7 which shows a significant room for enhancement across the RT network. Therefore, the results indicate that optimizing station design, improving surrounding amenities, and enhancing service quality may contribute to reliable PT development.

Addressing inefficiencies at underperforming RT stations is essential for improving public satisfaction, operational effectiveness, and the long-term viability of urban PT systems. Importantly, the methodology employed here is highly adaptable and can be applied to other cities globally, offering a structured approach for evaluating and refining urban transportation infrastructure.

By balancing technical performance and human-centric needs, this study supports the broader goal of creating more inclusive, efficient, and commuter-friendly transportation networks worldwide. Thus, the highlights of the research are as follows:

- A holistic TOPSIS-based framework is developed to assess tram station performance in Antalya, Türkiye.
- Both operational efficiency and commuter-centric factors, such as food accessibility and terrain slope, are integrated into the evaluation.
- Stations D16 and D17 excel due to high service frequency, commuter amenities, and operational performance, despite higher platform costs.
- Stations D9, D20, and D13 achieve strong rankings by balancing low construction costs with efficient operations.
- Stations D3, D4 and D15 are identified as the lowest-performing, highlighting the need for targeted improvements in service quality and commuter accessibility.
- The proposed methodology offers a replicable model for improving PT systems in developing cities worldwide.

Samsun E1 bus route analysis: Impacts of urban traffic regulations on public transportation

Dilara D. Erakman*[1], Erhan B. Pancar[1]

[1] *Ondokuz Mayıs University, Department of Civil Engineering, 55100 Samsun, Türkiye*

Abstract. The study focuses on analyzing the impacts of urban traffic regulations on public transportation by examining the E1 bus route in Samsun. The E1 route is a significant public transport corridor connecting the Canik, İlkadım, and Atakum districts and plays a critical role in providing access to Ondokuz Mayıs University Campus. The research addresses the effects of traffic regulations on the efficiency of this route, passenger satisfaction, and overall urban traffic. The study investigates changes in stop usage, travel times, passenger density at stops, and the general performance of the route. Particular attention is given to the impact of tramway extensions and other transportation projects on the E1 line. Data were collected through field studies and numerical analysis methods, and indicators reflecting the current situation were analyzed. Passenger numbers, changes in travel times between stops, and service frequency were thoroughly examined to compare the route's conditions before and after traffic regulations. Additionally, the effects of bus usage on traffic flow in high-demand areas were explored. The primary goal of this research is to develop improvement recommendations aimed at making public transportation systems more attractive by reducing individual car use. It seeks to enhance public transport efficiency, improve user satisfaction, and support environmental sustainability. The findings provide valuable insights for the planning of the Samsun E1 bus route and for implementing urban traffic regulations more effectively. The study aims to contribute significantly to solving urban transportation challenges and improving public transportation systems.

Keywords: Public transport efficiency; Traffic regulations; Traffic impact; Passenger flow; Sustainability

1. Introduction

Transportation refers to various systems and infrastructures that enable the movement of people and goods from one place to another, encompassing different modes such as land, sea, air, and railways. These modes offer various advantages depending on geographical conditions and societal needs, playing a critical role in achieving economic development and social welfare. Efficient and effective transportation systems contribute to the growth of trade volume, a more spatially efficient distribution of the workforce, and the optimization of resource usage. The effective management of transportation systems is a significant tool in reducing urban issues such as traffic congestion, environmental pollution, and energy consumption. Particularly, environmentally friendly and sustainable transportation solutions serve the goals of reducing carbon emissions and increasing energy efficiency. Moreover, the development of transportation infrastructure supports social equity by enhancing the accessibility opportunities of all segments of society within urban areas. Therefore, transportation is considered a multidimensional concept that directly affects not only individuals' daily mobility but also quality of life, economic competitiveness, and sustainable urbanization goals. In this context, public transportation systems play an indispensable role in urban transportation and have become one of the determining factors of quality of life in developed societies. In our country as well, reflecting the social state approach, various improvement efforts have been made in public transportation infrastructures to ensure that citizens can travel safely, quickly, and comfortably. These initiatives, including the expansion of networks of roads, stops, trams, metros, and buses, have aimed to increase the rate of public transportation usage. However, these efforts have been limited in achieving a transformation sufficient to reduce the widespread use of private vehicles. The continued preference for private vehicles can be attributed to several factors, such as the insufficient coverage of public transportation networks across the entire city, the long distances to access stops, low service frequencies, excessive crowding in public transport vehicles, and uncertain waiting times at stops. Additionally, the inability of public transport services to match the comfort level provided by private vehicles constitutes a significant barrier. All these factors make it difficult for individuals to voluntarily prefer public transportation, leading to efficiency losses in urban transportation systems.

In this study, the E1 bus line in Samsun province was examined to analyze the effects of urban traffic regulations on public transportation performance. The Samsun E1 line operates between the districts of Canik, İlkadım, and Atakum, serving as a critical transportation corridor, especially for access to the Ondokuz Mayıs University Campus. The research analyzed indicators such as stop usage, travel times, service frequencies, and passenger densities through field studies and quantitative analyses. Based on the findings, the overall performance of the line was evaluated, and the impacts of current traffic regulations on public transportation efficiency were examined. The main objective of the study is to develop strategies that will reduce the use of private vehicles, increase the attractiveness of public transportation, and contribute to environmental sustainability and energy efficiency goals. Based on the findings, suggestions for more effective planning of the Samsun E1 line are presented, contributing to the adoption of a public transportation-oriented approach in urban mobility. In this regard, the study aims to offer valuable contributions to both the literature and practice concerning the rational management of urban transportation and the improvement of public transportation systems.

1.1. Literature review

Public transportation systems in urban areas have been developed to offer sustainable solutions to challenges such as increasing population density, traffic congestion, and environmental concerns. By providing an alternative to private vehicle use, public transportation contributes to enhancing transportation efficiency, reducing environmental impacts, and supporting social mobility (Kaya, 2024). Comprising various modes such as buses, trams, metros, commuter trains, and ferries, public transportation systems are structured according to the geographical and socio-economic conditions of cities, offering different advantages. Among these, bus systems particularly stand out in many cities due to their flexible route structures and low infrastructure costs. The role of public transportation in reducing environmental impacts, alleviating traffic congestion, and addressing socio-economic inequalities has become even more critical today. Numerous studies have emphasized that public transportation is an effective solution for mitigating negative externalities caused by private vehicles, such as carbon emissions, air pollution, and traffic accidents (Culum, 2013). In this context, it is essential to continually improve public transportation systems in terms of accessibility, punctuality, and comfort. The integration of urban traffic regulations with public transportation systems has emerged as an important research area aimed at enhancing transportation efficiency and reducing congestion in cities. Tona, Maraş, and Demir (2024) analyzed intersection densities along Atatürk Boulevard in the Atakum district of Samsun using Geographic Information Systems (GIS) and found that implementing grade-separated intersections and modern roundabouts, particularly in high-density areas such as the Karayolları Intersection, could significantly improve traffic flow. Their findings highlight the importance of intersection improvements on urban main arteries, especially along routes with intense passenger movements like the E1 bus line (Tona, Maraş, & Demir, 2024). Research focusing on the optimization of bus service schedules in urban areas is also closely linked to traffic management. In a study conducted by Polat, Sağbaş, and Dermenci (2024), the optimization of bus services was achieved through linear goal programming methods, targeting reductions in fuel consumption and carbon emissions. Optimizing service schedules not only increases cost-effectiveness but also makes significant contributions to environmental sustainability (Polat, Sağbaş, & Dermenci, 2024). Applying such optimization models to the Samsun E1 line could present considerable opportunities for enhancing both environmental and operational efficiency.

Studies addressing transportation issues on a national scale in Turkey have shown that increasing numbers of motor vehicles have led to major problems such as traffic congestion, insufficient public transportation, and parking shortages (Bostancı & Tanrıvermiş, 2024). Field studies conducted in Ankara suggest that increasing the availability of bicycle lanes, making public transportation more attractive, and ensuring integration between different transportation modes could offer effective solutions to traffic-related problems. These strategies could likewise be beneficial for medium-sized cities like Samsun. Furthermore, an examination of the historical development of urban transportation planning practices in Turkey reveals that a focus on short-term solutions and the insufficient integration of sustainable transportation policies have limited planning effectiveness (Karataş Çifçi & Düzgün, 2024). Therefore, it is crucial to adopt long-term, integrated, and environmentally friendly transportation policies in the planning of major public transportation routes such as the E1 line. Research on demand forecasting and route planning for public transportation systems emphasizes that monitoring passenger movements through electronic systems and applying dynamic planning based on such data can enhance service quality (Ozan, Ceylan, Haldenbilen, & Yaşar, 2010; Arıç Döner, 2012). Implementing passenger movement-based planning on the Samsun E1 line could enable more efficient use of bus capacity and allow the optimization of service frequencies based on actual demand. Finally, a study by Çalışkan (2020) on the effectiveness of bus-priority lanes revealed that such applications significantly reduce travel times for public transportation and positively influence user preferences. Planning bus-priority lanes along specific corridors of the Samsun E1 line could enhance public transportation efficiency while reducing traffic congestion caused by private vehicles. In light of all these findings, it is possible to improve the usage rates of public transportation and achieve a more organized urban traffic flow in Samsun city center through traffic regulations, intersection improvements, service optimizations, and bus-priority applications implemented along the E1 bus line.

2. Materials and methods

When evaluated specifically within the context of Samsun city, the E1 bus line, which is a key component of the public transportation system, provides a connection between the districts of Canik, İlkadım, and Atakum. Extending along the main arteries surrounding the city center, this line experiences high passenger circulation, particularly during commuting hours, and meets a significant portion of the city's internal transportation demand. The buses operating on the E1 line are equipped with advanced technological systems such as large passenger capacities, electronic ticketing systems (Samkart), GPS-based real-time location tracking, digital information displays, and stop announcement systems. Moreover, the selection of environmentally friendly vehicles aims to minimize emissions, thereby supporting environmental sustainability. The implementation of Intelligent Transportation Systems (ITS) in Samsun has made significant contributions to enhancing the efficiency of traffic management and improving the functionality of public transportation systems. Traffic management systems monitor city traffic flow in real-time and allow for dynamic adjustment of traffic lights based on congestion levels (Samsun Metropolitan Municipality, 2023). Supported by sensors and cameras, these systems continuously measure traffic density and direct drivers to alternative routes by detecting potential bottlenecks early. Additionally, smart bus stops enable passengers to track bus arrival times via digital screens, thus allowing for more efficient use of waiting times. GPS-based bus tracking systems also facilitate real-time monitoring of bus locations along their routes, thereby contributing to more reliable operations. Analyses conducted specifically for the E1 line indicate that its extensive network connects key points in the city, frequent services reduce passenger waiting times, and high-capacity buses ensure efficient transportation. However, it has been identified that during morning and evening peak hours, service comfort levels decrease due to overcrowding, service times become irregular due to dependence on urban traffic, journey times are extended because of the long route, and passenger satisfaction is negatively affected by large distances between some stops. Furthermore, during periods of high urban traffic density, prolonged waiting times at traffic lights hinder the timely operation of the line. Over the years, significant structural changes have been made in the city’s transportation systems. Intersection layouts in Samsun have been extensively revised; additional lanes have been added to certain intersections, turning radii of roundabouts have been expanded, and many intersections have been equipped with intelligent traffic management systems. Electronic control systems (EDS) have been established to enhance road safety, and roadside enforcement infrastructure has been strengthened. Bus stops have been upgraded by adding bus bays or expanding existing ones, thus allowing buses to load and unload passengers without disrupting traffic flow. Additional bays have also been created at intersections to support turning movements.

Meanwhile, various changes have occurred within the fleet of the Samsun E1 bus line. At one point, electric buses were introduced but later withdrawn, and articulated buses were incorporated into the fleet instead. Although most vehicles are now newer models, a limited number of older buses remain in operation. Furthermore, with the extension of the tram line to the Ondokuz Mayıs University campus, the campus shuttle bus service was discontinued, and adjustments were made to the organization of public transportation services. Under the scope of bus route modifications, new stops have been added, and the route of the E1 line has been revised over time. Initially comprising 32 stops, the number has increased to 39 following the adjustments. Moreover, the diversification of bus routes serving the E1 corridor has directly influenced stop-based passenger movement. To enhance service quality, measures such as organizing additional services during peak hours, increasing the number of articulated buses, expanding heavily used stops, implementing bus-priority lanes, and granting priority to buses at traffic lights are proposed. In addition, integrating real-time bus tracking systems with mobile applications, installing digital information displays at stops, and increasing infrastructure improvements to facilitate access for disabled individuals are among the measures expected to boost passenger satisfaction. It is further suggested that Samsun could benefit from best practices exemplified by the Munich public transportation system, including integrated ticketing, real-time information dissemination, public transportation-prioritized policies, and environmentally friendly transport infrastructure. The Munich model, with its emphasis on sustainability, integration, and user-oriented transportation principles, serves as a significant example for developing cities like Samsun (Arslan, 2010). In conclusion, enhancing the effectiveness of public transportation in Samsun requires both the optimization of existing routes and the broader integration of intelligent transportation systems. Regular monitoring of heavily used bus lines such as the E1 through systematic data analysis, implementing flexible planning based on emerging needs, and carrying out passenger-oriented improvement initiatives will make substantial contributions to achieving a more sustainable and efficient urban transportation system.

2.1. Characteristics of the E1 (express) bus line

The E1 (Express 1) bus line, operating in Samsun, is an important component of the city's urban public transportation system. Managed by SAMULAŞ Inc., a subsidiary of the Samsun Metropolitan Municipality, the line connects the districts of Canik, İlkadım, and Atakum, operating between Belediye Evleri (Canik) and Ondokuz Mayıs University Faculty of Education (Atakum). The majority of the route runs along Atatürk Boulevard, passing through central locations such as Cumhuriyet Square, Samsun Bus Terminal, and the Atakum coastal area, thus meeting various transportation needs related to work, education, and social activities. The line comprises a total of

44 stops, and a single trip takes approximately 54 minutes. Weekday services operate between 06:15 and 23:00 at intervals of 15–20 minutes, while weekend services operate between 06:35 and 23:00 at intervals of 20–25 minutes; in addition, regular services are also provided during night hours. The vehicles operating on the E1 line are predominantly BMC Procity brand buses, equipped with Euro 6 standard engines, featuring a 6.7-liter engine capacity and 209 kW (284 PS) of power. These buses are fitted with automatic transmissions and have a total passenger capacity of 163, including 39 seated and 124 standing passengers. Currently, a total of eight vehicles are allocated to the E1 (Express 1) line. Seven of these vehicles are newly designed, articulated buses with a length of 18 meters. The other vehicle is an older model 12-meter-long bus, which has a lower passenger capacity compared to the new-generation articulated buses. As part of the service scheduling plan, each bus completes six or seven trips per day on a rotational basis. The E1 line utilizes modern payment systems, including Samkart and mobile payment options, and by offering 24-hour uninterrupted service, it significantly enhances accessibility and safety in urban transportation, thereby playing a critical role in strengthening the effectiveness of public transportation in Samsun.

2.2. E1 (eXPRESS 1) route and service frequency

The E1 (Express 1) bus line operates along a route that begins at the Soğuksu stop in the Canik district of Samsun and extends to the Karadeniz Male Student Dormitory stop in the Atakum district (Fig. 1). This route structure connects the three major central districts of the city: Canik, İlkadım, and Atakum. Starting from Belediye Evleri and continuing along Atatürk Boulevard to the University Junction, the route passes through key business, educational, and social hubs of the city, effectively meeting daily transportation demands. This strategic route selection is one of the key factors supporting the high usage of the line. The service times and frequencies of the E1 bus line are presented in Table 1.

Table 1. Service Times and Frequencies (SAMULAŞ, 2025)

Time Interval	Average Service Interval on Weekdays (minutes)	Average Service Interval on Weekends (minutes)
00:00 - 00:59	60 minutes	60 minutes
01:00 - 01:59	60 minutes	60 minutes
02:00 - 02:59	-	-
03:00 - 03:59	60 minutes	60 minutes
04:00 - 04:59	-	-
05:00 - 05:59	60 minutes	60 minutes
06:00 - 06:59	13 minutes	20 minutes
07:00 - 07:59	10 minutes	20 minutes
08:00 - 08:59	10 minutes	20 minutes
09:00 - 09:59	13 minutes	20 minutes
10:00 - 10:59	13 minutes	22.5 minutes
11:00 - 11:59	15 minutes	20 minutes
12:00 - 12:59	20 minutes	25 minutes
13:00 - 13:59	20 minutes	22.5 minutes
14:00 - 14:59	20 minutes	20 minutes
15:00 - 15:59	20 minutes	25 minutes

22:00 - 22:59	20 minutes	30 minutes
23:00 - 23:59	-	-

Fig. 1. E1 (Express 1) line route (SAMULAŞ, 2025)

The E1 (Express 1) line schedules frequent services on selected corridors to minimize travel time losses and deliver faster service to passengers. Its operational efficiency is enhanced by carefully optimizing the distances between stops. Moreover, the specific stop names and their inter-stop distances play a crucial role in streamlining the line's overall performance. Detailed information on the stop names and distances for the E1 (Express 1) line is provided in Table 2 below.

Table 2. E1 (Express 1) Stop Names and Inter-stop Distances

Stops	Distance Between Stops (m)	Stops	Distance Between Stops (m)

3. Findings and discussion

In this study, data from three different years has been evaluated between the dates of March 9, 2019 - March 20, 2019, March 21, 2022 - April 2, 2022, and March 12, 2025 - March 24, 2025. To capture different segments of the week, measurements were conducted on Monday (start of the week), Wednesday (midweek), and Saturday (weekend), each day at 09:00, 12:00, and 17:00. The route segment between Belediye Evleri and the Faculty of Education was selected as the study area, and passenger boarding and alighting counts, waiting times at stops, and delays at traffic signals were recorded; the average vehicle speeds were also calculated. For the 2025 measurements, boarding and alighting durations were determined in detail. In addition to these quantitative data, field observations were used to identify problematic stops, passenger difficulties, and traffic flow issues at intersections. Thus, the aim was to perform a comprehensive analysis of operational disruptions, passenger service quality, and traffic regulation along the corridor. The collected data including trip-related metrics such as stop and signal waiting times, total trip duration, average speed, and overall time losses were analyzed to assess changes in service performance over the years. Measurements were taken in 2019, 2022, and 2025 on Monday, Wednesday, and Saturday at 09:00, 12:00, and 17:00. Based on these findings, Table 3 was constructed to illustrate the temporal evolution of service performance indicators.

Table 3. Service Performance Indicators and Time Management Data

Service Performance Indicators and Time Management Data	2019	2022	2025
Number of Passengers Using Samkart per Trip	1085	1059	1682
Total Waiting Time at Stops (min)	218.36	8078	12068
Total Waiting Time at Traffic Signals (min)	49.08	2490	5638
Trip Duration (min)	899	861	995
Average Speed (km/h)	37.61	35.24	32.24
Total Time Loss (min)	267.45	176.13	295.1

In 2019, an average of 1,085 passengers were transported per trip, which slightly decreased to 1,059 in 2022. However, by 2025, the number increased significantly to 1,682. During the same period, there were notable increases in the total waiting times at stops and at traffic lights. The total waiting time at stops was 218.36 minutes in 2019, which increased to 8,078 minutes in 2022 and reached 12,068 minutes in 2025. Waiting times at traffic lights followed a similar trend. Examining average speed data, it was found that the speed, which was 37.61 km/h in 2019, decreased to 35.24 km/h in 2022 and further dropped to 32.24 km/h in 2025. Although trip durations decreased slightly in 2022 compared to 2019, they rose again in 2025, reaching 995 minutes. Total time loss was at its lowest level in 2022 but increased significantly in 2025 to 295.10 minutes. These findings indicate that the increase in passenger numbers has negatively impacted trip performance by extending waiting times at stops and traffic lights. The boarding and alighting times, as well as the waiting times at stops, for the E1 bus line stops in Samsun were compared for the years 2019, 2022, and 2025 (Table 4).

The findings indicate that significant changes in stop-based travel behavior occurred over the years. Notably, the Belediye Evleri stop, which recorded zero boardings in 2019, experienced a remarkable increase to 185 boardings by 2025. This growth may be related to route adjustments or changes in local population density. Conversely, the Stad Kavşağı stop saw an 80% decrease in boardings accompanied by a dramatic reduction in waiting times, possibly due to a loss of function at that stop or the emergence of alternative transport options. At the Samsunspor stop, boardings more than doubled, and waiting times increased substantially, suggesting that new developments in the area or shifts in public transport preferences have driven this trend. In the centrally located Cumhuriyet Meydanı stop, boardings decreased while alightings increased, indicating its growing role as a transfer point or final destination. Both the Güzel Sanatlar and Eczaneler stops recorded significant increases in boardings and alightings, along with marked rises in waiting times, implying the emergence of new attraction points around these stops. At some stops, alightings increased even as boardings declined (e.g., Poliklinikler and Tıp Fakültesi), while other stops (e.g., Fen-Edebiyat Fakültesi) experienced decreases in both directions. The most pronounced variations in passenger movements between 2019 and 2025 at each stop are summarized in Table 5.

These findings may indicate changes in the user profile around the stops or shifts in service delivery in the region. Based on the data obtained, it can be concluded that significant spatial and temporal changes have occurred on the Samsun E1 bus line over the years. The sudden increase in boardings at certain stops, such as Belediye Evleri, can be explained by the introduction of new residential areas, route changes, or an increase in the attractiveness of public transportation. In particular, the increase in waiting times should be considered a result of the higher passenger volume at these stops. On the other hand, the dramatic decrease in boardings at stops like Stad Kavşağı suggests a reduction in the need for public transportation in that area, or that passengers have shifted to alternative transportation modes. The decrease in boardings but increase in alightings at Cumhuriyet Meydanı indicates that the stop is being used more as a point of alighting towards the city center. This situation reveals a shift in demand towards central areas in Samsun's transportation network. The increases observed at stops such as Güzel Sanatlar and Eczaneler can be associated with the emergence of new services, educational, or healthcare facilities on a micro scale. Particularly high alightings and low boardings around university campuses (such as the Faculty of Medicine, Dentistry, etc.) suggest that these areas are primary destinations during the day, but the return trips occur on different lines. These data provide valuable information that can be used in decision-making processes such as route optimization, stop-based improvements, and resource allocation based on passenger density in urban transportation planning. Additionally, it has been highlighted that user trends can change over time, indicating the importance of developing data-driven dynamic transportation management policies.

Table 4. Samsun E1 Bus Line Stop-Based Passenger Movements and Waiting Times (2019-2025)

Stop Name	2019 Input	2022 Input	2025 Input	2019 Output	2022 Output	2025 Output	2019 Waiting Time (sec)	2022 Waiting Time (sec)	2025 Waiting Time (sec)

Table 5. Summary of the Most Significant Changes (2019–2025)

Stop Name	Summary of Changes
Belediye Evleri	Boardings rose from zero in 2019 to 185 in 2025. Waiting time increased by 17%.
Stad Kavşağı	The number of boardings decreased from 186 to 38 (an 80% decrease). Waiting time significantly decreased.
Samsunspor	Boardings increased from 53 to 109 (a 105% increase). Waiting time quadrupled.
Cumhuriyet Meydanı	Boardings decreased (171 → 106), while alightings increased (21 → 136). Waiting time increased by 37%.
Büyük Cami	Both boardings and alightings increased. Waiting time nearly doubled.
Güzel Sanatlar	Boardings increased from 27 to 54, and alightings rose from 15 to 39. Waiting time increased by 150%.
İlkadım Öğrenci Yurdu	Boardings decreased dramatically (46 → 2). Waiting time fluctuated irregularly.
Türk-İş	Boardings remained stable, while alightings doubled.
Atakent	Boardings decreased by 35%, while alightings slightly increased. Waiting time decreased.
Eczaneler	Boardings increased from 1 to 22, and alightings rose from 36 to 63.
Poliklinikler	Boardings were low, while alightings nearly doubled.
Tıp Fakültesi	Boardings remained very low, while alightings stabilized. Waiting time decreased.
Fen-Edebiyat Fakültesi	There were no boardings, and alightings significantly decreased (57 → 8). Waiting time decreased by 77%.

4. Conclusion

This study was conducted to evaluate the performance of the E1 (Express 1) bus line in Samsun, analyze the effects of urban traffic regulations on public transportation, and reveal the temporal and spatial changes in passenger mobility. Measurements and field observations were made using data from three different years (2019, 2022, and 2025), and it was determined that significant dynamic changes had occurred in the line's operation. Notably, a distinct increase in passenger density was observed, with the number of passengers per trip rising from 1,085 in 2019 to 1,682 in 2025. Additionally, it was found that the waiting times at stops and at traffic lights had significantly increased, average speed had decreased, and total time loss had risen. This situation indicates that the increasing passenger demand and traffic congestion have negatively impacted trip performance. In stop-based analyses, significant increases in passenger boardings and alightings were recorded at stops such as Belediye Evleri, Samsunspor, and Güzel Sanatlar, while severe passenger losses occurred at stops like Stad Kavşağı. These results show that changes in urban dynamics and route adjustments directly reflect on public transportation usage habits. Furthermore, despite technical and operational improvements made on the E1 line, excessive congestion during peak hours and irregularities in trip durations have prevented service quality from reaching the desired level. It is understood that additional structural and managerial adjustments are needed for public transportation to become a strong alternative to individual vehicle use across the city.

Based on the findings, the following recommendations can be made to increase the efficiency of the Samsun E1 bus line and to make public transportation a more effective alternative for urban mobility. To improve the effectiveness of urban transportation and enhance the attractiveness of public transport, various structural and managerial improvements need to be implemented for the Samsun E1 line. Firstly, the establishment of bus-priority lanes in areas with high traffic congestion along the route and the prioritization of public transport vehicles at intersections will help reduce irregularities in trip durations. Additionally, increasing the frequency of trips during periods of high passenger movement and strengthening the existing fleet with high-capacity, new-generation buses will help improve service quality sustainably. Physical expansion efforts should be made at bus stops to reduce waiting times, and infrastructure adjustments for disabled individuals should be implemented considering accessibility criteria. Furthermore, to enable public transport users to obtain real-time information about bus schedules and locations, digital information screens should be placed at stops, and this information should be synchronized with mobile applications to enhance the passenger experience. Regular analysis of passenger mobility data and dynamic route and schedule planning based on these data will also increase operational efficiency. In line with environmental sustainability goals, the inclusion of electric or low-emission vehicles in the fleet should be encouraged, and strategies such as campaigns to promote public transportation usage and integrated ticketing systems should be implemented. Finally, by examining the best practices of integrated transportation policies in Munich's public transport system and adapting them to Samsun, a holistic and user-oriented model for urban transportation can be developed.

Estimation of air pollution indices from road transport in Turkey for 2024 based on fuel types using the IPCC Tier 2 Method

Muhammed Enes Çelebi*[1], Emre Kuşkapan[1]

[1] *Erzurum Technical University, Engineering and Architecture Faculty, Erzurum, Turkey*

Abstract. Road transport is one of the largest sources of greenhouse gas emissions and air pollution on a global scale. Vehicles relying on fossil fuels, in particular, stand out as the primary sources of environmentally harmful pollutants such as CO_2, CO, NO_x, and PM. The amount of emissions varies significantly depending on the fuel type and engine technology. This variation necessitates the detailed and accurate calculation of emissions in efforts to mitigate air pollution. The IPCC Tier 2 methodology is one of the most advanced methods used in this field, enabling more precise evaluations of emissions by taking detailed parameters such as vehicle types, fuel consumption, and engine efficiency into account. In this study, the registered motor vehicle inventory in Turkey for 2024 is analyzed based on fuel types, and air pollution indices caused by road transport are calculated using the IPCC Tier 2 methodology. In line with data from Turkish Statistical Institute, detailed analyses are conducted on fuel consumption, engine technologies, and annual mileage performance of vehicles. Key emission types, including CO_2, CH_4, N_2O, CO, and PM, are calculated, revealing the environmental impacts of Turkey's vehicle fleet. The results highlight the significant share of diesel and gasoline vehicles in greenhouse gas emissions and air pollution in Turkey. Conversely, it is shown that widespread adoption of electric vehicles could substantially reduce emissions from road transport. This study provides actionable insights and solutions for developing sustainable transportation policies and improving air quality, serving as a guide for Turkey to achieve its environmental goals.

Keywords: Air pollution; Road transport; IPCC Tier 2 Method; Emission factors; Fuel types; Sustainable transportation

1. Introduction

Road transport, especially passenger car usage, is considered one of the most significant sources of air pollution worldwide. According to the World Health Organization (WHO) and the European Environment Agency (EEA), a substantial portion of measured urban pollutants such as particulate matter ($PM_{2.5}$), nitrogen dioxide (NO_2), and ozone (O_3) originates from motor vehicles (WHO, 2021; EEA, 2022). Automobiles, particularly those powered by fossil fuel-based internal combustion engines, release considerable amounts of pollutants through exhaust emissions, negatively impacting both environmental quality and human health.

Advanced calculation methods such as the IPCC Tier 2 methodology allow for a more accurate estimation of automobile emissions by differentiating according to fuel types. These methods provide detailed calculations for major pollutants such as carbon dioxide (CO_2), methane (CH_4), nitrogen oxides (NO_x), and particulate matter, considering the different emission profiles of gasoline, diesel, and alternative-fuel vehicles (IPCC, 2006). Such comprehensive approaches play a critical role in the development of air pollution mitigation strategies for countries and cities.

Pollutants such as nitrogen dioxide (NO_2) and particulate matter ($PM_{2.5}$) emitted from automobiles directly contribute to increased rates of respiratory diseases, cardiovascular disorders, and premature deaths. Especially diesel-powered vehicles have significantly higher emission factors for NO_x and PM compared to gasoline-powered vehicles (Kuşkapan, 2024). Studies conducted in Turkey also reveal that a significant portion of measured NO_2 concentrations in major cities can be attributed to automobile emissions and show a strong correlation with traffic density (Coşkun & Oktay, 2020)

Although the use of electric and hybrid vehicles has been increasing in recent years, the share of fossil-fueled automobiles in Turkey's road transport remains quite high as of 2024. This situation leads to the continued contribution of the transport sector to both greenhouse gas emissions and local air pollutants. Particularly during

*Corresponding author, E-mail: muhammed.celebi52@erzurum.edu.tr

https://doi.org/10.31462/icearc2025_ce_tra_704

peak traffic hours, emissions from motor vehicles can seriously impact human health, even with short-term exposure (Anenberg et al., 2019).

In this context, in developing countries like Turkey, monitoring, modeling, and reducing emissions from automobiles are of great importance. Emission estimates conducted using the IPCC Tier 2 methodology provide detailed data categorized by fuel type, forming the scientific basis for strategies such as establishing low-emission zones, promoting public transport, and increasing the use of alternative-fuel vehicles. Thus, it would be possible to improve local air quality while contributing to the fight against climate change.

Vehicle type plays a critical role in determining the amount and type of pollutants emitted. Heavy-duty vehicles, such as trucks and buses, despite being fewer in number compared to passenger cars, contribute disproportionately to air pollution due to their larger engines and higher fuel consumption rates. Moreover, diesel-fueled heavy vehicles are major sources of NO_x and PM emissions, which persist longer in the atmosphere and cause cumulative air quality degradation. Therefore, policies aimed at reducing emissions must consider vehicle type-specific strategies to be effective (Nelson et al., 2008).

Similarly, the type of fuel used in vehicles significantly influences emission profiles. While gasoline engines primarily emit carbon monoxide (CO) and hydrocarbons (HCs), diesel engines are associated with higher NO_x and particulate matter emissions. The adoption of alternative fuels such as compressed natural gas (CNG), liquefied petroleum gas (LPG), and biofuels can lead to a measurable reduction in certain pollutant emissions. However, the overall environmental benefit depends on the life-cycle emissions, including production and distribution stages of these fuels (Yakın and Behçet, 2021).

2. Material and methods

This section details the methodology, data sources and calculation process used to calculate GHG emissions from road transportation in Turkey for 2023. The calculations are based on the most recent methodology developed by the Intergovernmental Panel on Climate Change (IPCC). The main objective of the study is to determine the main GHG emissions from motor vehicles in Turkey. For this purpose, the IPCC Tier 2 approach was preferred, which provides more accurate results due to the availability of country-specific activity data. The methodological framework is based on the "2019 Refinement to the 2006 IPCC Guidelines for National Greenhouse Gas Inventories" (IPCC, 2019). Emission values were calculated according to the Tier 1 and Tier 2 approaches provided by IPCC. While the Tier 1 method requires more superficial data, the Tier 2 method requires more detailed data. Due to the fact that some data for the Tier 2 method are not province-based, calculations were carried out by preferring general data on a country basis.

The activity data forming the basis of emission calculations were obtained from official statistics published by the Turkish Statistical Institute (TÜİK). The main datasets used are; the Energy Market Regulatory Authority Annual Sector Reports (EPDK, 2024) for the Tier 1 method, and the "Vehicle-kilometer Statistics, 2023" (TÜİK, 2023) for the Tier 2 method. The latter includes the numerical distribution of distances traveled by cars registered in Turkey, categorized by fuel type (gasoline, diesel, LPG, hybrid, electric).

The emission factors (CO2, CH4, and N2O) used in the calculations were taken from the 2006 IPCC Guidelines (IPCC, 2006). The selected emission factors are compliant with the Tier 1 and Tier 2 approaches, Turkey's specific conditions, and the vehicle/fuel type breakdowns in the activity data obtained from TÜİK.

According to the IPCC Tier 1 methodology, emissions are calculated by multiplying the amount of fuel sold by a default emission factor.

Tier 1 emmissions of CO2, CH4 and N2O:

$$Emission = \sum_a [Fuel_a \bullet EF_a] \quad (1)$$

Emissions = emission in kg

EF_a = emission factor (kg/TJ)

$Fuel_a$ = fuel consumed, (TJ) (as represented by fuel sold)

a = fuel type a (e.g., diesel, gasoline, natural gas, LPG)

In the Tier 2 methodology, vehicle type and emission control technology are also taken into account.

Tier 2 emmissions of CO_2, CH_4 and N_2O:

$$Emission = \sum_{a,b,c} [Fuel_{a,b,c} \bullet EF_{a,b,c}] \quad (2)$$

Emission = emission in kg.

$EF_{a,b,c}$ = emission factor (kg/TJ)

$Fuel_{a,b,c}$ = fuel consumed (TJ) (as represented by fuel sold) for a given mobile source activity

a = fuel type (e.g., diesel, gasoline, natural gas, LPG)

b = vehicle type

c = emission control technology (such as uncontrolled, catalytic converter, etc)

Calculations were performed separately for all provinces and fuel types, and subsequently, province-based total CO2e emission values were obtained.

Microsoft Excel software was used for data processing, analysis, and calculation processes. It was assumed that all vehicles were actively in traffic throughout the year.

2.1. Scope and limitations

This study covers the CO_2, CH_4, and N_2O emissions originating from gasoline, diesel, and LPG-fueled cars registered in Turkey for the year 2023.

The study has some limitations. Among these are; the average annual distance traveled by cars was not considered separately for each province; instead, the Turkish average was applied to all provinces. When calculating the distribution of registered cars by fuel type, the national percentage distribution for Turkey was assumed to be the same for every province. When calculating CH_4 and N_2O emissions from cars, the vehicle combustion technology was assumed to be Euro 4 and later, taking into account the average age of registered cars (TÜİK, 2024).

3. Results and discussion

According to the Tier 1 and Tier 2 methods in the IPCC standards, the emission values obtained for each province are first proportioned to the surface area of the provinces and then to the population of the provinces. The aim here is to reveal the emission values of the provinces per square meter and per capita. Fig. 1 shows the emission/surface area according to Tier 1 method and Fig. 2 shows the emission/population density maps.

Fig. 1. Emission/surface area density map according to Tier 1 method

Fig. 2. Emission/population density map according to Tier 1 method

Fig. 1 shows that the amount of emissions per surface area in Istanbul is significantly high. After Istanbul, Kocaeli has the highest amount of emissions per surface area. However, the amount of emissions per surface area of this city is about one-third of that of Istanbul. Among the other provinces, Edirne, Bursa, Sakarya, Yalova and Tekirdağ, which are close to Istanbul, have higher emissions per surface area than many other cities. Apart from these, cities such as Gaziantep, Hatay and Ankara have higher values than other cities. Hakkari and Tunceli have the lowest emissions per surface area.

When the emission values of the provinces in Fig. 2 are analyzed according to population, it is seen that the highest value is in Edirne, followed by Bolu, Kırıkkale and Çankırı. Hakkari, Iğdır and Van have the lowest emission values according to population.

Similarly, the analysis was repeated using the Tier 2 methodology, which incorporates more country-specific data such as local fleet characteristics, vehicle kilometers traveled (VKT), and more detailed emission factors reflecting local driving conditions. The resulting maps for Tier 2 emission/surface area and emission/population are presented in Fig. 3 and Fig. 4, respectively.

Fig. 3. Emission/surface area density map according to Tier 2 method

Fig. 4. Emission/population density map according to Tier 2 method

Fig. 3, illustrating Tier 2 emissions per surface area, shows a pattern largely similar to Tier 1, with İstanbul, Kocaeli, İzmir, Ankara and Bursa exhibiting the highest emission densities. These regions are among the most urbanized and industrialized in the country, contributing to concentrated emissions. On the other hand, provinces such as Hakkari, Tunceli, Ağrı, Ardahan, and Şırnak show the lowest emissions per surface area, reflecting lower population and vehicle densities.

When examining emissions per capita (Fig. 4), according to Tier 2 Ankara, Antalya, Muğla, İstanbul and Burdur as having the highest values. These provinces likely have higher vehicle ownership relative to population or frequent intercity transport. Conversely, the lowest per capita emissions in both tiers are consistently observed in Hakkari, Şırnak, Ağrı, Siirt and Bitlis, indicating relatively low motorization rates.

Comparison Between Tier 1 and Tier 2

In addition to spatial patterns, total emissions were also analyzed:

- Tier 1 Total Emissions: 67,063.89 Gg CO_2e
- Tier 2 Total Emissions: 33,581.19 Gg CO_2e
- Overall Reduction: –49.93%
- When the percentage changes on a provincial basis are averaged, the decrease in the Tier 2 method is -61.97%

This substantial reduction highlights the importance of localized data in greenhouse gas inventories. Tier 1's reliance on default emission factors may lead to overestimations, especially in regions with low vehicle ownership or unique driving patterns. In contrast, Tier 2's use of local data yields more accurate and policy-relevant results.

4. Conclusions

This study highlights the critical importance of methodological precision when estimating emissions from road transport, particularly in the context of a country with diverse vehicle usage patterns like Turkey. The comparative application of IPCC Tier 1 and Tier 2 methodologies revealed substantial differences in emission estimates, both in total values and regional distribution. Tier 1, relying on generalized default factors, consistently produced higher emission figures, while Tier 2, grounded in country-specific parameters such as vehicle type, annual mileage, and fuel consumption characteristics, provided more nuanced and locally relevant results.

The findings confirm that emissions are disproportionately concentrated in major metropolitan areas such as İstanbul, Ankara, and İzmir, reflecting dense populations, industrial activities, and high vehicle volumes. In contrast, provinces in Eastern Anatolia, including Hakkari, Şırnak, and Ardahan, demonstrated the lowest emission intensities, underscoring regional disparities in motorization and transport-related environmental impacts.

Importantly, the Tier 2 method yielded a national emission total nearly 50% lower than Tier 1, emphasizing the risk of overestimation when relying solely on generic coefficients. This discrepancy reinforces the necessity for policymakers to prioritize refined calculation methods in national inventories to inform sustainable transport strategies effectively. Furthermore, emission intensity per capita and per surface area varied significantly across provinces, illustrating the multifactorial nature of transport emissions and the need for tailored mitigation measures.

Future research should expand the scope beyond passenger cars to include freight transport and public transit systems, integrating life-cycle assessments where possible. Enhancing the availability and granularity of regional transport data will also be essential to develop more precise and equitable emission reduction strategies. As Turkey advances toward its climate goals, adopting higher-tier IPCC methodologies and aligning transport policies with region-specific realities will be crucial steps in reducing environmental burdens from the road transport sector.

Abstract. Interlocking concrete paving coating (Pavements), which can be produced locally in developing countries and offer ease of construction, is frequently used on urban low-traffic roads. In the study, driving at urban speeds (10, 20, 30, 40, and 50 km/h) on a newly completed interlocking concrete paving road network was performed and the vibrations affecting the vehicle interior and the driver from the road surface were measured. The service level of the pavement was determined simultaneously. The measured vibrations were evaluated by the ISO 2631 standard. In addition, a pavement condition index (PCI) study was conducted using the ASTM E2840 standard, which allows evaluation in the range of 0-100. It was determined that there was a close relationship between the PCI values of the superstructure obtained from the irregularities on the interlocking concrete paving surface and the vertical vibrations coming to the vehicle and the driver during the drives at the determined speeds.

Keywords: Interlocking concrete pavement; Urban road; Whole-body vibration; PCI; Comfort

1. Introduction

The first examples of interlocking concrete paving superstructures are found in the Roman Empire. In addition to traditional asphalt and concrete paved roads, the use of interlocking concrete paving pavements is constantly increasing today (Gogoi, 2019).

The use of interlocking paving stones became widespread in the United States from the early 1970s onwards. At that time, the use of interlocking concrete paving stones was relatively slower to enter the market in Africa, Australia and Japan (Shackel, 1979). Interlocking concrete pavement production in North America has doubled every five years since 1980. In 1989, the Interlocking Concrete Pavement Institute (ICPI) was established in the USA (Smith, 1992).

Organizations such as the American Concrete Institute (ACI), the National Concrete Pavement Association (NCPA), the National Ready Mixed Concrete Association (NRMCA), the Asphalt Institute, and the National Asphalt Pavement Association (NAPA) have acted as the voice of their industries. Universities, the Federal Highway Administration (FHWA), the Federal Aviation Administration (FAA), the Transportation Association of Canada (TAC), the American Association of State Highway and Transportation Officials (AASHTO), the American Society for Testing and Materials (ASTM), and the Transportation Research Board (TRB) have helped to sustain the use of asphalt and concrete pavements (Smith, 1992). Between 1998 and 2005, the use of concrete paving stones in the United States increased by an average of 6 million m^2 per year (Hein & Burak, 2007).

Concrete paving has mostly entered the market for aesthetic purposes. However, since aesthetics were not enough for US and Canadian highway engineers, performance data on municipal and industrial projects were needed. In 1990, a list of ideas was published by obtaining the opinions of 22 senior pavement experts to improve existing product features, improve structural design methods, develop maintenance and life cycle information, and create promotional projects. In 1992, 15-16 million m^2 of concrete paving was produced in the USA (Smith, 1992).

Interlocking concrete paving resilient pavers have high resistance to freeze-thaw and de-icing salts, high abrasion and shear resistance, high resistance to temperature-induced deformation, and high resistance to damage from fuel spills and other petroleum products. They can also be designed with excellent drainage properties and are often used to help reduce stormwater runoff. In a typical municipal application, joint sand between individual concrete pavers facilitates the transfer of vehicle wheel loads through shear transfer, and the joints also facilitate controlled crack locations to minimize stress cracking and surface distress. Concrete paving pavers are typically placed on coarse bed sand placed over an untreated aggregate base. They can also be placed over bituminous or

https://doi.org/10.31462/icearc2025_ce_tra_754

cement-treated (stabilized) base, asphalt concrete, or Portland cement concrete. The voids between individual paving units are filled with clean, durable, high-quality joint sand (Hein et al., 2007; 2009).

The unevenness of the surface of the pavement layer on the new highways that have been completed or on the highways that have been built before and which are currently in service can affect the driving comfort, safety, fuel economy of the vehicles, etc. affects many factors. The characteristics of the material used (binder type, quality, aggregate type) and external conditions (traffic load, climate, application of materials, etc.) play an important role in the service life of the coating (Kırbaş, 2013).

Since the 1950s, researchers have applied the panel evaluation technique, which requires the evaluation of at least three evaluation experts, to determine the current service level of the superstructures. Although the evaluators are experts in their fields, since objective results cannot always be obtained during human evaluation, mechanical measurement and evaluation techniques were developed in the following process (Hass et al., 1994).

The AASHTO road test (1950-1960) shows that there is a very high correlation between ride comfort and the level of service of the superstructure. It states that vertical vibrations are the most effective factor in determining driver comfort and that the main causes of vertical vibrations are road surface distresss and vehicle origin. The most important element of superstructure performance and therefore ride comfort is the distresss and deformations in the interlocking concrete pavement. Ride comfort is explained by whole body vibration assessment methods in ISO 2631-1 and BS 6841 international standards (Kırbaş, 2021).

2. Materials and methods

2.1. PCI for interlocking concrete paving roads

Interlocking concrete pavement superstructures can be kept in a 25-50 year monitoring program if the relevant procedures are followed and timely maintenance, repair and rehabilitation processes are implemented (Hein & Smith, 2009).

In order to objectively evaluate the service level of the pavements, performance indices such as pavement condition index (PCI), pavement serviceability (PSI), number of rides (RN), ride comfort index (RCI), international roughness index (IRI) that can express the current status with a numerical value have been developed in relation to the surface condition of the pavement. Today, the pavement condition index (PCI), which uses surface distress type inputs, is frequently preferred by authorities, especially in the evaluation of urban pavements. The current condition of the pavement and the vertical vibrations coming to the driver and passengers due to distresss on the pavement surface have a very high correlation (Hein et al., 2009).

Although the types of distress and cut-off values presented in the standard E2840-11 published by ASTM and based on the guide published by ICPI are specific to interlocking concrete pavements, it is based on the same principles as the MicroPAVER/ASTM procedure in terms of selecting sample units, conducting the survey, and using the corrected cut-off value for multiple types of distress (Hein et al., 2009).

Table 1. Types of distress of interlocking concrete pavements (ASTM, 2011)

Distress Number	Description
101	Damaged Pavers
102	Depressions
103	Edge Restraint Damage
104	Excessive Joint Width
105	Faulting
106	Heave
107	Horizontal Creep
108	Joint Sand Loss/Pumping
109	Missing Pavers
110	Patching
111	Rutting

Table 1 includes the distress types and their numbers to be taken into account in the PCI assessment of interlocking concrete paving roads according to the ASTM E2840-11 standard.

The initial design of the pavement is a critical factor in pavement performance and life cycle cost assessment. The service life of a pavement is usually determined during the initial design. The service life takes into account the subgrade, pavement layer materials, thicknesses and expected traffic on the roadway. This service life depends on the environmental and loading conditions of the pavement. By monitoring and rating pavement performance using standard pavement management tools such as the Pavement Condition Index (PCI), it is possible to establish typical pavement performance curves for the pavement (ICPI, 2007).

Table 2. Standard PCI rating scale (ASTM, 2011)

PCI	Verbal Rating
86-100	Good
71-85	Satisfactory
56-70	Fair
41-55	Poor
26-40	Very Poor
11-25	Serious
0-10	Failed

PCI numerical and verbal evaluation scale according to ASTM E2840-11 standard is shown in Table 2. Before PCI assessment, the road route to be measured must be determined. Then, the measurement area information such as street name, road length, lane width, pavement type, etc. are transferred to the survey sheets. Then, the types of distress on the surface are determined. After the type, severity and amount of each distress are determined, the data is processed for PCI evaluation in the paver package program PAVER prepared for this study.

The PCI value obtained can be interpreted as follows depending on the situation. In superstructures with interlocking concrete paving, the minimum serviceability PCI value is accepted as 60. However, in sections with low speed and traffic volume, this value can be reduced to 50 for moderation (Hein & Smith, 2009).

Fig. 1. Top view of Uzunkar Street in Ondokuz Mayıs district of Samsun

Fig. 1 shows the top view of Uzunkar Street. The points on the figure are the location points that the measuring device sends at second intervals while driving. The dots shown represent the measured speeds of 10 km/h. Uzunkar Street is 250 meters long and 6 meters wide. This two-lane road, which has a very low traffic volume, was taken as a single lane for both safety and suitability for use. Observations made at the measurement site generally did not reveal any two-way traffic.

Uzunkar Street has a very smooth road surface as seen in Fig. 2 and is an interlocking concrete paving road whose construction was completed recently. The use of the interlocking concrete paving road on this street means that heavy tonnage vehicles do not use this road and it has a very low traffic volume, which also extends its future service life.

In many studies, it is seen that ride comfort is evaluated with weighted frequency root mean square (a_w) with vertical vibration analysis. In addition, although not very often, the vibration dose value (VDV) parameter is also preferred (Griffin, 2007; Múčka, 2020).

Fig. 2. View of Uzunkar Street with interlocking concrete pavement in Ondokuz Mayıs district of Samsun

2.2. Comfort levels with whole body vibration and vertical acceleration

Research on the problems related to irregularities of pavements has increased significantly in recent years. Highway authorities try to reduce and eliminate irregularities in pavements in order to improve ride comfort on the road network. Irregularities in pavements cause whole body vibration (WBV) of the users during vehicle movement and generally reduce ride comfort (Cantisani & Loprencipe, 2010).

The importance of ride comfort and safety on superstructures with fast traffic flow has been known for many years. However, recent studies have shown that ride comfort depending on pavement conditions also significantly affects road safety on superstructures with low speed limits (Chan et al., 2010; Li et al., 2013). Regression models have been proposed and subjective evaluations have been developed between five objective measurements (hand, hip, foot, back and whole body) to evaluate ride comfort. It has been determined that the highest correlation between objective measurements and subjective evaluations was obtained in the hip (Kırbaş & Karaşahin, 2019).

Vibration measurements should be made with vibration transducers placed between the body and the surface. When a person is sitting in a vehicle, the supportive seat surface, seat back and feet are the areas that perceive vibration (Fig. 3). When we sit, especially on hard ground, there is a bony prominence in the lower back part of the pelvis that comes into contact with the ground. This area is called the ischial tuberosity. Measurements on the supportive seat surface should be made under the ischial tuberosity with a soft, flexible seat cushion (ISO, 1997).

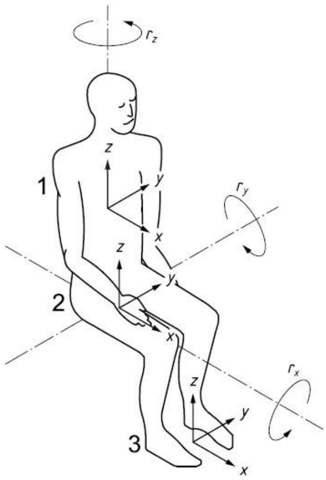

Fig. 3. Translation and rotation axes for TVT of seated driver or passenger (ISO, 1997)

The ISO 2631-1 standard specifies how to determine the effects of vibrations on human comfort, starting from vertical acceleration. In order to determine ride comfort, the standard requires the use of frequency-weighted root mean square RMS accelerations.

$$a_{wz} = \sqrt{\sum_i (W_{k,i} \cdot a_{iz}^{RMS})^2} \quad (1)$$

In formula one, a_{wz} is the weighted vertical frequency acceleration, W_i is the corresponding weighting factor (ISO 2631-1), a_{iz} is the vertical RMS value for the 1/3 octave bandwidth.

Table 3. Comfort levels related to a_{wz} threshold values (ISO, 1997)

a_{wz} Values (m/s^2)	Comfort Levels
<0.315	Not uncomfortable
0.315–0.63	A little uncomfortable
0.5–1	Fairly uncomfortable
0.8–1.6	Uncomfortable
1.25–2.5	Very uncomfortable
>2	Extremely uncomfortable

Table 3 shows the comfort assessment scale according to the ISO 2631-1 standard. Table 3 is used to verbally express the vertical vibration data (a_{wz}) obtained during the rides to investigate comfort levels.

According to the December 2024 data of TÜİK, motor land vehicles, there are more than 31 million land vehicles in Türkiye. 51.9% of these vehicles are automobiles. Therefore, a sedan vehicle in the C segment of the Euro Car classification was used in this study. A brand new car was preferred to minimize errors caused by the vehicle suspension and powertrain.

Fig. 4. C segment automobile and measuring equipment, GPS antenna, datalogger, laptop, seat cushion and vertical accelerometer and power battery

With this equipment (in Fig.4), vibration data will be collected from the interlocking concrete paved roads divided into sections and determined in the field with the accelerometers located on the driver, passenger (front right seat) and ground center axis. The accelerometers used (three pieces) have ±4g, sensitivity 500±15 mV/g feature and can collect 1000 data per second. GPS antenna (<15 m accuracy) can record location data instantly to the computer. Vertical vibration data is recorded on interlocking concrete paved roads with this equipment.

Three runs were made for each speed on the interlocking concrete paving road at speeds of 10, 20, 30, 40 and 50 km/h. With each run, vertical vibration data from three separate points in the vehicle (driver's seat, passenger seat, ground center axis) were recorded as 1000 data per second. At the same time, the position of the GPS antenna measuring vehicle operating simultaneously was recorded as one data per second.

3. Results and discussion

For PCI assessment, the severity and amount of distress types were calculated using specific apparatus from the ASTM standard (3 m ruler, 15 m rope, 1 m ruler, 30-50 cm steel ruler, etc.).

Uzunkar street was taken as a single lane and in the PCI assessment, the lane width used by the vehicle was determined as 3 m. The total length of the road is 250 m. The road section is divided into sample areas at 50-meter intervals, each sample area is 150 m^2 and is within the sample area determination limit of 225 $m^2 \pm 90$ m^2 specified in the ASTM standard. Thus, a PCI evaluation was carried out on Uzunkar Street, consisting of 5 sample areas and an area of 750 m^2 (Fig. 5). Five sample areas constitute one section.

When evaluating PCI, the types, severity and amount of distress were determined and recorded in each sample area. The total amount of each type of distress was divided by the total area of the sample unit at each severity level and multiplied by 100 to obtain the percentage density of each type of distress and severity. Deduct value (DV) was determined for each combination of type of distress and severity from the deduct value curves. Then, after determining the correct deduct value (CDV) value from the deduct curves within the relevant standard, this value was subtracted from 100 to calculate the PCI values of the sample areas. The average of the PCI values of the sample areas also showed the PCI value of Uzunkar Street.

Fig. 5. Uzunkar Street consisting of 5 sample areas

Since Uzunkar Street is a newly constructed road, it was determined that the PCI values of the sample areas were 87 and above. Among the types of distress sought in the PCI assessment of interlocking concrete paved roads on the road surface (Table 1), only 101 and 110 types of distress were found (Fig. 6). While a 110 type distress due to a manhole cover was found in the fourth sample area, the 101 type distresss were quite low and almost did not affect driving comfort.

Fig. 6. Distress types and severities on interlocking paving road pavement

Table 4. Calculated PCI values of sample areas on Uzunkar street

Sample Unit	Types of distress detected	PCI	Verbal Rating	Section PCI	Section Verbal Rating
1	101 (L)	93	Good		
2	101 (L)	93	Good		
3	101 (L), 101 (M)	87	Good	92	Good
4	101 (L), 110 (L)	88	Good		
5	101 (L)	97	Good		

The PCI evaluation is shown in Table 4. As mentioned before, 101 and 110 types of deterioration were encountered. PCI values were found as 93, 93, 87, 88 and 97 according to the numerical order of the sample areas. When the average was taken, it was determined that Uzunkar Street was 92, that is, "good" in terms of road pavement.

Table 5. Vibration data of aw_z according to in-vehicle measurement points of the entire road section

Section ID	Measuring Point	Sample Unit (PCI)	Speed (km/h)/a_{wz} (m/s^2)				
			10	20	30	40	50
Uzunkar Street	Driver's Seat	1 (93)	0.21	0.33	0.43	0.51	0.59
		2 (93)	0.21	0.33	0.43	0.51	0.64

	Average	92	0.22	0.36	0.45	0.50	0.62
	Passenger Seat	1 (93)	0.30	0.44	0.64	0.77	0.80
		2 (93)	0.25	0.43	0.57	0.74	0.97
		3 (87)	0.24	0.45	0.59	0.83	0.96
		4 (88)	0.25	0.50	0.62	0.79	0.88
		5 (97)	0.28	0.52	0.55	0.51	0.79
	Average	92	0.26	0.47	0.60	0.73	0.88
	Center Axle	1 (93)	0.20	0.31	0.48	0.56	0.59
		2 (93)	0.16	0.31	0.42	0.57	0.74
		3 (87)	0.19	0.33	0.48	0.59	0.78
		4 (88)	0.18	0.38	0.43	0.60	0.66
		5 (97)	0.16	0.36	0.40	0.34	0.63
	Average	92	0.18	0.34	0.44	0.53	0.68

Vertical directional (a_{wz}) vibration data were obtained at speeds of 10, 20, 30, 40, 50 km/h with whole body vibration measurement equipment combined and calibrated according to ISO 2631-1 standard. Three rides were made at each speed and the vibration data obtained from the rides were averaged (Table 5).

As seen in Table 5, the vertical vibration data on this interlocking concrete paving road with a high PCI value could not exceed 1 m/s^2. While it was observed that the vibration values increased as the speed increased, the lowest value was determined to be 0.16 m/s^2.

In the table below, the comfort levels of the vertical vibrations obtained from the driver's seat, passenger seat and floor center axis measurement points are verbally evaluated according to Table 3. As can be seen, on an interlocking concrete paving road with a good service level, even at 50 km/h within the urban speed limits, the comfort threshold has not exceeded the expression "fairly uncomfortable". The smoother the road, the higher the driving comfort will be.

Since the service level of the interlocking concrete paving road measured is high, it can be stated that the increase in discomfort in the driver's seat depends on the speed variable (Table 5). If we interpret this increase in discomfort through driving experiences, it can be said that interlocking concrete paving roads consist of fragmented elements and that there is a -x-directional impact (Fig. 3) between the joints on the vehicle's wheel and from there into the vehicle.

Table 6. Comfort levels of Uzunkar Street according to driver's seat, passenger seat and ground center axis

Section ID	Measuring Point	Sample Unit	Speed (km/h)/a_{wz} (m/s^2)				
			10	20	30	40	50
Uzunkar Street (PCI:92)	Driver's Seat	1	Not *	A little *	A little *	A little *	Fairly *
		2	Not *	A little *	A little *	A little *	Fairly *
		3	Not *	A little *	A little *	A little *	Fairly *

*Uncomfortable

Table 6 includes verbal vibration assessments for the driver's seat, passenger seat and ground center axle according to sample areas and speeds. When we look at the linear correlation between aw_z and PCI according to the driver's seat, it is seen that the highest correlation is at 30 km/h speed. The lowest correlation is at 20 km/h driving speed. (Table 7).

Table 7. aw_z-PCI linear correlation according to driver seat speed

	10 km/sa	20 km/sa	30 km/sa	40 km/sa	50 km/sa	PCI
10 km/sa	1.000					
20 km/sa	0.334	1.000				
30 km/sa	0.809	0.155	1.000			
40 km/sa	0.500	-0.202	0.895	1.000		
50 km/sa	0.724	-0.382	0.755	0.748	1.000	
PCI	-0.800	-0.154	-1.000	-0.898	-0.747	1.000

When we look at the aw_z-PCI relationship in the passenger seat, it is seen that the 40 km/h measurement speed has a higher relationship. When we look at the awz-PCI relationship in the passenger seat, it is seen that the 40 km/h measurement speed has a higher correlation. Again, as in the driver's seat, it was determined that the 20 km/h speed has a lower correlation than the other speeds (Table 8).

Table 8. aw_z-PCI linear correlation according to passenger seat speed

	10 km/sa	20 km/sa	30 km/sa	40 km/sa	50 km/sa	PCI
10 km/sa	1.000					
20 km/sa	0.085	1.000				
30 km/sa	0.294	-0.331	1.000			
40 km/sa	-0.411	-0.618	0.707	1.000		
50 km/sa	-0.890	-0.519	-0.146	0.588	1.000	
PCI	0.653	0.219	-0.491	-0.865	-0.598	1.000

When we examined the relationship between the vibration data taken from the ground center axis point and PCI, it was determined that the 40 km/h measurement speed on the passenger seat had a higher correlation, while the 20 km/h speed had a lower correlation than the other speeds (Table 9).

Table 9. aw_z-PCI linear correlation according to center axle speed

	10 km/sa	20 km/sa	30 km/sa	40 km/sa	50 km/sa	PCI
10 km/sa	1.000					
20 km/sa	-0.431	1.000				
30 km/sa	0.982	-0.515	1.000			
40 km/sa	0.572	-0.354	0.646	1.000		
50 km/sa	-0.107	-0.265	0.077	0.398	1.000	
PCI	-0.516	-0.013	-0.596	-0.838	-0.535	1.000

As mentioned in the previous sections of the study, taking measurements from the driver's seat using a sitting type accelerometer as in the measuring equipment gives the most accurate results. This is shown in Table 7.

4. Conclusions

As a result of this study in determining the service life and driving comfort levels of newly constructed interlocking concrete paving roads;

- A PCI assessment was carried out to see the serviceability of a newly completed interlocking concrete paving road according to the ASTM E2840 standard. The PCI value of the interlocking concrete paving road consisting of five sample areas was determined as 92 "good".
- On the interlocking concrete paving road section where PCI assessment was made, drives were made with a brand new Euro Car C segment vehicle and vibration measurement data set at urban speed limits of 10, 20, 30, 40, and 50 km/h.
- Whole body vibration data were collected at determined speeds by measurements made from the driver's seat, passenger seat and floor center axis points.
- The comfort levels of the road measured according to the ISO 2631-1 standard were determined.
- When comfort levels were examined, it was determined that "Not uncomfortable" was found at all measurement points at 10 km/h.
- It was determined that "A little uncomfortable" was generally found at 20 and 30 km/h.
- While it was "A little uncomfortable" at 40 km/h except for the passenger seat, it was found that "Fairly uncomfortable" was found at other measurement points.
- At 50 km/h, it was interpreted as "Fairly uncomfortable" at all measurement points.
- When the linear correlation between the awz values taken from the driver's seat, passenger seat and ground center axis and PCI is examined, it is determined that the tightest relationships are when there is a driver and the highest relationship is at the 30 km/h measurement speed in the driver's seat.
- As a result, with this technique, which can be used by institutions and organizations responsible for the construction, maintenance-repair and renewal activities of interlocking concrete paving roads, the current status of interlocking concrete paving roads can be determined and their service life can be extended when necessary.

Abstract. Researchers in asphalt mixtures have concentrated on optimizing mix designs to improve performance and meet specified requirements. The accurate estimation of Voids in Mineral Aggregate (VMA) has become a critical topic in this optimization process. Advanced computational techniques, such as LightGBM and XGBoost, have gained prominence due to their reliability and efficiency in handling complex datasets and enhancing VMA prediction accuracy. This study emphasizes the significance of identifying and quantifying critical features in VMA estimation using gradient-boosting algorithms. Permutation importance is proposed as a robust and interpretable method for assessing the influence of each input variable on model performance. This approach evaluates the impact of individual features by measuring how much the model's performance is affected when the values of a specific feature are randomly shuffled. Cross-validation is applied to evaluate the models across multiple data splits to ensure reliability and generalizability. Accordingly, this study computed permutation importance on the different test subsets in the cross-validation approach, enabling the gradient-boosting models to provide more objective and broadly applicable insights into VMA estimation. This methodology yielded feature-importance results that closely aligned with field knowledge, enhancing the interpretability of the models. Specifically, the specific gravity (G_{mb}) of the compacted hot mix asphalt and the bulk specific gravity of the aggregate blend (G_{sb}) were validated as pivotal parameters for VMA estimation, consistent with established empirical formulas. Consequently, this study demonstrates the effectiveness of combining cross-validation with permutation importance in LightGBM and XGBoost models to achieve reliable and consistent feature importance, thereby minimizing biases from individual data splits.

Keywords: Voids in minerals aggregates; Mix design; Gradient-boosting algorithms; Feature importance; Permutation importance

1. Introduction

Asphalt mix design has critical procedures to determine appropriate aggregate gradation and optimum binder content to meet specified volumetric and mechanical requirements (Gardete et al., 2022). It can also be stated that a proper mix design is a critical step in pavement construction, as it directly affects the performance of the pavement during its service life. Well-designed mixtures ensure long-lasting pavements, while poorly designed ones can lead to premature failure. Using empirical methods, traditional asphalt mix design mainly focuses on volumetric properties (e.g., air voids, VMA), which are required by specifications and strongly influence pavement performance. However, there has been a shift toward performance-based approaches to better predict long-term pavement behavior since the late 1990s (Wang, 2019). As a result, developed as part of the Strategic Highway Research Program, the Superpave mix design method was introduced to address the limitations of earlier methods, such as the Marshall and Hveem mix designs (Cooper et al., 2014; Lee et al., 2023). Another important role of the Superpave mix design method is to improve pavement performance by solving common problems such as rutting, thermal cracking, and fatigue cracking.

While this method includes specifications on rutting and fatigue resistance, actual field performance is not directly incorporated into the initial design phase. Moreover, the implementation of the Superpave mix design necessitates extensive experimental procedures, including preparing multiple trial samples and evaluating the volumetric properties associated with the asphalt binder, aggregates, and mixtures. In short, this process requires

[*] Corresponding author, E-mail: ddemirturk@aybu.edu.tr

https://doi.org/10.31462/icearc2025_ce_tra_755

a substantial investment of labour, materials, and financial resources (Liu et al., 2022). In the literature, studies on traditional asphalt mixture design are primarily based on experimental methods and extensive laboratory studies, while recent studies have evolved into optimization-based approaches that are compatible with modern engineering standards and increase performance and efficiency (Hossain & Chen, 2002; Liu et al., 2022; Sebaaly et al., 2018).

According to Hossain and Chen (2002), optimising volumetric properties is very important in designing asphalt mixes because changing one property can directly affect the others. Changing the binder content, for instance, can thin the binder film, raise the VMA, and lower the air voids. This interaction highlights the importance of precise control over volumetric parameters to achieve the desired mix performance. Therefore, they advocated the need for more accurate and practical methods to predict and optimize volumetric properties. Among these volumetric properties, it is obvious that VMA is an important volumetric property in the design of asphalt mixtures (Kandhal & Chakraborty, 1996; Roquier, 2023; Shen & Yu, 2011a). This is because the requirement to meet McLeod's minimum VMA is a critical but often challenging step in Superpave mix design, as it may eliminate cost-effective mixtures with acceptable performance (Hislop & Coree, 2000). Some researchers also underlined that it is overly restrictive and not universally applicable to all asphalt mixtures (Hinrichsen & Heggen, 1996; Mallick et al., 2000). In properly designed mixtures, the VMA value serves as a decisive parameter in preventing the formation of low-performing mixtures. To infer this statement, past studies have investigated the effects of factors such as aggregate grading, nominal maximum aggregate size (NMAS), surface texture, and aggregate shape on the VMA of asphalt mixtures (Pouranian & Haddock, 2018; Prowell et al., 2005).

Shen and Yu (2011) noted that precise prediction of VMA is still a difficult subject due to its complex and nonlinear relationship with aggregate grading and packing behavior, which usually requires iterative and trial-and-error methods. Therefore, they focused on a theoretical method to predict the VMA parameter in hot mix asphalt by analyzing aggregate packing using discrete element modeling (DEM). In the same study, the gradation weighing factor (f_v), was introduced to directly link aggregate gradation to the VMA, enabling faster and more accurate predictions without extensive laboratory testing (Shen & Yu, 2011b). Moreover, in the study, DEM effectively simulated aggregate compaction and structure and produced volumetric results that agreed well with experimental data. However, due to computational constraints, this model excluded particles smaller than 1.18 mm and did not fully replicate actual molding processes, thereby limiting its potential to entirely replace laboratory testing (Dai et al., 2024). Based on the defined deficiencies, researchers increasingly need machine learning (ML) techniques to predict volumetric properties more accurately and efficiently in asphalt mix design (Rahman et al., 2021). In the past, volumetric design parameters, such as VMA, have traditionally been determined using empirical methods and have rarely been the subject of prediction using ML techniques. Nowadays, most ML research-based pavement engineering studies have primarily addressed performance-related outputs such as rutting, fatigue cracking, and dynamic modulus (Eleyedath & Swamy, 2022; Haddad et al., 2022; Krcmarik et al., 2016).

On the other hand, in traditional Superpave mix design, test data is generated through a trial and error approach, and most of it is unused (Liu et al., 2022). ML models can use these data sets to support more efficient data-driven asphalt mix design processes. Rather than relying solely on trial-and-error methods, ML enables optimized decisions regarding aggregate gradation and binder content. For example, Hosseini et al. (2021) offered various ML algorithms, including Artificial Neural Networks (ANNs), Support Vector Regression (SVR), Decision Trees, and Ensemble models, to predict the complex shear modulus and phase angles of modified bitumens. Their study reported optimal dosages and test conditions for different modifiers (e.g., rubber, SBS, PPA), thereby supporting a more rational choice of mix design (Hosseini et al., 2021). Furthermore, the growing availability of comprehensive asphalt mix data has enabled the effective training of ML models to predict volumetric properties (Jweihan et al., 2022; Zavrtanik et al., 2016; Zhang et al., 2021a). Notably, Dai et al. (2024) developed an interpretable ML-based framework that integrates Extreme Gradient Boosting (XGBoost) with SHapley Additive exPlanations (SHAP) analysis to predict and explain the volumetric properties of asphalt mixtures, including air voids and VMA. The approach employed advanced outlier detection, combining Kernel Density Estimation (KDE) and Local Outlier Factor (LOF), significantly enhancing the model's robustness. The study concluded that asphalt content and fine aggregate were the most significant parameters affecting air void content. In contrast, the coarse aggregate ratio had the most significant impact on VMA. The method achieved high prediction accuracy (R^2 = 0.9441 for air voids) and reduced design time by up to 70% (Dai et al., 2024).

In addition, integrating ML models with feature importance techniques such as SHAP or permutation importance, researchers can determine which mix design parameters (e.g., asphalt content, aggregate classification) most influence key volumetric properties. Among these techniques, SHAP, introduced by Lundberg and Lee (2017), has been widely adopted in predictive modeling due to its consistency and ability to quantify feature contributions across a broad range of ML algorithms (Lundberg & Lee, 2017). Liu et al. (2024) applied SHAP to interpret the influence of input variables on the predicted volumetric properties of asphalt mixtures, revealing that asphalt content (P_b) and aggregate bulk specific gravity (G_{sb}) were the most influential factors for both air voids (AV) and maximum theoretical specific gravity (G_{mm}) (Liu et al., 2024). Then, Junaid et al. (2024) applied a Multilayer Perceptron Model (MLP) to predict the dynamic modulus of asphalt mixtures modified with polyethylene. They conducted a feature importance analysis based on the model's internal weights. Their results showed that frequency had the greatest influence on the prediction results, followed by temperature and low-density polyethylene (LDPE) content, demonstrating the effectiveness of neural network-based models in capturing and quantifying feature contributions (Junaid et al., 2024).

Although ML techniques have been used in many studies on observed problems in pavement engineering, the combined use of permutation-based feature importance and cross-validation to estimate VMA has not been studied before. This work focused on this issue by proposing an interpretable approach to improve the accuracy of VMA prediction using advanced gradient boosting algorithms, specifically LightGBM and XGBoost. This study also advocated permutation importance as a reliable and easy-to-understand method for identifying and quantifying the impact of each input variable on VMA. Accordingly, the feature importance was calculated across multiple test sets using a cross-validation strategy to ensure the results were robust and applicable to different data conditions. This helped reduce bias from individual data splits and provided a clearer understanding of the most important variables. Finally, the study compared the model findings with well-known engineering knowledge to confirm the accuracy and practical relevance of the results.

2. Dataset

The data set used in this study belongs to 200 asphalt mixtures collected from previously conducted experimental studies. In this dataset, there are 13 variables, such as asphalt binder content (P_b), theoretical maximum specific gravity (G_{mm}), bulk specific gravity of the compacted mix (G_{mb}), bulk specific gravity of the aggregate blend (G_{sb}), effective asphalt content (P_{be}), effective aggregate specific gravity (G_{se}), air voids (V_a), Voids in Mineral Aggregate (VMA), Voids Filled with Asphalt (VFA), and dust ratio. These features are crucial for evaluating and forecasting the volumetric behavior of hot mix asphalt (HMA). Additionally, Table 1 presents the descriptive statistics of these variables, including the mean, standard deviation, minimum, maximum, and median values.

Additionally, the statistical distributions of selected input and output variables in the asphalt mix design dataset are presented in Fig. 1. The histograms, combined with kernel density estimation curves, provide insight into the data structure of variables such as asphalt binder content (P_b), bulk specific gravities (G_{sb} and G_{mb}), air voids (V_a), Voids in Mineral Aggregate (VMA), and Voids Filled with Asphalt (VFA). Most variables, including P_b, VMA, and VFA, exhibit approximately normal distributions, while others, such as V_a and G_{sb}, display slight skewness or multimodal tendencies. These visual assessments are essential for understanding variable behavior and ensuring the appropriateness of the dataset for predictive modeling.

Table 1. Descriptive statistics of input and output variables used in the asphalt mix design dataset.

Variables	N Total	Mean	Standard Deviation	Sum	Minimum	Median	Maximum
P_b	200	5.53	0.56	1105.26	4.00	5.50	7.00
G_{mm}	200	2.54	0.04	507.61	2.46	2.54	2.63
G_{mb}	200	2.43	0.06	486.30	2.33	2.44	2.55
G_b	200	1.029	0	205.80	1.029	1.029	1.029
G_{sb}	200	2.71	0.05	541.96	2.63	2.69	2.77
P_{ba}	200	0.91	0.44	182.15	0.45	0.69	1.62
P_{be}	200	4.62	0.50	923.11	3.03	4.58	5.80
G_{se}	200	2.78	0.04	555.21	2.69	2.80	2.81

Histogram and kernel density plots showing the distribution of selected asphalt mix design variables: (a) binder content (P_b), (b) bulk specific gravity of aggregate (G_{sb}), (c) bulk specific gravity of the mixture (G_{mb}), (d) air void content (V_a), (e) voids in mineral aggregate (VMA), (f) voids filled with asphalt (VFA), (g) maximum specific gravity of the mixture (G_{mm}), and (h) mixture density.

3. Methodology

It is widely accepted that, in a high-dimensional feature set, not all features contribute equally to the ML model. Since ML models are often considered black-box models, the contribution of each feature is typically assessed only after the model has been trained. The assessment of each feature's contribution after model training is referred to as feature importance. A typical workflow for constructing an ML model is as follows: A dataset is prepared, then divided into train and test sets (typically 80% for train and 20% for test). The model is trained on the train set and evaluated on the test set. After the modelling part is done, feature importances are calculated. Several methods have been proposed to assess the importance of the feature. One of them is Permutation Feature Importance (PFI) (Kaneko, 2022). The main idea of the PFI is to shuffle the value of feature $\boldsymbol{i}$, which will break down the association between feature $\boldsymbol{i}$ and outcome $\boldsymbol{x}$. Thus, if the ML model relies on the feature $\boldsymbol{i}$, shuffling it results in high error. This will indicate that the feature $\boldsymbol{i}$ is an important feature for the dataset. When the output after permutation does not produce a high error on feature $\boldsymbol{i}$, it indicates that feature $\boldsymbol{i}$ is not important.

However, there is no consensus on using training and test data when assessing feature importance. When constructing the ML model on training data, inevitably, the ML model overfits. For this reason, calculating feature importance on training data will eventually be erroneous, and calculated feature importance will be unimportant. Revealing feature importance on training data only answers the question, "What are the variables that the model uses for prediction?" A figurative example of PFI on both test and train sets on a randomly, non-correlated dataset is given in Fig. 2.

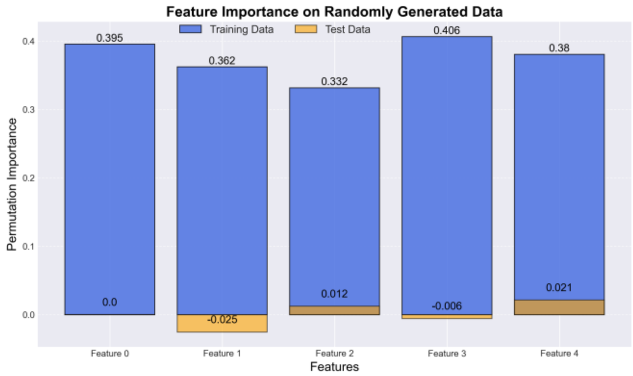

Fig. 2. Feature importance for non-correlated variables.

As seen from Fig. 2, even if the dataset was constructed with no correlation, PFI will assign each feature an importance value, which is obviously incorrect. Moreover, PFI is higher on the train set than the test set, proving the mentioned problem above. The optimal way to calculate the importance of the feature is to let the model be evaluated on unseen data. For this reason, PFI should be calculated on the test set to obtain reliable feature importances. Another important aspect of calculating PFI is to let the model see not only a constant portion of the dataset but also all subsets of the dataset. For this reason, cross-validation (CV) can be considered when calculating PFI. Using the CV approach, the model can see all portions of the data, and by calculating PFI for each test subset of the data, the importance of each feature can be assessed objectively. This study employed K-Fold CV to evaluate an ML model by dividing the dataset into K equal parts (folds). The model is trained on K-1 folds and tested on the remaining fold, repeating this process K times. A classical K-Fold CV as a figure is given in Fig. 3.

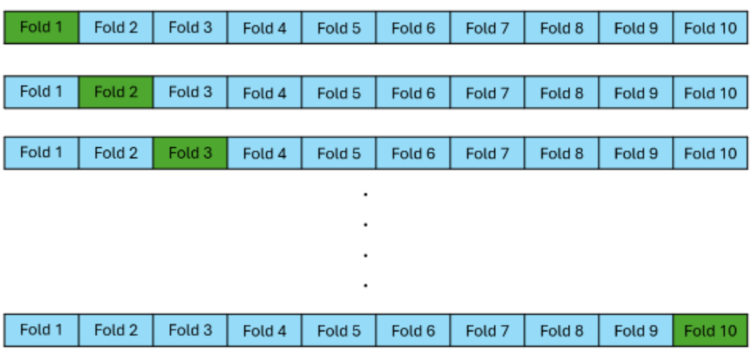

Fig. 3. K-Fold cross validation (K=10).

To objectively evaluate the PFI, we employ two state-of-the-art ML algorithms: Light Gradient Boosting Machine (LightGBM) (Chen et al., 2019) and eXtreme Gradient Boosting (XGBoost) (Ibrahem Ahmed Osman et al., 2021). Both are based on the Gradient Boosting Decision Tree (GBDT) framework, which constructs an ensemble of decision trees, in which each successive tree attempts to correct the errors of its predecessors. Unlike traditional models that learn independently from data, GBDT leverages this sequential learning strategy to produce a more accurate and robust model. LightGBM, developed by Microsoft, introduces a key innovation to enhance the efficiency of GBDT, particularly when dealing with high-dimensional feature spaces. The innovation is Gradient-based One-Side Sampling (GOSS), which improves training speed and accuracy by prioritizing instances with large gradients. Moreover, while traditional GBDT splits nodes based on information gain, GOSS utilizes variance gain as a splitting criterion. XGBoost, another powerful implementation of GBDT, distinguishes itself from LightGBM primarily in its tree construction strategy. Whereas LightGBM grows trees in a leaf-wise manner, focusing on the branch that maximally reduces loss, XGBoost adopts a level-wise approach that grows all branches evenly. In summary, LightGBM and XGBoost are among the most widely adopted gradient boosting frameworks and have been selected as two ML models in this study. The general working mechanism for both LightGBM and XGBoost is presented in Fig. 4.

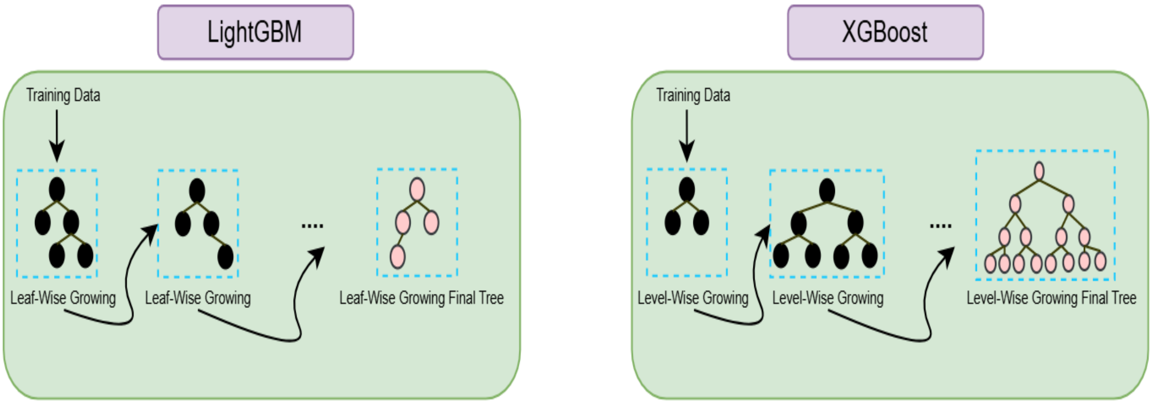

Fig. 4. LightGBM and XGBoost algorithms (Adapted from Chen et al., 2019).

To assess the impact of PFI in both the classical train-test split and K-Fold cross-validation, we divided our experimental setup into two parts. In the first part, the entire dataset was split into 80% for training and 20% for testing, following common practice in the literature. We then applied the two ML models mentioned above and calculated the PFI on the training and test sets. In the second part, we employed K-Fold CV, calculated the PFI for each fold, and then averaged the PFI, in which the ML models were trained on the training fold, and the PFI was computed on the corresponding test fold. Moreover, we calculated the performance metrics of both ML models using the classical train-test split approach and K-Fold CV approach, namely Root Mean Squared Error (RMSE) and Mean Squared Error (MSE). The formula for RMSE and MSE is given in Equations (1) and (2), respectively.

$$RMSE = \sqrt{\sum_{i=1}^{n} \frac{(\hat{y}_i - y_i)^2}{n}} \tag{1}$$

$$MSE = \frac{1}{n}(\hat{y}_i - y_i)^2 \tag{2}$$

Where n represents the total points in the dataset, $\hat{y}_i$ represents the output of the ML model for a specific point (i), and y_i shows the real value of point (i) in the dataset. We selected these error metrics because the problem at hand is essentially a regression task. All experiments were conducted using Python programming language (version 3.8.13). LightGBM and XGBoost were used with their default parameter settings, and no additional optimization techniques were applied.

4. Experimental results

In this section, the study first presents the results using the PFI calculated based on the classical 80%-20% training-test split of the dataset. Accordingly, the PFI results for the LightGBM and XGBoost models are shown in Fig. 5. Additionally, the RMSE and MSE for both ML models are provided in Table 2.

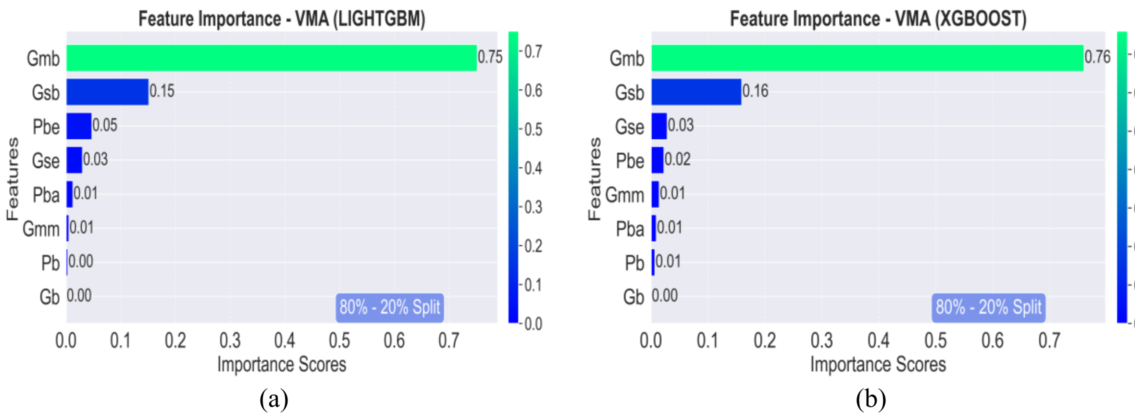

Fig. 5. PFI Scores for Both Models on 80%-20% Split. (a) LightGBM (b) XGBoost

Table 2. Error metrics for 80%-20% split

Error Metric	Train Set		Test Set	
	LightGBM	XGBoost	LightGBM	XGBoost
RMSE	0.2221	0.00021	0.235	0.1155
MSE	0.0493	0.0000047	0.055	0.0133

In the classical 80%-20% split, both ML models consistently identified G_{mb} as the most important feature in the dataset. In other words, the findings indicate that G_{mb} plays the key role in predicting VMA. Additionally, both models agreed that G_{sb} is the second most important feature. However, they diverged in identifying the third most important variable: LightGBM emphasized P_{be}, whereas XGBoost highlighted G_{se}. Regarding predictive performance, both models exhibited significant overfitting under the classical split, as reflected in the error metrics. This is a classical, expected result on small datasets, since in the classical splitting method, ML models do not see all of the dataset and perform poorly on the test set. In this study, XGBoost achieved the lowest RMSE (0.1155) and MSE (0.0133), indicating a more accurate prediction of VMA compared to LightGBM, which recorded higher test errors (RMSE: 0.235, MSE: 0.055). Hence, in terms of both evaluation metrics, XGBoost clearly outperformed LightGBM.

To improve interpretability and mitigate overfitting, we also applied K-fold CV to the dataset and calculated the PFI for each test fold in this study. An average PFI score was then computed for each feature. Similarly, average RMSE and MSE values were obtained for each model under different K values. Accordingly, Fig. 6 presents the PFI values obtained for different values of K in the CV approach.

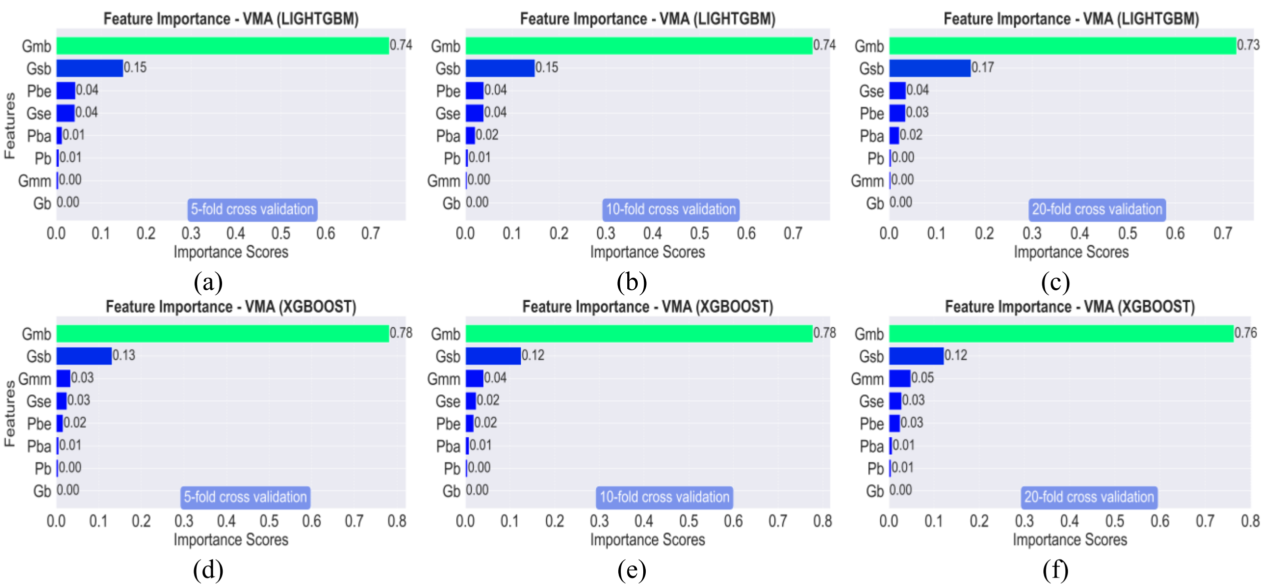

Fig. 6. PFI scores for both models across different K values in cross-validation. (a) LightGBM 5-Fold (b) LightGBM 10-Fold (c) LightGBM 20-Fold (d) XGBoost 5-Fold (e) XGBoost 10-Fold (f) XGBoost 20-Fold.

Similar to the results obtained from the 80%-20% split, both LightGBM and XGBoost consistently found G_{mb} and G_{sb} as the top two influential variables influencing VMA across all folds. However, while LightGBM showed minor variations in ranking the third most important feature depending on the K value (alternating between P_{be} and G_{se}), XGBoost demonstrated a more stable pattern by consistently ranking G_{mm} in third place. This discrepancy implies that XGBoost can pick stronger structural patterns, whereas LightGBM appears more sensitive to data partitioning effects. Especially under CV in XGBoost, G_{mm}'s significance became quite clear despite its minor relevance in the 80%-20% split, therefore highlighting the need for repeated sampling in revealing hidden relationships. On the other hand, the binder specific gravity (G_b) showed negligible importance in both the 80%-20% train-test split and the cross-validation setups (see Fig. 5 and Fig. 6). This is mainly due to two factors. First, as indicated in Table 1, G_b remained constant across all samples (mean = 1.029, SD = 0), providing no variation for the models to learn from. Since ML models rely on feature variability to assess influence, a fixed input like G_b has no predictive contribution. Second, G_b does not appear directly in the theoretical VMA formula, as seen in Equation (3).

$$\mathrm{VMA} = \left(1 - \frac{G_{mb}(1 - P_b)}{G_{sb}}\right) \mathrm{x}100 \tag{3}$$

Given their direct occurrence in Equation (3), G_{mb}, G_{sb}, and P_b are inherently critical in calculating VMA and are likely to emerge as the highest-ranked features in any feature importance analysis. Furthermore, binder-related effects are already captured through P_b and P_{be}, making G_b redundant. These findings hold across both model types (LightGBM and XGBoost) and all CV folds, confirming that the low importance of G_b is both statistically and theoretically well-founded. In short, the observed feature importance rankings strongly align with the analytical VMA equation, where G_{mb}, G_{sb}, and P_b are the primary contributors. Consistently, both LightGBM and XGBoost identified G_{mb} as the dominant feature, followed by G_{sb}, reflecting the structural formulation of the empirical equation. Furthermore, the emergence of features such as G_{mm} and P_{be} in PFI results, despite not being explicitly part of the original formula, suggests that ML models can detect latent interdependencies within mix design parameters. This reinforces the reliability of the PFI method and highlights its potential for both validating known empirical relationships and uncovering additional influential factors in asphalt mix design.

In addition to the PFI scores for both models under various K-fold CV settings, Table 3 presents the corresponding error metrics. The significant disparity between training and test errors indicates that both LightGBM and XGBoost show signs of overfitting over all K values. However, an interesting observation is that LightGBM appears to overfit less than XGBoost. Another insight is that LightGBM's overfitting decreases as the K value increases, suggesting improved generalization with more folds. In contrast, XGBoost does not exhibit this trend. This discrepancy may be attributed to the different feature set that each model emphasizes. To further support these findings, Fig. 7 illustrates the PFI scores computed individually for each fold in the cross-validation process.

In Fig. 7, each bar shows the normalized PFI value of a particular feature for a particular fold, allowing an assessment of the stability of importance ratings over the folds. Across all configurations, G_{mb} consistently maintained the highest normalized importance scores, with relatively low variation between folds. XGBoost shows greater stability across folds, as evidenced by the more tightly clustered importance scores in graphs (b), (d), and (f), indicating lower sensitivity to data partitioning compared to LightGBM. As a result, these fold-wise analyses expose the uncertainty around secondary variables and confirm the stability of important predictors (G_{mb} and G_{sb}). Particularly when calculating PFI, they show even more the importance of cross-validation for feature interpretation as well as for model performance.

5. Conclusion

This study tried to test and validate the reliability of interpretable ML methods in engineering problems related to asphalt mixture design, such as VMA estimation. Based on the results, it is possible to reach the following specific findings:

- It is emphasized that reliable identification of the most important input variables is possible by combining K-fold CV with Permutation Feature Importance (PFI).
- XGBoost consistently had lower RMSE and MSE values, indicating higher prediction accuracy. It also had a more stable feature importance distribution across all folds, indicating greater robustness to data partitioning.
- While LightGBM was slightly less accurate overall, it demonstrated lower overfitting and improved generalization as the number of folds increased, indicating its strength in handling small datasets.
- The specific gravity of the compacted mix (G_{mb}) and the aggregate blend (G_{sb}) were consistently ranked as the most important properties, which agrees with the empirical VMA equation. This finding demonstrates the reliability of ML approaches in creating predictive models for engineering problems.
- Variables such as G_{mm} and P_{be} that are not explicitly included in the empirical formula were found to impact the VMA significantly, demonstrating the potential of ML models to uncover hidden relationships.

Design and estimation of plastic properties of gradations for flexible pavement courses

Mustafa Aytekin*[1]

[1] University of Bahrain, Department of Civil Engineering, 973, Sakhir Campus, Kingdom of Bahrain

Abstract. In the design of flexible pavements, there are several layers that must be designed according to the specifications such as subgrade-improvement, subbase, base, and surface courses. Most of the time, it is needed to use materials that must be blended from several stockpiles to generate an adequate gradation for the courses of flexible pavements within the range that is given by specifications. Also, the liquid limit and plasticity index of the mixture must have specific values given by the specifications. For this purpose, a rational approach and formulation that allows engineers to do the job effectively and faster are developed. In the proposed method, the materials provided from two stockpiles or more without any limitations would be taken into consideration for the design of mixture gradation. Then, the liquid limit and plasticity index of the designed mixture would be estimated accordingly. An "MS-Excel Spread Sheet" has been created and the gradations for all types of requirement given by the specifications can be designed with any number of material stockpiles. A numerical example of the method is also provided.

Keywords: Flexible pavement design; Gradation of materials; Plastic properties of mixture; Rational method; Mix design

1. Introduction

In the design of flexible pavements, there are several layers that must be designed like subgrade-improvement, subbase, base, and surface courses Garber, and Hoel (2015). The materials used in these courses must satisfy the certain properties. For example, the gradation of the materials used in any of these courses should be within a range given by the specifications. Researchers in this subject have studied the impact of aggregate gradation on mixture properties and mixture performance. Thus, many research studies have been conducted for this purpose, Ahmed and Attia (2013), Chen and Liao (2002), El-Basyouny and Mamlouk (1999), Fang, Park, Singuranayo, Chen, and Li (2019), Garcia, V. M., Barros, L., Garibay, et al (2020), Stakton and Bahia (2003). It has been discovered that aggregate gradation strongly influences the rutting resistance of mixtures, and a mixture made with high-quality materials would fail without suitable gradation, Stakton and Bahia (2003). The material specifications should be checked to assure that hydraulic conductivity, strength, load-distribution, and construction stability requirements are met, Al-Saoudi and Kawla (2017). An estimation of the proper proportions of available materials in the field is possible and depends on manual and visual inspections, Reimer (1992). There are a few methods to determine the proper gradation and estimation of the plastic properties of these mixtures in the literature, Mallick and El-Korchi (2013). Even, there is a graphical method to determine the gradation if you will blend only two materials to be blended, Reimer (1992). However, the usage of these methods is not rational. For instance, when more than two material-stockpiles are available to create a mixture for an adequate gradation, the methods are very subjective and time consuming like trial and error method. The trial and error method is still in use, Shakhan and Sengoz (2022).

A new method of the determination of mix gradation is presented in this paper. It is believed that this new method will be very useful while designing a gradation that would be within the zone specified by the standards and/codes.

2. Setting up the specified gradation mixtures

In this paper, a new approach is offered to setup the gradation curve within the zone that is specified by the codes or specifications. The gradation of mixture can be set up from the any number available sources that might be two sources or more with no upper limitation. For example, five different sources have been considered in Example 1.

https://doi.org/10.31462/icearc2025_ce_tra_800

3. Vectors to be created on the design of gradation

In the proposed method, the following vectors must be created first to design of a mixture by blending a number of materials from different stockpiles. Of course, the sieve analyses and gradation of each material that would be blended must be available before starting any calculation. A vector, named as vector O that would have openings of sieves employed in the determination of the gradations, The gradation data for each material should be included in a vector. In other words, the number (n) of the vectors that must be created would be equal to the number of materials in the mixture to be designed. Let's call the gradations vectors as Gi, i = 1 to n. Other vectors are listed below:

MS: selected gradation of the mixture vector, BU: upper boundary of the mixture given by the specification. BL: Lower boundary of the mixture given by the specification. Di: differences of the gradations between the selected gradation (matrix MS) and the materials' gradations to be included in the mixture. DD: summations of absolute differences between the selected gradation and each material that would be included in the mixture. PR: Percentages of absolute differences of each material in matrix DD. MF: Final gradation of the mixture.

The numerical values in PR vector must be arranged from the maximum to minimum values. The values in vector DD must be arranged from minimum to maximum values. Then, the gradation values represented by the minimum value in vector DD must be multiplied by the maximum value of PR vector. Similarly the gradation values represented the maximum value in vector DD must be multiplied by the minimum value of PR vector. The other percentages of the remaining materials must be calculated accordingly.

It seems to be a little bit complicated procedure. However, this procedure is very easy to apply in a spreadsheet like the excel spreadsheet or a software like MATLAB. An example (Example 1) is given here to understand the method more clearly.

4. Plastic properties of the mixture

The plastic properties of the mixture can be estimated by considering percentages of materials in the mixture passing No.40 sieve that has an opening of 0.425mm. The reason for this approach is that the plastic properties of any soil are determined by using the portion of the material passing No.40 sieve. First, the plasticity indexes (PI) and liquid limits (LL) of all materials blended to create the mixture must be known along with their gradations. Example 2 illustrates the estimation of plasticity index, PI, and the liquid limit, LL, of the mixture designed in Example 1.

Example 1: Design a mixture of that the gradation must be between the upper and lower borders given by the code. In Table 1, the openings (sizes) of sieve set, the gradation of soils from five stockpiles are given. Also upper and lower borders are provided.

Solution:

- Step 1: It would be a good approach to plot gradations of all materials in a graph as seen in Fig.1. Then, the upper and lower borders should be plotted on the same graph to see the zone in which the gradation of the mixture would take place as seen in Fig 2. It is obvious that soil 4 should have the largest percentage in the mixture because its gradation is the closest one to the band as seen in Fig 2. Similarly, soil 2 should have the least percentage in the mixture since its gradation is far from the band. First of all, an initial gradation of the mixture to be designed is selected between upper and lower borders for each diameter (Table 2). Then, the differences of gradations between the selected mix-gradation and the gradations of the each material (soil) that would be in the mixture is calculated as seen Table 2. At the bottom of the columns in Table 2, the summations of absolute values of the differences between selected one and each soil is shown.

Table 1**.** Gradations (% finer) of soils and specified range of the mixture to be designed

Sieve Size (mm)	Soil 1	Soil 2	Soil 3	Soil 4	Soil 5	Upper Border	Lower Border
19.000	100	100	100	100	100	100	100
12.500	100	81	100	100	100	100	90
9.500	93	15	100	100	100	90	80
4.750	24	1.7	98.7	95.3	100	75	65
2.360	7.5	1.5	79	77.4	84.5	60	50
1.180	5.8	1.4	57.4	50	57.4	50	35
0.600	5.1	1.3	39.7	31	40.5	30	20
0.300	4.5	1.2	16.9	17.7	29.2	20	10
0.150	3.5	1	6.9	5.7	21.1	15	5
0.075	1.6	0.7	2.8	1.6	14.2	10	0

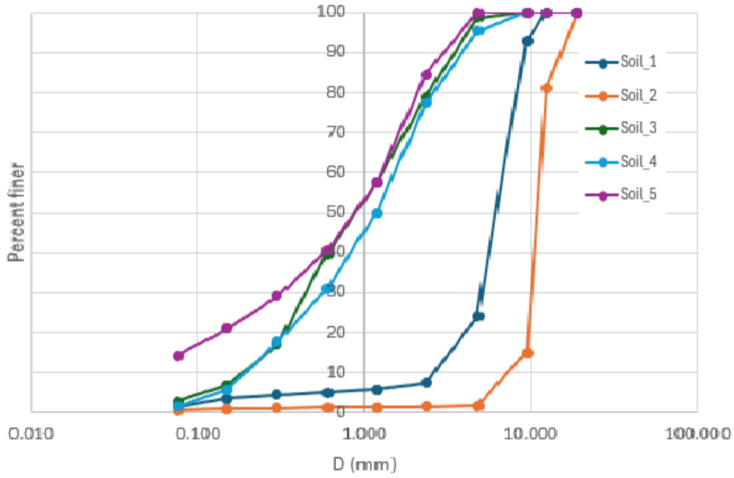

Fig.1. Gradations of five materials that would be in the mixture.

- Step 2. The ratios of the total absolute differences for each soil to the total of all differences will be calculated as follows:
  Soil 1: 176/834.2 = 0.211
  Soil 2: 290.2/834.2 = 0.348
  Soil 3: 117/834.2 = 0.140
  Soil 4: 99.1/834.2 = 0.119
  Soil 5: 151.9/834.2 = 0.182

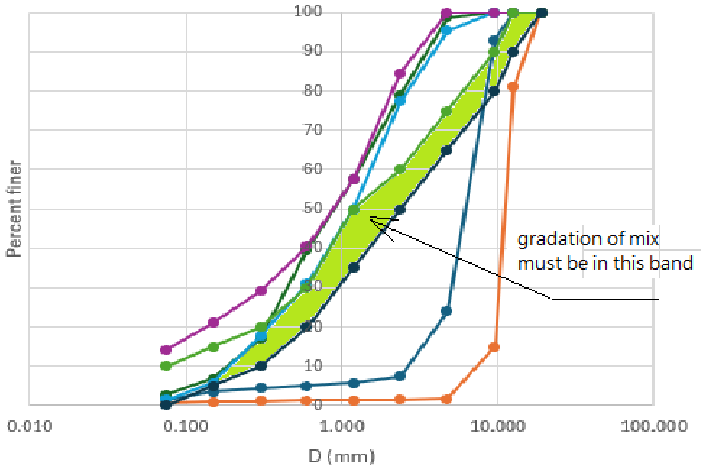

Fig. 2. The zone of gradation of the mixture

Table 2. Selected gradation and its difference with 5-soil gradations

Upper Border	Lower Border	Selected Mix - MS	MS-Soil 1	MS-Soil 2	MS-Soil 3	MS-Soil 4	MS-Soil 5
100	100	100	0	0	0	0	0
100	90	95	-5	14	-5	-5	-5
90	80	85	-8	70	-15	-15	-15
75	65	70	46	68.3	-28.7	-25.3	-30
60	50	50	42.5	48.5	-29	-27.4	-34.5
50	35	40	34.2	38.6	-17.4	-10	-17.4
30	20	25	19.9	23.7	-14.7	-6	-15.5
20	10	15	10.5	13.8	-1.9	-2.7	-14.2
15	5	10	6.5	9	3.1	4.3	-11.1
10	0	5	3.4	4.3	2.2	3.4	-9.2

Table 2 continued

Vector DD= Total absolute differences =	176	290.2	117	99.1	151.9
DT, Total of all absolute differences =	834.2				
Ratios, Vector PR	0.211	0.348	0.140	0.119	0.182
Sum of the ratios	1.00				

*Summation of these ratios must be equal to 1. (0.211+0.348+0.140+0.119+0.182)= 1.00 OK.

- Step 3. The final percentages of the soils that would be in the mixture can be determined as follows:
  a. The smallest ratio among the calculated values (in this example, it is 0.119) is taken the percentage of soil that has the largest sum of absolute differences (in this example it is 290.2-Soil 2). Thus, the percent of Soil 2 in the mixture will be 11.9%.
  b. The largest ratio among the calculated values (in this example, it is 0.348) is taken the percentage of soil that has the smallest sum of absolute differences (in this example it is 99.1-Soil 4). Thus, the percent of Soil 4 in the mixture will be 34.8%
  c. Then, the second largest value of the ratios (in this example, it is 0.211) is taken the percentage of second smaller sum of the absolute differences (it is 117-Soil 3 in this example). Thus, the percent of Soil 3 in the mixture will be 21.1%.

By the same procedure, the percentages of Soil 1, and Soil 5 would be 14,0%, and 18.2%, respectively. The calculated percentages of each soil and the final gradation of the mixture are seen in Table 3.

Table 3. Percentages of the soils in the mixture and the final mixture gradation

% of Soil 1	% of Soil 2	% of Soil 3	% of Soil 4	% of Soil 5	MF Final Mix
14.03	11.88	21.10	34.79	18.21	100.00
14.03	9.62	21.10	34.79	18.21	97.74
13.04	1.78	21.10	34.79	18.21	88.92
3.37	0.20	20.82	33.15	18.21	75.75
1.05	0.18	16.67	26.93	15.39	60.21
0.81	0.17	12.11	17.39	10.45	40.94
0.72	0.15	8.38	10.78	7.37	27.40
0.63	0.14	3.57	6.16	5.32	15.81
0.49	0.12	1.46	1.98	3.84	7.89
0.22	0.08	0.59	0.56	2.59	4.04

It should be shown graphically that the gradation of final mixture takes place within the zone as seen in Fig.3.

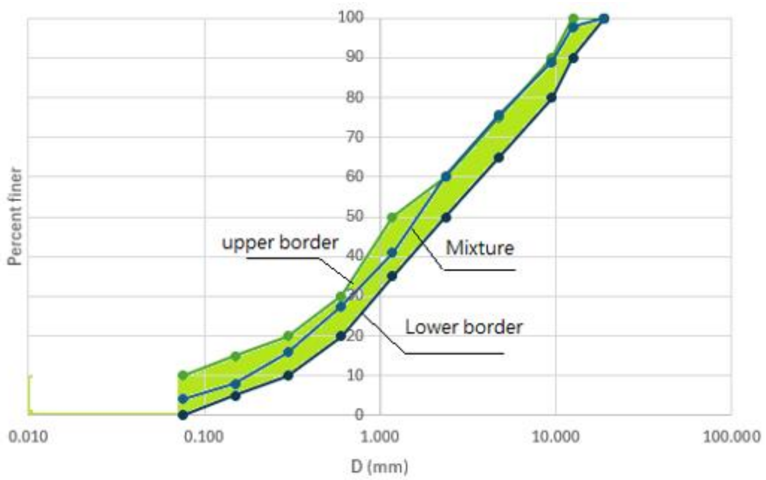

Fig. 3. Designed gradation of the mixture within the borders by blending five materials

Example 2: Estimate the plasticity index, PI, and the liquid limit, LL, of the mixture designed in Example 1 if the PI and LL values of each materials are given as seen Table 4. Estimate the PI, and LL values of the mixture.

Table 4. Plastic properties of the materials used in Example 1.

Materials (Soils)	Plasticity Index, PI	Liquid Limit, LL
Soil 1	3	15
Soil 2	2	10
Soil 3	7	30
Soil 4	8	25
Soil 5	11	31

Solution: As seen in Table 5, the data of the columns from 1 to 3 are readily available. The data of column #4 are taken from Table 3, and column #5 is filled by the data taken from Fig. 1. Column #6 is filled by (column #4 * column #5). Column #7 is filled by (column #6 * 25,25 which is total amount of materials' portions passing No.40 sieve) / 100. Finally, estimated values of the PI ((3×2.78 + 2×0.94 + 7×31.75 + 8×38.57 + 11×25.96)/100 = 8.27) and LL ((15×2.78 + 10×0.94 + 30×31.75 + 25×38.57 + 31×25.96)/100 = 27.73) of the mixture will be calculated.

Table 5. Estimation of the Plasticity Index and Liquid Limit of the mixture in Example 1.

Materials (Soils)	PI	LL	Amount (kg) of each soil in 100kg mix Table 3	% passing No.40 sieve Fig 1	Amount (kg) of each soil passing No.40 in 100kg mixture	% of each soil passing No.40 sieve in mix
Soil 1	3	15	14.03	5	0.70	2.78
Soil 2	2	10	11.88	2	0.24	0.94
Soil 3	7	30	21.10	38	8.02	31.75
Soil 4	8	25	34.79	28	9.74	38.57
Soil 5	11	31	18.21	36	6.56	25.96
Mixture	8.27	27.73	100.0	---	25.25	100.00

In this study, MS-Excel spread sheet has been employed to show readers the details of the calculations. Actually, a MATLAB code might be prepared to get the results only when there is no need to details of the calculations and the procedure.

5. Conclusions

The conclusions drawn from this investigation can be summarized as follows. Once the available methods to set up a specified gradation of mixtures have been evaluated. It is seen that these methos are okay to be employed in the mix design processes but they have several deficiencies like a trial and error approach is used. This might be ended a subjective results and time consuming for the design stages. In this study, it is shown that there is a new approach by which engineers can design the gradation of the mixtures by a more rational method that is proposed and explained with two examples in this study.

The impact of big data and artificial intelligence on public transportation optimization

Tolga Avci*[1], Ilgin Gokasar[1]

[1] Bogazici University, Department of Civil Engineering, 34342 Istanbul, Türkiye

Abstract. With the rapid development of big data and artificial intelligence, the promising applications have widely and profoundly spread to many fields, such as public transportation. This work surrounds the utilization of big data analytics and artificial intelligence-based solutions in enhancing public transit systems. Through a systematic literature examination, the paper presents a new concept and its role in improving cost structure, increasing operational effectiveness, and satisfaction of the user. The findings indicate that the merger of AI technology with big data allows accurate forecasting of demand, determination of routes and supervision, and conditions which leads to a greater transport system optimization.

Keywords: Big data; Artificial intelligence; Public transportation

1. Introduction

Public transportation infrastructures serve as the engine of urban mobility, facilitating the movement of millions of individuals daily. Still, they also greatly influence the way cities run. This system is essential since it influences commuter behavior, economic activity, and social contacts. Although some would argue that private cars are handier, the benefits of public transportation overall cannot be emphasized. Maintaining and upgrading this infrastructure becomes more crucial, yet as cities develop. Demand for fast, economically priced, environmentally friendly transportation choices rises along with the population living in metropolitan megacities. Public transportation systems do, however, have significant issues even given their significance. These are in the form of schedule, routing, and capacity utilization inefficiencies; traffic congestion during peak travel hours; environmental issues related to high carbon emissions, and increasing passenger needs, which can result in vehicles being very crowded. Conventional approaches to the problem of public transportation are not sufficient enough to justify solutions to these problems. Such methods, although they are quite effective, are indeed becoming more and more ineffective in the context of a dynamic world in which real-time reactions to the situation change are necessary. Big Data is defined as a large amount of data originating from various sources such as ticketing systems, mobile applications, GPSs, social networks, and IoT sensors. The sheer volume, variety, and velocity of this data offer and pose a challenge. If well managed and leveraged, big data has the potential to reveal patterns and insights that can better influence decision-making, operational efficiency, and passenger experience. In public transport, even a lot of potentially different data sources may be considered big data sources, including real-time GPS-based one-commercial vehicle location data, passenger behavior data, supplied by mobile applications, and environmental data collected from IoT devices installed in the transport facility. In contrast, natural intelligence comprises a wide concept of machinery to mimic human intelligence. Concrete examples of machine learning, deep learning, natural language processing, and reinforcement learning. AI can analyze huge data sets efficiently and extremely rapidly, can reveal underlying patterns, and can generate predictions that are impossible to derive manually for humans. Artificial intelligence offers public transportation various advantages, including predictive maintenance and dynamic route optimization as well as other optimization tasks. Paris Metro, for example, has used an artificial intelligence-based predictive maintenance system to boost operational efficiency; the London Underground employs big data analytics to identify areas of congestion and hence improve dependability. Tokyo Metro has also embraced demand forecast artificial intelligence models to maximize passenger flow; in Barcelona, the public transportation system uses deep learning methods to process both past and present data, therefore guaranteeing improved service adaption and efficiency. For now, these real-life applications have been provided in a general manner, but it is possible to find detailed explanations in the later sections of the paper. Integration of big data with AI is one of the most important forces causing the transformation of public transportation systems. These types of technologies enable data-driven decisions, real-time control, and dynamic management. For

https://doi.org/10.31462/icearc2025_ce_tra_870

example, by employing predictive analytics, the demands can be forecasted. The resources can be optimally allocated and disruptions can be more effectively dealt with and responded to by transit agencies. Furthermore, AI-powered systems have a promise to improve customers´ satisfaction by providing more customized suggestions, and by facilitating safer routes with less time at their execution. This paper explores the potential use of big data and AI in optimizing public transport systems and provides an overview of their possible advantages and challenges. This work will highlight the role of data size and artificial intelligence technologies in demand forecasting, route optimization, and improving operational efficiency, drawing on case studies and current literature analysis. Additionally, we will explore the technological, ethical, and infrastructure challenges that come with integrating these technologies into effective transportation systems. The structure of the work is laid out like this: Section 2 explores the various techniques of artificial intelligence that are applied in public transportation, along with the data sources that support them.

Demand prediction approaches are discussed in Section 3 and the approaches used in the AI methods for the demand prediction of passenger demand and how the prediction model can contribute to system efficiency. In Section 4, route and scheduling optimization is addressed, where AI and big data serve as the foundation for dynamic routing and adaptive scheduling. Section 5 discusses the challenges of using big data and AI technology for transit systems, and addresses the possible ways to overcome these challenges. The conclusion reports the results and discusses the direction of future research in this dynamic area.

2. Data sources and AI methodologies

The sources of big data used for common supervision and optimization in public transportation include GPS through its acquisition managers, as well as smart ticketing systems that provide valuable insights. A few devices track the real-time location, speed, and status of public transport vehicles to improve fleet management. Mobile applications provide huge data on users' preferences, ticketing, and traveling behavior, which help in understanding the demand of passengers. Social media sites like X (or formerly, Twitter) and Facebook offer a wealth of information on the public's mood, troubles, and activities that could impact transportation systems. Some of the data that can be easily obtained include passenger counts, travel paths, and peak hours from the ticketing systems which help in making sound demand estimates. The AI approaches used in this area are also as varied as supervised learning for predictive analytics and reinforcement learning for adaptive control systems. For example, neural networks are very effective in demand forecasting while genetic algorithms (The genetic algorithm is a method for solving both constrained and unconstrained optimization problems that is based on natural selection) have been efficient in solving the complex transit network design problem.

Some of the applications of AI are predictive analytics where machine learning models are used to forecast future trends of transit; optimization techniques like linear programming and meta-heuristic (metaheuristic is a higher level procedure or heuristic designed to find, generate, or select a lower level procedure or heuristic (partial search algorithm) that may provide a sufficiently good solution for an optimization problem.) for improving resource management and scheduling; real-time data analysis applied via stream processing systems for decision-making. Using artificial intelligence (AI) and the Internet of Things (IoT), a case study offers a strategy for maximizing energy demand in metropolitan systems. For dynamic energy demand prediction, it employs real-time data from IoT sensors applying machine learning methods such as Random Forests and Neural Networks. Metro operators can thus instantly change energy use, hence increasing efficiency and lowering waste. Using Paris Metro system data, the method was tested; simulations revealed notable energy savings, especially concerning regenerative braking systems (Rziki et al., 2025) and another case study (the London Underground) shows some valuable insights as follows: The London Underground implemented a remote condition monitoring system on the Victoria Line to enhance reliability for 200 million annual passengers. The Underground may now remotely monitor track circuit conditions in real-time by using variable length frequency-driven tuned electrical track circuits and the NI CompactRIO system. By allowing maintenance workers to forecast and stop equipment breakdowns, this proactive method guarantees the least disturbance. With anticipatory alarms provided to operators, the system monitors and analyzes track circuits using over 7,000 data samples every second. This has cut maintenance expenses and greatly increased system efficiency (Etchell et al., 2025).

3. Demand prediction

Effective planning depends on knowing the expected demand ahead of time for public transportation authorities to properly allocate services, lower expenses, and raise passenger satisfaction. For demand forecasting, several techniques (time-series analysis, regression models, and more lately deep learning) have value depending on the availability of certain auxiliary tools. Short-term demand forecasting benefits especially from time-series analysis since it allows one to recognize trends, seasonal fluctuations, and cyclical patterns in past rider data. Patterns from the previous week, the month, or the previous day (simply, any past time) can be analyzed to predict demand with a relatively high accuracy, especially in transit modes, where movement patterns do not escape the predictability. The models are particularly helpful for planning on a daily and weekly level (e.g., rush hours, holidays).

On the other end, for more complex and timely forecasting, deep neural networks. Neural networks, or deep learning models are inherently capable of featuring the dynamic non-linear relationships among multiple covariates features (weather, public events, socio-economic variables, and so on.) that might be influencing passenger movement behavior. These represent approaches that potentially can synthesize data from a variety of sources - for example, real-time ticketing data, GPS information from buses and subways, and social media produce more precise and finely grained predictions of travel demand at different times of day and places. Through consideration of the interaction among various contributors, DNNs (Deep neural networks) provide large improvements in learning about optimal demand peaks, which can guide adaptive changes over time for transit agencies on how to offer their services. Moreover, hybrid models that combine traditional statistical methods with machine learning algorithms or ensemble approaches will enhance the reliability and precision of demand forecasting tools. These hybrid models combine both long-term and current information and therefore can adapt to dynamic environments.

In many fields, demand prediction has practical applications, in the area of public transit management, for instance, dynamic pricing and supply planning are perhaps the most consequential. In dynamic pricing, the fare scheme is made to change in real-time according to the forecast of the demand to enhance off-peak travel and avoid congestion during peak travel periods. For example, travel fares could be lower when the need for transportation is minimal and higher when the usage of transportation is intense, to achieve demand balance and efficient use of transportation resources. This can, moreover, be used as a stimulus to passengers to change travel times and thus relieve overloaded lines so it is possible to increase the efficiency of the system as a whole. Accurate demand forecasting also enables more optimum capacity planning, where the availability of resources such as buses, trains, and drivers is provisioned based on expected peak-hour demand.

Many instances of practical uses shed light on the effects demand prediction driven by artificial intelligence has on public transportation. For instance, a case study on Tokyo Metro offers a simulation model meant to lower passenger congestion and delays during Tokyo Metropolitan Area rush hour. It models train travel times by using daily ticket gate data and on-site inspections, therefore accounting for unplanned events like passenger crowding onto trains. The model shows how demand fluctuations and schedule changes affect travel time and provides ideas for lowering delays. The model showed notable travel time savings during peak hours by modeling several demand scenarios; recommendations for staggered commuting help to further ease congestion (Adachi et al., 2019))

With a target toward lowering congestion and carbon emissions, sustainable mobility projects in Barcelona have greatly enhanced urban transportation. By including real-time data in its public transportation system, the city guarantees correct bus and train schedules; therefore, boosting public transportation usage by 15%. With 6,000 bikes spread across 420 stations, Barcelona's bike-sharing program Biking facilitates 14 million rides yearly, therefore reducing congestion and pollution. Along with incentives like free parking and low-emission zone access, the spread of more than 500 electric vehicle charging stations supports greener transportation and lowers air pollution (Inam, 2024).

4. Route and scheduling optimization

Route and schedule optimization is an important aspect of lowering operating costs and improving passenger experience. AI-driven approaches offer dynamic and flexible solutions. High-tech methods include genetic algorithms, which mimic an evolutionary process to find the best-suited routes taking also into account the constraints of the traffic and the number of passengers, and reinforcement learning, which trains AI agents to update schedules in real-time, based on the interaction with a dynamic transit system, to achieve the highest possible effectiveness under evolving situations. Clustering algorithms are used to partition passenger information into groups according to similar origins and destinations, which allows the optimization of routes to reduce travel time.

Public transportation applications range from dynamic route planning, performed by AI algorithms wherein AI processes override current traffic patterns and demand fluctuations to optimize travel, to Just-in-Time optimization, where the machine learning models reason the optimal departure time delays to reduce passengers queuing times and facilitate those passengers will best utilize the traveling bus, car or train. The Smart Nation Initiative of Singapore is a success tale since it expanded and maximized dynamic bus lines using artificial intelligence. By combining several forms of transportation (buses, trains, bicycles, and ride-sharing services) into a multi-modal network, Singapore has achieved great strides toward public transportation system optimization. This integration lessens transportation congestion, improves accessibility, and lessens environmental impact. Among important projects include the use of real-time data analytics to enhance bus frequencies and schedules, hence increasing on-time performance. Additionally, the city has instituted a vibrant, on-demand bus system whereby users may schedule pick-ups via a smartphone app. These developments show Singapore's will to design a data-driven, sustainable urban mobility system fit for smart city objectives (Chadalawada, R. (2022).

5. Challenges and future considerations in ai-driven public transport and possible ways to overcome these challenges

Still, obstacles exist. Data quality is still a big problem since inadequate or biased datasets could make AI models useless. Particularly concerning the gathering and processing of passenger data, privacy issues call for strong data governance systems and ethical AI values adherence. The deployment of these technologies is also hampered by infrastructure constraints, mainly in areas where public transport is underfunded or obsolete. Breakthroughs in addressing these challenges are best achieved through a multifaceted policy that includes investments in infrastructure, the creation of ethical guidelines, and standardization of data interfaces to enable interoperability among systems.

The paper further identifies the community-private partnership in facilitating faster evolution of technologies and making them sustainable in the process of implementation. Joint work between governments, technology suppliers, and academics can promote innovation, bring down costs, and allow that which is proven to be viable pilot projects to be expanded to general transit systems. Like predictive maintenance on Shanghai Metro Lines and deep learning for capacity optimization at Barcelona, both of which are instances of artificial intelligence producing major innovation if sufficiently funded and supported with experience.

Future studies should concentrate on building transparent, inclusive, scalable artificial intelligence systems. These systems cannot only take into consideration the complexities of urban mobility, but they must also guarantee the accessibility of services to different groups. Further, investigations of hybrid models involving combinations of conventional transportation planning approaches and AI-driven analysis techniques could provide a hybrid solution to the tradeoff between reliability and efficiency.

6. Conclusions

The disruptive capacity of big data and artificial intelligence (AI) in public transportation is becoming more obvious. Through the use of large data sets and state-of-the-art algorithms, transportation systems around the world are now beginning to address legacy problems, such as lack of efficiency, uncertainty in demand changes, and environmental issues. The combination of these technologies makes it possible to do precise demand forecasting, efficient routing, and real-time tracking, all of which lead to operational excellence and better user experience.

A comprehensive review of the literature highlights the significance of data sources such as GPS, IoT devices, ticketing systems, and mobile applications, which provide the foundational inputs for AI algorithms. Complex models able to forecast passenger demand, optimize routes, and dynamically update schedules can be produced using deep learning, genetic algorithms, reinforcement learning, and other artificial intelligence approaches. Case studies (Singapore, Madrid, Tokyo, London, Barcelona) let one realize improvements in passenger experience, traffic performance, and transport efficiency.

Ultimately, the combination of artificial intelligence and large data marks a public transportation framework change. Though the road to completely ideal and, finally sustainable transportation systems is still under development, the knowledge gained from past application and research projects lays a firm foundation for the next developments. Through the remediation of current issues and synergies between stakeholder groups, these technologies can be used to develop smarter, greener, and more resilient transport networks that serve the needs of an urbanizing world.

Rheological characterization of BARC-modified asphalt binder via frequency sweep testing

Merve Gülfer Bozdemir*[1], Hacer Yeşilçiçek[2], Şeref Oruç[3]

1 Erzurum Technical University, Department of Civil Engineering, 25050 Erzurum, Turkey
2 Karadeniz Technical University, Faculty of Of Technology, 61830 Trabzon, Turkey
3 Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Turkey

Abstract. Asphalt binders are widely used in road pavements due to their favorable physical and rheological properties. However, increasing traffic volumes and loads, climatic factors, and production defects negatively affect the performance of asphalt pavements. These issues lead to a reduction in service life and a rise in maintenance and repair costs. In this context, polymer additives have been utilized in recent years to improve the rheological properties of asphalt. Nevertheless, the high cost and environmental concerns associated with these additives have highlighted the need for sustainable and cost-effective alternatives. This study investigates the rheological effects of a bio-based additive called Boron Added Rosin Compound (BARC), developed using naturally occurring colophony resin and locally sourced boron oxide. For this purpose, BARC was incorporated into a base binder at concentrations of 0.5%, 1%, and 1.5% by weight. Unaged base and modified binders were tested within a temperature range of 40–70 °C and a frequency range of 0.1–100 rad/s. Master curves were constructed at a reference temperature of 40 °C using the complex modulus (G*) and phase angle (δ) data obtained from frequency sweep tests. The results indicated that the binder containing 1.5% BARC exhibited the highest G* values at low frequencies. Additionally, modified binders demonstrated lower phase angles, indicating more elastic behavior, and showed greater stability with increasing temperature compared to the unmodified binder. These findings suggest that the BARC additive enhances the elasticity of asphalt binders and improves their resistance to rutting.

Keywords: Asphalt binder; Bio-based additive; Boron oxide; Colophony resin; Rheological properties; Frequency sweep.

1. Introduction

The majority of road pavements worldwide are constructed using asphalt binders, which are utilized in various forms due to their physical and rheological properties (J. Zhu, 2014). In recent years, increased traffic loads driven by economic growth and rising living standards, along with environmental and climatic influences and construction-related deficiencies, have negatively affected asphalt pavement performance (H. Wang, 2010; J. Baek, 2010). These deteriorations reduce the service life and ride quality of highways and necessitate earlier-than-planned maintenance and repair interventions, thereby increasing overall costs. Particularly under the influence of growing traffic volumes, asphalt pavements experience various types of distress, such as rutting, fatigue, and cracking at different temperature conditions. To mitigate these forms of deterioration and improve the overall performance of asphalt pavements, various additives are incorporated into asphalt binders through modification techniques (Geçkil, 2008; Arabani et al., 2010; Yıldırım, 2014). A wide range of materials have been utilized for this purpose, including different types of polymers (Yılmaz et al., 2013; Sengoz & Işıkyakar, 2008; Liang et al., 2015; Adeboje et al., 2020), nanomaterials and nanocomposites (Yao et al., 2015; Yusoff et al.,2014; Zhou et al., 2021), bio-based materials (Portugal et al., 2017; Rahman et al., 2014), and waste-derived materials (Gürü et al., 2014;Kumar et al.2018). These modifiers aim to enhance the durability, mechanical performance, and environmental sustainability of asphalt mixtures under varying service conditions.

In modification studies, polymer-based additives are widely used. However, due to their high cost, the requirement for specialized mixing facilities, and their potential to cause environmental pollution, there is a growing need to develop alternative additives that are cost-effective, environmentally friendly, and capable of enhancing asphalt pavement performance. With increasing environmental concerns, the investigation of bio-based

*Corresponding author, E-mail: merve.ozcan@erzurum.edu.tr

https://doi.org/10.31462/icearc2025_ce_tra_875

and biodegradable polymers (molecules) has gained significance, aiming to expand the palette of renewable polymers used in asphalt modification.

Colophony resin, a type of pine resin, has emerged as a suitable renewable modifier due to its chemical compatibility with asphalt binders. Studies have reported that binders modified with resin and resin-based materials exhibit improved resistance to rutting and moisture damage compared to conventional binders, and that resins enhance the flexibility of the binder structure (Yao, 2013).

Boron and its derivatives, which are abundantly available in our country and considered a valuable national resource, are utilized across various industries. Studies on asphalt modification have also indicated that boron can enhance the properties of asphalt binders (Yılmaz, 2016). However, for effective use in asphalt modification, boron must be synthesized with another compatible material before being incorporated into the binder. In this context, a novel modification additive containing bio-based boron and colophony resin has been developed in the laboratory and is referred to as BARC. The objective of this study is to investigate the viscoelastic behavior of asphalt binders modified with BARC through frequency sweep analyses.

2. Materials and method

2.1. Materials

In this study, PG 64-16 asphalt cement (penetration grade 50/70) obtained from the Turkish Petroleum Refinery (Izmit) was used. To determine the properties of the neat asphalt binder, conventional tests listed in Table 1 were conducted.

Table 1. The physical properties of the pure asphalt binder.

Specifications	Value	Standard
Penetration (25 °C, dmm)	56	ASTM D5/D5M-13
Softing point (°C)	50	ASTM D36/D36M-14
Ductility (25 °C, cm)	100 +	ASTM D113-17
Flash point (°C)	249	ASTM D92-18
Specific gravity (g/cm3)	1.028	ASTM D70M-21
Viscosity (135 °C, cP)	500	ASTM D4402M-15
Viscosity (165 °C, cP)	100	ASTM D4402M-15

The BARC additive, possessing the desired consistency and homogeneity, was synthesized in the laboratory through the reaction of boron oxide and colophony resin. The resulting additive is dark in color and solid at room temperature. This synthesized additive can be produced industrially through a relatively short manufacturing process. The general appearance of the boron oxide and resin compound (BARC) synthesized additive is shown in Fig. 1.

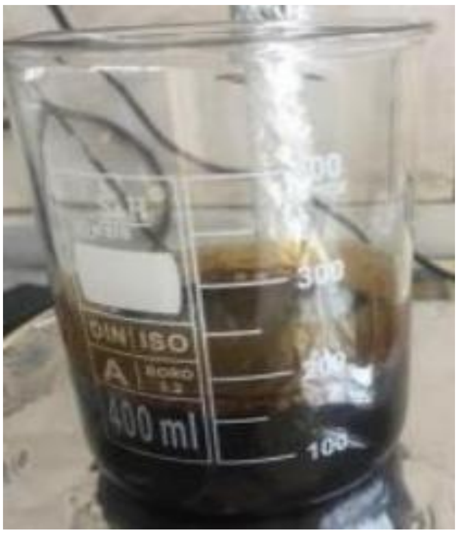

Fig. 1. General Appearance of the Additive

2.1.1. Preparation of modified asphalt binders

According to the 1000 g weight of the pure asphalt binder, synthesized additive was added separately at rates of 0.5%, 1%, 1.5%, and 3% by weight into mixing containers. The modified binders were prepared using a high shear mixer at 150 ± 5 °C and 2000 rpm for 30 minutes. The binders used in this study and their corresponding designations are presented in Table 2.

Table 2. Symbols of Binders Used in the Experiments

Additive (BARC) Content	Symbols
50/70 Asphalt binder	BA
50/70 Asphalt binder + % 0.5 BARC	BA0.5
50/70 Asphalt binder + % 1.0 BARC	BA1.0
50/70 Asphalt binder + % 1.5 BARC	BA1.5
50/70 Asphalt binder + % 3.0 BARC	BA3.0

2.2. Methods

2.2.1. Frequency sweep test

Frequency sweep tests were conducted on pure and modified asphalt binders using a Malvern DSR+ rheometer. The tests were performed at temperature intervals of 5 °C between 10 °C and 30 °C, and 10 °C intervals between 40 °C and 70 °C.

At lower temperatures (10–30 °C), an 8 mm parallel plate with a 2 mm gap was used, while at higher temperatures (40–70 °C), a 25 mm parallel plate with a 1 mm gap was employed (Airey G. D., 2002). The tests were carried out within the linear viscoelastic (LVE) region of the binder using a constant strain level of 0.01%. The frequency range was set between 0.1 and 100 rad/s.

The obtained complex modulus (G*) and phase angle (δ) data were horizontally shifted to a reference temperature of 40 °C using the time-temperature superposition principle (TTSP) with the assistance of the Malvern DSR+ software. As a result, master curves were generated, representing the viscoelastic behavior of the binders over an extended frequency range.

3. Results

Fig. 2 presents the master curves of the complex modulus values for pure and modified binders at the reference temperature of 40 °C. As the frequency (loading rate) increases, the complex modulus values also increase. As shown in the figure, the pure binder exhibits the lowest complex modulus values across the entire frequency range.

At low frequencies, the highest G* values are observed for the binders modified with 3% additive, whereas at high frequencies, all modified binders exhibit similar G* values. The influence of the additive is more pronounced at low frequencies compared to the pure binder, while this effect diminishes as the frequency increases. Among the binders, the one with 1% additive shows the lowest G* values after the pure binder at low frequencies. At high frequencies, the modified binders demonstrate comparable performance.

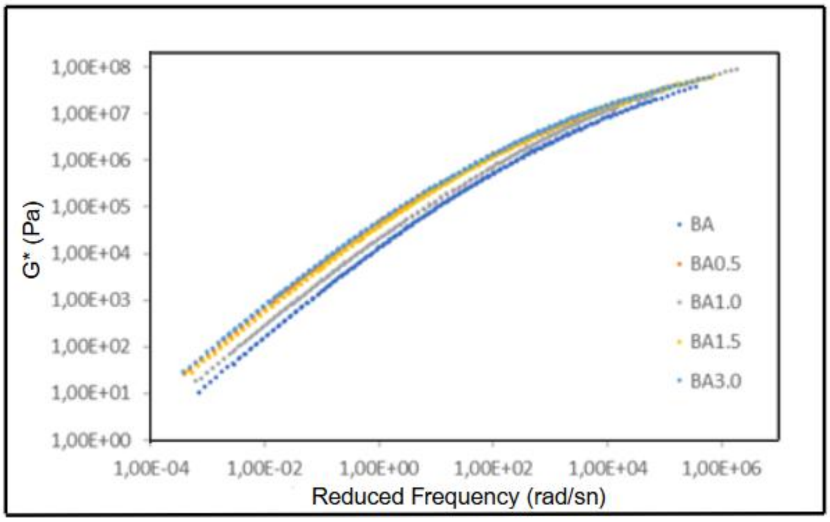

Fig.2. The master curves of G* at a reference temperature of 40 °C for pure and modified binders

Fig. 3 illustrates the variation of phase angle with frequency for pure and modified binders. As seen in the figure, at low frequencies (10^{-3} rad/s), all binders exhibit similar phase angle values. However, beyond a frequency of 0.01 rad/s, the phase angle of the modified binders decreases more significantly compared to the pure binder, indicating a transition toward more elastic behavior.

Among the modified binders, those containing BA0.5 and BA3.0 additives show lower phase angle values. At higher frequencies, the phase angles of the B0.5, BA1.5, and BA3.0 modified binders tend to converge, indicating similar viscoelastic characteristics.

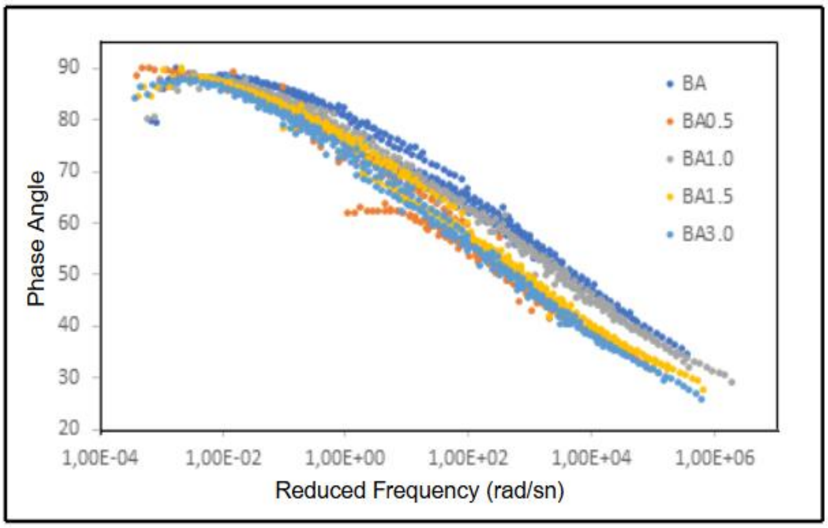

Fig.3. The master curves of phase angle at a reference temperature of 40 °C for pure and modified binders

Fig. 4 presents the changes in elastic and viscous moduli (Cole-Cole diagram) for unmodified and modified binders. As seen in the figure, at low frequencies, the elastic and viscous moduli of both unmodified and modified binders are similar. However, as the frequency increases, the modified binders shift toward the elastic modulus axis, indicating a more elastic behavior.

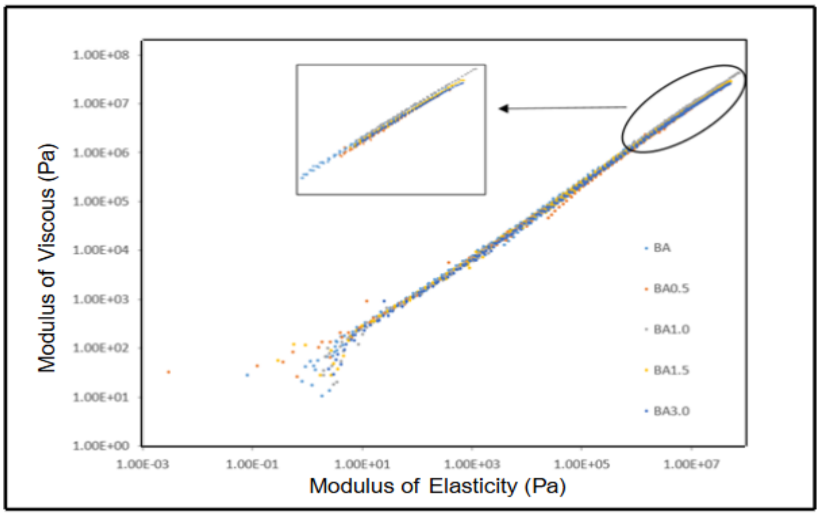

Fig.4. Cole-Cole diagram

4. Conclusions

The BARC additive was produced in a laboratory environment and used for asphalt modification. The rheological behavior of the additive on conventional asphalt binder was investigated, and the findings are summarized below:

- Under low-frequency (high temperature) and high-frequency (low temperature) conditions, the asphalt binder modified with 3% BARC exhibited increased complex modulus values and decreased phase angle values, indicating enhanced elastic behavior of the binder.
- According to the Cole-Cole diagram, the modified binders exhibited a noticeable shift toward the elastic modulus axis, suggesting that the additive contributed to an enhancement in the elastic behavior of the conventional binder.

Comparison of terrain modeling approaches: evaluating software performance in infrastructure projects

Kadir Akgol*[1], Omer Faruk Ozturk[1], Yelda Nur Kara[1]

[1] *Giresun University, Department of Civil Engineering, 28200 Giresun, Türkiye*

Abstract. In highway and various infrastructure projects, terrain models play a crucial role in shaping key stages such as planning, design, and cost estimation. These models are typically generated from x, y, and z coordinate data collected from field surveys and processed using different software tools and modeling techniques. However, ensuring that these models accurately represent real-world terrain conditions often requires expert adjustments, particularly when using automated triangulation or interpolation methods. This study investigates the accuracy and reliability of terrain models generated by two widely used software environments, NetCAD and MATLAB, based on the same reference dataset collected from a complex terrain in Gümüşhane Province, Turkey. The initial triangulated model created in NetCAD exhibited notable discrepancies, which were corrected through expert intervention. In contrast, MATLAB applied various interpolation methods, including Natural Neighbor, Linear, and V4 (biharmonic spline), to produce grid-based terrain models. These models were then compared to the expert-adjusted reference model to assess their performance. The findings reveal that while Natural Neighbor interpolation in MATLAB produced results closer to the reference terrain, even this method showed minor deviations. Moreover, significant differences emerged among interpolation techniques, emphasizing that the choice of modeling method greatly affects terrain representation accuracy. This study underscores the limitations of automated modeling processes and highlights the need for advanced approaches, such as machine learning-based methods, to minimize the need for manual corrections. The results demonstrate the importance of software selection and modeling strategies in achieving accurate terrain models, which are essential for reducing risks and improving decision-making in engineering projects.

Keywords: Terrain modeling; Infrastructure projects; Highway design; Triangulation; Accuracy assessment.

1. Introduction

Terrain modeling processes have critical importance in highway engineering and infrastructure projects in general. A Digital Terrain Model (DTM) is typically established at the initial stage of a project and forms the basis for all subsequent design and engineering calculations (Gigović, 2010). DTM data is utilized in fundamental engineering design phases, including determining the optimal road alignment, generating longitudinal and cross-sectional profiles, and calculating excavation and fill volumes. As each of these steps directly depends on the accuracy of the terrain model, creating an accurate and reliable DTM is crucial for the project's overall success.

Each of these design stages directly relies on the accuracy of the terrain model. If the DTM contains inaccuracies, significant engineering errors may occur, ranging from incorrect route selection to erroneous volume calculations. Indeed, obtaining a precise and reliable terrain model is essential for both the safety and cost-effectiveness of a project (Kaźmierczak, 2013). Having a high-accuracy DTM during the early design phase enables engineers to clearly visualize existing terrain conditions, thereby facilitating safer and more efficient infrastructure designs (Sun et al., 2015).

In the literature, various methods have been developed for terrain modeling in infrastructure projects. The most common approach is the Triangulated Irregular Network (TIN) model, which aims to create surfaces from irregularly distributed points. In this model, scattered X, Y, Z point clouds collected from terrain surveys are interconnected through triangles to define the surface geometry (Thekdi & Lambert, 2012). During the triangulation process, the Delaunay triangulation algorithm is commonly employed, as it enforces the condition that no data points should fall within the circumcircle of any triangle formed. This constraint results in triangles with relatively uniform angles (close to equilateral), thereby preventing the formation of long, thin ("sliver") triangles and significantly improving the representation accuracy of the model (Ma et al., 2015). Delaunay-based TIN models are frequently preferred in digital terrain modeling because they realistically represent abrupt changes

* Corresponding author, E-mail: kadir.akgol@giresun.edu.tr

https://doi.org/10.31462/icearc2025_ce_tra_878

golden light publishing

in slopes and fault lines. Common engineering software like NetCAD typically utilizes TIN/Delaunay triangulation as the default method for terrain modeling (Kidner et al., 2000; Yomralıoğlu, 2005). This method offers distinct advantages, especially in handling irregularly distributed measurement points and effectively representing terrain surfaces with varying levels of detail.

However, several limitations of the triangulation method have been emphasized in the literature. In scenarios involving irregular or sparse data distributions, or complex terrain morphologies, automatically generated TIN models may include incorrectly connected triangles. Specifically, improperly positioned, elongated triangles connecting distant points on the surface may create artificial ridges or depressions, which do not exist in reality. Such inaccuracies can lead to significant errors in engineering calculations, necessitating manual intervention and correction by experts (Zhu et al., 2008). Indeed, some studies have highlighted the unreliability of the initial terrain models automatically generated by software, requiring engineers to manually adjust the triangulation networks to align models with actual terrain conditions (Yeu et al., 2006). These issues indicate that existing commercial software packages may not fully meet expectations for automatic terrain modeling processes, highlighting the necessity of careful consideration before applying their results directly in projects (Darnell et al., 2010). For instance, within NetCAD software, users are advised to set parameters such as minimum and maximum edge lengths during triangulation to prevent the formation of defective triangles (Ren & Liu, 2013). Such precautions aim to minimize triangulation errors during the modeling process.

Alternatively, grid-based modeling and interpolation methods are widely used for terrain modeling purposes (Garnero & Godone, 2014). In this approach, the study area is divided into a regular grid structure at specified intervals, and the elevation value at each grid node is estimated from surrounding measured points through interpolation techniques. Continuous surfaces are generated by calculating elevation values on grid points using various interpolation methods, such as Inverse Distance Weighted (IDW), Kriging, and Natural Neighbor interpolation (Gaffar et al., 2018).

In the literature, several studies have compared the performance and accuracy of different interpolation methods. For instance, in one comparative study, five distinct methods—including IDW, Kriging, and Delaunay triangulation—were applied to the same terrain dataset (Üstüntaş, 2006). The study concluded that Delaunay triangulation generally provides the optimal balance between computational efficiency and accuracy. However, the highest accuracy under certain conditions was achieved by the Kriging interpolation method.

The grid-based approach is particularly preferred for analyses requiring regularly spaced elevation data, such as raster-based hydrological modeling, and offers flexibility in estimating missing data. Programs like MATLAB facilitate the application of these interpolation methods, allowing the generation of a regular grid surface from a set of measured points. For instance, in the MATLAB environment, functions like griddata enable users to create a regularly spaced grid and perform surface interpolation based on point data obtained from software like NetCAD (Gümüş & Şen, 2013). Consequently, it becomes feasible to generate a grid-based terrain model using MATLAB alongside the TIN model created in NetCAD, allowing the comparison of surfaces produced by two different approaches. Indeed, in one practical application, digital terrain data derived from NetCAD was imported into MATLAB, and the surface models produced by both software were evaluated comparatively.

Studies focusing on triangulation errors and discrepancies between different terrain models have revealed significant findings regarding their impact on engineering projects. In particular, deviations in automatically generated models have been shown to cause serious errors in excavation-fill volume calculations and alignment design. As a result, several researchers have conducted comparative analyses of various terrain modeling methods to identify potential inaccuracies inherent in each approach (Liu et al., 2012). However, many of these studies remain limited to specific regions or focus solely on individual methods, leaving a gap in comprehensive evaluations. For instance, only a limited number of studies have directly compared TIN-based and grid-based terrain models against actual field measurements. This gap highlights the continuing need for more reliable terrain modeling in engineering projects.

In conclusion, the appropriate selection of modeling methods and the careful adjustment of model parameters are indispensable for the success of infrastructure projects. Recognizing these challenges, the authors of this study aim to address these gaps in the literature by emphasizing the necessity of accurate terrain modeling. The objective is to comprehensively evaluate the accuracy of terrain models produced by widely used software tools (e.g., NetCAD) and modeling approaches. Specifically, this study compares the TIN-based model generated in NetCAD with the grid-based model produced in MATLAB, using the same real-world terrain dataset. The differences between these models, the sources of potential errors, and their impacts on design processes will be analyzed. In doing so, the study seeks to reveal performance disparities between various terrain modeling methods and to develop recommendations for achieving more reliable results in engineering applications. Ultimately, this research reaffirms the critical role of terrain modeling in infrastructure projects and aims to clearly identify the limitations of current approaches.

2. Methodology

2.1. Selection of reference terrain data for model evaluation

In order to compare the accuracy and performance of terrain modeling methods, it is essential to utilize a reference dataset that has been verified against real-world terrain conditions. For this comparative study, a terrain model located in Alemdar Village, Gümüşhane Province, surrounding a stream bed, was selected as the reference dataset. The primary reason for selecting this area lies in its complex and variable topographic features, which pose significant challenges for accurate terrain modeling. The terrain data, consisting of (X, Y, Z) coordinates, was originally modeled using the triangulation method within the NetCAD software as part of a real-world engineering project.

However, during the course of this project, it was observed that the initial terrain model generated by the software exhibited notable discrepancies from the actual terrain conditions in certain areas. These discrepancies were primarily caused by incorrect triangulation connections formed between inappropriate points on the terrain surface. As a result, manual adjustments were made to the triangulated model by the project team, based on expert judgment, to align the model accurately with the real terrain conditions. This situation clearly highlights the limitations of current commercial software in automatically generating accurate terrain models and underscores the ongoing need for manual intervention.

Consequently, the terrain dataset selected for this study serves as a robust and reliable reference for comparison and analysis due to its validation against actual field conditions and its ability to reflect the potential issues associated with triangulation methods. This ensures that differences between modeling approaches and their potential impacts on engineering projects can be clearly demonstrated.

2.2. NetCAD terrain model

NetCAD is widely used in engineering and surveying projects and offers various methods for terrain modeling processes (Doytsher et al., 2009; Yomralıoğlu, 2005).

2.2.1. Terrain modeling with the triangulation method

For numerical modeling of terrain surfaces, NetCAD typically employs the Triangulated Irregular Network (TIN) approach. In this method, the terrain geometry is digitally defined by forming triangles between irregularly distributed data points with x, y, and z coordinates collected from the field. The triangulation process utilizes the Delaunay triangulation algorithm, which ensures that no other point lies within the circumcircle of any triangle formed. This condition results in triangles with more balanced geometric angles, thereby enhancing the precision of the modeling process.

During Delaunay triangulation, for a given set of data points $P = \{p_1, p_2, \dots, p_n\}$, each triangle is constructed in such a way that no point p_k lies within the circumcircle of any triangle $\Delta(p_i, p_j, p_m)$. This method enables the accurate representation of abrupt slope changes and morphological discontinuities on the terrain surface. Through NetCAD's interface, users can further guide the triangulation algorithm by defining boundary conditions and breaklines specific to the terrain's characteristics.

Nevertheless, although the software provides automated numerical modeling capabilities, it is well-documented that irregular data distributions, varying point densities, and complex morphological features of the terrain can negatively impact the quality of triangulation.

2.2.2. Grid-based modeling and interpolation

An alternative approach to terrain modeling is grid-based methods. In this approach, the study area is divided into a regular grid composed of cells with specified dimensions. The elevation value for each grid cell is estimated through various interpolation techniques, based on the elevation data of surrounding known points.

One of the most commonly used interpolation techniques within this method is the Inverse Distance Weighted (IDW) method. According to this approach, the elevation value z_p of an unknown grid point P is calculated as a weighted average of the elevations from n surrounding known points, as follows:

$$z_p = \frac{\sum_{i=1}^{n} \frac{z_i}{d_i^p}}{\sum_{i=1}^{n} \frac{1}{d_i^p}} \tag{1}$$

In this formula, z_i represents the elevation value of a known point, d_i is the distance between the unknown grid point and the known point, and p is the weighting power parameter, which is typically set to 2. This formulation ensures that points closer to the unknown location have a greater influence on the estimated elevation value.

2.3. MATLAB terrain model
MATLAB typically generates regular grids for terrain modeling and evaluates the obtained GPS data using various interpolation techniques. Among the widely used methods are Natural Neighbor, Linear, and V4 (biharmonic spline) interpolation techniques. Each method offers a different approach for estimating elevation values on the terrain surface and is preferred based on specific use cases (Salekin et al., 2018; Watson, 2013).

2.3.1. Natural neighbor interpolation
In MATLAB, Natural Neighbor interpolation estimates the elevation value of a given point based on the geometric relationships of its nearest neighbors. This method utilizes Voronoi diagrams to define natural neighbors and calculates the elevation of new points according to the area weights of these neighbors. Voronoi cells form equidistant boundaries around each data point in the dataset. The value of a new point located within these boundaries is computed as the area-weighted average of the surrounding natural neighbors. The elevation value z_p of a new point P is calculated using the following formula:

$$z_p = \sum_{i=1}^{n} z_i \frac{A_i}{A} \tag{2}$$

In this equation, z_i represents the elevation value of the neighboring point, A_i denotes the area weight associated with the i^{th} natural neighbor, and A represents the total weight area. This method provides reliable results, especially for irregularly distributed datasets, as it considers the geometric arrangement of nearby points and distributes influence proportionally based on their Voronoi areas.

2.3.2. Linear interpolation
Linear interpolation estimates the unknown elevation value at a given point by applying linear functions between known data points. This method, implemented in MATLAB via the griddata function, first constructs planar triangles in two dimensions from the known data points and then computes the unknown elevation values within each triangle using linear height functions.

The elevation value z_p at a new point $P(x, y)$ is calculated based on the elevation values at the vertices of the triangle that contains the point, using the following equation:

$$z_p(x, y) = a + bx + cy \tag{3}$$

In this equation, the coefficients a, b, c are determined by solving the system of equations based on the three known elevation values at the vertices of the triangle. This approach is computationally efficient; however, it may yield lower accuracy in terrains with complex topographic features, as it assumes linear variation of elevation within each triangle.

2.3.3. V4 interpolation (MATLAB V4 method)
One of MATLAB’s specialized interpolation techniques is the V4 method, which is based on two-dimensional biharmonic spline interpolation. This method is particularly effective for producing smooth and natural surfaces in datasets with irregular structures and complex topographies. The V4 interpolation solves the following biharmonic equation:

$$\nabla^4 z(x, y) = 0 \tag{4}$$

In this equation, ∇^4 represents the biharmonic operator, which ensures that the resulting surface maintains maximum smoothness while fitting the available data points as accurately as possible. This interpolation method is preferred for its ability to maintain surface continuity and smooth transitions. However, it requires greater computational power, especially when applied to dense datasets, due to the complexity of the underlying calculations.

3. Results
In this study, the GPS data obtained from the selected reference terrain were initially imported into NetCAD software, and a terrain model was generated using the triangulation method. The version of this terrain model, which had previously been refined through expert adjustments within the same NetCAD environment as part of an earlier project to better align with actual field conditions, is presented in Fig. 1.

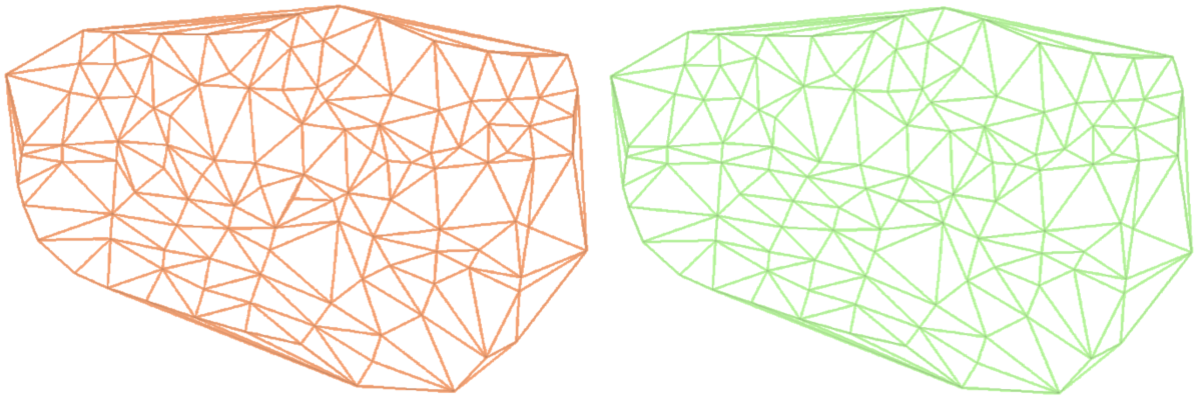

Fig. 1. The original triangulated terrain model generated by NetCAD (orange) and the expert-adjusted terrain model aligned with actual field conditions (green).

Although the models presented in Fig. 1 appear similar at first glance, a closer examination clearly reveals differences at the triangle connection points. These discrepancies in the triangulation connections are subtle enough to escape notice during a quick evaluation by users. However, failing to detect these differences can lead to erroneous calculations in subsequent planning stages and cause unexpected deviations in project costs. The specific area where the differences become more pronounced when the models are overlaid is shown in detail in Fig. 2.

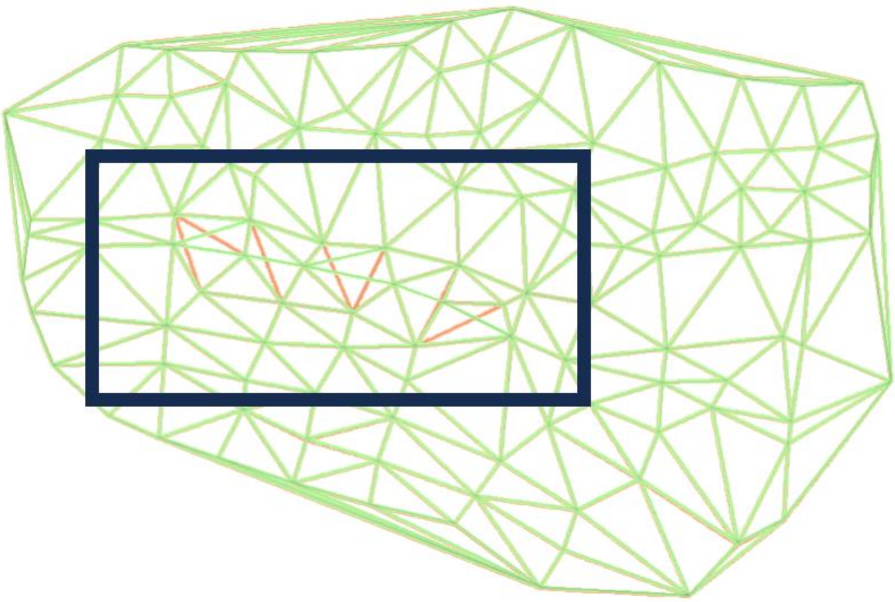

Fig. 2. Detailed view of the triangle connections requiring adjustment in the triangulated model.

If these connections are not adjusted, erroneous contour maps emerge, as illustrated in Fig. 3. When adjustments are made and the model is aligned with actual terrain conditions, the accurate contour map shown in Fig. 4 is obtained. A comparison between the two contour maps reveals that, particularly in the lower sections of the stream bed, artificially curved structures appear in the unadjusted model, whereas the expert-corrected model accurately reflects this area as having a flatter and more natural structure.

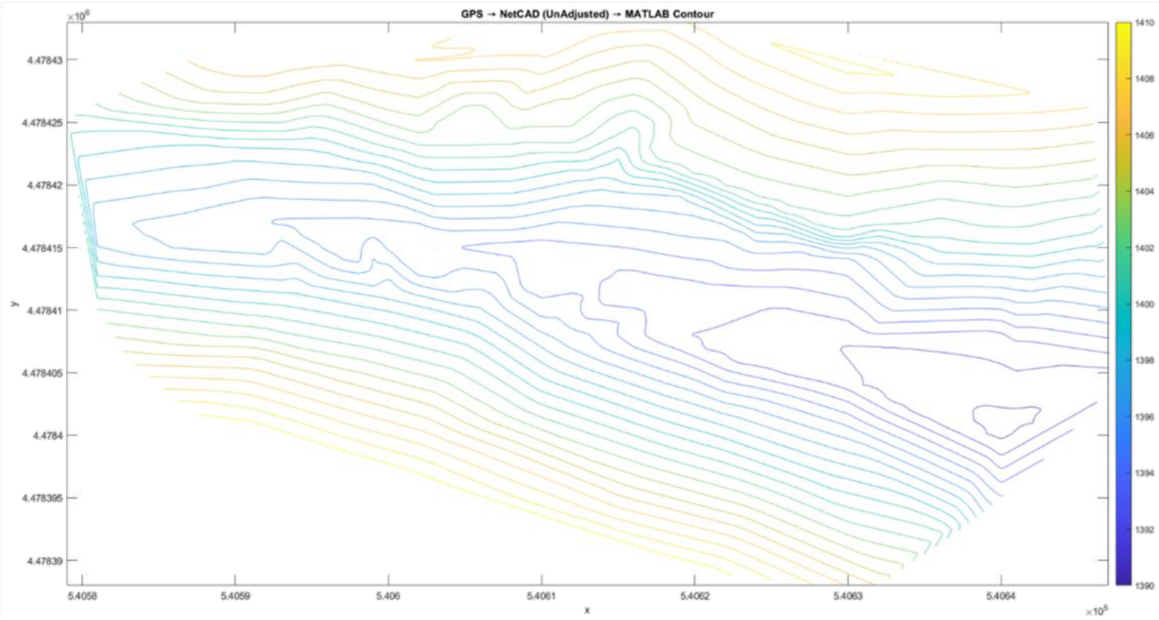

Fig. 3. Contour map generated by NetCAD without expert adjustments.

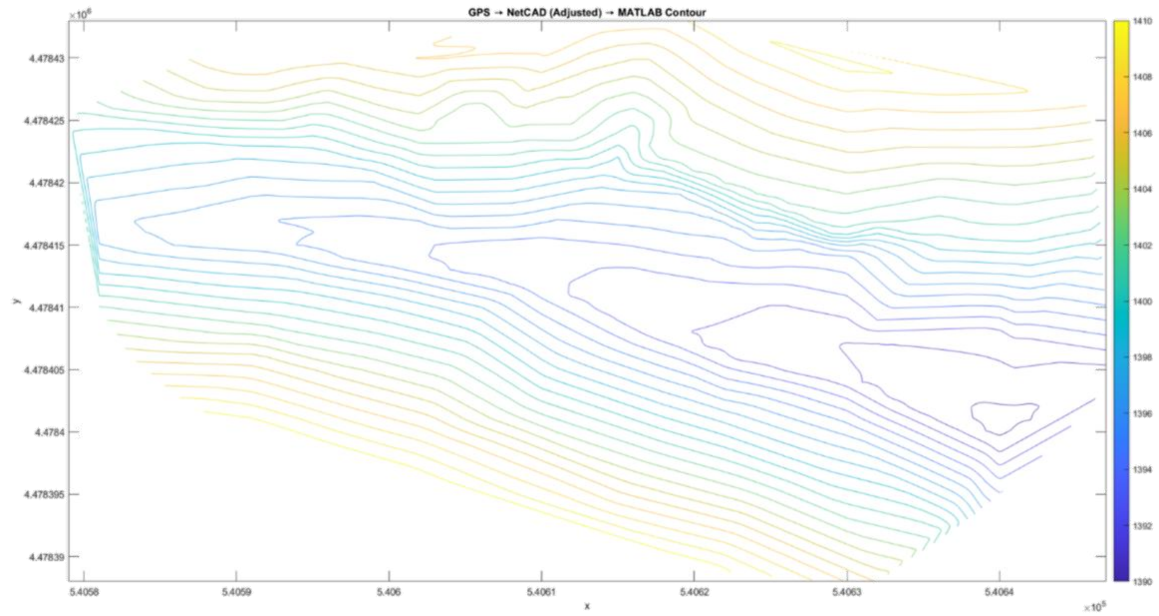

Fig. 4. Contour map adjusted by experts in NetCAD to align with actual terrain conditions.

When comparing the validated contour map in Fig. 4 with the contour map generated by MATLAB using the Natural Neighbor interpolation method (Fig. 5), it is observed that an artificial curvature appears in the lower right section of the stream bed in the MATLAB-generated model. Such errors are difficult to detect and correct without direct comparison to actual terrain data, making field validation an essential step in the modeling process.

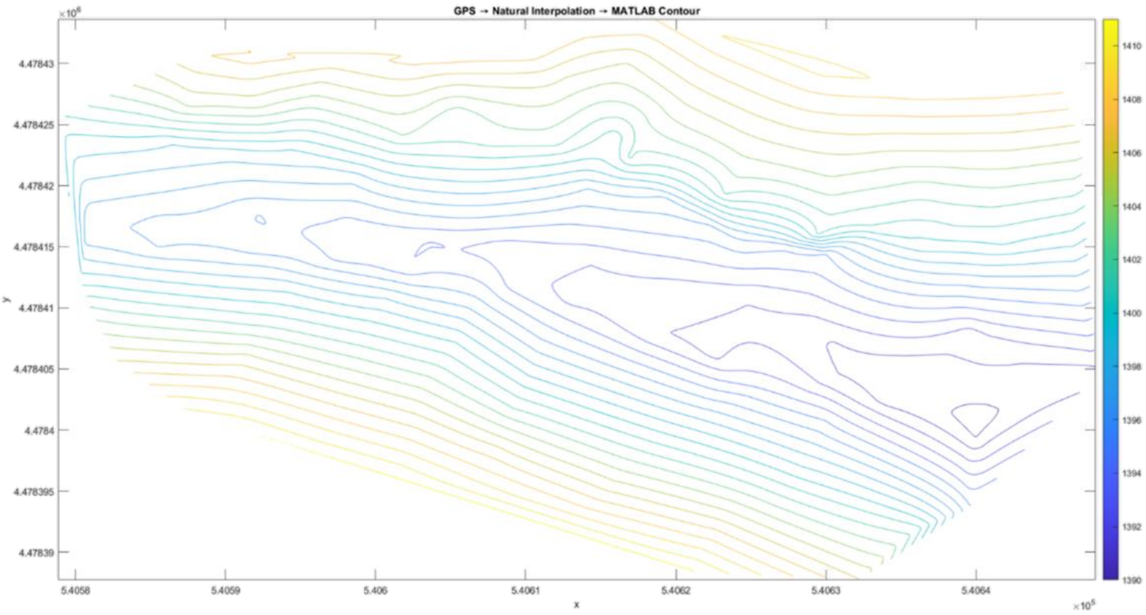

Fig. 5. Contour map generated using the Natural Neighbor interpolation method in MATLAB.

When comparing the terrain models generated by MATLAB using other interpolation methods, notable differences emerge. The terrain model produced using the Linear interpolation method, shown in Fig. 6, exhibits sharper transitions and discontinuities compared to the Natural Neighbor method. Additionally, several erroneous curvatures can be clearly observed in different sections of the model. This demonstrates that even within the same software environment, different interpolation techniques can yield significantly different results.

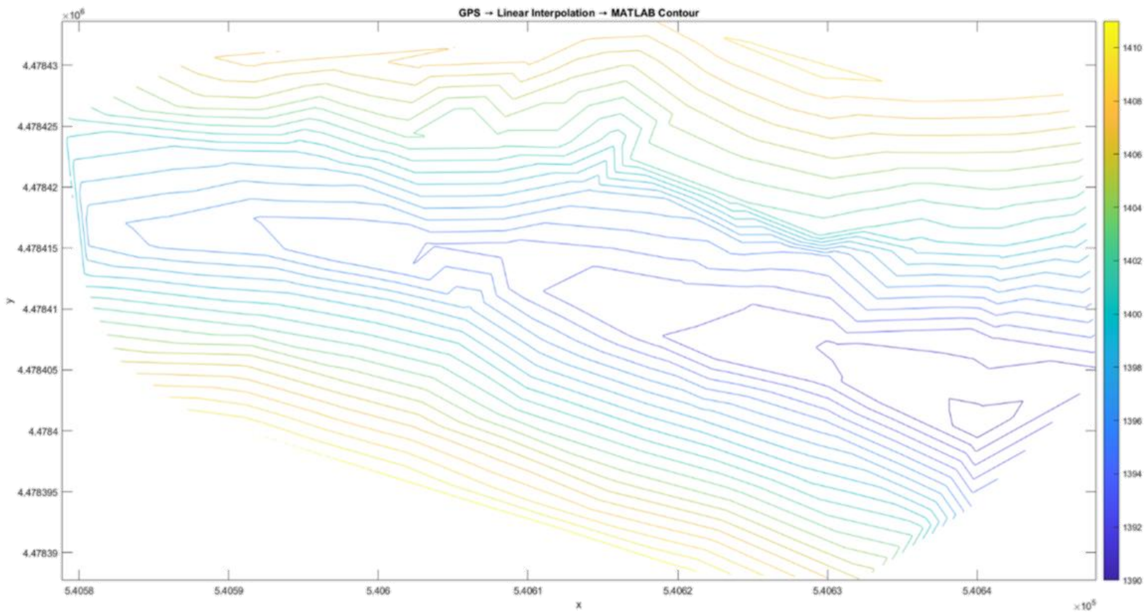

Fig. 6. Contour map generated using the Linear interpolation method in MATLAB.

The contour map produced using MATLAB's V4 interpolation method is presented in Fig. 7. Although this method generates smoother and more continuous contour lines compared to other techniques, it tends to deviate further from actual terrain conditions. Therefore, applying this method in engineering projects that require high precision may lead to significant planning errors.

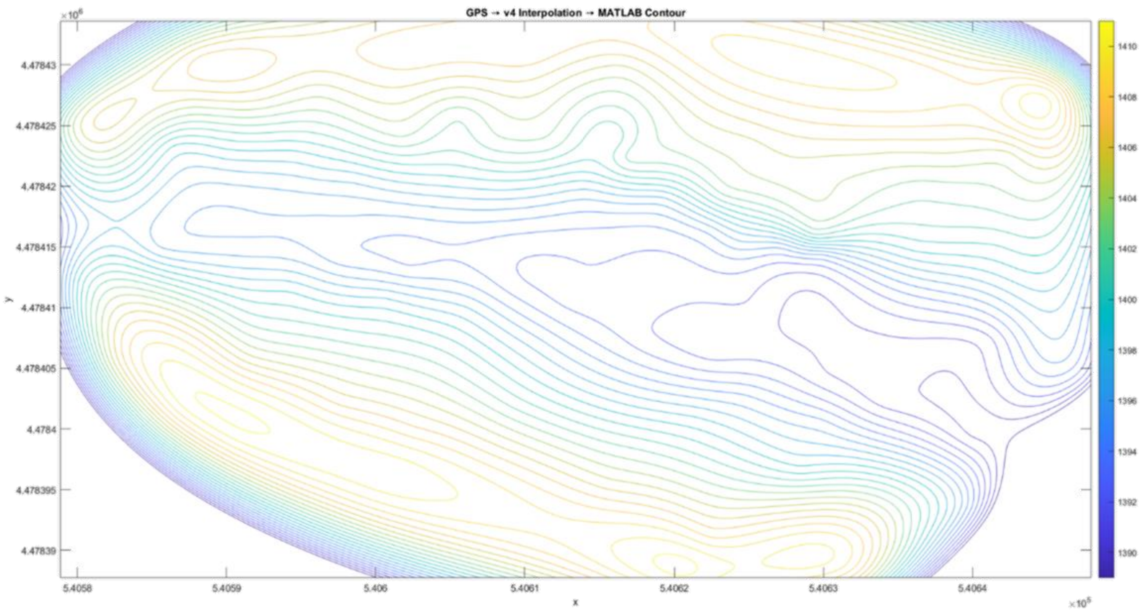

Fig. 7. Contour map generated using the V4 interpolation function in MATLAB.

When the examined terrain models are evaluated as a whole, it is observed that the Natural Neighbor interpolation method in MATLAB provides results that are closer to the actual terrain compared to other methods. However, even this approach contains minor deviations from the real terrain data upon closer inspection. These findings reveal that the accuracy of terrain modeling is significantly influenced by the choice of interpolation methods within existing software tools, emphasizing the need for developing new approaches to achieve more reliable terrain models.

4. Conclusion and recommendations

In this study, the accuracy levels of different software tools and modeling methods used in terrain modeling—an essential process in highway projects—were comparatively analyzed. Various terrain modeling approaches employed by widely used software such as NetCAD and MATLAB were applied to the same reference dataset, and the results were compared.

In the terrain model generated by NetCAD's default triangulation algorithm, connection errors requiring expert intervention were identified. These errors were shown to have the potential to cause planning inaccuracies and unexpected cost deviations in real-world project applications. Although MATLAB's Natural Neighbor interpolation method yielded results closer to the reference model compared to other methods, even this approach failed to produce a fully accurate terrain model.

In engineering applications that demand high precision, such as terrain modeling, even minor discrepancies can lead to significant deviations. In this context, the need for manual intervention during terrain modeling processes in existing software and the limited accuracy of the algorithms employed expose users to potential errors during decision-making processes.

As a result of this study, it is recommended that new-generation modeling approaches be developed as alternatives to conventional interpolation or triangulation methods. These new approaches should aim to achieve higher accuracy without requiring expert intervention. In particular, the applicability of artificial intelligence (AI) and machine learning (ML)-based techniques in this field should be explored, focusing on the development of algorithms capable of producing generalizable results across different terrain types and data distributions. Additionally, it is essential that these advanced modeling approaches be integrated into software environments in an accessible and user-friendly manner for broader adoption by practitioners.

For future research, it is recommended to conduct comprehensive performance analyses of the proposed methods by testing them across different geographical regions and varying data densities. Furthermore, the impact of terrain modeling accuracy on project costs should be quantitatively assessed to support the development of decision-support systems for guiding software selection processes in engineering projects. This study contributes to the understanding of how different terrain modeling approaches affect engineering outcomes and highlights the necessity for more reliable modeling techniques in practice.

Investigating severity of motorcycle-involved crashes in the context of developing countries

Sina Asgharpour *[1], Kouros Mohammadian[1]

[1] Department of Civil, Material, and Environmental Eng., University of Illinois Chicago, Chicago, IL.

Abstract. Despite special attention to the motorcycle-involved crashes in the safety research, little is known about their pattern in developing countries. The widespread adoption of motorcycles in such regions in tandem with the vulnerability of motorcyclists exacerbates the likelihood of severe crashes. The main objective of this paper is to investigate the underlying factors contributing to the severity of motorcycle-involved crashes through employing crash data between March 2018 to March 2019 in Iran. Firstly, we showed the significance of injury severity of motorcycle-involved crashes among others. In this sense, the data statistics suggest that motorcycle-involved crashes account for 20% of all crashes of which 82% contain injury; however, only 36% of the crashes involving other vehicles (i.e., 80%) has resulted in injury. Subsequently, we focused on eliciting the factors associated with motorcycle crash severity. To this end, we employed a random parameter ordered probit model with heterogeneity in mean to address: 1) the ordinal nature of injury classes (i.e., property-damage-only, injury, and fatal crashes), and 2) unobserved heterogeneity across the crash records. The estimation results indicate that several factors significantly contribute to severe crashes including collision type, road type, spatial, temporal, and motorcycle rider characteristics. According to estimated marginal effects, crashes involving not-at-fault riders and unlicensed riders are the most significant crash types contributing to injury. Finally, upon the insights obtained from the results, we propose safety countermeasures, including 1) strict traffic rule enforcement upon riders and pedestrians, 2) educational programs, and 3) road-specific adjustment policies.

Keywords: Crash data; Motorcycle; Severity; Developing countries

1. Introduction

Motorcycles are a popular transportation mode in many developing and low-income countries owing to their affordability and flexibility on congested roads (Lin & Kraus, 2009). For instance, motorcycles constitute less than 3% of all motorized vehicles in the United States with a per capita income of $56,180 (World Health Organization, 2018). However, in countries such as Pakistan (with a per capita income of $1,510) and Iran (with a per capita income of $6,530), motorcycles account for nearly 74% and 38% of all motorized vehicles, respectively (World Health Organization, 2018). In Tehran, the capital of Iran, there are 3.5 million registered motorcycles, among which 600,000 are used for daily commuting (IRNA, 2021). Despite the prevalence of motorcycles in developing countries, road traffic legislation in these countries is often inadequate noting that only 6% of countries with standard legislation for motorcycles are low-income (World Health Organization, 2018).

The extensive use of motorcycles in developing countries, coupled with inadequate road traffic legislation, poses a significant peril to motorcyclists' safety, leading to a surge in accident injuries and fatalities. Recent evidence suggests that motorcycles are involved in almost 45% of all road accidents in Karachi, Pakistan (Pervez et al., 2021). Furthermore, developing countries, especially Southeast Asia and Africa, account for over 80% of global motorcycle fatalities (World Health Organization, 2018). These statistics highlight the pressing need for effective measures to reduce the injury and fatality risk associated with motorcycle use in developing countries. To this end, identifying the underlying factors influencing the severity of motorcycle crashes can aid in the development of targeted interventions and policies to enhance motorcycle safety.

Despite the high risk of injury associated with motorcycle-involved crashes in developing countries, the existing research on this topic is limited. Furthermore, a review of the literature indicates that studies analyzing motorcycle crash severity in developing countries mostly concentrate on urban areas. This limitation is particularly problematic since motorcycles are often a primary mode in some rural regions, where infrastructure and public transportation options are limited. Therefore, further research is needed to compare the pattern of injury severity

*Corresponding author, E-mail: sasgha3@uic.edu

https://doi.org/10.31462/icearc2025_ce_tra_887

of motorcycle crashes between urban and rural settings in developing countries, identify the underlying factors affecting motorcycle crash severity, and develop targeted policies to improve motorcycle safety in both settings.

This study aims to investigate the severity of injuries associated with motorcycle-involved crashes in Iran, a developing country, with a specific focus on comparing injury severity trends in rural and urban areas. To accomplish this objective, we employ police-reported crash data from Iran spanning from March 2018 to March 2019. Firstly, we demonstrate a marked difference in injury severity between motorcycle-involved and other types of crashes. Subsequently, focusing on motorcycle-involved crashes, we examine injury patterns in urban and rural settings in motorcycle-involved crashes. To identify the factors affecting the injury severity of motorcycle crashes, we estimate two separate Random Parameter Ordered Probit models for urban and rural settings accounting for unobserved heterogeneity. Additionally, we perform a transferability test to determine the need for model separation. By analyzing the estimation results, we identify the factors that impact the injury severity of motorcycle crashes in urban and rural areas.

The findings of this study will have significant implications for policymakers in developing effective policies for motorcycle safety in developing countries. The study will characterize the most significant factors that contribute to injury severity of motorcycle-involved crashes, specific to urban and rural area. These findings can be used to develop targeted interventions to reduce motorcycle-related injuries and fatalities in developing countries. The study will also provide a basis for understanding the differences in injury severity between urban and rural areas. Such insights can be used to develop interventions that are tailored to the specific contexts of rural and urban areas.

The structure of the remainder of this paper is as follows: Section 2 provides a thorough literature review of the analysis of injury severity in motorcycle-involved crashes. Section 3 details the methodology employed in this study. In Section 4, we present descriptive statistics of the dataset used in the analysis, including a comparison of motorcycle crashes to other types of crashes in terms of injury severity. Further, Section 5 reports the results of the analysis and provides a discussion of the findings. In Section 6, policy recommendations resulting from the study are presented. Lastly, Section 7 presents a summary of the study.

2. Literature review

The severity of crashes involving motorcycles has been extensively studied in recent years, and significant efforts have been made to identify the key factors influencing injury severity of these crashes. For instance, among collision characteristics, single and multi-vehicle motorcycle crashes are widely examined and found to be significant (Farid & Ksaibati, 2021; Geedipally et al., 2011; Marizwan et al., 2018; Savolainen & Mannering, 2007; Shaheed & Gkritza, 2014). In this regard, motorcycle-pedestrian (Chen & Fan, 2018; Quddus et al., 2002; Sohrabi et al., 2021; Solagberu et al., 2006) and stationary object collisions (Lin et al., 2003; Shaheed & Gkritza, 2014; Waseem et al., 2019) are usually correlated with severe crashes. Moreover, road type and road geometry (Farid & Ksaibati, 2021; Jones et al., 2013) (e.g., horizontal/vertical curves) are also two paramount factors. Special ambient conditions, such as light level (Geedipally et al., 2011), motorcyclist conspicuity (Wali et al., 2019), and surface condition (M. Haque et al., 2012), are recognized as factors influencing crash severity. Regarding the attributes of a motorcycle rider, young riders are one of the most vulnerable groups, mainly for lack of experience (Das et al., 2018; Farid & Ksaibati, 2021; Halbersberg & Lerner, 2019). Furthermore, human factors, such as helmet use (Shaheed & Gkritza, 2014), alcohol or drug impairment (Shaheed & Gkritza, 2014), and speeding behavior (Shankar & Mannering, 1996), are of special interest. As a summary, Table 1 presents the significant explanatory variables in the reviewed studies of motorcycle accidents from 2003 to 2021.

Various modeling tools are used to assess the impact of different factors on motorcycle crash severity. Lin et al. (Lin et al., 2003) utilized an ordered logit model to ascertain risk factors associated with injury among young riders. Savolainen and Mannering (Savolainen & Mannering, 2007) employed nested and multinomial logit models to assess the contributing factors to the severity of single and multi-vehicle crashes. In addition, Wahab and Jiang (Wahab & Jiang, 2019) utilized machine learning algorithms to investigate risk factors impacting injury severity of motorcycle crashes. Furthermore, Halbersberg and Lerner (Halbersberg & Lerner, 2019) determined factors associated with fatal crashes of young motorcycle riders using the Bayesian network.

In crash data analyses, it is impossible to collect all possible factors affecting the response variable. Therefore, a dataset may always have some unobserved factors. If the unobserved factors are not taken into account, the estimated parameters would be biased and incorrect (Mannering & Bhat, 2014) . This issue is referred to as unobserved heterogeneity which is especially important in police recorded crash data (Mannering et al., 2016). Different approaches are employed in the literature to address this issue. For instance, Rahimi et al. (Rahimi et al., 2020) employed a random parameter random threshold hierarchical ordered probit model to analyze truck-involved crashes. Fountas et al. (Fountas et al., 2021) used a random parameter ordered probit model to study severity of bicycle crashes. Besides, several studies utilized a latent class approach (Eluru et al., 2012; Xie et al., 2012). Comparing latent class and random parameter logit models, Cerwivk et al. (Cerwick et al., 2014) showed that the latent class model has a slightly better fit, while the random parameters model has more accurate predicted probabilities. Meanwhile, unobserved heterogeneity is adequately addressed in the context of motorcycle crashes.

From a few, Shaheed and Gkritza (Shaheed & Gkritza, 2014) used a latent class multinomial logit model to identify dominant severity factors of single-vehicle motorcycle crashes in Iowa. Moreover, Pervez et al. (Pervez et al., 2021) utilized a random parameter ordered logit model to assess the underlying factors associated with motorcycle crash severity in Pakistan.

Motorcycle crashes in developing countries have some distinct characteristics that challenge utilizing policies implemented in developed countries to improve motorcycle-related safety. Lin and Kraus (Lin & Kraus, 2009) identified some of these characteristics, including 1) rapid growth of motorcycle use, 2) roadway environment features (e.g., traffic congestion), 3) poor traffic rules enforcement or inadequate education. Analyzing crash data from Karachi city, Pervez et al. (Pervez et al., 2021) suggested strict enforcement measures to control motorcyclists’ risky behavior and exclusive motorcycles lanes. Additionally, Manan et al. (Marizwan et al., 2018) determined risk factors associated with motorcycle single and multi-vehicle fatal crashes in Malaysia and recommend exclusive lanes for motorcyclists. Despite the studies mentioned above, few works investigate motorcycle crash severity in developing countries compared to developed ones (Lin & Kraus, 2009).

3. Method

To investigate the injury severity of crash data, a wide range of econometric models have been employed in the research background. As the most basic models, binary logit/probit (Al-Ghamdi, 2002; Lee & Abdel-Aty, 2008), multinomial logit/probit (Chen & Fan, 2019; Tay et al., 2011), and nested logit models (Holdridge et al., 2005; Patil et al., 2012) have been broadly utilized. Probit models are preferred more than logit models since they assume a normal distribution for error term avoiding the estimation difficulties (Washington et al., 2020). The modeling approaches have become more elaborate over time to incorporate more realistic aspects into injury severity analyses. Mannering and Bhat (Mannering & Bhat, 2014) extensively reviewed the different methods employed in the road safety research.

Ordered probability models have been used to account for the ordinal nature of the injury classes (Mannering & Bhat, 2014). In this sense, ordered logit/probit models have been widely used to estimate injury severity (Khattak et al., 2002; Yasmin & Eluru, 2013; Zhu & Srinivasan, 2011). Ordered models consider a common utility function across all injury classes which can be written as Eq. (1), where i is the observation indicator, U_i represents the utility function of observation i, ϵ_i captures the unobserved factors of observation i (i.e, the error term), and $\mathbf{X_i}$ and $\boldsymbol{\beta}$ are the exogenous variable vector and parameter vector, respectively. In the ordered models, there are $J-1$ cut-off points separating J classes. According to Eq. (2), the probability of being classified into class j equals to the probability of U_i being between two adjacent cut-off points (i.e., C_j and C_{j-1}); where y_i is the discrete class of observation i.

$$U_i = \mathbf{X_i} \cdot \boldsymbol{\beta} + \epsilon_i \qquad ,\forall i = 1, 2, \dots, N \qquad (1)$$

$$\Pr(y_i = j) = Pr\big(C_{j-1} < U_i < C_j\big) \qquad ,\forall i = 1, 2, \dots, N, \ \ \forall = 1, 2, \dots, J \qquad (2)$$

According to Eq. (1) and (2), $\Pr(y_i = j)$ takes the form shown in Eq. (3) in terms of ϵ_i , the random variable signifying the error term. As a solution to Eq. (3), the ordered probit model assumes a normal distribution for ϵ_i (Train, 2003). Consequently, difference of two normally distributed variables also follows a normal distribution. Therefore, $\Pr(y_i = j)$ can be obtained by Eq. (4) where $\Phi(.)$ is the standard normal cumulative density function. Moreover, parameters of $\boldsymbol{\beta}$ and cut-off points are determined through the model estimation process.

$$\Pr(y_i = j|\mathbf{X_i}) = Pr\big(\epsilon_i < C_j - \mathbf{X_i} \cdot \boldsymbol{\beta}\big) - Pr\big(\epsilon_i < C_{j-1} - \mathbf{X_i} \cdot \boldsymbol{\beta}\big) \qquad ,\forall i = 1, 2, \dots, N, \ \ \forall j = 1, 2, \dots, J \qquad (3)$$

$$\Pr(y_i = j) = \Phi\big(C_j - \mathbf{X_i} \cdot \boldsymbol{\beta}\big) - \Phi\big(C_{j-1} - \mathbf{X_i} \cdot \boldsymbol{\beta}\big) \quad ,\forall i = 1, 2, \dots, N, \forall j = 1, 2, \dots, J (\text{if } j = 0 \colon C_j = 0) \qquad (4)$$

Unobserved heterogeneity is one of the essential limitations of the traditional ordered choice models (Fountas & Anastasopoulos, 2017a). Meanwhile, the random parameter models suggest a solution to the unobserved heterogeneity by allowing the parameters to vary across the dataset records. In this regard, a line of the literature has employed random parameter models to estimate crash severity (Fountas & Anastasopoulos, 2017b; Morgan & Mannering, 2011; Ye & Lord, 2014). Moreover, it is highly recommended to take unobserved heterogeneity into consideration in severity analyses of motorcycle crashes (F. Chang et al., 2021; Islam, 2022). In this sense, Islam (Islam, 2021) studied crash severity of single motorcycle crashes in Florida using a random parameter multinomial logit model. Using a similar model, Pervez et al. (Pervez et al., 2021) analyzed severity of motorcycle-involved crashes in Pakistan.

In order to incorporate the unobserved heterogeneity as well as the ordinal nature of the motorcycle crashes, we use a random parameter ordered probit model. In this model, the probability of each injury class is estimated according to Eq. (5) in which the constraint of fixed parameter ordered probit model is relaxed by replacing the $\boldsymbol{\beta}$ in Eq. (4) by $\boldsymbol{\beta_i}$. In Eq. (6), the form of $\boldsymbol{\beta_i}$ is specified where $\boldsymbol{\beta}$ is the vector of parameter mean, $\boldsymbol{\Gamma}$ is a diagonal matrix of standard deviation, and $\mathbf{v_i}$ is normally distributed term with zero mean and unit standard deviation.

$$\Pr(y_i = j) = \Phi\big(C_j - \mathbf{X_i} \cdot \boldsymbol{\beta_i}\big) - \Phi\big(C_{j-1} - \mathbf{X_i} \cdot \boldsymbol{\beta_i}\big) \qquad ,\forall i = 1, 2, \dots, N, \ \ \forall j = 1, 2, \dots, J \qquad (5)$$

$$\boldsymbol{\beta_i} = \boldsymbol{\beta} + \boldsymbol{\Gamma}\mathbf{v_i} \qquad ,\forall i = 1, 2, \dots, N \qquad (6)$$

4. Data

In this section, we present the details of data used in our study. Our data contain nationwide crash information of Iran recorded by traffic authorities from March 2018 to March 2019. Crash injury severity is the dependent variable in our model which is recorded in three categories/classes in the dataset: Property-damage only (PDO), injury (i.e., non-fatal injury), and fatal (i.e., fatal injury). Injury or fatal records refer to crashes in which at least one occupant involved in the crash is injured or died, respectively. Moreover, in this dataset, each record/observation constitutes information of a vehicle involved in a crash as well as the characteristics of the vehicle's driver. The vehicles involved in the same crash are linked to a crash ID. As a result, the crash-specific features (e.g., occurrence time) are identical across the vehicles involved in a crash. More details on the explanatory variables are discussed in section 4.2.

In the following, firstly in section 4.1, we demonstrate the significance of motorcycle-involved crash severity compared to other vehicles using the dataset of all crashes in the country. Subsequently, in section 4.2, we focus on the motorcycle-involved crashes, as a subset of all crashes. The dataset of motorcycle crashes is used for the further analyses in this paper.

4.1. Significance of motorcycle-related severity

As illustrated in Fig. 1, 20% of all accidents are motorcycle-involved. Yet, 82.2% of motorcycle-involved crashes contain injury, whereas this fraction for other vehicles is 35.6% signifying the remarkable share of motorcycle-caused injury. Moreover, motorcycle-involved crashes account for 5% of PDO (12,737 out of 280,948), 38% of injury (93,013 out of 244,659), and 15% of fatal (1,197 out of 7,802) crashes. These statistics are consistent with the background research highlighting the high injury of motorcycle crashes in developing countries in comparison to other vehicle types (Oxley et al., 2013; Salum et al., 2019; Shaker et al., 2014).

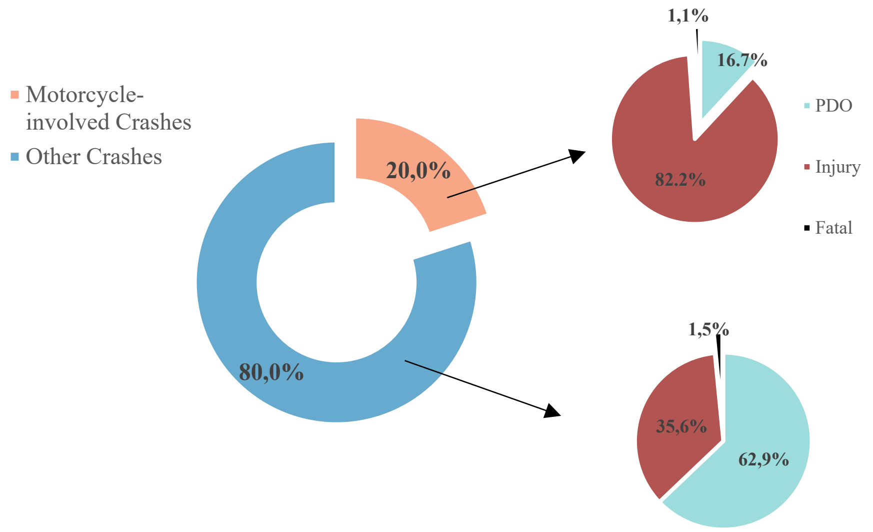

Fig. 1. Distribution of motorcycle-involved vs. other crashes and their corresponding share of PDO, injury, and fatal severity classes

To further elaborate on the significance of injury in motorcycle-involved crashes, we performed Pearson's Chi-square test (Donald, 2015) which captures the degree of association between two categorical variables by mapping associated counts in a cross-tabulated matrix. More specifically, this test measures the difference of counts within matrix cells with respect to uniformly distributed counts based on row and column sums. Chi-square test is defined according to Eq. (7) and (8) where χ^2 is the chi-square statistic, $res_{r,c}$ is the residual value for cell r, c (i.e., row r and column c), $E_{r,s}$ and $O_{r,c}$ represent the uniform and observed counts for cell r, c, respectively. Residual values represent the contribution of each cell to the chi-square statistic.

$$\chi^2 = \sum_{r,c} res_{r,c}^2 \tag{7}$$

$$res_{r,c} = \frac{E_{r,c} - O_{r,c}}{\sqrt{E_{r,c}}}\ , \qquad \forall r, c \tag{8}$$

We utilize the chi-square test to determine the association between vehicle type and severity level. The results indicate statistically significant correlation between these variables. Fig. 2 depicts the associated residual values as well as frequency percentage of each cell. In this chart, size of bubbles represents the residuals quantity associated with each cell. Also, color of the bubbles demonstrates the type of correlation, blue and orange representing positive and negative correlations, respectively. The number in each cell signifies the percentage of crash frequencies in that cell implying that the summation of all cells is 100. According the Fig. 2, the most degree of the association is captured by motorcycle-involved crashes. The residuals of the motorcycle category show a significant positive correlation of this category with injury crashes and a negative correlation with PDO. Even though the highest frequency of injury crashes is related to passenger cars (i.e., 23.8%), among all vehicle types, the motorcycle crashes have the highest positive and negative correlation with injury and PDO crashes, respectively.

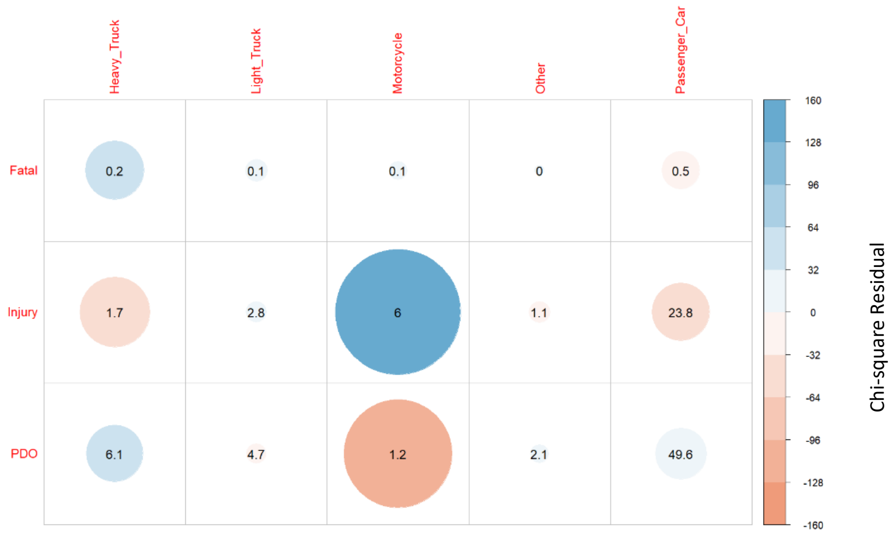

Fig. 2. Chi-Square Test Residual between Crash Severity and Vehicle Types (Size of bubbles is proportional to the residuals and numbers in cells signifies frequency % of them)

4.2. Statistics of the motorcycle dataset

Table 2 shows the descriptive statistics of the motorcycle-involved crashes. In this table, the crash frequency and the associated percentage of explanatory variables are presented cross-tabulated with the dependent variable of our model (i.e., crash severity). Moreover, the summation of frequency percentages in each row over three severity classes is 100%, for instance, there are 29,718 crashes in Motor-vehicle category from which 18.33%, 80.9%, and 0.8% are associated with PDO, injury, and fatal crashes, respectively. Similarly, the summation of percentages in Total column over categories of a variable is 100%.

The explanatory variables of Table 2 can be categorized into four broad groups: 1) collision characteristics (i.e., Collision Type and Collision Mode), 2) road characteristics (i.e., road type and road geometry), 3) spatial and temporal characteristics (i.e., region rain, land-use, season, and time of day), and motorcycle rider's characteristics (i.e., fault status, gender, age, education, license status, and human factors). In the following, details of each variable group are summarily discussed.

About the collision characteristics, collision type variable determines whether the vehicles involved in a motorcycle crash (i.e., motorcycle-vehicle, motorcycle-pedestrian, and two motorcycle) or the type of a single-motorcycle crash (e.g., overturn of a motorcycle without other vehicles involved). In this regard, as the most frequent crash type, motorcycle-vehicles crashes make up 76.5% of all crashes. Moreover, multi-vehicle and multiple categories refer to crashes with more tan two vehicles and compound crash types, respectively. Collision mode specifies the angle of the collision. For instance, front-side refers to a perpendicular collision angle.

Road characteristics group comprises road type and road geometry. Road type signifies the type of the road segment in which a crash occurred. For instance, nearly 67% of the crashes within the dataset took place in urban main streets. Similarly, road geometry specifies presence of a horizontal/vertical curve in proximity of the accident. About the spatial and temporal characteristics, region rain feature states the rain level of the region on average. Since the northern provinces of the country has noticeably high rains, we believe the rain variable in binary format can capture this effect. In a higher resolution, land-use variable specifies the location of the accident belonging to a residential or non-residential area. Furthermore, season and time of day variables are time attributes signifying the season and daytime of the crash, respectively.

Finally, motorcycle rider's variable group includes rider's fault status, their age, gender, education, license status, and human factors. Rider fault specifies the motorcycle rider being whether at-fault of not-at-fault in the crash. Human factors refer to cases that the traffic police detects some behavioral factors associated with the motorcycle rider which potentially led to the accident. In this regard, reckless and/or hurry driving is the most prevalent case of such human factors.

Table 2. Descriptive statistics of motorcycle-involved crashes

Variable		PDO		Injury		Fatal		Total	
	Total	6.486	16.7%	31.926	82.2%	421	1.1%	38.833	100.0%

5. Results

To estimate the model, we used NLOGIT 6 software and the simulation-based maximum likelihood approach. As the simulation process, it is shown that a Halton draw sequence with one tenth of a number of random draws is similarly efficient (Bhat, 2001). On this basis, we used 100 Halton draws to estimate the model. Furthermore, we set 10% significance level as the threshold to consider a parameter whether random or fixed. Moreover, as mentioned in section 3, we considered three injury classes, including PDO, injury, and fatal. As a part of the model specification procedure, we arranged these classes in an increasing order in our model. Accordingly, a positive sign of an estimated coefficient implies that an increase in the associated variable increase the probability of severe classes.

In order to better understand the impact of unobserved heterogeneity, we run both fixed and random parameters ordered probit models. Table 3 shows the overall fitting of these models. According to this table, both fixed and random parameter models are statistically significant. Moreover, two goodness-of-fit measures, ρ^2 and Akaike Information Criterion (AIC), are also presented in this table which are based on Eq. (9) and Eq. (10), respectively (Train, 2003). In these equations, $LL(\hat{\beta})$ and $LL(0)$ stand for the optimal log-likelihood at the estimated parameters and log-likelihood with parameters set to zero, respectively. Further, K represents the number of estimated parameters and N is the dataset size. According to ρ^2 and normalized AIC, the random parameter model has a better fitting compared to the fixed parameter version.

$$\rho^2 = 1 - \frac{LL(\hat{\beta})}{LL(0)} \tag{9}$$

$$AIC = -2LL(\hat{\beta}) + K \cdot \log(N) \tag{10}$$

Table 4 presents the estimation results comprising the coefficients' mean and standard errors for both random and fixed parameter ordered probit models. Additionally, in random parameters model, standard deviations of random parameters' distribution are shown in this table. Accordingly, the parameters without standard deviation are considered fixed across the observation. Furthermore, according to t-test-based statistical significance shown in Table 4, all variables of the random and fixed model have a significance level over 95%, and 90%, respectively.

According to Table 4, significance of random parameters' distribution standard errors demonstrates the advantage of the random parameters model over the fixed parameters model. As discussed, unobserved heterogeneity potentially leads to incorrect parameter estimates in fixed parameters model. This issue can be noticed in Table 4 by comparing estimated parameters of random and fixed parameters models. In most cases, the difference of estimated parameters between random and fixed parameter models is remarkable. For instance, the estimated coefficients for Highway variable for the random model is 0.103 while it is -0.072 for the fixed model. As a result, these differences can lead to incorrect conclusion in case of using the fixed parameter model. Therefore, we will focus on the results of the random parameter model in the remaining of the paper.

As shown in Table 4, if the cut-off point between PDO and injury classes is normalized to zero, 6.619 is the estimated cut-off point of random model between injury and fatal classes. In addition, the statistical significance of the threshold confirms the distinct difference between associated severity classes. Table 5 demonstrates the sample-average marginal effects of the random parameters model signifying the average change in the outcome probabilities as a result of a unit increase in a specific variable. In the following subsections, we interpret the estimation results presented in Table 4 coupled with Table 5.

Table 3. Overall fitting of estimated models

Measure	Random Parameters Ordered Probit	Fixed Parameters Ordered Probit
p-value (Significance)	0.000	0.000
$LL(0)$	-19,765	-19,765
$LL(\hat{\beta})$	-16,971	-17,223
ρ^2	0.141	0.129
$\frac{AIC}{N}$	0.876	0.888

5.1. Collision characteristics

Collision characteristics are represented by collision type and collision mode (i.e., collision angle) attributes in the estimated model. As shown in Table 4, three collision type variables (i.e., motor-pedestrian, overturn, and two motorcycles), and two collision mode attributes (i.e., head-on, and front-left) turned out to be statistically significant.

Per the results, motor-pedestrian crashes tend to be more severe since their associated coefficient mean is 2.038. According to Table 5, involving in a motor-pedestrian accident decreases the probability of the accident being PDO by 0.70, while increases the likelihood of injury and fatality by 0.0468 and 0.0233, respectively. This outcome is in line with the similar studies in motorcycle crash severity as specified in Shajith et al. (Shajith et al., 2019); Quddus et al. (Quddus et al., 2002); Chen and Fan (Chen & Fan, 2018). Even in minor motorcycle-pedestrian crashes, both sides of the accident (i.e., the rider and the pedestrian) are highly vulnerable which makes them susceptible to higher risks. In addition, the lack of traffic rule regulations in Iran, especially for the pedestrians, is a serious underlying factor contributing to more severe accidents. For instance, no rigorous traffic rules are imposed on pedestrians and motorcycle riders crossing a red light. Also, in congested areas, some riders prefer to take sidewalks instead of the main road, yet there are not enough regulations tackling this risky behavior. This is also in good agreement with Shajith et al. (Shajith et al., 2019) who acknowledged the motorcycle-pedestrian crashes on sidewalks as a noticeable factor affecting crash severity in Sri Lanka.

Overturn Crashes are the other collision type that contributes to increasing the odds of more severe crashes since it has a positive sign in the model. Overturn usually occur as a result of rider's loss of control in critical situations (e.g., slippery surface condition, attempt to avoid hitting other objects). Falling into this crash category raises the probability of injury and fatality by 0.0467 and 0.0141, respectively. This finding is also well in line with the findings of Pervez et al. (Pervez et al., 2021), and Shaheed and Gkritza (Shaheed & Gkritza, 2014), both studying motorcycle crash severity in developing countries. Similarly, overturn has identified as one of the harmful events associated with fatal motorcycle crashes in U.S. between 2004 to 2008 (Daniello & Gabler, 2011).

Furthermore, being involved in two-motorcycle crashes increases the likelihood of fatal and non-fatal injuries by 0.0024 and 0.0443, respectively. An underlying reason for this finding could be the high vulnerability of both motorcycle riders, especially at higher speeds, compared to motorcycle-vehicle crashes. In fact, unlike motor-vehicle accidents, here both sides are unprotected and at high injury risk. Analogous results can also be found in Savolainen and Mannering (Savolainen & Mannering, 2007). Another contributing factor to the significance of this collision type could be the high share of motorcycle use in developing countries which accounts for the relatively high frequency of two motor crashes (i.e., 8.1% of the whole motorcycle-involved accident according to Table 2).

According to the model results, the collision mode also plays a significant role in the severity of a motorcycle crash. In this sense, head-on and front-side motorcycle crashes are positively associated with more severe crashes. Compared to the other modes, a head-on motorcycle crash increases the odds of injury and fatality by 0.0144 and 0.0004, respectively. Head on crashes potentially lead to severe injuries due to the opposite movement direction and high relative speed of vehicles. This finding is also supported by evidence from the literature (Shajith et al. (Shajith et al., 2019); Savolainen and Mannering (Savolainen & Mannering, 2007)). Moreover, front-side crashes also positively affect the probability of more severe motorcycle crashes. It increases the probability of injury by 0.0161 and fatality by 0.005. In this regard, Rifaat et al. (Rifaat et al., 2012) found the front-side crashes significant factor studying the motorcycle crashes in Calgary. From another perspective, front-side motorcycle crashes usually occur at intersections and can be related to gap acceptance behavior of motorcycle riders which is identified as a major safety concern (Pai et al., 2009).

5.2. Road characteristics

The model indicates that the occurrence of a crash in highway segments increases the probability of severe crashes since the associated coefficient has a positive sign. According to Table 5, shifting from another road segments to highway segments increases the probability of injury and fatality by 0.0136 and 0.0004, respectively, whereas reduces the probability of PDO by 0.0140. As an underlying factor, high speed of vehicles (both motorcycles and cars) in highway segments can account for this trend. Similar findings are also reported for motorcycle crash severity in the literature (Farid & Ksaibati, 2021; Geedipally et al., 2011). Moreover, injury severity of crashes at highways has been studied widely due to the high risk of severe crashes (Ebnali et al., 2020; Fountas & Anastasopoulos, 2017a; Mahmud et al., 2021; Yingfeng & Yong, 2009).

Moreover, motorcycle crashes occurring at main streets are positively associated with more severe crashes, according to the results. Happening a motorcycle-involved crash in these road segments increases the probability of injury and fatal accidents by 0.0094 and 0.0003, respectively. Previous research also supports this finding (Marizwan et al., 2018). Fig. 3 illustrates the share of main streets form whole motorcycle crash locations in our dataset (Table 2) implying that motorcycle crashes mostly happen in main streets by far. Furthermore, most of them contain crash injury. The underlying reason can be the ease of access that main streets provide to motorcycles. This factor can also lead to risky and speeding behaviors by motorcycle riders increasing the risk of severe crashes.

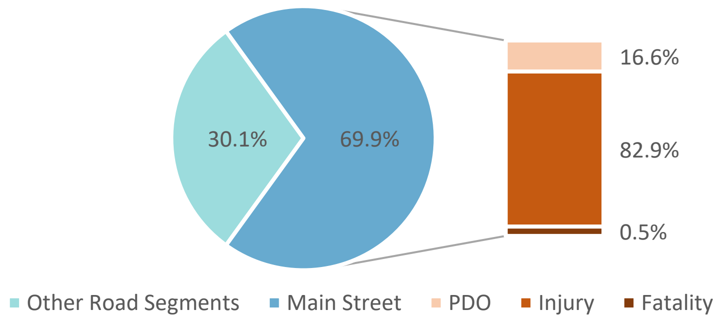

Fig. 3. Percentage of Crashes in the Dataset (by Severity Level) Occurring on Main Streets Compared to Other Road Segments

5.3. Spatial and temporal characteristics

In the estimated model, two spatial factors (i.e., crash location's land use, and region rain features) significantly affect the injury severity. In this regard, non-residential land-use is positively associated with more severe crashes since its estimated coefficient is 0.648. Accordingly, its marginal effect for injury and fatal crashes is 0.0661 and 0.0031, respectively. This trend is in line with a line of the literature (Prato et al., 2018; Zajac & Ivan, 2003) implying that populated and residential areas are associated with less severe crashes. This can be attributed to riders' cautious behavior in these regions. Moreover, crashes occurring in areas of the country with high rains are associated with more severe crashes increasing the probability of injury and fatal crashes by 0.0531 and 0.0046, respectively. In this regard, most of the literature investigated impact of inclement weather on crash severity (Omranian et al., 2018; Tay et al., 2011); however, we focused on the impact of regional climate on crash severity due to the unavailability of day-to-day weather information in our dataset.

About the temporal characteristics, two features turned to be statistically significant: season and time of the day. According to the results, spring/summer category affects crash severity by increasing the probability of injury and fatality by 0.0329 and 0.0009, respectively. This also implies that the base category (i.e., fall/winter) has an inverse effect. This conclusion is in line with Pervez et al. (Pervez et al., 2021). Rifaat at al. (Rifaat et al., 2012) (also truck involved)

A paramount reason for this trend is the different number of motorcycle trips in different seasons. According to Table 2, nearly 60% of motorcycle-involved crashes have occurred in warm seasons. Concerning the time-of-day attribute, night and Down/Dusk time intervals significantly affect the injury severity. Crashes happening at night increase the probability of the injury and fatal crashes by 0.0299 and 0.0010, respectively. Similarly, dawn or dusk variables also contribute to increasing the injury probability by 0.0422 and the fatality probability by 0.0024. These findings are also confirmed by previous research (Abrari Vajari et al., 2020; Marizwan et al., 2018; Pervez et al., 2021; Quddus et al., 2002), and reportedly, due to the drivers' fatigue and poor lighting level (Rowden et al., 2008). Furthermore, the malfunction of motorcycles, specifically the head-light problem, can aggravate this effect which is the direct consequence of non-compulsory maintenance checks and low enforcement in the country.

5.4. Motorcycle rider characteristics

According to the results, five motorcycle rider characteristics in the model have statistically significant impacts on the injury severity: rider's fault status, age, education, license status, and human factor associated with the accident cause.

The results suggest that the likelihood of more severe accidents increases when the motorcycle rider is not at fault. More specifically, shifting rider's status from at-fault to not-at-fault would raise the probability of injury and fatal crashes by 0.1168 and 0.0027, respectively. This result is reasonable considering if a motorcycle rider is at fault, he/she is more aware of the situation and can react quickly. This also means that in not-at-fault cases, motorcyclists have a higher chance of losing their control and balance due to unexpected conditions and become exposed to more severe damages. In this regard, the background research mainly investigated the factors affecting the fault status of the motorcycle rider (M. M. Haque et al., 2009; Schneider et al., 2012) and impact of fault status of motorcycle riders on crash severity is unexplored.

About the age variable, the model indicates that being a younger driver (i.e., aged less than 25 years) increases the probability of injury and fatal by 0.0334 and 0.0010, respectively. According to the literature, this finding could be attributed to the prevalence of unskilled riders and the tendency to disobey the rules at this age group (H. L. Chang & Yeh, 2007; Kashani et al., 2017; Quddus et al., 2002). Furthermore, being an elderly rider (i.e., over 56) also has a negative impact on injury severity by increasing the probability of injury and fatality by 0.0392 and 0.0019, respectively. This increase is even more considerable than that of young riders. The decline in vision, cognitive functioning, inability to react quickly are some challenges putting elderly riders at high risk of severe crashes (CDC, 2020), especially for the motorcycle riders, that on-time reaction and decision-making is of crucial importance. These results are in good agreement with Pervez et al. (Pervez et al., 2021); Quddus et al. (Quddus et al., 2002); and Vajari et al. (Abrari Vajari et al., 2020).

With respect to the education status, it is observed that riders with education levels of secondary school or less are positively associated with severe crashes. Belonging to this category engenders an increase in both injury and fatal crash probabilities by 0.0084 and 0.0002, respectively. Conversely, the negative sign for the college education coefficient implies that crashes in this category tend to be less severe. When a rider has a college or higher education, the probability of PDO increases by 0.0604, whereas the probability of injury and fatal crashes reduces by 0.0593 and 0.0011, respectively. These outcomes depict the positive impact of education on making individuals more disciplined riders. In other words, less educated riders may less adhere to traffic rules (e.g., helmet use, alcohol/drug use, and speeding), as has been emphasized by Waseem et al. (Waseem et al., 2019) and Kashani et al. (Kashani et al., 2017). The reverse correlation between rider's education level and crash severity is also identified in severity of truck-involved crashes (Rahimi et al., 2020).

As the model results suggest, motorcycle riders without a motorcycle license are more likely to involve in a severe crash. Associated marginal effects of this factor are 0.0818, and 0.0043 for injury and fatal crashes, respectively. The result of a decision tree analysis on motorcycle crashes in China revealed that the motorcycle riders without license are significantly associated with high-risk crashes (F. Chang et al., 2019). According to Table 1, license status is not widely included in the literature of motorcycle crash severity analyses; however, our finding is in line with some studies in the context (Kashani et al., 2017; Lin et al., 2003). Moreover, according to Table 2, almost 25% of motorcycle riders in our dataset do not have a valid license. In this regard, strict enforcement is needed to reduce the unlicensed motorcycle driving.

About the human factors associated with accident cause, rule ignorance by motorcycle riders is positively correlated with severe crashes. This factor raises the probability of injury and fatal crashes by 0.0453 and 0.0025, respectively. In our model, rule ignorance refers to traffic rule violation of any type (e.g., not using helmet, impaired by drug/alcohol, etc.) since we do not have access to more detailed information about the violation type. Previous studies confirmed the positive association between rule ignorance and motorcycle crash severity. For instance, alcohol use (Crocker et al., 2010; Rifaat et al., 2012), riding without helmet (Keng, 2005; Rutledge & Stutts, 1993), and traffic signal violation (Salum et al., 2019) are found to be remarkably increasing crash severity.

6. Policy implications

In this section, upon the results of the presented model, we recommend countermeasures to improve the safety of motorcyclists and reduce the number of motorcycle-involved accidents in developing countries. In this sense, we propose three types of applicable policies, including traffic rule enforcement, educational programs, and road-specific adjustments.

According to the model results, unlicensed driving and traffic rule ignorance are among the most influential variables increasing injury severity (i.e., based on the marginal effects). These findings are direct results of a wide gap in traffic rule enforcement upon motorcycle riders. The World Health Organization has assigned an enforcement score of 5 out of 10 to Iran in 2018 (World Health Organization, 2018). For example, helmet use among motorcyclists of Iran is estimated to be 59% (World Health Organization, 2018), whereas this rate in the United States, as a developed country, is at least 71% in the same year (National Highway Traffic Safety Administration, 2020). Further, as underlined in the case of motorcycle-pedestrian crashes, pedestrians are not penalized when violating the traffic rules. It is estimated that nearly 80% of pedestrians in the country do not comply with traffic laws (Aghdam et al., n.d.). These findings highlight the necessity of developing a comprehensive regulation enforcement system for motorcycle riders and pedestrians. According to Table 5, the maximum marginal effect of fatal crashes is related to motorcycle-pedestrian crashes. Accordingly, countermeasures targeting both riders and pedestrians would remarkably boost the safety of these crashes. Similar policy is suggested toward motorcycle crashes in Ghana (Dapilah et al., 2017).

As another countermeasure, the government can provide educational programs on assorted platforms, especially targeting young riders who are more likely to have risky riding behaviors. For instance, programs embedded in the licensing procedures can be effective. Licensing system in Iran lacks oriented educational programs, especially for motorcyclists, and individual's skills are developed as a result of the self-training process. Therefore, embedding educational programs as a prerequisite part of getting a motorcycle license can be substantially effective in the long run. Similar recommendations are also suggested by Chang and Yeh (H. L. Chang & Yeh, 2007) upon motorcycle licensing in Taiwan.

Last but not least, we recommend road-specific adjustments to upgrade the safety of motorcyclists and pedestrians. As mentioned in section 5.2, highway and main street urban road segments are associated with severe crashes. Rider's speeding and unsafe maneuvers due to the lack of traffic control systems may account for this trend. Installing traffic signs can be a general countermeasure to reduce the risk in such roads; however, depending on the condition of the road segments and the volume of motorcycle users, more specific measures can be considered. As shown in Fig. 3, nearly 70% of crashes in our dataset occurred in main streets implying that motorcyclists are more intended to take local streets instead of freeways and highways. Therefore, these road segments require special intention in terms of policy implementation. For instance, in main road segments with high motorcycle volume, a separate exclusive path can be designated to improve the safety of motorcycle riders. In this regard, implementation of exclusive motorcycle lanes in Malaysia has reduced motorcycle deaths by 600% (Radin Umar, 2006).

7. Conclusion

In this paper, we study the characteristics of the injury severity of motorcycle-involved crashes in Iran, as a developing country. In this regard, we employed Iran's crash records from March 2018 to March 2019. Notwithstanding 20% share of motorcycle-involved crashes from all, 82% of them are injury crashes. However, this ratio for the other crashes is nearly 36%. Moreover, the data statistics suggest that motorcycle-involved crashes make up 5% of PDO, 38% of the injury, and 15% of the fatal crashes. Furthermore, Chi-square test results revealed that the highest association between injury crashes and all vehicle types is related to motorcycles.

To determine the contributing factors to the severity of motorcycle-involved crashes, we utilized a random parameter ordered probit model with heterogeneity in mean. We also estimated a fixed parameters version of the model to better understand the impact of unobserved heterogeneity. By comparing the results of the fixed and random models, we showed that the estimated parameters of them are significantly different. As a result, using the fixed parameter models can lead to incorrect conclusions since it does not embed unobserved heterogeneity. Therefore, we focused on the random parameters model to draw conclusions.

The results of the random parameters model suggest that three collision types (motorcycle-pedestrian, overturn, and two-motorcycle crashes) increase the probability of severe crashes. Besides, head-on, and front-side collisions negatively affect severity in the collision angle category. About the road type, collisions taking place in highways and main streets are associated with injury and fatal crashes. About the spatial factors, areas with non-residential land use and provinces with high annual rain increase the crash severity. Three temporal characteristics are found to be significant in increasing the likelihood of severe crashes (spring/summer seasons, night hours, and dawn/dusk hours). Moreover, not-at-fault motorcycle riders are more susceptible to injury and fatal crashes. Moreover, regarding rides' age, under 25 and over 56 aged motorcycle riders are more likely to be involved in severe crashes. About the rider's education, per the results, riders with secondary school or less education are more likely to be categorized in more severe crashes. In contrast, riders with college degrees decrease the probability of severe crashes. Further, riders without a motorcycle license significantly contribute to crash severity increase. Finally, traffic rule ignorance behavior of riders is also found to be influential.

Based on the model's marginal effects, the most effective attribute on fatal crashes is collision type comprising two variables motorcycle-pedestrian and overturn. Being involved in a motorcycle-pedestrian and overturn crashes results in an increase in the probability of fatality by 0.0233 and 0.0141, respectively. About the injury crashes, the most influential variables are related to not-at-fault riders, rule ignorance, all three collision types (motorcycle-pedestrian, overturn, and two-motorcycle crashes), respectively.

As per the research findings, we recommended three countermeasures for safety improvement regarding motorcycle-involved crashes, including traffic rule enforcement, educational programs, and road-specific adjustments. We also highlight the lack of traffic rule enforcement for motorcyclists and pedestrians. The score of traffic law enforcement upon motorcyclists in Iran in 2018 is 5 out of 10 (World Health Organization, 2018), which is consistent with our results.

As a rewarding future extension of our research, we recommend employing more crash severity classes in the context of developing countries. Since the data availability limited our model to consider three injury classes, we were unable to distinguish slight injuries from incapacitating injuries that may have different patterns. This issue is addressed by several studies for developed countries (Abrari Vajari et al., 2020; Eustace et al., 2011; Jones et al., 2013) usually because of the availability of rich and detailed crash databases.

Abstract. The need for bituminous binders is growing daily around the world as a result of the increased demand for transportation brought on by rising living standards, economic development, and population expansion. Significant factors include the depletion of bituminous binders, a byproduct of petroleum refining that are used in the paving layer, the fact that nearly all freight and passenger transportation is done via highways and that a significant portion of it is imported, the decline in all types of maintenance and repair expenses incurred for the paving layer from an economic standpoint, and the improvement of certain characteristics of the current paving layer material. The effects of the new synthesis TOBO additive, which was created by chemically synthesizing tall oil, a by-product of the paper industry, and boron compound, a strategic raw material for industry, on the rheological characteristics of bituminous binders at different temperatures were examined in this study. The rheological characteristics of the binders with additives were assessed using the frequency sweep test after 1% and 3% TOBO were added to the base asphalt binder. The unaged binders underwent frequency sweep tests with a frequency range of 0.1-100 rad/s and 31 frequency values, at test temperatures ranging from 10°C to 70°C (in increments of 10°C). The test results showed that adding TOBO additive to the base asphalt binder reduced the binder's complex modulus (G*) values. Additionally, the asphalt binders with additives behaved more rigidly and were more resistant to rutting, particularly at low frequencies, such as low vehicle speeds or stationary traffic. Every binder showed viscous behavior and comparable phase angle (δ) values. Nevertheless, the modified asphalt binders started to behave more elastically as the frequency value rose, and their phase angle value decreased more than that of the base asphalt binder. Consequently, it was found that the binders modified with TOBO performed better than the base asphalt binder in terms of rheological qualities.

Keywords: Asphalt; Modification; Boron oxide; Rheology

1. Introduction

With the swift expansion of highway networks caused by population growth, the demand for additives to strengthen asphalt binders as well as to maintain and repair asphalt pavements has gradually increased since the beginning. Meanwhile, the supply of refined crude oil for asphalt binder products is becoming increasingly scarce. As a result, to address the lack of raw materials and uncertainties in asphalt binders, experts have concentrated on the development of new generation and future research alternative additives (Colbert et al., 2016).

Researchers and professionals all around the worldwide utilize additives such as polymer-based materials (Li et. al., 2024, Arabani et. al., 2024, Yu et. al., 2023, Zhang et al., 2023, Huang et. al., 2025), rubber (Morea et. al., 2023, Zhang et. al., 2024, Ansari et. al., 2023), bio-oils (Liu et. al., 2025, Huo et al., 2024, Peng et al., 2023), different wastes (Ye et al., 2023, Feng et. al., 2025, Zhang et. al. 2023), waxes (Yuan et. al., 2024, Useche-Castelblanco et. al., 2023), and lastly nanomaterials (Arabani et. al., 2024, Kadhim et. al., 2024, Shafabakhsh et. al., 2020) as asphalt binders. A comprehensive literature study revealed that very few research used boron in asphalt modification (Oruç & Yılmaz, 2016, Oruç et. al., 2016, Oruç et. al., 2022, Yeşilçiçek et. al., 2022, Bozdemir et. al., 2023)

Boron oxide, a boron mineral component found in Turkey, which accounts for around 73% of the worldwide economy, had been used. According to the data gathered from the literature research and early examinations, adding boron oxide singly to the asphalt binder proved inefficient (Oruç & Yilmaz, 2016, Oruç et. al., 2016). Based

https://doi.org/10.31462/icearc2025_ce_tra_920

on this, the fact that pine forests constitute 60% of Turkey's wooded lands was reacted with boron oxide utilizing tall oil, a by-product of paper produce with a high quantity of unsaturated fatty acid. As a consequence, TOBO, a novel additive not previously available in the literature (Yeşilçiçek et. al., 2022), was developed using local resources, has a quick manufacturing process, is cheap in cost, and is fully ecologically friendly.

In this investigation, the previously obtained TOBO additive was applied to the asphalt binder at 0%, 1%, and 3% rates to carry out the modification process. To investigate the rheological characteristics of the modified binders, frequency sweep tests were performed across different kinds of temperatures and frequencies.

2. Materials and method

2.1.Materials

This investigation employed 50/70 penetration grade bitumen supplied by Turkish Petroleum Refinery. The characteristics of the base asphalt binder were established using standard test procedures, as indicated in Table 1.

Table 1. Physical properties of the asphalt binder.

Properties	Value	Standard
Penetration (25°C, dmm)	56	ASTM D5/D5M-13
Softening point (°C)	50	ASTM D36/D36M-14
Ductility (25°C, cm)	100 +	ASTM D113-17
Flash point (°C)	249	ASTM D92-18
Viscosity (135°C, cP)	500	ASTM D4402M-15
Viscosity (165°C, cP)	100	ASTM D4402M-15
Viscosity (180°C, cP)	50	ASTM D4402M-15

Previous research show that TOBO can be synthesized successfully in a laboratory setting (Yeşilçiçek et. al., 2022, Bozdemir et. al., 2023). The resulting TOBO additive was shown to have excellent extensibility. Furthermore, it was visually noted that it possessed the requisite homogeneity; the material transitioned from the liquid phase to the solid phase and remained solid at room temperature. Fig. 1 shows a representation of TOBO.

Fig. 1. Visual of the additive.

2.1.1. Preparation of modified asphalt binders

Before adding the TOBO, the base asphalt binder was heated at 150 °C until liquid. TOBO was applied to the asphalt binder at three different rates: 0%, 1%, and 3% of the asphalt weight. Based on promptly test findings and previously literature study [45, 50-53, 64-67], the modification method and ratios were determined to be a high-shear mixer with a rotation speed of 3000 rpm for 30 minutes. After this procedure was done, the modified asphalt binder was ready for testing. Table 2 outlines the description of the asphalt binders.

Table 2. The description of the asphalt binders

Sample content	Code
Asphalt Binder+ % 0 TOBO	BA
Asphalt Binder+ % 1 TOBO	BA1
Asphalt Binder+ % 3 TOBO	BA3

2.2. Method

2.2.1. Characterization of TOBO
TOBO's chemical structure was disclosed by FTIR study and its microstructure by SEM investigation.

2.2.2. Determination of rheological properties of modified binders
The frequency sweep test involves the oscillation of the material at different frequencies under constant strain. Since the frequency is based on the inverse of time, it is possible to evaluate the time-dependent viscoelastic character of a material by changing the oscillation frequency. Since these tests are performed in the linear viscoelastic region, microstructural fingerprinting of the material is provided without compromising the structural integrity (Airey, 2011, Akpolat, 2023).

The Malvern DSR rheometer was used to evaluate base and TOBO-added binders at 10°C increments in the temperature range of 10-70°C. The test was based on a prior research, which used two distinct temperature ranges and test geometries (Hu et. al., 2024). The test was conducted such that the bituminous binders stayed in the linear viscoelastic (LVE) zone. The frequency ranged from 0.1 to 100 rad/s, with 31 possible possibilities to determine. To replicate viscoelastic behavior throughout a large frequency range, master curves of the complex modulus (G*) and phase angle (δ) values were generated using the time-temperature superposition principle (TTSP) at 40°C as the reference temperature.

Within the scope of this research, frequency sweep tests were carried out on unaged binders at 31 various frequencies (0.1-100 rad/s) and 7 different temperatures (10 °C, 20 °C, 30 °C, 40 °C, 50 °C, 60 °C, and 70 °C).

3. Results and discussion

3.1. Structure of the TOBO
Infrared spectroscopy was employed to achieve chemical property changes in the TOBO's functional groups. . The FTIR spectra of TOBO are displayed in Fig. 2. Vinyl C=C-H bonds are detected at 2922 cm^{-1} in the TOBO spectrum, whereas aliphatic C-H tension bonds are found at 2853 cm^{-1}. In TOBO, the deformation bands of CH_3 and CH_2 peaks stay at 1455 cm^{-1} and 1376 cm^{-1}, respectively. The additive exhibits numerous carbonyl peaks (1704 cm^{-1} and 1735 cm^{-1}), while the C=O tension band shrinks significantly. The esteric carbonyl peak (O=C-O-C) in the FT-IR spectrum at 1273 cm^{-1} becomes minor or vanishes in the produced TOBO molecule. This shows that there is an exact change in the ester function, implying that the intended additive was properly produced (Yeşilçiçek et. al., 2022).

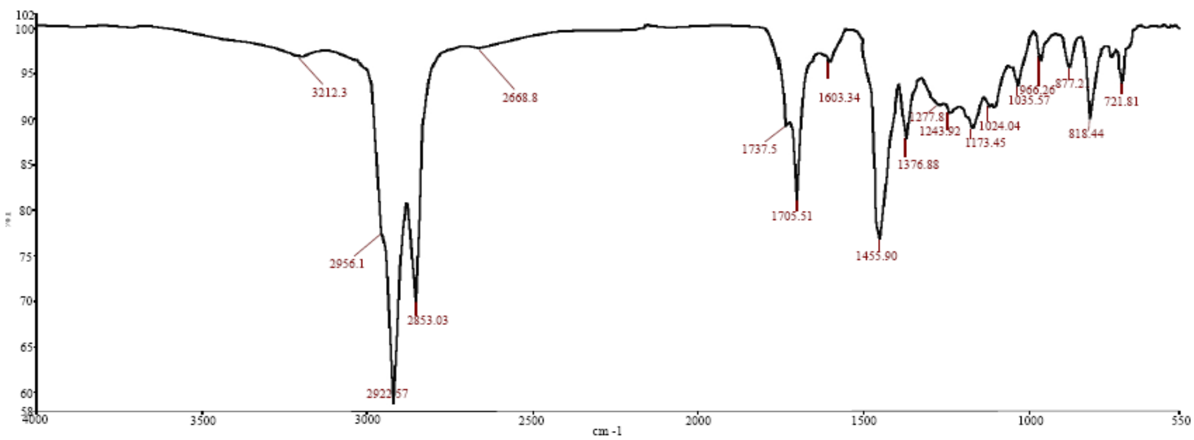

Fig. 2. FT-IR spectrum of TOBO (Yeşilçiçek et. al., 2022).

Fig. 3 displays SEM images of the TOBO additive at magnifications of 958 X (a) and 4.06 K (b). The surface of the tall oil matrix exhibits microscopic bubbles and droplet-like solidified formations, influencing its shape. These forms are believed to be boron oxide (Shadab et. al., 2023). These solid forms in TOBO material are defined as an increase in surface area that will interact with bitumen.

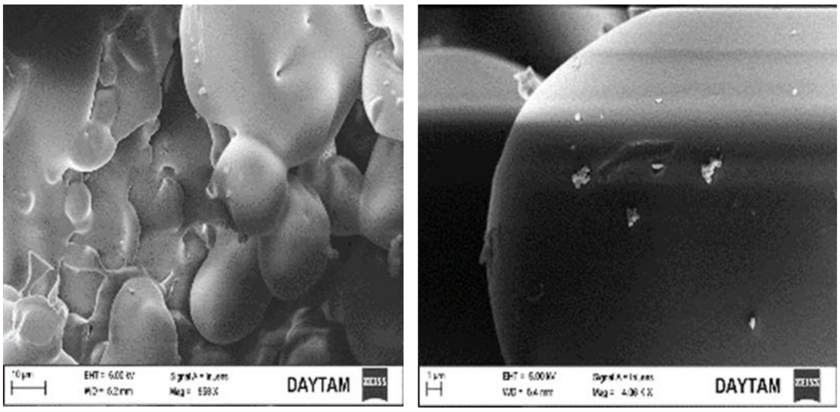

Fig. 3. SEM images of TOBO at different magnifications (Yeşilçiçek et. al., 2022).

3.2. Frequency sweep test results

Fig. 4 shows the change in the complex modulus of asphalt binders with 0%, 1%, and 3% TOBO at different temperatures with frequency, as well as the major curves of the binder with 0%, 1%, and 3% TOBO at 40°C for comparison. According to the figures, complex modulus decrease as temperature increases. Asphalt binders with additives exhibited greater complex modulus values than base asphalt binders at all frequencies and 40°C reference temperature.

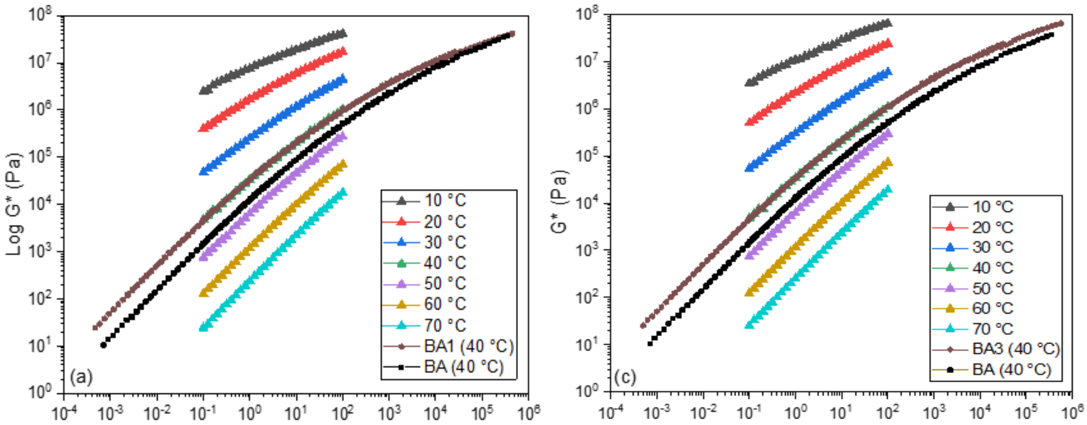

Fig. 4. Variation of complex modules at different temperatures with frequency.

Fig. 5 shows the main curves for all asphalt binders at the reference temperature of 40°C. The figure shows that asphalt binders with 1% and 3% TOBO with addittives have greater complex modulus values than base asphalt binders at all frequencies, indicating more rigid behavior. Asphalt binders with additions displayed more stiff behavior and were more resistant to rutting, particularly at low frequencies, such as low vehicle speeds or stationary traffic. As frequency grew, the complex G* values approached each other. It was discovered that the base asphalt binder had the lowest complex modulus value at all frequency levels. Using 3% additives resulted in the greatest complex modulus values.

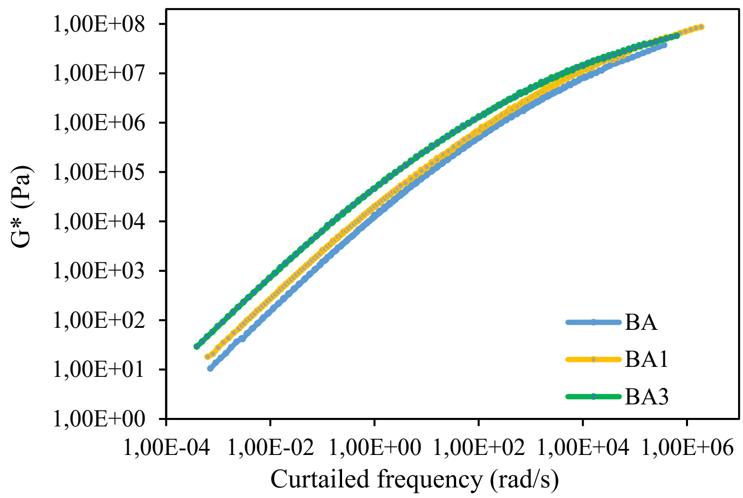

Fig. 5. G* master curves of asphalt binders at 40°C reference temperature.

Fig. 6 depicts how the phase angles of base and modified asphalt binders vary with frequency. As seen in the figure, at low frequencies (low vehicle speed or standstill traffic), all asphalt binders displayed viscous behavior, resulting in identical phase angles. However, when the frequency value grew, the modified binders' phase angle value decreased faster than the base asphalt binder's, and the modified asphalt binders began to behave more elastically.

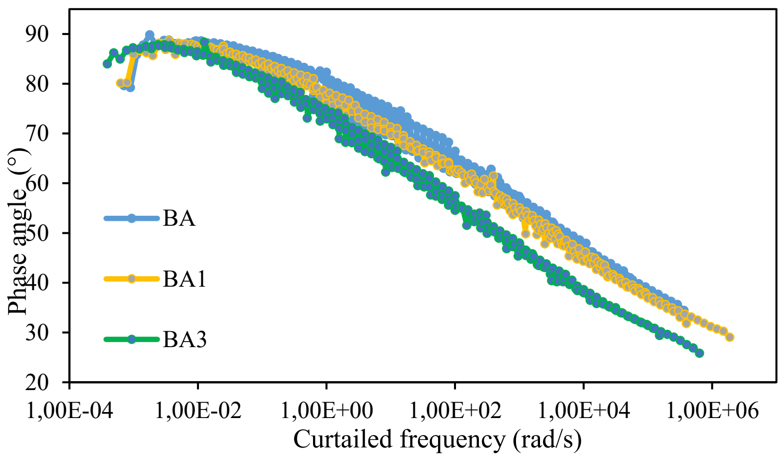

Fig. 6. Phase angle master curves of the connectors at a reference temperature of 40°C

The phase angle related to the complex shear modulus is shown by the Black space diagram (Figure 7). It defines the rheological characteristics of modified bitumens. It is used to assess the veracity of the displayed curve's distinctive time-temperature superposition as well as its simplicity in thermorheological terms (Qin et. al., 2015). In general, an increase in the elastic behavior of the asphalt binder is represented by a low complex modulus and a matching low phase angle value. All asphalt binders performed similarly.In comparison to the base asphalt binder, the rheological data of each modified bituminous binder changes towards the lower phase angle, showing the presence of a network in the additive-bitumen combination (in short, more elastic behavior). As seen in the picture, BA1 and BA3 asphalt binders displayed stronger elastic behavior, resulting in high complex modulus values, particularly at low phase angles. This demonstrates that 1% and 3% ratios will be beneficial in preventing rutting. At higher phase angle values, all binders performed similarly.

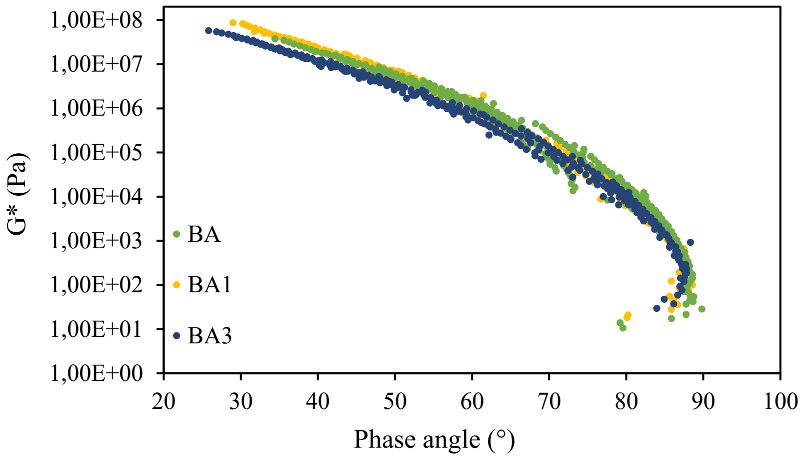

Fig. 7. Black space diagram.

4. Conclusions

The structural characterization of a TOBO additive produced under laboratory situations was the first stage in this investigation. Second, the rheological characteristics of modified binders utilized at certain ratios in bitumen modification were examined. The findings obtained are summarized as follows:

- The FTIR spectrum shows that the C=O tension band of the TOBO additive moves while the esteric carbonyl peak (O=C-O-C) diminishes, showing that the additive is chemically produced.
- When the SEM study is performed, it is discovered that the structure is primarily constituted of tall oil, with little bubbles forming on the surface. It is believed that these solidified forms are boron oxide, and the surface area that interacts with the bitumen rises.
- According to the frequency sweep test, asphalt binders with a high complex modulus and a low phase angle show stronger elastic behavior. This newly synthesized TOBO additive has been shown to have highly positive effects in rutting resistance at rates of 1% and 3%.

Examining the link between property development and transportation infrastructure

Ilgin Gokasar*[1], Mahmut G. Tülü[1], Volkan Yıldız[1]

[1] *Bogazici University, Department of Civil Engineering, 34342 İstanbul, Türkiye*

Abstract. As cities continue to expand, access to public transportation can play a crucial role in advancing sustainable urban growth and enhancing overall quality of life. In this context, transportation is one of the fundamental criteria that boost the real estate prices. Numerous studies have explored the relationship between transportation investments and real estate markets, highlighting the share of public transportation in shaping urban property values. The studies in the literature suggests that access to efficient public transport could increase economic growth, reduce commuter costs, and enhance urban mobility, making surrounding areas more attractive for both residents and investors. Research further emphasizes that improvements in public transportation networks contribute to rising property values by increasing accessibility, reducing travel time, and stimulating commercial activity. While previous studies have identified key elements of real estate values such as property size, age, location and amenities. This research integrates these factors with a specific focus on public transportation access. Closeness to transportation hubs such as metro stations, bus rapid transit lines, or railway connections, has been shown to have a positive effect on property prices, particularly in densely populated urban centers. A comparative analysis of the literature provides a clearer understanding of how access to public transportation interacts with traditional real estate valuation factors, such as property size, age, location, and amenities. Beyond serving as an academic contribution, this study also offers practical value by enhancing decision-making for real estate professionals and acting as a reference for policymakers in urban planning and transportation investment strategies.

Keywords: Real estate pricing; Transportation; Public transportation; Accessibility

1. Introduction

Since the middle of the 20th century, the world's population has grown by more than three times. With an extra 1 billion people since 2010 and 2 billion since 1998, the world's population increased from an estimated 2.5 billion in 1950 to 8.0 billion in mid-November 2022. Furthermore, 55% of people on Earth already live in cities, and by 2050, that percentage is expected to increase to 68% (United Nations, 2018). Many nations will face difficulties meeting the growing demands of urban populations for housing, infrastructure, employment, and essential services. Without strategic planning and timely investments, many nations may struggle to meet these expanding demands. Consequently, urban development could create an array of complex and multifaceted challenges for cities (McHale et al., 2015). In this context, sustainable urbanization is no longer just an ideal, it has become a pressing necessity for ensuring long-term economic stability, social well-being, and environmental sustainability. As cities grow at an unprecedented pace, there is an urgent need for thoughtful planning strategies that can accommodate rising populations while preserving quality of life.

One of the most critical strategies in achieving sustainable urbanization is the development of efficient public transportation systems. Ensuring the long-term effectiveness and appeal of these systems requires continuous evaluation and improvement. Since businesses must constantly enhance their performance to draw in more customers while planning and providing services in a highly competitive market with limited resources, performance measurement is becoming increasingly popular in the public transportation sector (Georgiadis et al., 2014). As cities grow denser, access to transit becomes a key factor not only in shaping mobility patterns and urban form but also in influencing real estate values. Properties located near transportation hubs often become more desirable due to improved accessibility and reduced travel times, leading to increased demand and higher property prices. Understanding this relationship is essential for managing the spatial and economic outcomes of rapid urban growth.

This study aims to explore in greater depth how access to public transportation influences property values in urban settings. By focusing on this specific relationship, it seeks to uncover the dynamics at play and offer detailed

* Corresponding author, E-mail: ilgin.gokasar@bogazici.edu.tr

insights that can support more informed decision-making among policymakers, urban planners, and real estate professionals.

2. Literature review

The literature has a large number of research that look at the factors influencing the real estate market. Because there are so many variables to consider, estimating real estate values has always been a difficult task for scholars. Numerous factors, including infrastructure, immigration, economic stability, social amenities, and demographics, can affect real estate values.

First of all, age distribution and social cohesiveness are two demographic characteristics that might boost economic vitality and raise real estate prices (DellaVigna & Pollet, 2007). For example, future realized excess returns on equities will be little as the baby boom generation retires and moves out of the middle-aged, peak-saving years (Ang & Maddaloni, 2005). In addition, those who live in financial instability throughout their life are more cautious when it comes to investing as a direct result of dramatic occurrences like the Great Depression (Malmendier & Nagel, 2011).

Furthermore, it is acknowledged that economic factors have a significant impact on the real estate market. The real estate market generally exhibits a cyclical pattern characterized by booms, or periods of sharp price increases, which are frequently followed by downturns, in which property values sharply decrease (Smith & Tesarek, 1991). Although well-known economic variables like employment rates and income levels are important, research also suggests that there are other, more subtle economic forces at work. According to Li & Chu (2017) bankers and investors have a substantial impact on Taiwanese market trends through their lending and investment methods, which in turn affects real estate values.

Moreover, according to analytical frameworks, factors such as firm production amenities, worker and household accessibility, legal growth restrictions, and land supply conditions influence long-term office and commercial space rents, with transportation access playing a crucial role in shaping these dynamics (Franco & Cutter, 2022). Besides, findings indicate that the price of real estate is influenced economically by features from various dimensions such as amenities and emotions (Zhao et al., 2022).

Also, environmental factors are yet another crucial component. In addition to the natural beauty, a number of environmental concerns are linked to land use, which means they have an impact on land markets and real estate (Segerson, 2001). According to study conducted in Geneva, Switzerland, environmental quality such as air quality and the presence of green spaces is a major influencer of real estate market success (Din et al., 2001).

In addition, the suburban real estate market is driven by rising demand for construction sites, with property prices mainly influenced by proximity to the city and strong transport links, which notably raise values (Szczepańska, 2021). As cities expand toward their boundaries, nearby suburban areas face increased investment demand, and this process of suburbanization is closely tied to the accessibility provided by transportation networks (Wolny, 2016).

From a similar but different perspective, immigration is another underlooked component of real estate market. Examining how immigration affects real estate markets provides clear insights into the social and economic ramifications of immigration, even though the majority of the literature on immigration concentrates on labor market implications (Scheve & Slaughter, 2004). Although it is commonly believed that immigration to wealthy, established cities raises real estate values, this is not always the case. For instance, an analysis of Miami's rental prices showed a negative relationship between the city's immigration rate and rental prices (Saiz, 2007).

Among the various factors influencing real estate markets, transportation access emerges as a key component also. Although mentioned in broader urban development literature, its direct relationship with property values warrants deeper investigation. Therefore, in the following section, the connection between transportation investments and real estate will be examined in greater detail.

3. Transportation and real estate

Property values are influenced by a number of significant factors, including location demands like accessibility to public transportation (Haider & Miller, 2000). The relationship between transportation infrastructure and real estate markets is a critical dimension of urban development and expansion (Debrezion et al., 2011; Efthymiou & Antoniou, 2013). Transportation systems not only serve as conduits for mobility but also act as catalysts for shaping land use, urban form, and economic activity. Researches have demonstrated that transportation infrastructure in cities and metropolises significantly improves socioeconomic daily activities, individual lifestyles, real estate values, and urban land usage (Aliyu et al., 2018). As cities expand and population densities rise, the spatial relationship between transit accessibility and property values becomes increasingly pronounced.

Public transportation investments such as metro lines, bus stops and rail connections tend to enhance the desirability of nearby locations. For example, it is revealed that impact of bus transportation accessibility on real estate prices showed a positive trend in a Spain-based research (Ibeas et al., 2012). Likewise, it was anticipated that rail transportation would have positive effects if the surrounding area's accessibility and appeal were enhanced (Suhaimi et al., 2021). What’s more, properties within close proximity to major transit hubs often provide higher market values due to increased accessibility, reduced commute times. The reason behind is the fact that Mass transit serves as a primary mode of transportation in many urban areas, and improving access to main transit hubs can enhance city mobility by easing transfers between different modes (Yu et al., 2012, 2013).

From a supply-demand perspective, improved transit access broadens the geographic reach of potential buyers and tenants, thereby intensifying competition for conveniently located properties. In the USA, rent plays a crucial role in property valuation and development decisions, as it reflects economic feasibility, with mobility especially proximity to workplaces or central locations being a key factor influencing rent and shaping urban growth (Benjamin & Sirmans, 1996). On the demand side, individuals and households may be willing to pay a premium for the convenience and cost savings associated with reduced reliance on private vehicles. On the supply side, landowners and developers may respond by intensifying land use near transit corridors, further reinforcing the cycle of investment and value appreciation. To improve both sides, by entering into agreements with transportation corporations, real estate developers may either construct residential properties close to public transit or introduce public transportation into their neighborhood (Wang & Yan, 2011).

Moreover, fixed-guideway transit systems play a key role in reinforcing agglomeration economies, essential drivers of urban economic development, by reducing automobile dependency and enhancing connectivity, thereby unlocking the full potential of densely concentrated economic activity and supporting more sustainable metropolitan growth (Nelson, 2017). At the same time, transportation investments often signal broader governmental commitments to urban revitalization and infrastructure renewal, prompting speculative activity in real estate markets; as a result, perceptions of future accessibility can shape property values and trigger anticipatory shifts in urban form and land use even before construction begins. All things considered, transportation infrastructure serves as both a physical link between locations and a source of income for the real estate market.

3. Policy implications

The findings of this study highlight the strategic importance of integrating transportation planning with real estate development. Policymakers should recognize that investments in public transportation do not only serve mobility goals but also significantly influence urban land values and development patterns. Proximity to well-connected transit hubs increases the attractiveness of surrounding areas, which can guide zoning decisions, infrastructure prioritization, and housing policies.

To maximize the benefits of public transport investments, coordinated planning efforts between transportation authorities, urban planners, and local governments are essential. Using real estate market data in evaluating transit projects can help align mobility improvements with sustainable urban growth objectives. In this way, transportation infrastructure can be leveraged not only to enhance accessibility but also to support long-term goals for livability, economic resilience, and inclusive development. Special attention should also be given to suburban areas, where improved transit access can help manage urban sprawl, reduce car dependency, and promote more balanced regional development.

4. Conclusions

This study examined the connection between public transportation investments and real estate values within the context of rapid urbanization. As cities grow, access to efficient transit systems plays a key role in shaping land use, improving mobility, and enhancing property values. The literature shows that while many factors influence real estate markets, transportation access remains a consistent and powerful driver of value.

Efforts to measure and improve public transport performance further support sustainable urban development by making transit systems more efficient and appealing. Understanding this relationship is essential for policymakers, planners, and stakeholders aiming to create livable, resilient, and well-connected urban environments.

While this study provides valuable insights into the relationship between transportation and real estate, it does not include empirical data or case-specific analysis. Additionally, regional variations, regulatory frameworks, and socio-economic conditions may influence outcomes in ways that are not fully captured here.

Future research could incorporate quantitative methods and spatial data analysis to measure the real-world impacts of transit investments on property values. Comparative studies across different cities or countries would also help clarify how local context shapes the strength and direction of this relationship. Further investigation into equity impacts and the role of transit in shaping affordable housing access would also be valuable in guiding inclusive urban development strategies.

Streetmeter as a tool for human-centered urban analysis: Expanding the metrics

Ilgin Gokasar*[1], Volkan Yıldız[1]

[1] Bogazici University, Department of Civil Engineering, 34342 İstanbul, Türkiye

Abstract. Quality of life is affected by the design and functionality of urban spaces, particularly streets, which serve as the backbone of daily social and economic interactions. To enhance street quality, streets could be transformed. In this context, street transformation is crucial for improving urban livability, promoting social inclusion and enhancing welfare of the society in general. Measuring street quality requires a multidimensional approach, incorporating metrics such as environmental quality, pedestrian safety, economic impact, gender equality and religious equality. These factors are interlinked and collectively affect urban experiences. This study utilizes Streetmeter, a digital assessment tool, to compare and analyze different streets based on different parameters such as geometry of the road and buildings located on the street. By prioritizing pedestrian mobility over vehicular movement, the study aims to re-examine how we understand the concept of urban planning. This concept is called as human-centered design. This term indicates that streets should be designed for the people who use them daily rather than accommodating vehicles. The findings contribute to policy development by providing data for decision-makers to enhance walkability, safety, and accessibility in urban spaces. Moreover, the study highlights the role of digital tools in fostering public awareness, empowering individuals, and advocating for pedestrian rights. By incorporating objective data into street evaluations, this research supports more equitable and sustainable urban planning approaches. Ultimately, this study emphasizes the importance of designing streets that serve as inclusive, safe, and vibrant public spaces, aligning with contemporary urban development goals and social justice principles.

Keywords: Quality of streets; Street transformation; Streetmeter

1. Introduction

Urban spaces play a fundamental role in shaping the daily experiences of city residents, with streets serving as dynamic environments where social, cultural, and economic interactions unfold. In this context, streets should be seen as communication centers shared by all living entities. They transcend the notion of public utilities, representing more than mere traffic arteries by facilitating the movement of people and things from one location to another (Jacobs, 1993). City streets also serve important urban purposes beyond transportation, such as play and commerce, leisure and social contact, and politics and innovation (Lydon & Garcia, 2015). As cities grow, humankind's perspective to life evolves. This evolvement requires changing our look to streets which will lead to redesign of the streets in a way that increases livability, fosters social inclusion and enhances general welfare. By achieving this transformation, human wellbeing will be prioritized over vehicular efficiency which will help assist the accomplish main goal, human-centered design that could be described as an approach that centers the needs of pedestrians and everyday users. To support this movement of change, the experimentation paradigm is increasingly adopted by citizens and governments seeking to reallocate urban streets from motorized traffic to active transportation and public spaces, facilitating "stationary" operations like play and socialization in pursuit of a vision of "streets for people" rather than "streets for traffic." (Bertolini, 2020). Also there is a consensus that livable streets aim to improve the street's pedestrian character by implementing design elements that reduce the detrimental effects of motor vehicle use on pedestrians and by maintaining a continuous network of pavements (Dumbaugh, 2005).

Measuring the quality of streets requires a comprehensive and multidimensional approach. Factors such as environmental quality, pedestrian safety, economic vibrancy, gender equality, and religious inclusivity must all be considered to accurately capture the lived experience of urban spaces. The perceived spatial quality of urban streets is considered a significant benefit to society (Ye et al., 2019). Also, maintaining air quality is crucial, as urban streets bordered by buildings often trap pollutants, exposing pedestrians, cyclists, drivers, and residents to

* Corresponding author, E-mail: ilgin.gokasar@bogazici.edu.tr

https://doi.org/10.31462/icearc2025_ce_tra_956

concentrations that exceed health standards (Vardoulakis et al., 2003). What's more, an enhanced comprehension of the link between design and safety may help designers in creating secure and habitable streets (Asadi-Shekari et al., 2015). In addition to them, street economics involves offering commercial and artistic goods and services in public spaces without a fixed location, and with around 2 million people working in this sector, the economic use of streets is vital (Sirkeci, 2020). It should also not be overlooked that an important influence on women's spatial behavior stems from the gender distribution of domestic labor and activities taking place outside the home at the household level (Lo & Houston, 2018). Recognizing the interconnectedness of these elements, this study employs Streetmeter, a digital assessment tool, to systematically evaluate and compare streets based on parameters like road geometry and building configurations.

By embracing the principles of human-centered design, this research challenges traditional car-centric models of urban planning. In doing so, it provides valuable data and insights for policymakers, urban designers, and community advocates striving to create safer, more inclusive, and more sustainable streets. Ultimately, this study seeks to contribute to a broader understanding of streets not just as pathways for movement, but as vital spaces for community life, aligned with contemporary goals of urban development, equity, and social justice.

2. Factors that effect quality of streets

Vibrant, sustainable cities and regions depend on well-designed pedestrian spaces. Researchers show that pedestrian-friendly streets improve the public space's social quality, that pedestrian traffic boosts local businesses' bottom lines, and that walking is a sustainable form of transportation that diminishes greenhouse gas emissions (Macdonald et al., 2018).

To achieve better streets, quality assesment is the initial step. Evaluating urban street quality requires a multifaceted strategy. The way people travel, participate, and experience urban life is influenced by the many social and functional systems that make up streets. In this regard, a number of factors significantly influence how inclusive, sustainable, and effective street environments are.

The Streetmeter tool, which assesses streets based on five dimensions such as health, social, economy, mobility, and environment is used in this study. Together, these categories' indicators offer a data-driven evaluation of street performance and livability (Streetmeter, 2025). This study also adds two important but frequently disregarded elements to these dimensions: gender equality and religious inclusivity. In order to include the social and cultural complexities of using public spaces, these dimensions have been added. By incorporating these perspectives, the analysis aims to advance more inclusive street design that takes into account the diverse needs and life experiences of various user groups.

2.1. Health

The health dimension plays a crucial role in evaluating the overall quality of streets, as urban environments have direct impacts on public well-being. Streets designed with health considerations in mind can significantly reduce physical and mental health risks for urban populations. Since individuals spend a significant portion of the day in public urban areas, the design and quality of these areas may have a direct effect on stress levels (Sadeghpoor et al., 2024). In a physical health manner, youth physical activity is directly related to street quality (Kaczynski et al., 2018).

A variety of indicators are used to assess the health-related quality of a street, each contributing to a more comprehensive understanding of how urban design affects residents.

Key metrics include noise level which influences stress and sleep quality since reducing environmental sources of excessive street-level noise should be a top goal for urban planning and public health (McAlexander et al., 2015). To add, the share of active transportation which promotes physical fitness through walking and cycling. Increased active transportation can result from more inclusive pedestrian infrastructure, and this can enhance people's physical health and overall wellness (Georgescu et al., 2024). Another critical factor is the risk of serious traffic injuries that reflect the safety of street users, particularly pedestrians and cyclists. This topic is so important that evidence-based traffic safety principles ought to be taught to all professionals involved in the planning of streets and road networks (Mohan, 2008).

Environmental health is also addressed through air quality indicators such as PM10, PM2.5, and NOx annual means. Streets with poor air quality contribute to an increased risk of asthma attacks, particularly among vulnerable populations such as children and the elderly. Researches shows that an increase in the number of trees can reduce the risk of asthma, thereby improving overall health quality and decreasing the burden of disease, which may also result in economic benefits (Eisenman et al., 2019).

Additionally, greenery's oxygen production represents the environmental contribution of vegetation along streets, offering cleaner air. It is a known fact that one of the beneficial effects of street greenery is the production of oxygen (Nowak et al., 2007). Together, these metrics underscore how the design, infrastructure, and ecological components of a street can profoundly influence public health.

2.2. Social

The social aspect of street quality focuses on how public areas promote inclusion, ease human contact, and strengthen an aura of community. Streets are not only physical corridors but also important locations for social life, where people gather, connect, and participate in everyday urban culture. Research has shown a strong relationship between the quality of the street environment and people's willingness to engage in social interaction (Mehta & Bosson, 2021). Evaluating social factors helps ensure that streets support diverse needs, equitable access, and opportunities for public engagement.

A core metric is the number of people using the space as a meeting place which indicates the social vitality of the street. Not only do streets serve as visual appearances of the community, but they also serve as crucial conduits that connect persons and make movement more efficient (Rahayu et al., 2017).

The presence of safe street spaces reflects how well streets are integrated into surrounding buildings and neighborhoods, enhancing both security and accessibility. Surface illumination is another element, affecting perceptions of safety and the usability of streets during evening hours. The streets are one of the primary locations where stranger harassment persists, which is tragically widespread in today's society and involves behaviors like physical contact, verbal abuse, staring, and stalking (Macmillan et al., 2000).

Physical amenities also play a crucial role in shaping social experiences. The availability and placement of public seating and outdoor dining encourage lingering, interaction, and leisure activities. Significant changes in the material environment (perceived space) could alter people's mobility, accessibility, and general quality of life (lived space), as well as their opportunities for involvement and movement through them (Saphan et al., 2022). These features are particularly important for vulnerable groups such as the elderly and children.

2.3. Economy

The economic dimension of street quality reflects how public spaces contribute to local prosperity, business activity, and property values. When talking about street economy, the first concept to come to mind is street vendors. Although once seen as outdated and nearing extinction, street markets and vending have grown increasingly popular over time (Cross, 2000). However, street’s economic benefits are beyond these open-air markets. Streets that support economic vitality not only benefit individual enterprises but also enhance the overall sustainability of urban areas increasing land value and encouraging community investment. Economic indicators are essential for understanding how spatial design decisions turn into financial outcomes.

One key set of indicators involves value creation: the extent to which streets contribute to residential and office value creation. Good street design can enhance land value by enabling more development and supporting investment in public goods (Hack & Sagalyn, 2011). Well-designed, accessible, and vibrant streets often correlate with increased demand for adjacent properties, reflecting their desirability as places to live or work. For example, Romsey’s annual folk and roots music festival, which activates the town’s medieval streets with performances, food stalls, and pedestrian-only access, illustrates how street environments can attract sustained public interest and enhance the overall desirability of the area (Rust, 2020). Similarly, retail turnover offers insight into the commercial productivity of the street, especially in areas where pedestrian traffic is high.

In terms of public revenue, metrics such as on-street car parking revenue and outdoor dining revenue quantify how street space can be used efficiently to generate income, either through vehicle-related fees or supporting local hospitality businesses. Research indicates that optimizing the prices of street parking spaces can become an important source of income as well as regulating traffic (Xu & Sun, 2024). These revenues can be reinvested in further street improvements or public services.

2.4. Mobility

Mobility is a fundamental component of street quality, as it determines how easily and safely people can move through urban environments. In fact, human mobility in street networks combines both topological jumps between streets and persistent movement along them, but this simplified view overlooks the purposive nature of real-world travel, which is often driven by specific destinations like homes, schools, or workplaces (Jiang et al., 2009). A high quality street supports a balanced, multimodal transportation system that prioritizes accessibility, equity, and efficiency. Streets could serve as public areas for all users when the emphasis is shifted. To add, walking on urban streets with human-centered street designs makes pedestrians feel better (Choi et al., 2016).

Key metrics include safe walking and biking from age which reflect how early children can independently wander streets which can be counted as a strong indicator of safety. Children are involved in road accidents for many different kinds of reasons, majority of which are out of their control (Riaz et al., 2022). Therefore, streets’ design must prioritize the safety of the children.

Passenger capacity and bus speed reveal the efficiency public transit infrastructure, critical for reducing dependence on private vehicles. What’s more, the use of public transportation is frequently promoted as a solution in an era of growing concern over environmental issues, including global warming (Holmgren, 2013). The motor traffic level of service shows the balance between vehicular flow and other modes, informing decisions about traffic calming and space allocation.

Accessibility is further addressed through indicators such as on-street car and bike parking access and wheelchair width ensuring that all users regardless of physical ability or transport mode can access and use the street comfortably. Wheelchair users, like everyone else, require broad mobility to live and work and should have access to a well-connected system of suitable walkways for transportation (Ning et al., 2022). Biking width and pedestrian crossing time also influence safety and ease of movement, particularly at intersections and high-traffic zones.

2.5. Environment

The environment dimension addresses how street design influences ecological sustainability, climate resilience, and the overall environmental health of urban areas. More and more, ecologists, planners, designers, and the general public are worried about how these changes impact day-to-day living and the sustainability of "quality of life" for the generations to come (McPherson et al., 2011). Streets are key interfaces between the built environment and natural systems, and their quality directly affects air quality, heat regulation, water management, and carbon emissions. For instance, in warm climates and especially in Mediterranean towns, it is essential to preserve and care for urban street trees in order to reap the benefits of their microclimate (Coutts et al., 2016). Environmentally responsive street planning contributes to both local well-being and global sustainability goals.

A central set of indicators involves CO_2 emissions which is a major contributor to climate change. Important thing is that it should not be forgotten that alongside CO_2, other greenhouse gases contributing to global warming—such as methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6)—are also listed in the Kyoto Protocol of 1998 (United Nations, 1998). Streets that prioritize human-centered mobility and greenery can help reduce these levels significantly.

Additionaly, since ancient times, it has been understood that stormwater from constructed places needs to be managed carefully since the pollutants and litter it contains can have an adverse effect on both quantity and quality, affecting both environmental and public health (Barbosa et al., 2012). Stormwater management is addressed in the Streetmeter through two distinct but complementary functions. Stormwater delay refers to the street's capacity to slow down the flow of rainwater. Stormwater cleaning, on the other hand, reflects the street's ability to remove pollutants from runoff before it enters the sewer system or local waterways.

2.6. Gender equality

While often overlooked in traditional urban planning, gender equality is a critical lens through which street quality should be assessed. Particularly when it comes to individuals of different genders, races, and classes, different cultures have varying thresholds for tolerance and acceptance (Rapoport, 1990). This situation results in the fact that public spaces are experienced differently based on gender, particularly in terms of safety, accessibility, and usability. Integrating gender-inclusive design ensures that urban environments are inclusive and supportive of all people, regardless of gender identity. Equity-focused policies, including those addressing gender, can have a broad community impact by helping to shift norms and promote a healthier, more inclusive society (Keippel et al., 2017).

Key considerations include perceived and actual safety, especially during evening or night hours. Factors such as adequate lighting, clear visibility, active frontages, and the presence of diverse users contribute to a sense of security. Streets that are poorly lit or isolated can deter women and girls from using them freely, especially for walking or cycling. It is found in a research that personal security issues for women and gender minorities go beyond the possibility of traffic-related injuries (McAndrews et al., 2023). This finding highlights how depressing the circumstances are.

Accessibility also intersects with gender in terms of caregiving responsibilities. Features like wide, smooth pavements, resting areas, ramps for strollers, and step-free crossings make a significant difference for individuals navigating with children, strollers, or mobility aids. Keep in mind that while both women and men with disabilities face inequality, women with disabilities experience greater challenges due to compounded effects of disability and gender stereotypes that reinforce traditional roles (European Institute for Gender Equality, 2018).

Moreover, the presence of gender-diverse street users, inclusive seating arrangements, and representation in street art or naming can signal cultural recognition and belonging. Local governments have the potential to promote gender equality through arts-based initiatives, as art can highlight inequities, empower women, spark dialogue, and inspire community action (Shearson et al., 2022).

2.7. Religious inclusivity

Religious inclusivity is a vital yet often underrepresented aspect of street design. Even, conflict assessments do not necessarily include an emphasis on faith and religious diversity (Wilkinson & Eggert, 2021). In diverse urban settings, streets should reflect and accommodate the cultural and religious practices of all community members. Policymakers, scholars, practitioners, and local communities must all work together to successfully interpret, protect, manage, and develop the many manifestations of heritage in order to make cities more sustainable (Giliberto, 2023). This not only fosters mutual respect and social cohesion but also ensures that public spaces are welcoming and functional for individuals of varying and beliefs.

Indicators of religious inclusivity in street quality could include the availability and visibility of culturally sensitive amenities. Notably, a empirical research has revealed how parish churches promote interactions that aren't frequently discussed in urban discourse on homophobia and transphobia (Andersson et al., 2011). Additionally, street design should allow for flexible use, such as accommodating increased foot traffic near places of worship during religious events, processions, or peak visitation times. This flexibility is important because religion influences long-standing planning issues, including community formation, public space use, land-use policy, and the placement and architectural style of religious buildings (Mazumdar & Mazumdar, 2013).

Furthermore, representation and recognition in public art, placemaking elements, or the naming of streets and features can foster a sense of belonging among religious groups. Since ancient times, art has drawn inspiration from myth, magic, and religion, maintaining its powerful and sacred appeal (Shusterman, 2008). Thoughtful design choices should therefore be mindful to avoid marginalization or exclusion, particularly in neighborhoods with significant religious or ethnic diversity.

3. Policy implications

The comprehensive evaluation of street quality across multiple dimensions provides a strong foundation for data-informed urban policy. These findings highlight the need for policies that not only address infrastructure and efficiency but also promote equity, inclusion, and sustainability in public space design. Embracing a human-centered design approach is essential to ensure that streets are planned for the people who use them.

Health indicators emphasize the importance of policies that reduce air pollution, noise, and traffic related injuries while promoting active transportation. Public health goals can be advanced through investments in safe, clean, and walkable street environments.

Social indicators highlight the role of streets in building community life. Policymakers should ensure that streets are welcoming and inclusive by supporting features such as seating, lighting, and public gathering areas. These elements foster social interaction and improve perceived safety, especially for vulnerable users.

Economic outcomes demonstrate the potential of well-designed streets to support local commerce and contribute to municipal revenues. Governments should facilitate flexible use of street space, such as outdoor dining and accessible storefronts, while aligning zoning and investment policies to enhance value creation.

Mobility related insights examines the street space from the perspective of active transport and public transport. Decision-makers should make streets easier to access, shorten the time it takes to cross safely, and ensure that people of all ages and abilities can move through them without difficulty.

Environmental considerations, such as stormwater delay and cleaning and temperature regulation, point to the need for streets that contribute to long-term climate resilience and improved urban health. Policy frameworks should incorporate these functions into infrastructure planning and performance standards.

Ensuring gender equality in street design is essential for creating fair and inclusive public spaces. Streets should promote safety, accessibility, and comfort for all genders, recognizing differing mobility needs and caregiving roles. Urban planning regulations should incorporate gender-sensitive principles to make streets more equitable for everyone.

Religious inclusivity is equally important in reflecting the cultural and spiritual diversity of communities. Streets should be designed to respect religious practices, provide space for inclusive use, and avoid elements that may marginalize specific groups.

By bringing all of these dimensions together, governments can create places where every individual feels a sense of belonging.

4. Conclusions

This study has provided a multidimensional evaluation of street quality using Streetmeter, assessing key factors including health, social interaction, economy, mobility, and environmental impact. To broaden the framework, gender equality and religious inclusivity were added as critical dimensions, emphasizing the importance of inclusive and human-centered street design in contemporary urban planning. This approach offers a more comprehensive understanding about function of streets.

This study adds to both academic and policy discussions by providing a clear, data-based way to understand how streets function. It helps decision-makers design urban spaces that are more livable, fair, and responsive to people's needs, while also paying attention to often-overlooked cultural and social aspects of street life.

Limitations of the study include the tool’s focus on numbers and measurable data, which may not fully show people’s personal experiences or the unique details of each street’s context. Additionally, the newly introduced aspects such as gender equality and religious inclusivity are not yet fully supported by standardized metrics within Streetmeter, and their assessment relies in part on qualitative interpretation. The findings may also vary depending cultural context, limiting direct generalizability across all urban settings.

Future work should focus on developing standardized indicators for social inclusivity dimensions, particularly gender and religious equity, to allow for more robust and comparable evaluations. Expanding the study to multiple cities with varying cultural and spatial characteristics could help to improve to software, also. Additionally, integrating participatory research methods such as community workshops, user interviews, and ethnographic observations would help capture lived experiences and bridge the gap between digital assessment and real-world perceptions of street quality.

17-19 May 2025, Trabzon, Türkiye

Are public transport ınformation systems equally effective? Insights from local and migrant passengers

Abdulkadir Özden*[1], Hakan Kocaman[2], Yavuz Halimergün[2]

[1] Sakarya University of Applied Sciences, Department of Civil Engineering, 54050 Sakarya, Türkiye
[2] Sakarya University of Applied Sciences, Graduate Education Institute, 54050 Sakarya, Türkiye

Abstract. This study investigates the differences in public transport usage patterns and perceptions of passenger information systems between migrant and non-migrant populations in Türkiye. Based on data collected from 513 participants through face-to-face surveys conducted in the cities of Sakarya and Istanbul, the research adopts a descriptive approach to explore demographic characteristics, transport mode preferences, and satisfaction with digital and on-site information services. The analysis reveals that migrants tend to be younger, more highly educated, and are more likely to use high-capacity transport modes such as metro systems. Interestingly, migrants also report higher satisfaction with information systems, particularly with mobile applications and language accessibility—an unexpected finding considering the generally limited multilingual support in Türkiye's public transport infrastructure. This may reflect positive experiences in cities like Istanbul, where such systems are more developed, as well as comparative perceptions shaped by migrants' countries of origin. Common challenges shared by both groups include long waiting times and concerns about vehicle safety. The study emphasizes the importance of inclusive, technology-supported transport systems and suggests that future research should expand to other cities—both metropolitan and less developed—in order to assess how infrastructure disparities influence public transport accessibility and user satisfaction among diverse urban populations.

Keywords: Public transport; Passenger ınformation systems; Immigirants; Accessibility

1. Introduction

Urban transportation systems play a fundamental role in ensuring social inclusion, economic vitality, and quality of life in modern cities. Efficient and accessible public transport (PT) services not only facilitate daily mobility but also contribute to broader societal goals such as environmental sustainability and social equity. In an increasingly diverse urban landscape, the inclusiveness of transportation systems—encompassing infrastructure, vehicles, information systems, and supporting digital applications—has become a central concern for both local authorities and policymakers.

For transportation systems to serve all segments of society effectively, they must address the needs of diverse user groups, including both native residents and migrants. Public transport inclusiveness is not limited to physical accessibility; it also encompasses the effectiveness of passenger information systems, the clarity of real-time announcements, the user-friendliness of route planning applications, and the availability of multilingual services (Sime & Fox, 2014). For migrants, who may face linguistic, cultural, and informational barriers, the ability to easily access and interpret public transportation information is a critical factor influencing their mobility patterns and integration into urban life (Li et al., 2024; Welsch et al., 2016).

Despite the recognized importance of inclusive transportation design, relatively limited research has focused on comparative analyses of migrants' and non-migrants' experiences with public transport, particularly in Türkiye's urban settings. Understanding the differences and commonalities between these groups can provide valuable insights into how transportation services—and especially digital passenger information systems—can be improved to better serve an increasingly heterogeneous population.

This study aims to contribute to this emerging field by conducting a descriptive analysis of public transport usage patterns among migrants and non-migrants. Based on survey data, the research examines how demographic factors correlate with transport habits, the perceived effectiveness of infrastructure and digital information tools, and the role of passenger information systems in facilitating urban mobility. Through this lens, the study seeks to highlight critical areas for enhancing the inclusiveness of public transportation services in Türkiye.

2. Literature review

Public transport systems play a crucial role in fostering social inclusion by enhancing accessibility, expanding infrastructure, and integrating digital passenger information tools. Academic research highlights these components as essential for creating equitable transportation networks that cater to the needs of diverse populations, including marginalized groups.

One foundational aspect of social inclusion in public transport is the accessibility of such systems. Saghapour et al. (2016) elaborate on how inadequate access to public transportation can hinder individuals' abilities to engage with various services and activities, leading to social isolation and exacerbating socio-economic disadvantages (Saghapour et al., 2016). This aligns with Yang et al., who advocate for comprehensive accessibility indices that consider various demographic factors to ensure that public transport serves all urban residents effectively (Yang et al., 2019). These infrastructural advancements are critical for building a connected urban environment that facilitates movement for all citizens.

The increasing integration of digital technology into public transport systems has significant implications for social inclusion. Digital tools can disseminate real-time information about services, enhancing the user experience and encouraging public transit usage (Davidsson et al., 2016). Digital maps and applications have been cited as effective means to promote green transportation, encouraging sustainable commuting behaviors among users, particularly in urban settings where congestion and emissions are concerns (Zhang et al., 2024). Furthermore, digital systems can streamline payments and expand access to transport services, making them more appealing to a broader audience, as evidenced by findings from Sener et al., which indicate that prior positive experiences with public transit foster ongoing use intentions (Sener et al., 2019). Research indicates that an integrated and well-structured public transport system enhances social cohesion among diverse communities.

Migrants face numerous barriers when using urban public transport systems, which significantly impacts their ability to integrate and access vital services. These barriers are often categorized into three primary areas: language difficulties, access to information, and navigation challenges. Insufficient proficiency in the local language can impede migrants' understanding of transit systems, leading to confusion and hesitation in using public transport. According to Nteliou et al., language proficiency directly influences the ability of migrants to navigate public facilities, including transport systems, exacerbating issues of exclusion and integration (Nteliou et al., 2021).This lack of understanding can deter them from accessing information necessary for effective public transport use.

Access to relevant information regarding transport options and services is another critical barrier faced by migrants. As indicated by Waitt et al., many migrants lack adequate information about public transport schedules, routes, and payment systems, which can hinder their mobility (Waitt et al., 2016). This situation is often worse in rural areas where public transport services are limited or non-existent (Pilling & Estes, 2016). In metropolitan areas, digital information tools have the potential to alleviate some informational barriers. However, the efficacy of these tools depends on their accessibility and usability for migrants. Studies indicate that many public transportation systems fail to provide multilingual and culturally relevant information, which can further marginalize non-native speakers and create disparities in service usage (Gruer et al., 2021).

Navigating public transport systems poses unique challenges for migrants, particularly those who may be unfamiliar with urban environments. Navigational challenges arise from inadequate signage, the complexity of transit maps, and a lack of user-friendly tools that cater to migrants. As highlighted by Welsch et al., migrants are less likely to own personal vehicles, making them more reliant on buses and trains; however, the unfamiliarity with the transport landscape can deter them from using these services (Welsch et al., 2016). Moreover, the experience of feeling lost or insecure in an unfamiliar environment can deter migrants from fully utilizing public transport systems. This navigation issue is compounded by the fact that many urban transport systems still operate with outdated or insufficient technology that does not accommodate the diverse needs of their users (Welsch et al., 2016).

The effectiveness of passenger information systems and mobile applications in improving public transport accessibility and user experience for diverse populations has garnered considerable attention. Recent studies highlight the various dimensions of how these digital tools facilitate better mobility and enhance the overall user experience across different demographics, including migrants, seniors, and individuals with disabilities. Real-time passenger information systems significantly enhance the user experience by reducing uncertainty and making travel more predictable (Corsar et al., 2018). Similarly, mobile applications have emerged as powerful tools that enhance public transport accessibility. The participatory design approach in creating mobile apps, as discussed by Vollenwyder et al., ensures that the needs of users with disabilities are met by incorporating their feedback into app development (Vollenwyder et al., 2020). This fosters user engagement and enhances the functionality of the digital tools, making transportation more accessible to all demographics. Furthermore, Setiabudi and Tjahyana (2015) demonstrate that hybrid mobile applications can improve public transport user experiences by addressing individual preferences and facilitating better planning through intuitive interfaces.

On the other hand, as migrants become more established within their new environments, their dependency on public transport tends to decrease, indicating a shift towards car ownership as financial stability increases (Blumenberg & Evans, 2010). This transition underscores the dynamic relationship between transportation availability, socio-economic status, and migrant integration processes. Cities that emphasize developing equitable public transport systems are better equipped to handle the influx of diverse populations and foster a sense of community among residents (Sime & Fox, 2014).

The implications of inclusive transport systems extend beyond mere mobility; they also encompass broader social integration. Inclusive transport facilitates access to essential services, such as healthcare and education, thereby enhancing migrants' quality of life and social connectivity (Li et al., 2024). Hence, it is evident that building inclusive public transport frameworks can play a transformative role in enhancing the social fabric of urban environments as they yield benefits not only for migrants but also for non-migrants by creating more interconnected communities.

3. Methodology

This study adopts a descriptive research design to examine public transport usage patterns and perceptions among migrants and non-migrants in Türkiye. The primary objective is to explore how demographic characteristics relate to transport habits and the use of passenger information systems, without applying inferential statistical modeling.

3.1. Data collection

Data were collected through a structured survey instrument administered via face-to-face interviews. The survey was conducted in two major metropolitan cities, Sakarya and Istanbul, in November and December 2024. These locations were selected due to their diverse populations and significant levels of immigration, which provide a rich context for analyzing public transport accessibility and usage patterns among different demographic groups.

A total of 513 valid responses were obtained. Participants were approached in public areas such as transport hubs, community centers, and marketplaces to ensure a diverse representation of public transport users. Participation was voluntary, and respondents were assured of anonymity and confidentiality. The questionnaire included items covering participants' demographic profiles, transportation usage frequency, types of public transport utilized, satisfaction with passenger information systems, and the use of mobile applications related to public transportation.

Survey items consisted of both categorical variables (e.g., gender, age, education level, employment status) and Likert-scale items (ranging from "Strongly Disagree" to "Strongly Agree") that assessed perceptions of accessibility, information availability, and overall service quality.

3.2. Sample characteristics

The sample includes individuals representing a broad range of socio-demographic backgrounds. Respondents were classified into two main groups based on self-reported citizenship status:

• *Non-migrants:* Native Turkish citizens born in Türkiye.

• *Migrants:* Individuals who were either born outside of Türkiye or had migrated within the last 10 years, regardless of their citizenship status.

This classification allows for a comparative descriptive analysis between migrants and non-migrants regarding their transport experiences and informational needs.

3.3. Data analysis

The analysis was exclusively descriptive. Frequencies, percentages, and cross-tabulations were employed to summarize the data across the key demographic and usage variables. Initially, general demographic distributions were examined to outline the profile of respondents. Subsequently, descriptive comparisons were made between migrant and non-migrant groups in terms of transport usage frequency, satisfaction with transport services, and experiences with passenger information systems.

4. Findings and results

The findings of this study provide a descriptive overview of public transport usage patterns, perceptions of passenger information systems, and demographic characteristics among migrants and non-migrants residing in Sakarya and Istanbul in Türkiye. Based on data collected through face-to-face surveys, the results highlight key differences and similarities between these two groups. The analysis focuses on how variables such as gender, age, education level, and household income relate to public transport behavior and access to information systems. By examining these patterns, the study aims to shed light on the inclusiveness of urban mobility services and the extent to which current public transport infrastructures meet the needs of diverse populations. This section first presents the demographic profile of the respondents, followed by a comparative evaluation of public transport usage and satisfaction across migrant and non-migrant groups. Table 1 summarizes the demographic distribution of migrants and non-migrants in the sample, categorized by gender, age, education level, and household income. The table reports both the number and percentage of respondents within each group, providing a basis for understanding the population diversity among public transport users.

Table 1. Demographic characteristics of survey respondents

Category	Migrant	Migrant Percentage	Non-Migrant	Non-Migrant Percentage
Gender				
Male	105	29,91	246	70,09
Female	64	40,25	95	59,75
DNPS	1	33,33	2	66,67
Age				
< 18	13	44,83	16	55,17
18-24	79	50,00	79	50,00
25-34	38	28,15	97	71,85
35-44	27	26,21	76	73,79
45-54	8	14,81	46	85,19
55-64	3	20,00	12	80,00
65+	2	10,53	17	89,47
Education				
Middle school or less	9	8,11	102	91,89
High school	23	17,69	107	82,31
College or above	138	50,74	134	49,26
Household income				
<17,000 TRY	21	70,00	9	30,00
17,000–29,000 TRY	52	52,00	48	48,00
30,000–44,000 TRY	38	26,39	106	73,61
45,000–59,000 TRY	32	25,00	96	75,00
60,000–79,000 TRY	15	19,74	61	80,26
80,000–99,000 TRY	1	5,26	18	94,74
100,000+ TRY	11	68,75	5	31,25

*DNPS: Do not prefer to say

The following Fig. 1 illustrates vehicle ownership status among migrants and non-migrants. A significant disparity is observed between the two groups. While 170 non-migrants reported owning a vehicle, only 33 migrants indicated the same. Conversely, 137 migrants reported not owning a vehicle, compared to 173 non-migrants. This suggests a notably lower rate of vehicle ownership among migrants, potentially reflecting economic disparities, differences in mobility needs, or access to private transportation. Such insights are critical for informing inclusive transportation and mobility policies targeting vulnerable populations.

On the other hand, Fig. 2 presents the distribution of public transport mode preferences among migrant and non-migrant respondents. Among non-migrants, the bus is clearly the most preferred mode, with 252 selections, followed by 224 for minibus, 65 for heavy rail/metro, 42 for tram. In comparison, migrants show a more balanced distribution across multiple modes. While the minibus (99) and bus (98) are the most frequently selected modes by migrants, the heavy rail/metro system also receives notable attention with 30 selections. This indicates that migrants make significant use of both formal and semi-formal systems and tend to diversify their public transport usage more than non-migrants, possibly due to their residential dispersion across urban peripheries and high-density corridors.

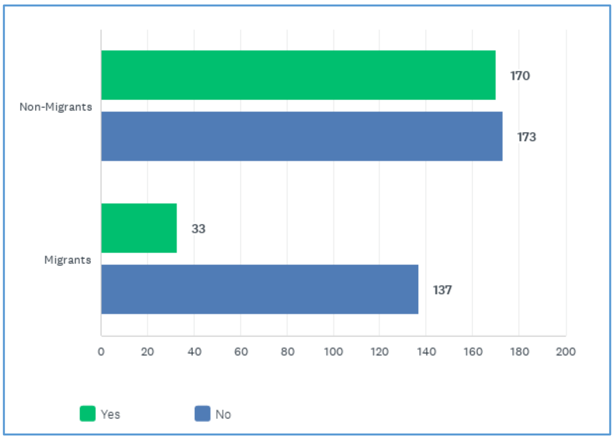

Fig. 1. Vehicle ownership by migration status

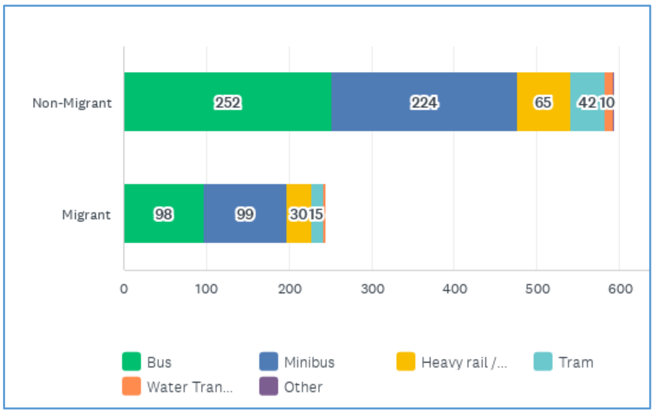

Fig. 2. PT mode/type preference

Fig. 3 compares the attitudes of non-migrant and migrant respondents toward public transport (PT) and associated information systems. Each statement was evaluated using a three-point Likert scale (Agree, Neutral, Disagree), allowing for a visual contrast between the two groups. Overall, both groups exhibit relatively positive perceptions; however, migrant respondents consistently demonstrate slightly higher levels of agreement across most items, indicating a more favorable evaluation of the transport services and digital tools available to them.

Regarding general public transport usage, both groups show high levels of agreement with the statements *"I prefer to use PT in my daily life"* and *"Using PT is cost-effective for me"*. These findings highlight the essential role that public transport plays in the daily routines of both populations. However, the slightly higher agreement among migrants suggests that they may be more reliant on public transport for economic and practical reasons, likely due to lower rates of private vehicle ownership and a greater need for affordable mobility.

Satisfaction with public transport operations—particularly in terms of routes and schedules—also appears to be slightly higher among migrants. Migrant respondents more frequently agree that *"The routes and schedules of PT meet my needs"* and that *"I can easily access up-to-date information about PT schedules."* This may be attributed to their more active use of mobile applications or their greater sensitivity to transport reliability as newcomers navigating unfamiliar environments.

Interestingly, a notable and somewhat unexpected difference between the two groups emerges in their evaluation of passenger information systems. Migrants report higher satisfaction with onboard announcements and the availability of language options compared to non-migrants. This finding is surprising given that passenger information systems in Türkiye are often perceived as inconsistent, with limited multilingual support and uneven technological integration, especially outside major urban centers. However, it is possible that some migrant respondents reside in Istanbul, where relatively advanced and accessible transport infrastructure—including digital displays, audio announcements, and mobile app integration—is more widely available.

Moreover, the higher levels of satisfaction among migrants may also be influenced by their comparative perspective: when contrasted with the public transport environments in their countries of origin, Türkiye's infrastructure—particularly in metropolitan contexts—may represent a notable improvement in terms of clarity, modernity, and accessibility. This contrast could enhance their perception of effectiveness, even if the system still presents gaps from a local policy or universal design standpoint. Therefore, this result underscores not only the importance of localized infrastructure investment, but also how relative expectations and past experiences shape perceived quality among diverse user groups.

In relation to mobile technologies, both groups express strong approval of mobile applications as tools for planning and navigating public transport. Statements such as *"I regularly use PT mobile applications on my smartphone"* and *"I can quickly access PT schedules and route information"* received high agreement from both groups, with slightly greater enthusiasm from migrants. This reinforces the critical role of digital tools in enhancing the public transport experience, especially for users who may depend on real-time information to reduce uncertainty and plan their journeys efficiently.

Despite these generally positive evaluations, certain areas reveal shared challenges. Both groups identify *long waiting times during travel* as a persistent issue. Additionally, non-migrants express more concern regarding the *safety of PT vehicles*, with higher disagreement levels in this item. These findings suggest that while information systems and mobile applications are functioning effectively, there are still operational aspects of the public transport system—particularly reliability and safety—that require attention for all users.

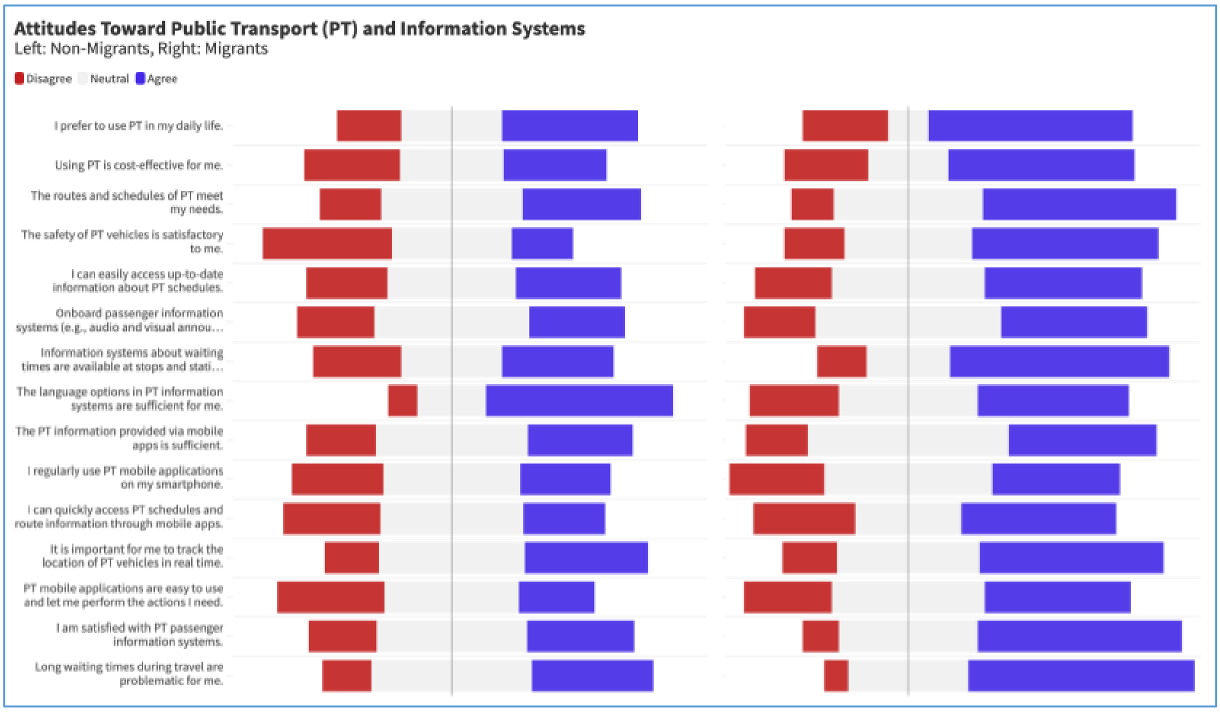

Fig. 3. Comparison of attitudes toward public transport (PT) and passenger information systems among non-migrant and migrant respondents.

5. Conclusion and discussions

This study provided a descriptive analysis of public transport usage patterns and perceptions of passenger information systems among migrant and non-migrant populations in Türkiye. Drawing on data collected through face-to-face surveys conducted in Sakarya and Istanbul, the findings offer valuable insights into how different user groups experience and evaluate urban mobility services.

The demographic analysis revealed that migrants tend to be younger, more likely to have higher educational attainment, and more concentrated in both the lowest and highest income brackets. These findings suggest a heterogeneous migrant population, consisting of both economically vulnerable individuals and highly mobile professionals or students. In contrast, non-migrants were generally spread in various age and income categories, reflecting a more stable, long-settled urban population.

Public transport usage patterns showed that both groups rely heavily on buses and minibuses; however, migrants reported greater use of metro systems, suggesting that they are more engaged with high-capacity and multimodal networks, particularly in metropolitan areas like Istanbul. Migrants also demonstrated slightly higher satisfaction levels with public transport routes, schedule information, and affordability, indicating a relatively positive experience despite broader system-level limitations in Türkiye.

A particularly notable finding was the migrants' more favorable evaluation of passenger information systems, especially in terms of onboard announcements, language accessibility, and mobile applications. This result was somewhat unexpected, given that Türkiye's information systems are often criticized for inconsistency and lack of multilingual support outside of major cities. However, this positive perception may stem from both the higher-quality infrastructure available in cities like Istanbul and a comparative advantage when contrasted with the public transport conditions in migrants' countries of origin. These experiences highlight the role of digital tools and inclusive communication strategies in improving accessibility and reducing uncertainty, particularly for newer or more vulnerable urban residents.

Despite these positive trends, both migrant and non-migrant groups expressed dissatisfaction with waiting times and, to a lesser extent, concerns about vehicle safety. These shared pain points emphasize the ongoing need to improve not only digital and informational infrastructures but also the operational reliability of public transport services.

Future research could build on these findings by expanding the geographical scope beyond Istanbul and Sakarya. While this study offers valuable insights from two urban centers with relatively developed transport infrastructures, it remains important to examine whether similar patterns and perceptions emerge in other parts of Türkiye. Comparative studies that include other metropolitan cities such as Ankara, Izmir, or Bursa, as well as smaller urban centers with less advanced public transport infrastructure, would help determine the extent to which infrastructure quality influences migrant and non-migrant experiences. Moreover, exploring cities with limited multimodal integration or reduced availability of digital information systems could reveal whether satisfaction and accessibility gaps widen under less favorable transit conditions. Such efforts would contribute to a more comprehensive understanding of transport equity and informational inclusion across different urban contexts in Türkiye.

In conclusion, the study underscores the importance of maintaining and expanding inclusive, multimodal, and technology-enhanced transport systems that meet the needs of a diverse urban population. Policymakers should pay particular attention to the mobility challenges of migrants—not only through equitable route and fare planning, but also by ensuring that information systems are accessible, multilingual, and responsive to varying levels of digital literacy. Doing so will support more inclusive, efficient, and resilient public transport networks in Türkiye's rapidly urbanizing contexts.

Acknowledgement

The authors would like to thank all participants who contributed to the survey conducted in Istanbul and Sakarya. Special appreciation is extended to the local institutions and community centers that supported access to respondents during fieldwork. This study was conducted as part of an independent academic research initiative. The authors also acknowledge the use of artificial intelligence-based tools (ChatGPT) for language editing, text structuring, and terminology support during the writing process, which contributed to the clarity and consistency of the manuscript.

Abstract. Replacing some Microfine Cement (MCEM) with Silica Aerogel (SA), Aerogel Aggregate (AA) and Ash Residue (AR) derived from Incinerated Bottom Ash (IBA) during concrete casting were studied. During fabrication, aerogel materials made from IBA exhibited excellent characteristics, such as low thermal conductivity, low density and high porosity, making it heatproof, hydrophobic, fire resistant and highly absorptive. The SA and AR were added to replace 5% - 30% in volume of MCEM. The compressive strength of the concrete cubes were then tested after 7, 14 and 28 days. The compressive strength of the SA concrete mix were measured ranging from 19.10 MPa to 34.19 MPa, within the same range of normal concrete mix. It was also observed that the compressive strength could reach up to 25.58 MPa after 28 days of casting period when 5% of MCEM being replaced with AA. The average compressive strength of AA concrete mix is higher than those in SA concrete mix but comparable to those in AR concrete mix. Overall, the replacement of MCEM with 5% of AR or AA maintained the same compressive strength of the 100% MCEM concrete mix. In conclusion, the replacement of MCEM with silica aerogel components might reduce the cost of concrete making, while the fabrication of aerogel could minimise the waste disposal to Semakau landfill of Singapore.

Keywords: Compressive strength; Incinerated bottom ash; Micro-Cement; Silica aerogel, Sustainable material

1. Introduction

Singapore is a city-state island that holds a growing population of 5.704 million (2019). In a tiny country where land is scarce, Singapore's only waste landfill, Pulau Semakau, is expected to be completely stocked by 2035. It is essential to divert incineration ash and use it for construction purposes to avoid potential crises for a new landfill (Patra *et al*., 2021). Singapore's garbage is burned in four Waste-to-Energy incinerator plants, 7% of the total burned rubbish is converted into energy, and the remaining 93% generates approximately 600 tonnes of non-incinerable ash, including incinerated bottom ash (IBA) (Tan, 2021). It is predicted that a new landfill with a size equivalent to Pulau Semakau has to be constructed every 25 to 30 years. Such a man-made landfill island is extremely highly-priced, costing about $610 million to create (Murdoch, 2021). Due to this, Singapore has to constantly upgrade and implement new technologies such as more effective incinerators to keep abreast with the demands of waste produced per year. It is also estimated by the World Bank that global waste could grow by 70% by 2050 from 2.01 billion tonnes to 3.40 billion tonnes with the buildup of urbanisation and increasing population. Therefore, it is vital that we implement proper and cost-efficient methods in the treatment of ash and also find ways to create products out of ash such as Silica Aerogel (SA), Aerogel Aggregate (AA) and Ash Residue (AR) to better improve on other aspects of the current materials such as concrete, widely used in the construction and infrastructure industries.

SA has ultralight weight, high porosity with 99% air by volume, low density, and thermal conductivity range (0.002 ~ 0.03 W/mK) lower than still air (0.6 W/mK). The highly porous and flame retardant SA is also superhydrophobic at 99% under normal temperature. The extremely low thermal conductivity which results from the composition of 99% air is the characteristic of the SA that we intend to utilize to improve the fire resistance of concrete. Aerogel is also known as a very strong material. Although a typical SA could hold up to 2000 times its weight in applied force, this only holds when the conditions of the force are gently and uniformly applied (aerogel, 2021). Meanwhile AA and AR could described as a SA derivation and SA by-products during SA fabrication. In this laboratory work, a different concentrations of SA, AA, and AR were added during concreting work to test the compressive strength of the SA, AA and AR concrete mixes.

golden light publishing

One of the most common cement that is used in the construction industry is Ordinary Portland Cement (OPC). This type of cement is made by combining limestone with other raw ingredients such as argillaceous, calcareous, and gypsum to make powder. It is preferred in places where fast construction is required. This cement is available in the market in three grades namely OPC 33, OPC 43 and OPC 53. After 28 days, these grades show the maximum strength of cement (Civil Digital, 2021).

A part of concreting works, Microfine Cement (MCEM) is widely used in pre-excavation grouting and post excavation grouting, both in drill and blast, and Tunnel Boring Machine (TBM) construction (Stalprotect, 2021). MCEM is a specialized cement that is mainly used in underground construction works such as tunnels, caverns, fixation, water sealing of tunnel walls and water scaling in fractured zones during tunnel construction (Engro-global, 2021). They can provide exceptional advantages and benefits over OPC due to the MCEM's ability to penetrate finer rock fractures. This decreases its rock mass permeability to the required level through the primary grouting operation. The use of MCEM indirectly minimise the need for a secondary microfine grouting or the injection of low viscosity chemical resins. Furthermore, the material is cured into hardened concrete which does not cause pollution to underground soils or water supplies (Cement, 2021). Moreover, it also offers an improvement in rock stability from filling rock discontinuities with its high strength properties. It is also commonly used for stabilisation or consolidation of soils as OPC grains are too coarse. MCEM is a polymer modified cement-based coating possessing more than twice the specific surface area (> 800 m^2/kg) (Engro-global, 2021a) in comparison to OPC (331 m^2/kg) (Aso-cement, 2021) with excellent permeability, strength, and durability properties. There are mainly 3 types of Microfine Cement: MCEM, Prefine 60/80, and RapidSet 150 (Engro-global, 2021). Each of them varies in terms of their specific surface area, cost and application. Despite its greater functionality, there is a huge price difference between MCEM and OPC, resulting in many companies opting for OPC over MCEM. Based on one of SP industry partners, EnGro Corporation Limited, OPC costs SGD 0.12/kg whereas MCEM can costs 5- 6 times more expensive or as much as SGD 0.65/kg.

The main objective is to investigate the compressive strength of concrete mix with replacement of cement by aerogel compound made from IBA. While comparing the compressive strength with a standard, the project aimed to replace MCEM/ OPC with SA, AA and AR as the main cost in concreting works. The secondary objective was to prolong the Semakau landfill in Singapore as it could serve a cheaper alternative by-products.

2. Materials and methods in fabricating aerogels and designing concrete mix

2.1. Fabrication process of SA, AA and AR

Raw IBA, provided by an industry partner, was oven dried to remove the moisture and stench. The raw ash was grinded into finer power size using a ball milling machine at 250 rpm for 30 minutes. Afterwards, the powerised ash is sieved in 300 µm of ASTM Standards by using a sieving machine and the grinded ash is stored in bottled containers. A chemical treatment was then carried out by adding IBA into 30% of HNO_3 and letting it stirred using a magnetic stir bar in a 1 L of glass beaker for 30 minutes to remove unwanted chemicals including metals present in the ash. The magnetic stir bar ensures proper mixing of the process. The solution containing ash is then poured into bottled containers and placed into the centrifuge machine for another 30 minutes to separate the ash from the acid solution. The remaining ash sludge that is settled at the bottom of the bottle container is then washed with deionized water and placed in the centrifuge machine for 30 minutes to remove excess acid that may still be present in the ash. The solution was then disposed of into an acid waste container. The rinsing process was repeated to ensure that the ash sludge is clean and all the acid was washed away. The ash sludge was removed from the bottle container and transfer it onto a weighing boat before placing it in the oven for drying as shown in Fig. 1.

Silica extraction is carried out by using 1 M NaOH solution in stainless steel autoclave at 180°C for 3 hours. After that, the ash was filtered out from the solution to obtain the water glass solution. Filtering of solution is conducted by using a fibre filter paper placed on a vacuum pumping machine. The filter paper and the pumping process was repeated until the solution becoming visibly clear from residue. Lastly, the ash sludge was extracted from the flask and place in the oven for drying. This ash sludge will be used for concrete cube casting known as AR after drying. After obtaining water glass solution. 0.1 M Hydrocloride Acid is then added drop by drop to fabricate silica gel via sol-gel method. In this process, silica gel is smashed and added slowly into triple solution containing trimethylchlorosilane, isopropanol and n-hexane . This step is to make the silica gel hydrophobic. The layer of white gel is then transferred onto a petri dish and put into the oven at 150 °Cfor drying for 1 hour. The SA that was produced after drying will be used for concrete cube casting.

AA was made by cutting the Aerogel Blanket (AB) that purchased from Guangdong Alison Technology (China) into small cubes of 1 cm^3. AB is a product by the combination of fibreglass mixed with SA. AB is known as a good heat and sound insulator. It also inherits most of the characteristics of the SA such as it has low density, ultralight, and hydrophobic. In terms of cost-effectiveness, AA is higher than SA because it only contains about 10% of SA and 90% of fiberglass.

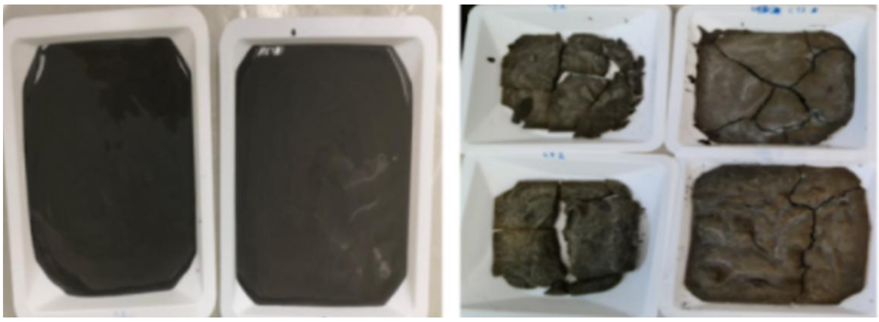

Fig. 1. Ash Sludge Before (left) and After drying (right)

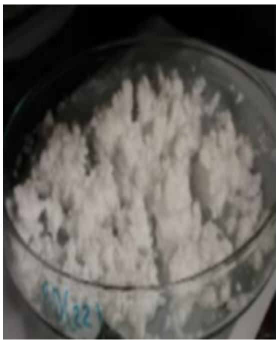

Fig. 2. SA after being over dried

2.2. Design of Concrete Mix

Quantity of SA was calculated in percentage by volume instead of weight since SA and AA has a very low density of 0.100 g/cm^3 and 0.180 g/cm^3 respectively. Table 1 showed the design of 1,000 cm^3 of concrete mix composition with various water/ cement ratios. In details, Table 2 showed an example of the compositions of individual material in making 1,000 cm^3 of SA concrete cubes with water/ cement (W/C) ratio of 0.625. Similar composition was shown in Table 3 for the making of 1,000 cm^3 of AA concrete mix at W/C of 0.65. Quantity of AR was calculated in percentage by weight since the density was similar to MCEM and OPC (density of 0.850 g/cm^3). Table 4 showed the composition of individual material in making 1,000 cm^3 of AR concrete cube.

Table 1. Design of 1,000 cm^3 of concrete mix composition

Coarse Aggregate	1.000 kg
Fine Aggregate	0.770 kg
Cement (MCEM / OPC)	0.400 kg
Type of mix	Water/Cement ratio (W/C
MCEM + Silica Aerogel (SA)	0.625
OPC + Aerogel Aggregate (AA)	0.650
OPC + Ash Residue (AR)	0.700

Table 2. Composition of materials in making 1,000 cm3 of SA concrete cubes at water/cement ratio of 0.625

Item	Material composition			
	MCEM (% in weight)	MCEM (kg) ± 5%	SA Powder (% in Volume)	Mass of SA (g)
100% MCEM	100	0.40	NA	0
95% MCEM + 5% SA	95	0.38	5	2.35
90% MCEM + 10% SA	90	0.36	10	4.70
85% MCEM + 15% SA	85	0.34	15	7.05

75% OPC + 25% AR	75	0.30	25	100
70% OPC + 30% AR	70	0.28	30	120

2.3. Concrete Making

SA, AA and AR are weighed using a digital analytical balance based on the required amount calculated in Section 2.2. Steel cube moulds, each with dimension of 10 × 10 × 10 cm^3, were coated with one layer of oil throughout surfaces in contact with concrete to ensure for easy extraction. After weighing the required amount of cement either MCEM or OPC, fine aggregate and coarse aggregate, all the materials are poured into a concrete mixer. Thereafter, SA/AA/AR are added into the mixture and mixed for one minute. Water was poured into the mixture and stir thoroughly until the water is completely mixed with the mixture. After the mixture is thoroughly mixed, half of the mixture was poured into the mould and compacted using a square compacting bar 35 times. The procedure was repeated for the second half of the mixture before smoothening the top surface of the cube with a finishing trowel. The cubes were strored in a dry and well-ventilated area for 1 day. All the screws were on the mould were removed, the samples were extracted and stored in water bath for 7, 14 and 28 days (Fig. 3) before proceeding with compressive testing. All sample were made in duplicate with the total samples being made up to 42 concrete cubes.

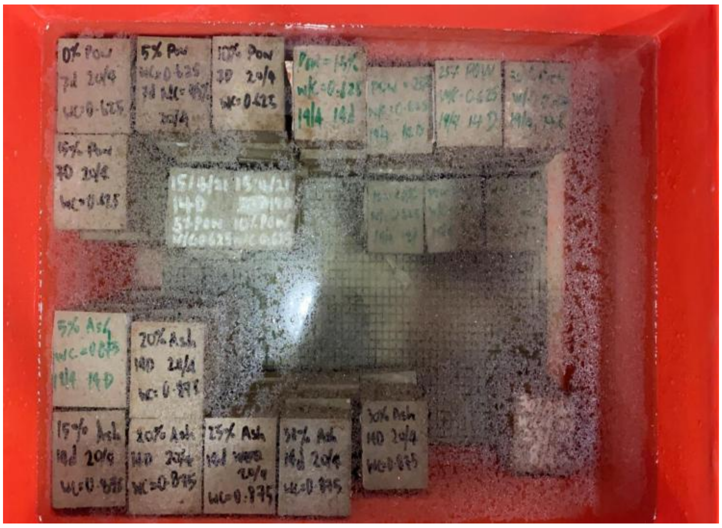

Fig. 3. Storage of concrete cubes in water bath (hydration)

3. Experimental results and discussions

3.1 X-Ray Fluorescence (XRF) scanning result

The elements of raw IBA, SA, AR, MCEM and OPC were analysed and the content was listed in 3.1 to understand the change of elemen composition in each sample of materials. Table 5 indicated that the first 3 main elements in IBA were silica (Si) and calcium (Ca) and iron (Fe), which Si and Ca filled more than 30% of IBA sample. In contrast, Table 6 indicated that Si was successfully embedded in SA (> 90%) to replace other elements, except chloride compound (Cl). It also showed that AR was contained similar composition of elements as extracted in IBA but with Ca compound had tripled up to >30% than those in SA. Table 6 also showed that Ca compound was the main element found in MCEM and OPC at 84.646% and 78.735% respectively.

3.2 Compressive strength measurements

To test the concrete mixes strength, two samples of each mix (different % of MCEM to SA or AA or AR) were casted for 7 days, 14 days and 28 days and the result shown in Fig. 4. The minimum strength of the structural concrete of 2500 psi (17.24 MPa) (ACI, 2021) was used as the baseline compressive strength for the discussion.

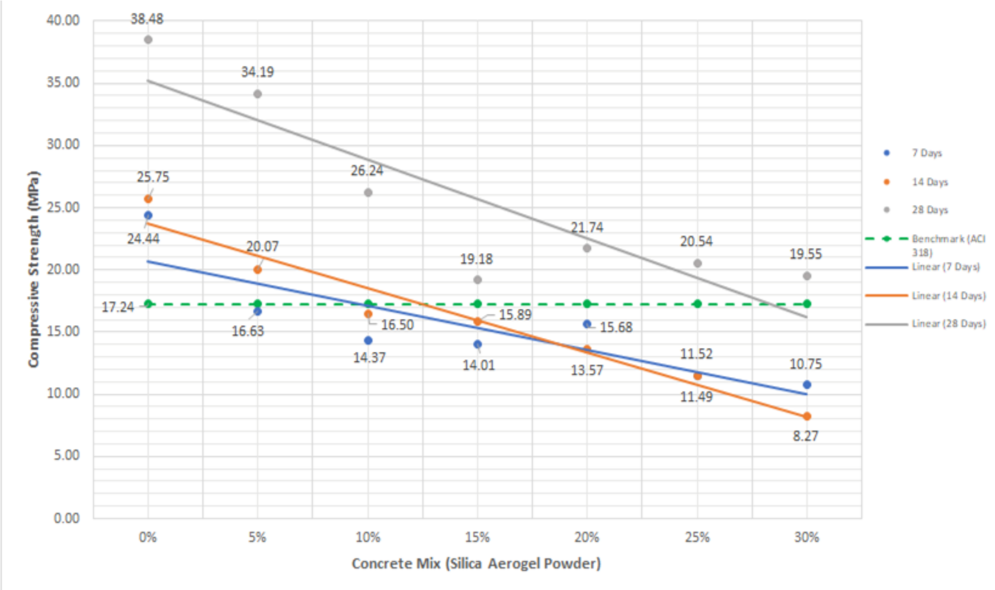

Fig. 4. Compressive strength of SA concrete cubes after 7, 14 and 28 days casting periods

Fig. 4 showed that the percentage of SA in concrete mix increasing from 5% to 30% while the compressive strength of the concrete cubes decreasing quite significantly. The reduction in compressive strengths from 0% to 30% SA content (highest value - lowest value) for casting periods of 28 days, 14 days and 7 days are 18.93 MPa, 17.48 MPa and 13.69 MPa respectively. The replacement of Ca with Si compounds could be the reason for the reduction of the compressive strength, as shown in Table 5 and 6. Hence, the replacement of MCEM with SA in concrete mix without using any binding agents have significantly lowered the compressive strength of concrete.

In constract, the compressive strength of AR in concrete mix decreased insignificantly. Fig. 5 showed that the average compressive strength dropped approximately 3 MPa for the 7, 14 and 28 days after AR replacement in concrete mix from 0% to 30%. This data showed a consistent decreasing trend of compressive strength. Overall, all of the concrete samples reached their maximum compressive strength after 28 days of casting period.

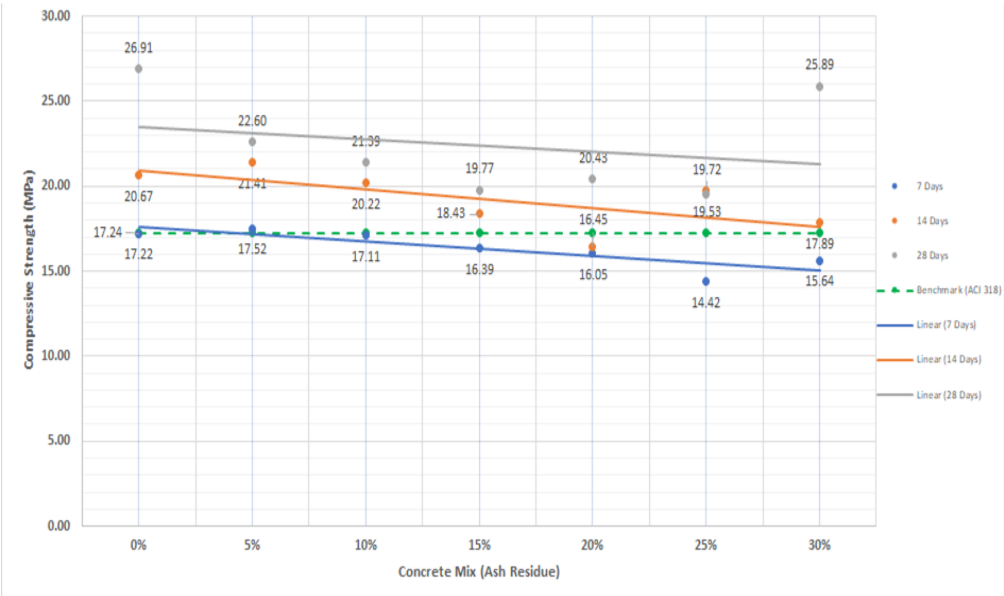

Fig. 5. Compressive strength of AR concrete cubes after 7, 14 and 28 days casting periods

Fig. 6 showed that the range of decrement for samples with different AA replacement in concrete samples was approximately between 0.15- 7.45 MPa. The average compressive strength dropped after replacement of AA from 0% to 30% for 28, 14 and 7 days of casting periods were 5 MPa, 9.2 MPa and 7.5 MPa respectively. During observation, it showed that AA results were more fluctuative than SA as AA was irregular form of aggregates.

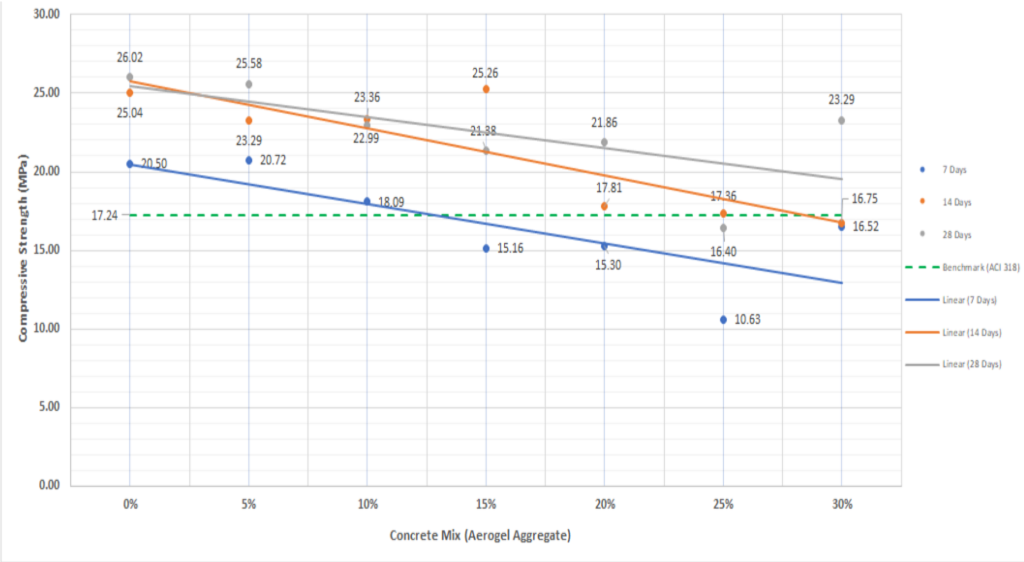

Fig. 6. Compressive strength of AA concrete cubes after 7, 14 and 28 days casting periods

4. Conclusions

In general, IBA derivatives shows a potential by- product material to replace cement in concrete mix based on the compressive strength. The replacement of cement using IBA can eventually prolong the Semakau landfill. Some specific discussions can be detailed as follows:

- The compressive strength of concrete decreased as SA replacement increased. However, the compressive strength of the SA concrete (19.55 - 38.48 MPa) is relatively strong compared to the reference of the average value (20 MPa ~ 40 MPa, ranging from 0.4 ~ 0.6 W/C ratio (The constructor, 2021), considering that the W/C ratio of the SA concrete samples is 0.625 with no additional binding agents were used. However, SA might be not cost-effective for MCEM replacement.
- The AR concrete mix is relatively consistent with the lesser reduction of compressive strength than those SA concrete mix. Therefore, it may be potential to produce concrete with the same compressive strength as 100% cement with the replacement of 5% of cement with AR. The project may reduce the concrete cost more than 5% due to the double effect from zero cost of ash residue and lesser of the waste disposal to Semakau landfill.
- AR and AA possessed most of the characteristics of SA, some being low density, ultralightweight, and hydrophobic. These attributes may lead to new findings such as improved durability, heat resistance or improved noise insulation of concrete.
- MCEM concrete incorporating SA has a potential to be noise and thermal insulator as the two main characteristics of SA. However, based on the result from our experiment, the compressive strength of the concrete could not be maintained well thus the application may be limited to non- structural concretes.

Abstract. The rapid depletion of natural resources and the increasing accumulation of waste have become global concerns in terms of environmental sustainability, highlighting the importance of innovative recycling practices. The growing interest in sustainability practices in civil engineering has encouraged the exploration of alternative materials for infrastructure applications. Recycled asphalt pavement (RAP) materials are considered a potential alternative to natural aggregates (NA) due to their ability to reduce environmental pollution, conserve energy, and lower costs. This study examines the filtration and drainage properties of RAP in subgrade drainage systems. Laboratory tests were conducted to evaluate the long-term performance and clogging behavior of RAP-based drainage systems used in combination with nonwoven geotextiles of varying pore sizes. Long-term filtration tests (LFT) were carried out using a specially designed and remanufactured test setup developed by ASTM D5101 standards. In this setup, a constant hydraulic gradient of 0.33 was used. Parameters such as the hydraulic gradient ratio (GR) and the permeability ratio (KR) were monitored to assess the system's functionality under various geotextile apparent opening sizes. This study revealed that RAP materials meet the performance standards required for filtration applications in subgrade drainage systems. These findings suggest that RAP can contribute to waste management and provide more sustainable infrastructure solutions by reducing the reliance on natural aggregates.

Keywords: Recycled asphalt pavement; Geotextile; Filtration; Demolition waste; Sustainability

1. Introduction

The increasing global population, rapid urbanization, and expanding infrastructure demands place significant pressure on natural resources and pose a serious threat to sustainable development. In this context, the volume of construction and demolition (C&D) waste has substantially increased, and the effective management of this waste has become a strategic priority both environmentally and economically (Silva et al., 2017; Edeme & Chibuzo, 2018). Construction and demolition waste includes materials such as concrete, metal, wood, and ceramics, which have the potential to be processed and reused in various infrastructure applications (Lu & Yuan, 2011).

Recent studies have shown that recycling C&D waste within the framework of sustainability principles not only reduces environmental impacts but also generates economic benefits (Tošić et al., 2015; Caro et al., 2024). Accordingly, many countries have developed legal regulations that encourage recycling and have made the separation and reuse of waste at the source mandatory (Purchase et al., 2022; Kim, 2021).

Subsurface drainage systems in road infrastructure are of critical importance for both the service life of the road and vehicle safety. The particle size distribution, permeability coefficient, and long-term filtration behavior of the aggregate materials used in these systems directly affect their performance (Li et al., 2017). However, the use of natural aggregates contributes to environmental degradation and the rapid depletion of natural resources. As sustainability and environmental concerns gain prominence in modern road construction, the use of recycled materials in infrastructure systems has become increasingly widespread. In this regard, reclaimed asphalt pavement (RAP) stands out among C&D wastes as a significant alternative due to its economic advantages, potential to reduce natural resource consumption, and ability to ensure long-term filtration performance (Rout et al., 2023).

Subsurface drainage systems to function effectively, the filter material must have sufficient permeability and be capable of limiting the passage of fine particles. The suitability of RAP as a filter material must be evaluated in terms of its long-term filtration performance. To prevent damage to the drainage structure due to particle movement

*Corresponding author, E-mail: yemir7433@gmail.com

https://doi.org/10.31462/icearc2025_ce_was_312

caused by water flow, the hydraulic properties of the recycled asphalt material must be accurately determined, and the drainage system should be designed accordingly. In recent years, experimental studies on the use of RAP in drainage systems have shown that this material demonstrates adequate hydraulic performance (Dager et al., 2023).

Thanks to its particle structure and drainage properties, reclaimed asphalt pavement (RAP) has the potential to be used as a filter material in road infrastructure. However, the physical and mechanical behaviors of RAP differ from those of natural aggregates, which may limit its use as a standalone material in drainage systems. Therefore, to enhance the long-term filtration performance of RAP, it is often used in combination with nonwoven geotextile materials (Mijica et al., 2020). Nonwoven geotextiles are geosynthetic materials produced by bonding natural or synthetic fibers (usually polypropylene or polyester) through needling, thermal, or chemical methods. Due to their flexible structure, high water permeability, and large pore openings, these materials are widely used in many geotechnical engineering applications (Koerner, 2005; Wu et al., 2020). Nonwoven geotextiles typically serve filtration, drainage, separation, protection, and reinforcement functions. When used with soils that have heterogeneous particle sizes or with alternative aggregates such as reclaimed asphalt, the structural and hydraulic functions of the geotextile are of critical importance (Bouazza, 2002; Tanasă et al., 2022).

The long-term performance of RAP when used in conjunction with nonwoven geotextiles is evaluated using filtration tests conducted according to ASTM D 5101. In these tests, parameters such as the permeability ratio (KR) and gradient ratio (GR) are used to assess the potential for fines accumulation and clogging on the geotextile surface over time (Sariahmetoglu et al., 2020).

In this study, the behavior of RAP material with different geotextile properties in subsurface drainage systems was investigated experimentally. The GR values of the systems exceed the acceptable clogging threshold of 3 within a short period of time. Moreover, a a strong correlation between the geotextile's apparent opening size and the filtration parameters of the system

2. Materials

2.1. Materials

In the modified ASTM D5101 testing configuration, Recycled Asphalt Pavement (RAP) sourced from a decommissioned asphalt surface within the Karadeniz Technical University campus was employed alongside a nonwoven geotextile. The selection of these materials was guided by their potential contribution to the development of sustainable drainage systems. The incorporation of RAP promotes the recycling of construction and demolition debris, thereby enhancing environmental sustainability and resource conservation.

2.1.1. Recycled asphalt pavement (RAP)

In this study, recycled asphalt pavement (RAP) material, obtained from construction and demolition waste, was used in long-term filtration tests. The RAP material was tested according to ASTM D5101 standards. The material was oven-dried and sieved for 24 hours. The sieved RAP aggregate, based on particle sizes, is shown in Fig 1 below. Subsequently, density measurements were taken using a pycnometer (Table 1). Additionally, the Standard Proctor test (ASTM D698-12) was conducted to determine the optimum moisture content and maximum dry unit weight (Table 2). The data obtained from these tests provide insights into the filtration properties of RAP material (Table 3) and its potential for use in subsurface drainage systems.

2.1.2. Geotextile

The combined use of aggregate and geotextile materials has proven to be an effective method, especially in drainage applications. In such systems, the filtration capacity of the geotextile layer directly affects the performance of the entire drainage structure. Therefore, the correct selection of the geotextile material is of critical importance for the long-term efficiency of the drainage system. Determining the geotextile by the soil's particle size distribution and permeability characteristics contributes to the sustainable achievement of the desired filtration performance. In this study, the apparent opening size of the geotextile material used was specified as 0.3 mm (Fig 2) The selected geotextiles are presented in Table 4.

3. Methodology

In this study, a modified experimental setup was developed based on the geotextile-filtration test setup specified in ASTM D 5101 standard, to determine the filtration properties of reclaimed asphalt pavement (RAP). Cylindrical samples with a diameter and height of 150 mm were used in the experimental system. In the sample cell, three manometer connection points were placed at heights of 25 mm, 75 mm, and 125 mm, attached to geotextile layers positioned on opposite sides of the cell. This arrangement enabled a more precise monitoring of the hydraulic gradient variations throughout the sample.

The RAP aggregate, which was dried in an oven, sieved, and classified by particle size, was mixed in the proportions specified in Table 5, and then water was added in the amount determined by the Standard Proctor test to prepare the sample. The geotextile was initially positioned in the central chamber of the three-part system, followed by the sample, which was compacted in five layers. The properties of the placed geotextiles are presented in Fig. 2 and Table 5. Subsequently, the three components of the system were assembled using silicone to ensure proper sealing. The system was then allowed to rest for 24 hours to enable the silicone to cure and guarantee water-tightness. Following this, the system was gradually flooded from the bottom to prevent the loss of particles, facilitating the reduction of air trapped within the sample and ensuring full saturation. Upon completion of the saturation process, water was introduced into the system from top to bottom.

The experimental setup was adjusted to maintain a hydraulic gradient of 0.33, and regular manometer readings and water flow measurements were recorded throughout the day. Based on the collected data, the gradient ratio (GR) and permeability ratio (KR) were calculated, and the relationship between these two parameters was also assessed. The pressure data obtained from manometers placed at different positions within the sample were analyzed using appropriate mathematical equations (Equations 2–5) to determine the gradient ratios.

Table 5. Material percentages to be used according to sieve numbers

Sieve No	10	18	30	40	50	70	100	Pan
% Quantity	10	15	9	14	13	19	10	10

(a) (b)

Fig. 2. Geotextiles (a) GT1 (b) GT2

$$GR_1 = \frac{i_{0-25}}{i_{25-75}} = 2 \times \frac{h_{25} - h_0}{h_{75} - h_{25}} \quad (2)$$

$$GR_2 = \frac{i_{25-75}}{i_{75-125}} = \frac{h_{75} - h_{25}}{h_{125} - h_{75}} \quad (3)$$

$$GR_3 = \frac{i_{0-25}}{i_{25-125}} = 4 \times \frac{h_{25} - h_0}{h_{125} - h_{25}} \quad (4)$$

$$GR_4 = \frac{GR_1 + GR_2}{2} \quad (5)$$

h_0, h_{25}, h_{75}, h_{125} : Manometer readings at different heights
i : hydraulic gradient

According to the ASTM D 5101 Standard, the KR parameter (Equation 6) is defined as the ratio between the permeability coefficient of the aggregate (as expressed in Equation 7) and that of the entire system (as shown in Equation 8) (Sariahmetoğlu et al., 2024).

$$KR = \frac{k_{aggregate}}{k_{system}} \tag{6}$$

$$k_{system} = \frac{Q}{A \times t} \times \frac{1}{i_{system}} \times \frac{\mu_T}{\mu_{20}} = \frac{Q}{A \times t} \times \frac{l}{h_{150} - h_0} \times \frac{\mu_T}{\mu_{20}} \tag{7}$$

$$k_{aggregate} = \frac{Q}{A \times t} \times \frac{1}{(U_{avg} - A_{avg})} \times \frac{\mu_T}{\mu_{20}} \tag{8}$$

k_{system} : The permeability value of the system at 20°C is, (cm/s),
Q : The accumulated flow volume at time t, (cm^3),
i : Hydraulic gradient,
A : Cross-sectional area of the sample, (cm^2),
t : The time required to collect the amount of drained water, Q (s),
μ_T : The viscosity of water at temperature T.
μ_{20} : The viscosity of water at 20°C,
l : The length of the sample,
U_{avg} : The average of the upper manometer readings,
A_{avg} : The average of the lower manometer readings.

Fig 3. Test system

4. Results and discussion

By the ASTM D5101 standard, long-term filtration tests were conducted using reclaimed asphalt pavement (RAP) in combination with two geotextiles of different apparent opening sizes. The tests were performed under a hydraulic gradient of $i = 0.33$, and the experimental results were evaluated based on the Gradient Ratio (GR) and Permeability Ratio (KR) criteria defined in the standard.

According to ASTM D 5101, a GR value equal to 1 indicates no clogging within the system. A GR value greater than 1 signifies the onset of particle migration, leading to increased clogging and reduced flow, while a GR value less than 1 suggests the passage of fine particles through the geotextile, potentially resulting in piping and increased flow within the system. The rapid increase of GR values beyond 3 within a short period of time, indicates that the systems are experiencing significant clogging.

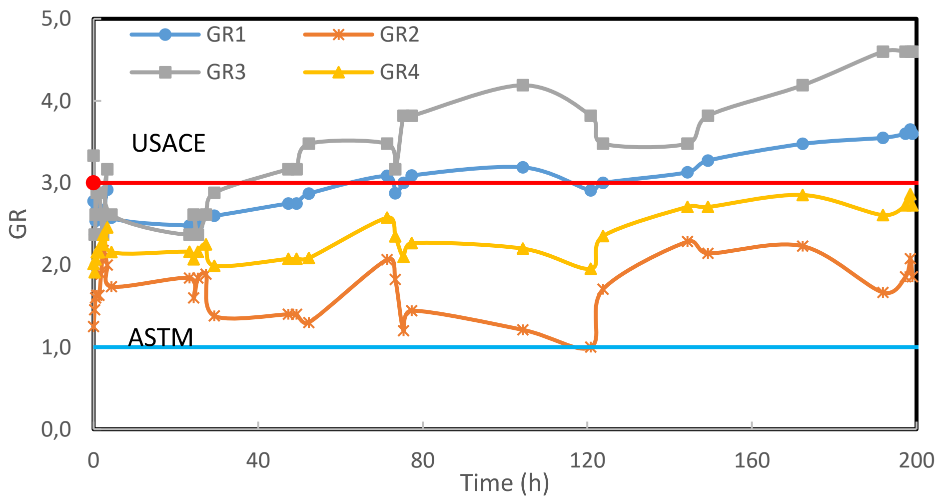

Fig 4. Time-dependent GR values of RAP-GT2

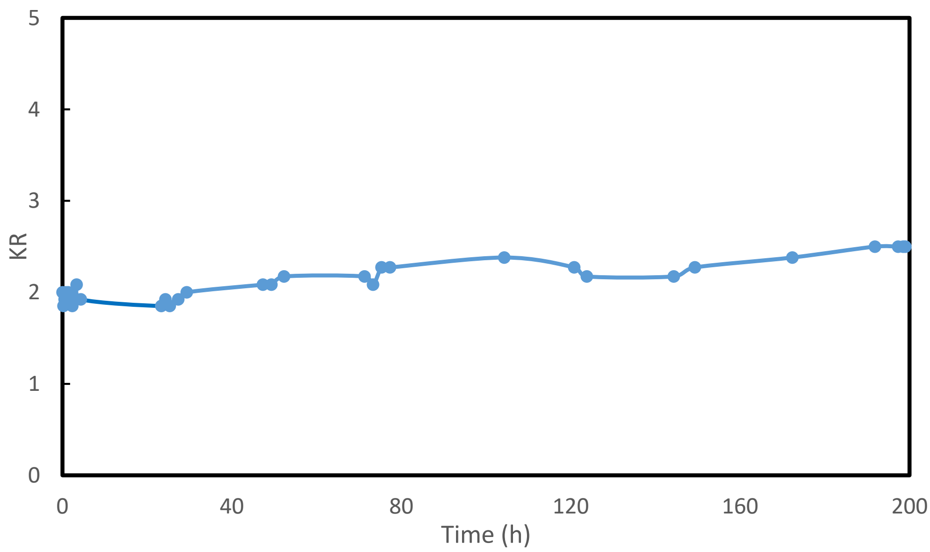

Fig. 5. Time-dependent KR values of RAP- GT2

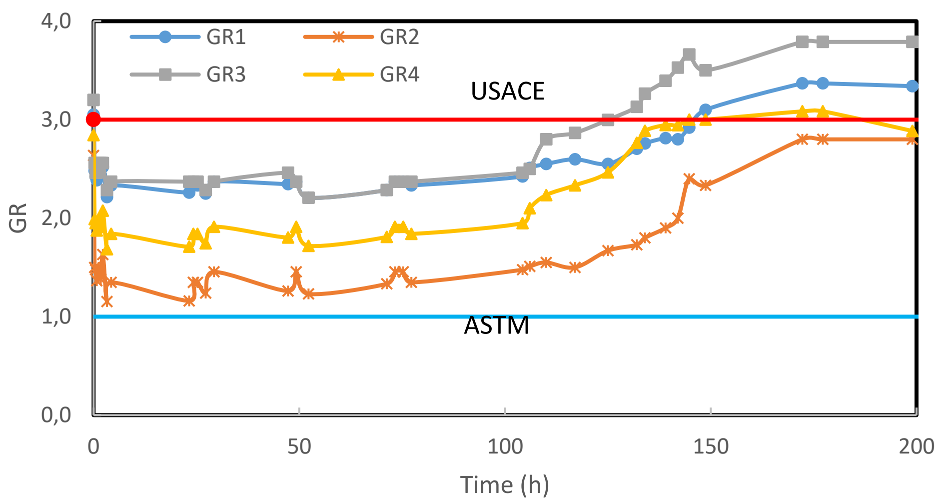

Fig. 6 Time-dependent GR values of RAP- GT1

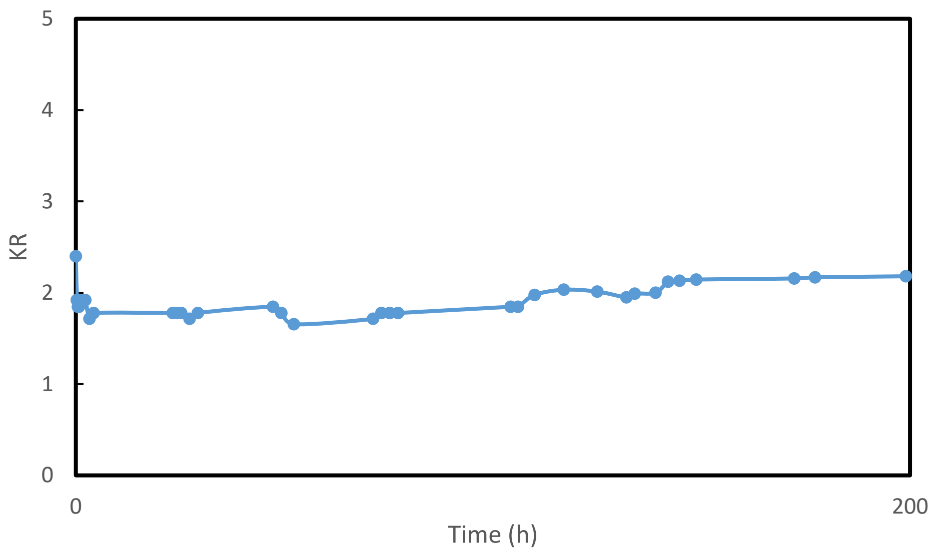

Fig 7. Time-dependent KR values of RAP-GT1

5. Conclusions

Filtration performance of RAP-geotextile system was tested using a enhanced version of long term filtration test apparatus specifically redesigned and manufactured according to ASTM D 5101 standard. Based on experimental data, the following conclusions were obtained:

- GR values exceeding 1 and show an increasing trend, suggesting the migration of fine particle material.
- Rapid increase in GR values beyond the critical threshold of 3 suggests that the system loses its drainage functionality within a relatively short duration
- It is difficult to assert a significant difference in filtration performance between the systems tested with two different geotextiles with different apparent opening sizes. Further research may be conducted by employing geotextiles with a broader spectrum of apparent opening sizes and subjecting the systems to different hydraulic gradients to gain deeper insight into filtration performance

Abstract. Over recent years, Gaza has faced extensive destruction due to military conflicts, resulting in the accumulation of approximately 40 million tons of demolition waste by Israeli aggression. This significant volume of waste poses severe environmental challenges and demands costly, long-term remediation efforts. Addressing this issue, the current study explores the potential for recycling demolition waste into building blocks to support reconstruction efforts in Gaza. With the anticipated restrictions on cement imports, gypsum, known for its lower environmental impact and energy requirements compared to cement, is proposed as a sustainable alternative binder. The study investigates the incorporation of various additives to enhance the mechanical and physical properties of gypsum-based blocks GB. Gypsum is weak against water, therefore, different types of additives are selected to be studied. The experimental program included two stages. In the first stage, gypsum is mixed with water and each type of additive and tested for compressive strength and absorption. The results of the first stage concluded that the Superplastisizer S is the best between the other types of additives, so it is selected to be used in the second stage. In the second stage, S is mixed with gypsum and aggregate produced from buildings demolished waste GA at different ratios and tested for compressive strength and absorption. It is concluded that mixing one part of gypsum with 4 parts of GA with 2% of S and 52% of water can produce the best mix to produce GB which can be cheaper and has lesser adverse effect on the environment.

1. Introduction

Concrete blocks are used in different construction applications, such as partition walls, load bearing walls and paving and floor blocks due to their unique feature ability to be molded into different shapes, and strengths for different civil engineering applications (Scholz & Grabowiecki, 2007; Zhu, Yan, & Liang, 2019).

Environmental problems caused by excessive mining and usage of natural resources such as aggregate and cement with approximately 275 MT of aggregate are extracted annually in the UK and this amount can increase by 1% annually (Mo, Alengaram, Jumaat, Yap, & Lee, 2016; Soutsos, Tang, & Millard, 2011a).

Moreover, the huge amount of industrial waste materials are either burnt or landfilled which cause serious environmental pollution and health risks (Karade, 2010) (Xuan, Poon, & Zheng, 2018). Therefore, there is a need to recycle waste materials.

Therefore, efforts to recycle and reuse waste materials have resulted in intensive research works being carried out to incorporate these wastes into concrete blocks. The incorporation of different types of demolition wastes such as recycled concrete, crushed bricks, and concrete slurry waste as aggregate enhanced the properties of concrete blocks such as compressive strength and fire resistance (Hossain, Xuan, & Poon, 2017; Kou, Zhan, & Poon, 2012; Xiao et al., 2013; B. Zhan, 2017; B. Zhan, Poon, & Shi, 2013; B. J. Zhan, Poon, & Shi, 2016).

The European Union (EU) produces about 850 million tons of recycled concrete waste RCW each year, representing 31% of the total waste generated within the EU (Fischer, Werge, & Reichel, 2009).

In Gaza, during 8 months of Israeli aggression, about 40 million tons of buildings demolished waste has been accumulated on sites causing serious environmental risks. Moreover, about 3 years of extensive efforts and costs are needed to get rid of these wastes (According to the UN). According to BBC Newspaper on the internet, by 29

golden light publishing

Jan 2024, about 61% of buildings in Gaza have been demolished due to the Israeli aggression as shown in Figure 1.

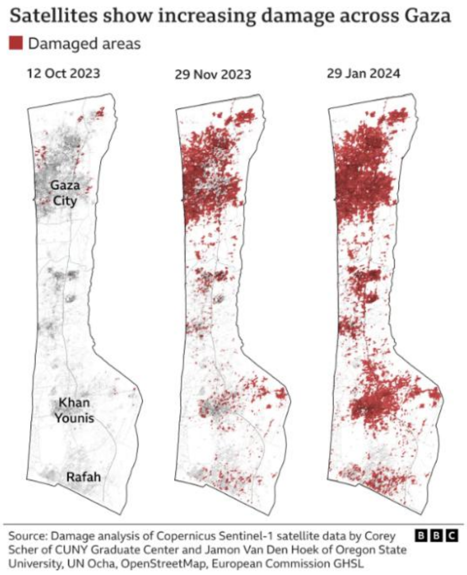

Fig. 1. Damage across Gaza due to Israeli aggression according to BBC Newspaper on internet published on 30 Jan 2024.

1.1 Concrete-waste aggregate block

Generally, researches revealed that the increase in RCW content caused a reduction in the compressive strength of concrete blocks (Pierre Matar & El Dalati, 2011; Sabai, Cox, Mato, Egmond, & Lichtenberg, 2013; Soutsos et al., 2011a; Soutsos, Tang, & Millard, 2011b). The compressive strength of RCW ranged from (5.2 to 10.4 N/mm2) compared to (14.2 N/mm2) for normal concrete with higher porosity (about 7 times) (Sabai et al., 2013).

Soutsos et al. (2011a) noted that the reduction in strength of concrete blocks was more significant when RCW was used as a fine aggregate. . Researchers also concluded that higher cement content is usually required for RCW concrete blocks to overcome the loss in compressive strength (Pierre Matar & El Dalati, 2011; P Matar & El Dalati, 2012; Soutsos et al., 2011a).

Researchers found that using crushed bricks as aggregate in concrete blocks reduced the density and compressive strength while increased water absorption of concrete block (Poon & Chan, 2006; Xiao, Ling, Kou, Wang, & Poon, 2011; Xiao et al., 2013). Xiao et al (2011). They suggested replacement levels of coarse and fine aggregate with crushed bricks to be less than 25% and between 50% and 75%, respectively.

On the other hand, the inclusion of ceramic tile waste and tile polishing waste as a sand replacement seems to have positive contribution to the compressive strength of concrete blocks while, using coarse aggregate decreased the compressive strength of concrete blocks(Penteado, de Carvalho, & Lintz, 2016; Sadek & El Nouhy, 2014).

1.2 Gypsum block

Gypsum is also widely applied in the construction industry due to some properties, such as fire resistance, high sound absorption and good decorative effects. Compared to cement, the temperature for producing gypsum is much lower, resulting in lower energy consumption and CO_2 liberation. Besides that, the gypsum plaster has better volume stability and lesser drying shrinkage than cement paste. However, gypsum has a lower water resistance (Zhang, Mo, Yap, & Tan, 2023).

Gypsum is used for the production of Non-bearing Gypsum Block GB by mixing gypsum with water and some additives to be shaped by special molds. The GB can be used in the construction of partition walls that are not subjected to the effect of moisture and weather.

Different studies were conducted in gypsum composites incorporating different waste streams (gypsum, insulation materials, plastics, wood, ceramic etc.). Pedreño-Rojas et al., conducted a research on recycled gypsum and showed different physical proprieties associated with the commercial gypsum (Pedreno-Rojas, Flores-Colen, De Brito, & Rodríguez-Linán, 2019). San Antonio Gonzalez, analyzed different compounds containing polystyrene waste, resulting in lightweight gypsums with good thermal behavior and resistance to water, while there was a decrease in the surface hardness and compression strength (San-Antonio-González, Merino, Arrebola, & Villoria-Sáez, 2015).

Another study was conducted by Santos Jimenez et al. They incorporated ceramic waste CW into the gypsum matrix. They found that the surface hardness and water absorption improved when less than 50% of CW was incorporated in a gypsum matrix (Jiménez, San-Antonio-González, Merino, Cortina, & Arrebola, 2015).

In general, these research works add one single type of waste and some properties improve, while others worsen. For this reason, more recent publications focus on materials incorporating a mixture of different wastes, in order to seek a synergistic effect and balance the properties obtained. Del Río Merino et al, analyzed the feasibility of adding CW and extruded polystyrene EPS waste from construction sites in two types of gypsums. Blends of gypsum with 50% CW and 1% EPS can be used to produce prefabricated elements or cladding materials (del Rio Merino, Astorqui, Sáez, Jiménez, & Cortina, 2018).

1.3 Objectives

The primary objective of this study is to develop sustainable building blocks using gypsum and recycled concrete waste (RCW) generated from the extensive demolition of buildings in Gaza City. Recognizing the potential restrictions on cement imports, gypsum is proposed as an alternative binder, offering lower environmental impact and production energy. However, given gypsum's inherent vulnerability to moisture, this study aims to enhance its mechanical and absorption properties through the incorporation of various additives.

The research is structured into two stages. In the first stage, the effect of individual additives on compressive strength and water absorption is evaluated to identify the most effective additive. In the second stage, the selected additive is incorporated into gypsum and Gaza aggregate (GA) at varying ratios to determine the optimal mix design. The ultimate goal is to produce building blocks that meet or exceed the Iraqi Standards for Blocks (IRS 1077) while minimizing costs and environmental impact. These findings are anticipated to support reconstruction efforts in Gaza by providing an economical and eco-friendly alternative to conventional building materials.

2.Experimental works.

2.1 Materials

Different types of materials are used for the preparation of mixes. The materials are collected from different sources.

2.1.1 Gaza Aggregate GA

It is impossible during the Israeli aggression against Gaza to collect RCW from demolished buildings. The only way is to simulate GA by collecting data about the most popular RCW in Gaza and the percentage of each portion of RCW. It is found that RCW consists of 80% of concrete waste, 10% of flooring waste and 10% of plastering waste. The data is used to make GA by collecting RCW from demolished buildings in Iraq. The RCW is milled and sieved and used for the preparation of mixes. Figure 2 shows the sieve analysis of GA used in the preparation of mixes used to make GB.

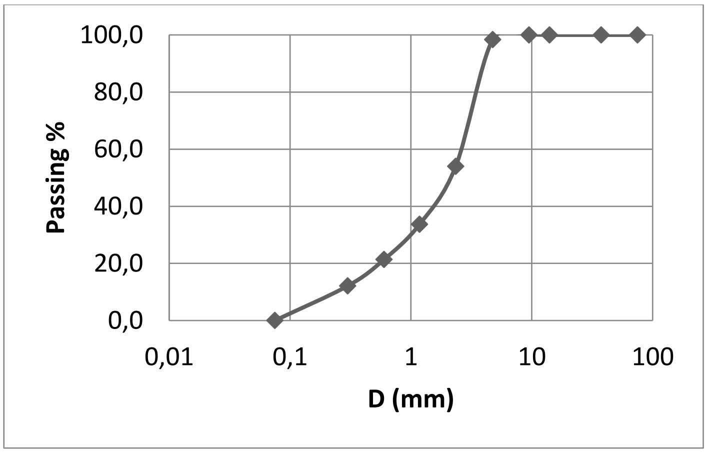

Fig. 2. Sieve analysis test result of GA.

Fig. 3 demonstrates GA before and after milling and sieving. Fig. 4 shows a demolished building in Gaza due to Israeli aggression against civilians.

Fig. 3. GA before and after milling and sieving.

Fig. 4. Destroyed buildings in Gaza due to Israeli aggression

2.1.2 Gypsum

Two types of gypsum are used:

- White Gypsum WG. This type of gypsum is purchased from AlMizan company in Iraq. The WG is pure gypsum with high specifications and it is usually used in finishing and decorative applications.
- Natural Gypsum NG. This type of gypsum is purchased from Alnibaee company in Iraq. the NG is not pure and has impurities such as sand. NG is usually used in layers before finishing to reduce the cost of finishing.

2.1.3 Additives

Superplasticizer S. It is used to increase workability of mixing while reducing the w/c ratio and increasing the compressive strength of concrete. Sika ViscoCrete – 180 GS from Sika company (Germany) is used in the mixes.

Silica Fume SF. It has a positive effect on the compressive strength of concrete so, it is expected that it has the same on the gypsum blend. SF type MegaAdd MS (D) from KONMIX Ltd. company (UAE) is used in mixes.

Citric Acid CA. It has a positive effect on the compressive strength of concrete and it is used as retarder and water reducer. It is locally available in local markets and used with food.

Citric Citrate CC. It has a positive effect on the compressive strength of concrete and it was investigated for use in clinical applications such as Vertebroplasty. CC from Segma company (England) is used to prepare mixes.

Sodium Bicarbonate SB. It is mainly used to produce air bubbles within the structure of the mixes and can reduce the weight of the products. It is locally available in local markets and used with bakeries.

MantuSur MS. It is one of the products of the KONIZMA company (Turkiye). It is used as an insulation plastering material for the outside of the buildings.

Thermostone Waste Tw. It is a byproduct of Thermostone production. It was collected from Thermostone Factory in the Ramadi city (Iraq). Tw was milled and the material passing sieve No.8 (less than 2.36 mm) is used as an additive with gypsum mixes.

Ammonia Am. It is mainly used to produce air bubbles within the structure of the mix and can reduce the weight of the products. It is locally available in local markets and used with bakeries.

River Sand Sa. It is mainly used to reduce the cost and can enhance the strength of the mix. It is purchased from the Ramadi quarry in Iraq. Water w. Tab water is used to prepare mixes.

2.2 Testing program

To study the effect of different types of additives on testing results, a testing program is conducted according to the stages below:

2.2.1 Stage 1

In this stage, gypsum is mixed with each type of additives and tested for compressive strength and absorption. A mold (10x10x10 cm) is used to conduct tests. The gypsum is mixed with additive. The water is added to the mix and blended together and poured into the mold. After 24 hours, the sample is extracted from the mold and left to dry until testing date. Table 1 shows the mixing weights of each type of mix.

Table 1. The mixing weight of each type of mix (Stage 1).

	Material type and weight (gm)											
Mix type	WG	NG	w	Am	MS	Tw	S	CA	CC	SB	SF	Sa
WG-NG-w40-Am 0.6	500	500	666.7	6	-	-	-	-	-	-	-	-
WG-NG-w40-MS10	500	500	666.7	-	100	-	-	-	-	-	-	-
WG-NG-w41-Tw30	300	300	420	-	-	180	-	-	-	-	-	-
WG-NG-w30-S0.6	500	500	428.6	-	-	-	5	-	-	-	-	-
WG-NG-w40-CA0.2-CC0.5	500	500	666.7	-	-	-	-	2	5	-	-	-
WG-NG-w40-SB0.5-CC0.5	500	500	666.7	-	-	-	-	-	5	5	-	-
WG-NG-w40	500	500	666.7	-	-	-	-	-	-	-	-	-

WG-NG-w40-Sa50	250	250	666.7	-	-	-	-	-	-	-	-	500

2.2.2 Stage 2

The results of Stage 1 are used to choose the best additive that makes the best mix in terms of compressive strength and absorption. According to the results of Stage 1, it was found that S is the best additive that when added to the mix satisfied the compressive strength and absorption limits required by the Iraqi standard of block. Accordingly, a mold of (38x18x20 cm) is used to make complete samples of GB to be tested for compressive strength and absorption . First, the gypsum is mixed with additive and GA. The water is added to the mix and blended together and poured into the mold. After 24 hours, the sample is extracted from the mold and left to dry until testing date. Figure 5 shows the samples of GB after extraction from the mold.

Fig. 5. Samples of GB after extraction from the mold (Stage 2)

Table 2 shows the mixing proportions of each type of mix for Stage 2.

Table 2. Mixing proportions of each type of mix (Stage 2).

Material type and proportions				
Mix type	WG	GA	w/WG (ratio)	S (% of WG)
WG1-GA3-w47	1	3	47/53	2
WG1-GA3-w50	1	3	50/50	2
WG1-GA3-w45	1	3	45/55	2
WG1-GA4-w52	1	4	52/48	2
WG1-GA4-w53.5	1	4	53.5/46.5	2

3.Results and discussion

3.1 Results of stage 1.

3.1.1 Compressive strength test results

Compressive strength tests were conducted after 7 days of curing at a constant temperature of 35°C. The results, as illustrated in Figure 6, indicate that reducing water content significantly enhances compressive strength. Among the tested additives, superplasticizer (S), silica fume (SF), thermostone waste (Tw), and insulation material (MS) positively impacted compressive strength, with superplasticizer (S) yielding the highest improvement. Conversely, additives such as ammonia (Am), citric acid (CA), and sodium bicarbonate (SB) exhibited a reduction in compressive strength, likely due to increased porosity and reduced binding efficiency. These findings emphasize the importance of additive selection in achieving the desired mechanical performance.

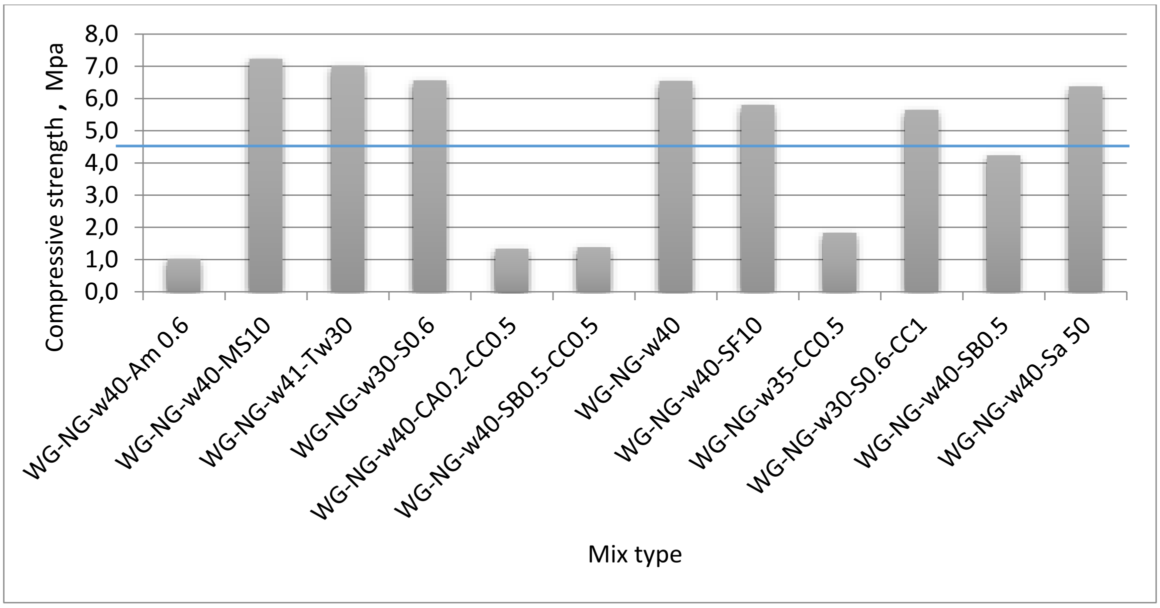

Fig. 6. Results of compressive strength test of samples (Stage 1)

The results of compressive strength cannot be discussed alone since the specifications of GB depend on the limits specified by compressive strength and absorption test together, so the discussion of this stage will be done after discussing the results of the absorption test.

3.1.2 Absorption test results

The test is conducted after 7 days of complete drying at a temperature of (35 Co). The results of test are shown in Fig. 7.

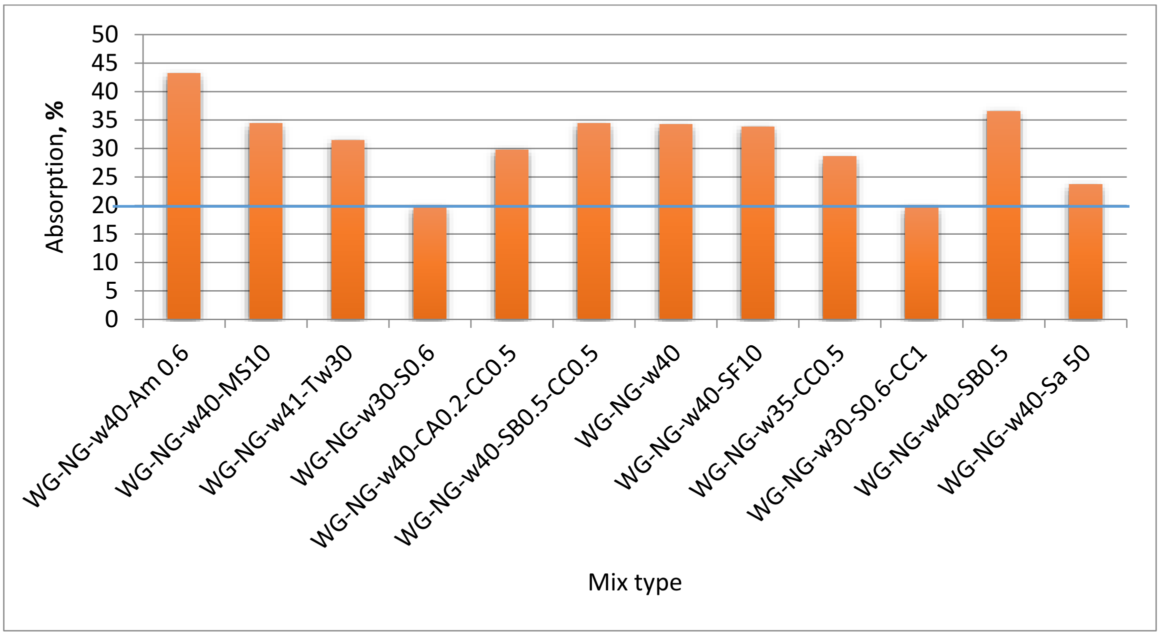

Fig. 7. Results of absorption test of samples (Stage 1)

The results show that only mixes containing (S and SB) are within the limits of Iraqi Specifications of Block (IRS 1077).

When combining the results of compressive strength with the results of absorption, only additive (S) succeeded in achieving the limits required by Iraqi Specifications of Block (IRS 1077) (Institution, 1988).

Accordingly, additive (S) was selected to be used for the preparation of complete GB samples in Stage 2.

3.2 Results of stage 2.

During the second stage, compressive strength and water absorption tests were conducted on gypsum block (GB) samples after 7 days of curing at 35°C. The results, depicted in Figures 8 and 9, reveal key insights into the effects of varying Gaza aggregate (GA) and water content ratios.

3.2.1 Compressive strength test results

Increasing the ratio of GA led to a noticeable reduction in compressive strength. This outcome is attributed to the lower binding capacity of gypsum when combined with higher proportions of aggregate.

- Nevertheless, all tested mixes exceeded the minimum compressive strength requirements set by the Iraqi Standards (IRS 1077).
- A higher gypsum content improved the compressive strength by approximately 100%, emphasizing gypsum's role as a binding agent.
- Reducing the water content from 52% to 45% further enhanced compressive strength by approximately 10%, likely due to the reduction in porosity and improved particle bonding.

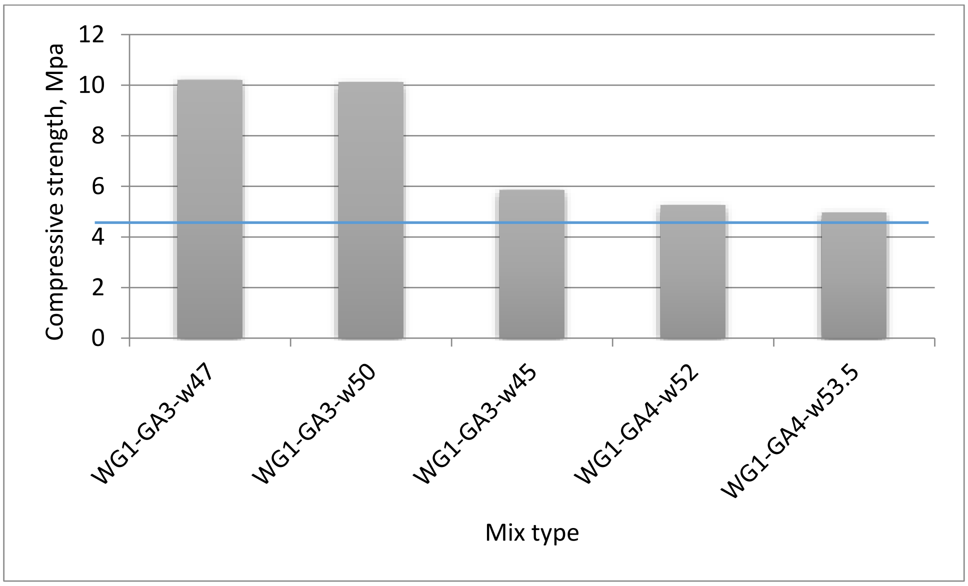

Fig. 8. Results of compressive strength test of GB samples (Stage 2)

3.2.2 Absorption test results

The results indicate that increasing the GA ratio resulted in higher water absorption. This is primarily due to the increased void content and reduced cohesion within the mix. Conversely, higher gypsum content reduced water absorption by filling voids and improving the overall matrix density. Despite the variations, all tested mixes met the minimum absorption requirements according to IRS 1077 standards.

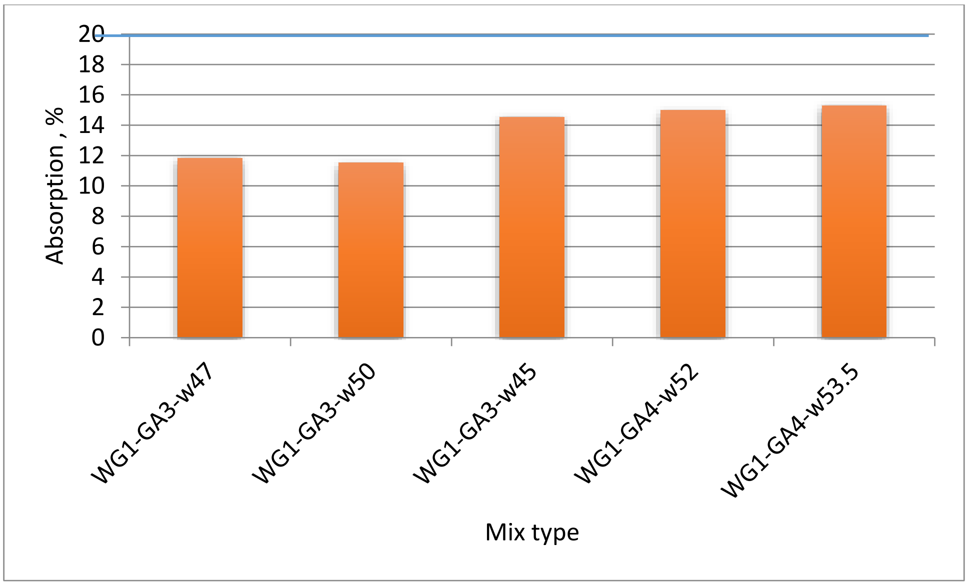

Fig. 9. Results of absorption test of GB samples (Stage 2)

Since all mixes passed the required minimum limits of compressive strength and absorption tests according to Iraqi Specifications of Block IRS1077, the selection of the best mix is based on two principles:

1-The most economic,

2-The less negative environmental effect.

Based on the results, the mix designated as (WG1-GA4-w52) emerged as the most suitable. This mix combines the highest GA content with sufficient gypsum and reduced water, achieving a balance between compressive strength and absorption. Additionally, it offers significant economic and environmental benefits by maximizing the use of demolition waste while minimizing gypsum consumption.

4. Conclusions

This study investigated the feasibility of producing gypsum-based blocks (GB) by incorporating recycled aggregates (GA) from demolition waste. A systematic experimental program was employed to evaluate the effects of various additives on compressive strength and water absorption. The results demonstrated that superplasticizer (S) was the most effective additive, achieving the required standards for both compressive strength and absorption. Furthermore, the optimized mix (WG1-GA4-w52) was identified as the most economical and environmentally friendly solution, with significant potential to reduce waste and reliance on cement in Gaza. Future research could focus on evaluating the long-term durability of these blocks under environmental stressors and exploring their scalability for mass production.

Acknowledgment

We would also like to express our gratitude to the members of the Concrete Laboratory/ Civil Engineering Department/Anbar University for their constructive criticism and valuable feedback, which contributed to enhancing the quality of this research.

Finally, we thank Civil Engineering Department/Anbar University for providing the necessary facilities and resources to conduct my research.

Optimizing selective demolition with BIM: A path toward sustainable concrete recycling

Mustafa C. Alp[1], Zeynep Başaran Bundur[*1], Gürşans Güven[2]

[1] Ozyegin University, Department of Civil Engineering, Istanbul, Türkiye

Abstract. The construction industry contributes roughly 39% of the annual global carbon dioxide emissions and is responsible for 35% of global waste generation in landfills due to the demolition of structures. To improve sustainability and material circularity in society, the construction and demolition sector holds a prominent position, particularly in recycling. With the release of EN 197-6 "Recycled Concrete), recycling of construction demolition waste (CDW) becomes more important. An essential step in recycling CDW is the efficiency of selective demolition techniques to maximize resource efficiency. However, major limitations of selective demolition includes increased duration of demolition, labor demand, and cost. This necessity underscores the importance of integrating selective demolition techniques with Building Information Modeling (BIM). This study aims to demonstrate the economic and operational perspective of smart demolition processes by using a BIM-based approach. A six-story residential building was modeled in Autodesk Revit to simulate the selective demolition process. This was followed by simulating the demolition process, enabling the recycling of concrete components. The results indicate that although optimizing the demolition process improves resource efficiency in recycling and enables the valorization of concrete components across various industries, selective demolition is currently an unfeasible option for demolition contractors in the absence of regulations or incentives.

Keywords: BIM (Building Information Modeling); Circular economy; Selective demolishing; Recycled Aggregates (RA)

1. Introduction

The world climate is changing rapidly due to increasing urbanization and industrialization activities, and this causes problems related to climate change. Excessive consumption of natural resources, such as unlimited concrete production, raw material extraction, waste storage, as well as greenhouse gas emissions caused by construction activities are among the main problems that accelerate climate change and environmental degradation. When these adverse effects of cement production are combined with the consumption of raw materials required for concrete production, like aggregate, water, and chemicals; the negative impact of construction activities on the environment increases even more. As a result of factors such as new building and infrastructure construction, demolition, reconstruction or renovation works, expansion of existing buildings, and maintenance activities, a large amount of Construction and Demolition Waste (CDW) is emerging, such as concrete, brick, ceramics, glass, and wood.

CDW represent the most significant waste volume, one-third of the waste generated in the European Union (Deloitte, 2015). Approximately 800 million tons of CDW are produced in Europe every year, and this figure is expected to increase further due to the increasing urban population, the continuous development of economies, and industrialization activities (Deloitte, 2015; Zajac et al., 2022). As a developing country, Türkiye anticipates demolishing or reconstructing 8.2 million buildings over the next two decades (Çalkıvik et al., 2024). Moreover, with the addition of population growth and increased infrastructure needs, CDW volume will be much more than expected. For instance, in the city of Istanbul, many buildings located in different districts of the city need to undergo urban transformation, and all the waste that will be generated due to the demolition of these buildings will be sent to landfills if they are not recycled or reused.

As CDW continues to pose environmental and logistical challenges, strategies such as selective demolition and on-site waste separation have emerged as effective approaches to improve material recovery and reduce landfill use. This way, the performance of waste after recycling can be improved and the recovery of valuable materials such as Recycled Concrete Aggregates (RCA) and Recycled Concrete Fines (RCF) becomes possible. In England, Portugal, and Japan, RCA can be substituted for 20% of the aggregates for new construction (de Andrade Salgado

[*] Corresponding author, Email: zeynep.basaran@ozyegin.edu.tr

https://doi.org/10.31462/icearc2025_ce_was_495

& de Andrade Silva, 2022). Thus, it contributes to the circular economy and creates landfill space (Purnell & Dunster, 2010). Recycling of concrete at the end of the life of a structure can also potentially reduce the depletion of virgin aggregate materials (Purnell & Dunster, 2010). While RCF, generated through concrete recycling, carbon dioxide can be captured under certain conditions through a process known as carbon capture or carbon sequestration. This transformation results in a high value-added material which can be used as a supplementary cementitious material, that contributes to more sustainable construction practices (Zajac et al., 2022).

For successful selective demolition, detailed planning, scheduling, and waste quantification are required. These make selective demolition more environmentally friendly and cost-effective. The efficiency of selective demolition also depends on having a skilled team and using the right equipment. In the selective demolition approach first non-bearing elements (brick walls and insulation material) can be manually dismantled with demolition drills, followed by the dismantling of the walls and insulation, and the concrete elements (structural walls, columns, floors, stairs) can be dismantled starting from the top floor with a jaw excavator and continuing down to the lowest floor (Public Fill Committee Civil, 2004).

To address the growing demands for sustainable construction practices and the limitations of traditional demolition methods; this study proposes to use Building Information Modeling (BIM) to apply selective demolition approaches for optimum material recovery from buildings. This paper investigates the economic benefits of selective demolition practices in construction, through a case study of a six-story residential building located in Istanbul.

2. Materials and methods

To model and simulate the selective demolition process, a 3D model of a six-story residential building was developed using Autodesk Revit 2025. The building model includes one basement level, a ground floor, three typical upper floors, and an attic (Fig. 1). The 3D model was created using the .dwg drawings of the building, and all structural and non-structural elements were modeled following standard design practices. The visual programming plug-in of Revit, namely Dynamo, was utilized to automate the extraction of material quantity take-offs from the BIM model, while Autodesk Navisworks Manage 2025 was used for simulating and scheduling the demolition phases.

Fig. 1. Render of Revit Model

2.1. 3D modeling in Revit

Two L-shaped columns of different sizes were modeled using the Revit Family Editor. Due to varying floor heights across different stories, two additional columns were created to accommodate those levels. Appropriate types and sizes of windows and doors were also added. All model elements were developed at Level of Detail (LOD) 300 (Shin & Song, 2024). Parameters of elements such as length, area, volume, floor levels, and attribute information like material type, material ID were defined. Finally, a custom "task ID" parameter was created in Revit to support the modelling and simulation process in Navisworks.

2.2. Quantity take-off with Dynamo
With the Dynamo visual programming, the quantity take-off process in Revit was automated. Custom scripts were developed to extract quantities and values such as volume, area, floor level, element ID (a custom parameter) and element name. For every element, different code blocks are created in Dynamo. Since the parameter names of floors are different for every material, different parameter names had to be used for Dynamo code blocks to extract the information from the BIM model to Excel. For example, the “Base Constraint” string is used to extract the floor level information of the walls, while the “Base Level” string is used to extract same information for structural columns. The stairs were manually modelled in Revit which allowed the geometry of the stairs to be customized precisely according to the building’s layout and dimensions. Since the geometry of the stairs is different, Revit does not allow the extraction of the volume of stairs with the “Volume” string in Dynamo. Therefore, “Solid Volume” string was used to extract the volume of stairs as seen in Fig.2.

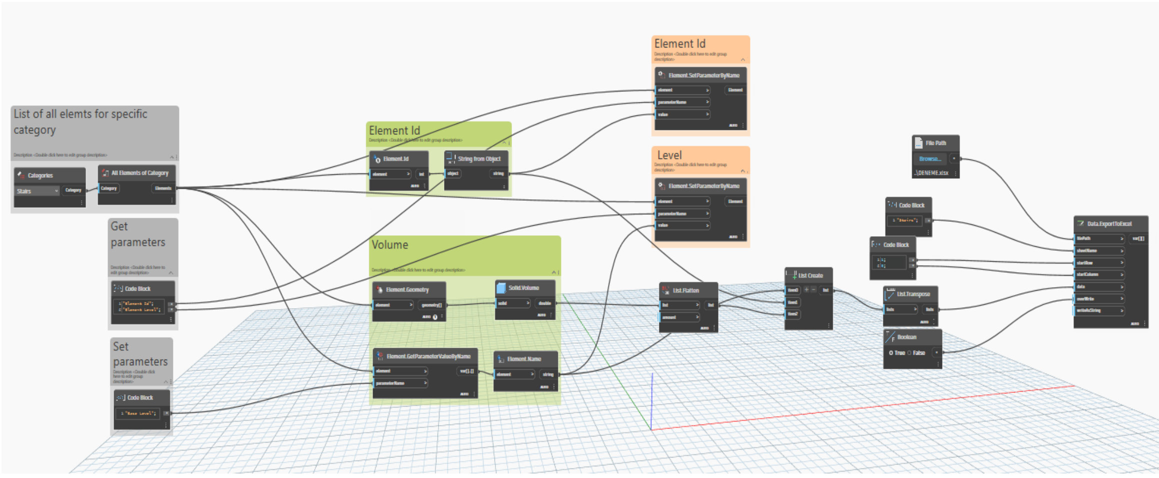

Fig. 2. Dynamo script for extracting information from Revit to Excel for Stairs

2.3. Simulation of the demolition process in Autodesk Navisworks Manage 2025
The completed Revit model was exported in NWC format and imported into Navisworks. Building elements were grouped as “demolition sets” according to their floor level and structural types (e.g., structural walls, walls, columns). Using Excel, a phased demolition schedule was developed and imported into Navisworks, considering the floor sequence from top to bottom, ending with the basement as seen in Fig. 3.

Each demolition phase was linked to a timeline task to simulate the selective demolition process. This 4D simulation provided a visual insight into the sequence and duration of demolition activities.

A new task type was defined in Navisworks to represent the to identify whether the demolition was done manually or with an excavator in the simulation. The demolition schedule prepared in Excel was then exported into Navisworks as a .CSV file, enabling simulation by linking the demolition sets with the custom Task ID parameter created in Revit using “auto-attach” rules.

Active	Name	Status	Planned Start	Planned End	Task Type	Attached

Fig. 3. Demolition schedule visualized in Navisworks after importing from Excel

3. Results and discussion

This study models and optimizes the demolition and recycling of a six-story structure in Istanbul, using an integrated BIM-based workflow. By combining various BIM tools, such as Revit, Dynamo, and Navisworks, with Excel, the methodology delivers precise material quantification, demolition scheduling and simulation. It also assists the calculation of waste logistics in a cost-effective manner. This section presents the results and compares the approach to traditional methods, highlighting its environmental and economic advantages.

3.1. Material quantification and demolition scheduling

A Dynamo script extracted detailed material volumes from the BIM model. Custom families created for L-shaped columns and sketch-based stairs ensured accurate calculations. Custom parameters (Task_ID, Element ID) enabled material categorization by floor and type, facilitating waste tracking and recycling analysis.

The BIM model was imported into Navisworks to develop a selective demolition schedule. Non-load-bearing brick walls and insulation were manually dismantled using demolition drills, followed by the C30 concrete elements (structural walls, columns, slabs, stairs) demolished top-down with a jaw excavator. Contractor interviews indicated that three workers could demolish brick walls on one floor in one day, while one worker was needed for dust control using water spraying during excavator operations. The demolition schedule projected 427.56 tons of waste over 10 workdays, including 149.7 tons of C30 concrete waste for the case study building. Daily waste quantities were tracked in Excel. Concrete volumes, extracted from the BIM model using Dynamo, were multiplied by a density factor of 2.3 t/m³ to calculate tonnage. Similarly, brick waste volumes were multiplied by 0.65 t/m³ for tonnage estimation.

3.2. Waste logistics and costs

The amount of waste produced per day was calculated using Dynamo, Naviswork schedule and Excel. A formula was created in Excel so vehicles with three different waste carrying capacities (Cevre Koruma Sube Mudurlugu, 2025)can optimally complete the daily waste transportation at the fewest turns and at the lowest price. Assuming that the waste would be transported from Beyoglu (where the building is located) to Arnavutkoy Waste Disposal Facility, it was multiplied by the fee for 1 ton of CDW transported for 1 kilometer, given by Istanbul Metropolitan Municipality. The distance between the building site and Arnavutkoy Waste Disposal Facility is 28 km. Table 1 presents the total cost of vehicles and related documentation.

Table 1. Cost and logistics data for construction and demolition waste management

Date	Volume	#Truck	Ton	Vehicle Price to Landfill (VPL)	Waste Carry Cost (WCC)	Transport and Acceptance Document (VAD)	TOTAL (VPL+WCC+VAD)
5.02.2025	12.90	1	8.39	3990	906.25	480.00	5376.25
6.02.2025	19.80	2	12.87	6840	1390.99	960.00	9190.99
7.02.2025	20.80	2	13.52	6840	1461.24	960.00	9261.24
10.02.2025	19.60	2	12.74	6840	1376.94	960.00	9176.94
11.02.2025	12.50	1	8.13	3990	878.15	480.00	5348.15

TOTAL	235.35	20	427.56	74100	46210.68	9600.00	129910.68

3.3. Excavator and labor cost

Excel spreadsheets were created to calculate the number of days the workers would work, and excavators would operate as seen in Table 2. and Table 3. According to the interviews with contractors, demolishing brick walls on one floor would take one day with three workers. Also, after manual demolition, the excavator would start demolition, and that one worker would need to be there to water the concrete to prevent dust on the day the excavator would operate. The interviewed demolition contractors stated that the jaw excavator can demolish approximately 1 to 1.5 floors daily. 3.000 TL per day will be paid to a worker for each working day and the daily rental cost of a jaw excavator including an operator is 50.000 TL. Given that the excavator is scheduled for use over five days, it was determined that commencing demolition at the start of the week would optimize cost efficiency and minimize additional expenses.

19.02.2025	1	50000
20.02.2025	1	50000
21.02.2025	1	50000
	TOTAL	250000

3.4. Cost analysis

To assess the potential contribution of recycling from the circular economy point of view, the mass of steel extracted from the structural project of the building was multiplied by the sales price of steel scrap obtained from scrap dealers, thereby calculating the revenue generated from the sale of steel waste (Table 4). Subsequently, using a script developed in Dynamo, a material take-off was extracted from the BIM model to determine the quantities of coarse aggregate, fine aggregate, and recycled concrete fines that could be produced from concrete waste by an on-site recycling plant. The percentages of these materials were obtained from a previous study (Shima et al., 2005). Sales prices for the recycled materials were used to calculate the potential revenue from their sales (Table 5).

As the costs associated with the excavator, labour, and waste vehicles for the demolition process had been previously calculated, the total expenses and revenues were aggregated in this step. Subsequently, a financial analysis was conducted to determine the potential profit or loss for demolition contractors, assuming selective demolition is performed, and the materials are sold at the specified prices.

Table 4. Revenue analysis of scrap iron sales

Iron Diameter	Weight(kg)	Total Price (TRY)
6-12 Phi	10327.99	109476.69
14-50 Phi	6982.16	74010.90
	TOTAL	183487.59

Table 5. Revenue analysis of concrete from recycling

Parts of Concrete	%	Ton	Selling Price (TRY)	Total Price (TRY)
Concrete Gross	-	372	-	-
Coarse Aggregate	35%	130	300	39,052
Fine Aggregate	30%	112	300	33,473
RCF	35%	130	1,300	169,224
			TOTAL	241,748

4. Conclusions

The cost analysis indicated that no profit could be generated from the sale of concrete and steel waste resulting from the building's demolition. This result was anticipated prior to the study, given the lack of an established market for recycled construction materials in Türkiye, as well as the absence of supportive regulations and incentive mechanisms. Moreover, the limited adoption of selective demolition practices can be primarily attributed to time and cost constraints. The findings of this study suggest that, with the implementation of appropriate regulations and incentives, demolition contractors may be more inclined to adopt selective demolition methods. Additionally, targeted training programs could enable contractors to carry out selective demolition in a more systematic and safer manner.

The implementation of BIM in this study played a critical role in accurately planning and analyzing selective demolition processes. Additionally, the 4D simulation supported the development of an effective work plan, leading to enhanced overall demolition efficiency for the case study building. Future work will involve consultations with additional demolition contractors to further refine the model. This will be followed by material-specific calculations, such as for recycled concrete waste, bricks, and other recoverable components, to evaluate the contribution of recycling efforts to a circular economy.

Acknowledgments

The authors would also like to thank Ender Bozkurt, and Ali Cimen for their collaboration and for sharing project-related information.

The effect of waste foundary sand on mixed-mode I/II fracture behavior of concrete

Mahdi Pakseresht[1], Javad Akbardoost*[1]

[1] Department of Mechanical Engineering, Faculty of Engineering, Kharazmi University, Mofatteh Avenue, P.O. Box 15719-14911, Tehran, Iran.

Abstract. As an important material in civil engineering, concrete contains naturally a large number of cracks and flaws which make the concrete components to be vulnerable against the mechanical loading. Therefore, the fracture behavior of concrete has been extensively investigated by engineers and researchers. On the other hand, the initial resource for constructing concrete has been limited and use of recycled materials such as waste foundry sand has been recently considered as an interesting approach for compensate of this limitation. In this study, the effect of waste foundry sand (WFS) which can be used instead of natural fine aggregate, on the mixed-mode fracture of concrete is assessed. For this purpose, five compositions of concrete with different contents of WFS (0%, 5%, 10%, 15% and 20% weight ratios) were made. Then, single-edge notched beam (SENB) samples were manufactured from these concrete mixtures. After that, the SENB samples were tested by symmetric and asymmetric three-point bending fixture in order to produce the pure mode I and mixed mode I/II loading conditions. The mixed-mode fracture curves obtained from experiments show that the increase of WFS content leads to decrease the mixed-mode fracture resistance of concrete due to microstructure variations. For example, by adding 20% WFS in concrete, the pure mode I fracture resistance decreases 22% relative to the normal concrete. Moreover, it is revealed that decreasing trend for mixed mode loading is more than that for pure mode I.

Keywords: Concrete; Waste foundry sand (WFS); Mixed-mode I/II fracture; Single-edge notched beam (SENB); Cracked sample.

1. Introduction

Concrete is one of the major materials in the construction of buildings, dams, tunnels and other civil projects. Civil researchers and engineers carry out extensively several studies about concrete and its compositions. They are interest to find new methods and sources for constructing the concrete due to the lack of initial sources. In this way, the use of recycled or waste materials is one of the most applicable approaches (Gupta, Siddique, Sharma, & Chaudhary, 2019; Jokar, Khorram, Karimi, & Hataf, 2019; T. Naik, Kraus, Chun, Ramme, & Singh, 2003; T. R. Naik, Kraus, Ramme, & Canpolat, 2012; Pathak & Siddique, 2012; Peighambarzadeh, Asadollahfardi, & Akbardoost, 2020; Pytel, 2014; Smarzewski & Barnat-Hunek, 2016; Smit, Nakum, & Bhogayata, 2014; Xie et al., 2019). One of the wasted material which can be considered in the construction of concrete instead of natural sand, is the foundry sand (FS) and/or waste foundry sand (WFS). The foundry sand (FS) is an important material in the metal casting mold and is often disposed after several casting procedures leading to environmental pollutions. It is reported by Bhardwaj and Kumar (Bhardwaj & Kumar, 2017) that 1.71 million tons and 6-10 million tons of WFS is annually discarded in India and USA, respectively. Thus, employing WFS as partial replacement of concrete sand not only reduces the problems of land-fill shortage and negative environmental pollution, but also can be a competent material for sand replacement and reduces the consumption of natural resources.

It is obvious that each component employed in concrete construction plays an important role in its strength and durability. Hence, the mechanical and chemical properties of the concrete will be changed when the waste materials are used instead of the natural resources and this variation should be assessed in order to use the waste materials appropriately. For example, the effect of FS as an alternative material for fine aggregate (sand) on the density, tensile and compressive strength, flexural strength, workability (slump test) and ultrasonic pulse velocity has been experimentally investigated by Ganesh Prabhu et al. (Ganesh Prabhu, Hyun, & Kim, 2014). They showed that although the flexural, tensile and compressive strengths of concrete with FS are relatively close to those values of the control mixture, FS decreases the workability of concrete. As another example, Singh and Siddique (Singh & Siddique, 2012a) revealed that the use of 5, 10 and 15 % WFS enhances the splitting tensile strength,

*Corresponding author, E-mail: akbardoost@khu.ac.ir

https://doi.org/10.31462/icearc2025_ce_was_529

compressive strength, modulus of elasticity and abrasion resistance. In other study, they (Singh & Siddique, 2012b) showed that partial substitution of WFS increases the value of ultrasonic pulse velocity and decreases chloride ion penetration in concrete.

On the other hand, concrete mixture includes a large number of microcracks which make this quasi-brittle material to be vulnerable to the mechanical loading. These microcracks might change to macro-cracks due to weather conditions, construction procedures or during the service life and lead to reduce significantly the load-bearing capacity of concrete parts. In this way, the concepts of fracture mechanics have been extensively used for assessing the fracture resistance of cracked concrete parts. In fracture mechanics, there are three major modes of loading: 1) mode I or opening mode in which the crack flanks open without any sliding, 2) mode II or in-plane sliding mode in which the crack flanks slide normal to the crack front without any opening or closing, 3) mode III or tearing mode in which the crack flanks slide parallel to the notch front without any opening or closing. Similar to other mechanical properties, the fracture behavior of concrete under different modes should be assessed. As the best of author's knowledge, almost all of the studies dealing with the fracture assessment of recycled concrete have focused only on the recycled aggregate concrete. For example, Kazemian et al. (Kazemian, Rooholamini, & Hassani, 2019) assessed experimentally the fracture behavior of concrete made with treated and untreated recycled coarse aggregates. There is only a study in the literature which investigates the fracture behavior of FS or WFS concrete. Aslani et al. (Aslani, Akbardoost, & Delnavaz, 2021) carried out several fracture tests on single edge notched beam (SENB) made of concrete with different contents of FS and WFS and under pure mode I. They revealed that fracture toughness of concrete reduces by using FS and WFS. This study has been limited on mode I loading the mixed mode I/II loading condition has not been investigated yet. Therefore, in the paper, the effect of WFS on the mixed mode I/II fracture behavior of concrete is studied. To this end, several single-edge notched beam (SENB) specimens were manufactured from concrete with five contents of WFS (0, 5, 10, 15 and 20% WFS). Then, the SENB samples were tested by three-point bend fixture until final fracture. The mixed mode loading conditions is achieved in this study by changing the distance between the bottom supports. The comparison between the experimental results of normal concrete and concrete with WFS is revealed that the mixed mode fracture resistance of concrete decreases by increasing the contents of WFS.

2. Experiments

There are 4 major components for manufacturing concrete: water, cement, fine aggregate (sand) and coarse aggregate (gravel). After mixing these four components in appropriate contents named concrete mix design, the mixture is poured in a mold and then is kept in water for a specific time referred as curing time.

In the present study, portland cement type II from Abyek cement factory (Abyek city in Qazvin province, Iran) was utilized. Water used in the present study for both construction of concrete mix and curing the concrete samples was tap water. The coarse aggregate was the gravel with maximum size of 20 mm determined according to ASTM C136/C136M-2 standard (" ASTM C136/C136M-19," 2019) for the sieve analysis. The fine aggregate was the twice-washed natural sand with a maximum size of 4.7 mm based on ASTM C136/C136M-2 standard (" ASTM C136/C136M-19," 2019) in normal concrete. Also, WFS were extracted from a small metal casting factory in Shahriyar industrial zone in Tehran, Tehran province, Iran. WFS is a by-product from the metal casting factory and is often disposed. The sand, gravel and WFS utilized for constructing the concrete in this study are shown in Fig. 1. Fig. 2 illustrates the gradation curves of sand, gravel and WFS.

Fig. 1: Gravel, sand and WFS utilized for constructing concrete in this study.

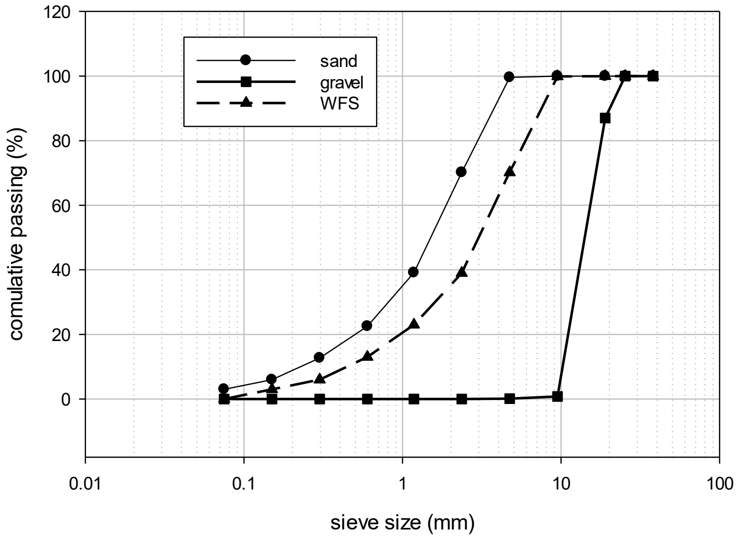

Fig. 2. Gradation of sand, gravel and WFS.

2.2. Mix contents

As mentioned earlier, five mix contents were considered in this study. The first one named as the control sample was made by the natural sand as fine aggregate. In the other samples, 5%, 10%, 15% and 20% weigth ratios of WFS were used instead of the natural sand. All mix contents were made according to the Iranian national mix design. The water-cement ratio (W/C) for all mixtures were constant values of 0.55 weight of cement. Table 1 shows the proportion of each mixture for one cubic meter of concrete. It is necessary to mention that increase of WFS more than 20% leads to decrease the slump and fluidity of concrete due to existence of clayey type fine materials in WFS (Bhardwaj & Kumar, 2017; Siddique & Singh, 2011).

Table 1. Mix proportion for one cubic meter of concretes

Category	Normal concrete	5% WFS	10% WFS	15% WFS	20% WFS
Cement (kg/m^3)	400	400	400	400	400
Sand (kg/m^3)	1000	950	900	850	800
Coarse Gravel (kg/m^3)	320	320	320	320	320
Fine Gravel (kg/m3)	480	480	480	480	480
WFS (kg/m^3)	0	50	100	150	200
Water (kg/m^3)	220	220	220	220	220
W/C	0.55	0.55	0.55	0.55	0.55
Slump (cm)	7	6	4	3	1
Concrete unit weight (kg/m^3)	2345	2356	2345	2343	2348

2.3. Sample preparation and test procedure

The single-edge notched beam (SENB) was utilized in this study for conducting the mixed-mode I/II fracture tests. The SENB specimen is a beam with width w, length L and thickness t. A crack of length a is created artificially in the middle of SENB specimen. Fig. 3 displays a schematic of SENB sample as well as loading condition. As shown, the SENB sample is loaded by a three-point fixture in which the bottom supports have distances S_1 and S_2 from the crack line and the applied load is along the crack line. In order to provide pure mode I loading, the SENB sample is subjected to three-point bending with symmetric distance in bottom supports, i.e. $S_1 = S_2$. The mixed-mode and pure mode II loading conditions are achieved in this sample by moving one of the bottom supports toward the crack. The sample tested in this study has the dimensions of $100\times100\times250$ mm^3 and includes a crack length of 25 mm. Using finite element method for the SENB sample with aforementioned dimensions, it is obtained that pure mode II is provided when S_1=100 mm and S_2=11.5 mm. In addition to pure mode I and pure mode II, two mixed-mode loading conditions were also tested in this study by considering the values of S_2=20 mm and S_2=30 mm.

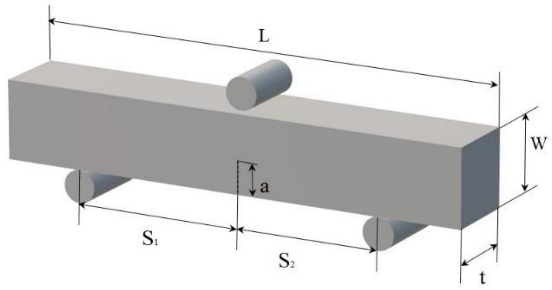

Fig. 3. Schematic of SENB specimen.

Fig. 4. The SENB specimens tested in this study.

After preparing concrete according to compounds given in Table 1, mixtures were poured in the molds with dimensions of 100×100×250 mm^3 for each WFS content. The concrete beams were removed from molds after a day and then were cured in tap water for 28 days. After that, a crack was created in one side of the concrete beams by means of a rotary fret saw with a thin saw blade of 0.3 mm in thickness. The total length of crack was nearly 25 mm for all specimens. Since 4 loading conditions were considered in this study and each test category were repeated four times in order to obtain reliable results, 16 beams were manufactured for each WFS content. Totally, 80 SENB samples were prepared in this study. Fig. 4 shows the all SENB samples prepared for testing in this study.

Finally, the prepared specimens were tested by a universal tension/compression test machine with a load cell capacity of 50 kN under three-point bending condition. Displacement control conditions with a constant cross head speed of 0.5 mm/min was utilized for all specimens. Table 2 shows the values of fracture loads obtained from the fracture experiments. Fig. 5 also displays some broken concrete samples. As seen in this Fig., the onset of fracture for all samples under pure mode II took place from bottom support which is undesirable. This point were observed after testing two SENB samples for each WFS content. Thus, the results obtained from this category and given in Table 2 (the last 10 fracture loads) is not reliable. This is mainly because the bottom support is very close to the crack flank and in materials with relatively low tensile strength such as concrete, the stress concentration generated at the contact point between the roller support and the edge of sample controls the crack path.

3. Results and discussion

In order to assess the mixed-mode fracture behavior of materials, the critical stress intensity factors for mode I and mode II defined respectively by K_{If} and K_{IIf} are often used. These parameters are usually calculated by numerical approaches such as finite element method (FEM). Since there are no values of K_{If} and K_{IIf} for teste SENB sample (SENB sample subjected to three-point bend with asymmetric supports), they were obtained numerically in this study. To this end, a 2D model of the SENB samples with dimensions of 250×100 mm^2 were generated in ABAQUS code. Then, the model was discretized by eigth-node iso- parametric elements. The singular collapsed elements were also used around the crack tip in order to take into account the high stress gradient at the crack tip. After that, loading condition and boundary conditions were set in FE models according to tested samples. Fig. 6 displays a sample of FE model for SENB under mixed mode loading, as well as applied load and boundary conditions. It is noteworthy that the average of fracture loads given in Table 4 were applied in the FE models. After solving process, the values of K_{If} and K_{IIf} were obtained directly from ABAQUS code.

Table 2: The fracture loads obtained from experiments.

Sample Code	% WFS	Fracture Load(N)	S_2(mm)	Average of fracture load (N)	Loading condition

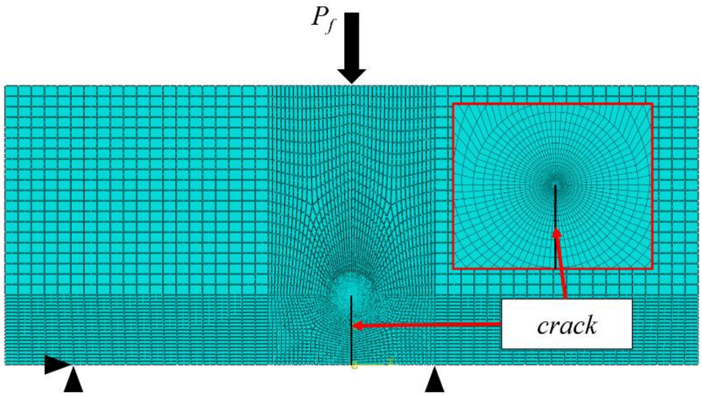

Fig. 6. A sample of FE model for SENB with S_1=100 mm and S_2=30 mm

The values of K_{If} and K_{IIf} obtained from FE analysis are listed in Table 3. Also, Fig. 7 illustrates the mixed mode fracture curves of tested samples with different contents of WFS. It is again mentioned that the values of K_{IIf} for pure mode II loading conditions listed in Table 3 or depicted in Fig. 7 are not reliable due to unreliable fracture loads obtained from experiments. It is observed from this Fig. that the fracture resistance of concrete decreases when the content of WFS becomes more.

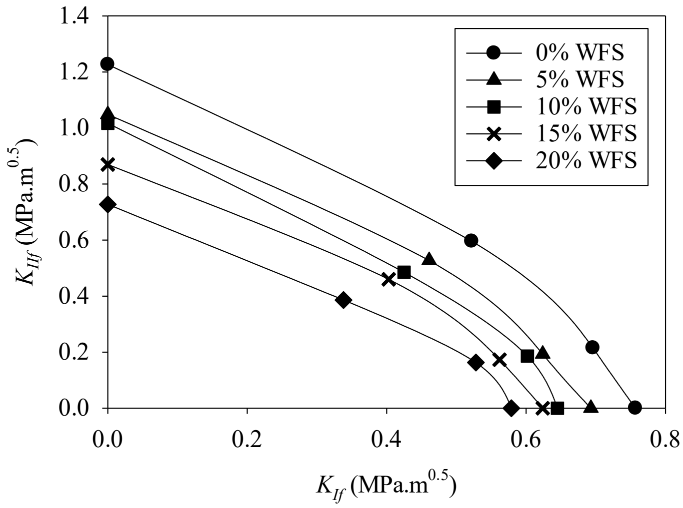

Fig. 7. The mixed mode fracture curves of tested samples with various contents of WFS.

As seen from Fig. 7, when the content of WFS increases from 5% to 20 %, the mode I fracture toughness decreases from 0.757 MPa.√m to 0.579 MPa.√m because WFS reduced coherence between aggregates. Aslani et al. (Aslani et al., 2021) showed previously this point by scanning electron microscopy (SEM) images. This decreasing trend can be observed for mixed-mode I/II behavior of concrete with WFS. Therefore, one can conclude that the existence of WFS leads to reduce the fracture resistance of concrete both in tension and shear.

4. Conclusions

The mixed mode fracture behavior of concrete including WFS was investigated in this study. For this purpose, 80 SENB samples in five contents of WFS (0%, 5%, 10%, 15% and 20%) and 4 mode mixity (pure mode I, 2 mixed-mode loading conditions and pure mode II) were prepared and then were tested by three-point bending fixture with symmetric and asymmetric bottom supports. In order to calculate the critical stress intensity factors K_{If} and K_{IIf} which define the mixed mode fracture resistance of materials, the SENB samples were modeled in a commercial finite element code. The experimental results indicated that the existence of WFS leads to decrease the fracture resistance of concrete both in pure mode I and mixed mode I/II loading (tension and shear). It was also observed in this study that the SENB sample with aforementioned dimensions and loading conditions for pure mode II (i.e. S_2=11.5 mm) is not suitable for pure mode II fracture test. This is mainly because the bottom support is very close to the crack flank and the fracture may initiate from the contact point between the SENB edge and roller of bottom support and then reach the crack flank. While the crack initiation from crack tip is expected in fracture mechanics, this type of fracture path is undesirable.

Abstract. Amid escalating global concerns over environmental sustainability in civil infrastructure, the pursuit of eco-friendly and durable pavement solutions has gained considerable attention. Among various waste streams, plastic waste presents a significant challenge due to its persistence and environmental impact. Incorporating plastic waste into pavement construction emerges as a promising strategy to mitigate plastic pollution while enhancing the mechanical performance of pavements. Prior research has demonstrated that asphalt binders modified with plastic waste exhibit superior durability, improved deformation resistance, and reduced maintenance demands. This approach aligns with circular economy principles by transforming waste materials into valuable resources, thereby fostering sustainable infrastructure development. In this study, the focus is directed toward improving the cracking resistance of asphalt pavements through the incorporation of chemically recycled polyethylene terephthalate (PET) in granular form. The PET additive, obtained via chemical recycling processes, were blended with a conventional asphalt binder to produce modified cylindrical specimens. Semi-Circular Bending (SCB) samples were subsequently extracted from these specimens to evaluate their fracture properties. SCB tests conducted at three different temperatures (-10°C, 0°C, and +10°C) assessed key fracture parameters, including fracture toughness (K_{IC}) and fracture energy (G_f). The results revealed substantial enhancements in both fracture toughness and energy, indicating improved cracking resistance across varying temperature conditions. These findings underscore the potential of integrating recycled plastic waste into asphalt mixtures as an effective means to advance pavement durability and sustainability.

Keywords: Asphalt pavement; Cracking resistance; Recycling; PET granules; Fracture energy; Fracture toughness

1. Introduction

Cracking represents one of the most prevalent and severe forms of structural distress in asphalt pavements, particularly in regions subject to extreme temperature variations or persistently cold climates. Fluctuations in service temperature significantly affect the viscoelastic properties of asphalt mixtures. At elevated temperatures, bitumen exhibits predominantly viscous behavior, allowing for plastic deformation. Conversely, at intermediate to low temperatures, bitumen becomes increasingly brittle, making the asphalt mixture more susceptible to crack formation (Aliha et al., 2021; Hong et al., 2020; Shahryari et al., 2021; Xiongzhou et al., 2021; Baradaran and Ameri., 2023; Baradaran and Ziaee., 2025). Asphalt pavement cracking can be categorized into several distinct types, including fatigue cracking, which is primarily load-induced; thermal cracking, triggered by temperature fluctuations; longitudinal cracking; and reflective cracking, often associated with differential movement or underlying layer behavior. These cracking types are all fundamentally linked to the fracture resistance of the asphalt materials in the pavement structure. Under traffic loading, pavements are subjected to complex stress states—ranging from tensile (Mode I) to shear (Mode II)—depending on the wheel position and load magnitude. In contrast, environmental temperature changes often induce thermal tensile stresses, which predominantly

[*] Corresponding author, E-mail: mrm_aliha@iust.ac.ir

https://doi.org/10.31462/icearc2025_ce_was_668

promote Mode I fracture opening (Aliha et al., 2015; Fakhri et al., 2018; Uzan & Levenberg, 2001; Zhu et al., 2017; Aliha et al., 2014).

The prediction and analysis of asphalt pavement cracking remain a challenging task for pavement engineers due to the heterogeneous and time-dependent nature of asphalt concrete (Alaswadko et al., 2019; Aliha & Mousavi, 2020). Consequently, ongoing research is devoted to understanding and improving the fracture behavior and resistance of asphalt mixtures. Linear Elastic Fracture Mechanics (LEFM) has been widely employed to characterize crack propagation mechanisms at low and intermediate temperatures, offering a reliable framework for assessing fracture behavior in brittle materials like asphalt under certain conditions (Ameri et al., 2012; Ziari et al., 2020; Fakhri et al., 2020; Motevalizadeh et al., 2020; Saha & Biligiri, 2016). At low temperatures, the stress intensity factor (K) is commonly used as a primary fracture criterion to evaluate the crack initiation resistance of asphalt mixtures (Aliha et al., 2017; Marasteanu et al., 2002; Aliha et al., 2023). At intermediate temperatures, where viscoelastic effects are more pronounced, energy-based parameters such as the critical strain energy release rate (G_c) and fracture energy (G_f) provide more meaningful insights into the material's resistance to cracking (Song et al., 2023; Ameri et al., 2016; Fatemi et al., 2023; Li et al., 2024; Tabasi et al., 2023; Alae et al., 2023). Various fracture test methodologies have been developed and adopted to characterize these properties, including the Single-Edge Notched Beam (SENB), Disk-Shaped Compact Tension (DCT), Edge-Notched Disc Bend (ENDB), and Semi-Circular Bend (SCB) tests, each providing different advantages for characterizing crack propagation and toughness in asphalt mixtures (Wagoner et al., 2005; Wagoner et al., 2006; Aliha et al., 2015; Qiu et al., 2024; Ren et al., 2023; Meng et al., 2024). In parallel with advancements in fracture characterization techniques, there has been a growing global emphasis on adopting eco-friendly and sustainable approaches in the development of construction materials. Utilizing recycled and waste materials not only addresses environmental concerns but also contributes to improving the mechanical resilience of infrastructure, ensuring longer service life and reduced maintenance. This increased focus reflects a strategic shift toward integrating sustainability and durability as complementary objectives in modern civil engineering practices (Baradaran et al., 2023; Baradaran et al., 2024a; Niri et al., 2024; Tareghian et al., 2024; Yazdi et al., 2024; Pargar et al., 2024; Yeganeh et al., 2024; Pournoori et al., 2024; Rajaee et al., 2025a, Rahaee et al., 2025b; Baradaran et al., 2024b).

To mitigate the susceptibility of asphalt mixtures to cracking, considerable research has explored the incorporation of various additives and modifiers into both the asphalt binder and the aggregate matrix. These include recycled and waste materials such as crumb rubber (Bazoobandi et al., 2024; Liang et al., 2024), waste glass (Phan et al., 2024; Yang et al., 2023), steel slag (Zhong et al., 2024; Xu et al., 2024), and waste polyethylene (Baradaran et al., 2024; Ayar et al., 2022). Among these, polyethylene terephthalate (PET) has garnered significant attention due to its abundance and high-value polymer properties. The global rise in PET waste generation, largely due to its widespread application in packaging, bottles, textiles, and industrial products (Salazar-Beltrán et al., 2018; Li et al., 2016), poses an environmental threat as PET is non-biodegradable (Mohammed, 2017). While several advanced methods—such as hydrogenation, glycolysis, methanolysis, and hydrolysis—exist for chemical recycling of PET (Thiounn & Smith, 2020; Ragaert et al., 2017), many are cost-prohibitive on a large scale (Webb et al., 2012). As such, integrating recycled PET into construction materials such as asphalt presents an economically and environmentally favorable solution, contributing to reduced landfill accumulation, lower greenhouse gas emissions, and decreased reliance on non-renewable materials (Sulyman et al., 2016; Yao et al., 2022). Several studies have validated the potential of PET to enhance asphalt performance. In a 2018 study by Leng et al., chemically treated PET-derived additives were incorporated into reclaimed asphalt pavement (RAP) mixtures. Laboratory evaluations using dynamic shear rheometer (DSR), bending beam rheometer (BBR), and moisture susceptibility tests revealed that the modified binders exhibited up to 60% improvement in fatigue resistance compared to traditional mixtures (Leng et al., 2018). In another investigation, Ghabchi et al. (2021) demonstrated that micronized PET (MPET) improved binder-aggregate adhesion, increased viscosity, and significantly enhanced resistance to stripping and cracking in asphalt mixtures. Similarly, research by Ma and Hesp (2022) explored the impact of PET fibers of varying lengths (6 mm and 18 mm) on fracture resistance. Results showed a notable increase (approximately 10%) in fracture energy at 20°C for the 6 mm PET fiber mixture, while the 18 mm fibers yielded even higher resistance across temperature ranges. At 10°C, only the longer fibers contributed to a substantial improvement in fracture toughness, emphasizing the critical role of fiber length in reinforcing asphalt composites. Further supporting these findings, Callomamani et al. (2023) conducted a comparative study on the use of synthetic fibers (PET and aramid) in asphalt mixtures. The inclusion of 0.1% PET fiber and 0.065% aramid fiber led to consistent increases in total fracture energy across all test temperatures, averaging 30% and 40% improvements respectively, thereby confirming the enhanced crack resistance afforded by PET fiber reinforcement.Although the global momentum toward sustainable infrastructure and circular economy practices has intensified in recent years, limited attention has been paid to the fracture behavior of asphalt mixtures modified with recycled polyethylene terephthalate (PET)—especially when PET is utilized in chemically processed forms.

While prior studies have investigated the general mechanical properties and durability improvements offered by PET-modified asphalt, the fracture resistance of such mixtures under critical service conditions remains underexplored. In particular, the impact of temperature-induced brittleness at low and intermediate temperatures—where asphalt pavements are most susceptible to cracking—has not been adequately assessed in the context of chemically recycled PET-based additives. To date, no comprehensive study has investigated the fracture performance of asphalt mixtures incorporating synthesized additives derived from PET granules through chemical recycling techniques. Most existing research has relied on PET in physically treated forms, such as flakes, powders, or short fibers, without considering the significant changes in molecular structure and chemical compatibility that result from recycling processes like aminolysis. Such chemical transformations have the potential to enhance the interaction between PET derivatives and asphalt binder, thereby improving crack resistance through better stress distribution and energy dissipation mechanisms. However, these effects remain largely undocumented in the existing body of literature. Addressing these gaps, the present study aims to assess the fracture resistance of asphalt mixtures modified with a value-added additive synthesized from PET granules via a chemical recycling pathway. Specifically, this research investigates the influence of this additive on crack propagation behavior under pure Mode I fracture conditions at two temperature levels representative of field service extremes: –10°C and 0°C (low temperature) and +10°C (intermediate temperature). Semi-Circular Bend (SCB) specimens were fabricated for each mixture type, including a control (0% PET) and a modified mixture containing 2% chemically recycled PET additive by weight of bitumen. All samples were subjected to Mode I loading using standardized SCB fracture testing procedures to evaluate tensile fracture resistance. By integrating chemically recycled PET into asphalt mixtures and analyzing its effect on low-temperature and intermediate-temperature fracture behavior, this study contributes not only to the scientific understanding of fracture mechanics in modified asphalt systems but also to the broader goal of sustainable construction. The findings are anticipated to inform the development of more resilient pavement materials while offering a practical and environmentally beneficial solution for the reuse of non-biodegradable PET waste in the construction sector.

2. Materials and methods

2.1. Materials

2.1.1. Aggregates

In this study, limestone aggregates were utilized, sourced from a quarry situated in the northeastern region of Tehran Province. The aggregate gradation was carefully selected in accordance with the specifications provided in ASTM D692. The selection process involved a thorough consideration of the standard’s designated upper and lower gradation limits to ensure compliance with the required criteria and to maintain consistency in aggregate quality throughout the experimental procedures. Fig. 1 shows the gradation curve of the limestone aggregate used in this study.

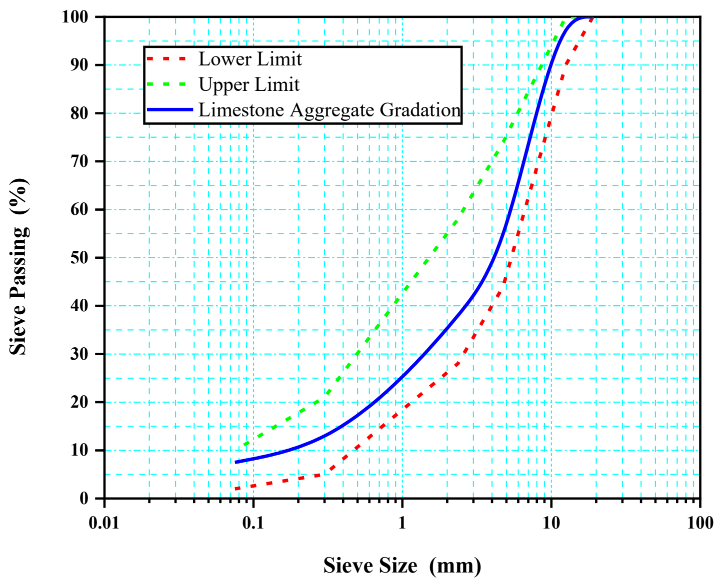

Fig. 1. Gradation curve of limestone aggregate used in this study

2.1.2. Asphalt binder

A conventional penetration-grade 85/100 asphalt binder was employed in this research. This binder was selected due to its common application in road construction and its compatibility with polymeric modifiers. The physical properties of the binder were verified in accordance with ASTM D5 and other relevant standards prior to mixture preparation. The properties of the asphalt binder used in this study are shown in the Table. 1.

Table 1. Physical properties of Pen 85/100 asphalt binder

Properties	Test Method	Result
Specific gravity at 25°C (gr/cm^3)	ASTM D70	1.011
Softening point (R&B) (°C)	ASTM D36	46
Penetration, at 25°C (0.1 mm)	ASTM D5	96
Ductility, at 25°C (cm)	ASTM D113	100
Rotational viscosity at 135°C (mPa.s)	ASTM D4402	250

2.1.3. Polyethylene terephthalate (PET)

Polyethylene terephthalate (PET), a widely used thermoplastic polyester, is a major contributor to global plastic waste due to its extensive application in consumer packaging—particularly in single-use beverage bottles. Owing to its non-biodegradable nature, PET poses persistent environmental challenges, with approximately 70% of PET waste being either incinerated for energy recovery or disposed of in landfills. In contrast, only about 26% undergoes mechanical recycling, and a mere 4% is chemically recycled, highlighting the underutilization of advanced recycling techniques. In response to this imbalance, innovative strategies are being pursued to repurpose PET waste into value-added materials with practical engineering applications. PET was utilized in its granular form in this study, as illustrated in Fig. 2.

Fig. 2. Granular form of PET used in this study

2.2. Methods

2.2.1. Additive derived from recycling of PET

Chemical recycling of polyethylene terephthalate (PET) is recognized as a sustainable alternative to conventional disposal methods, offering the potential to convert post-consumer plastic waste into high-value materials (Shojaei et al., 2020). Among the various chemical recycling techniques, aminolysis was selected in this study due to its efficiency and suitability for producing asphalt-modifying additives. Aminolysis involves the cleavage of PET's ester linkages through a reaction with primary amines—such as methylamine, ethylamine, ethanolamine, allylamine, and hydrazine—in an aqueous environment. Compared to alcohol-based methods like glycolysis, aminolysis proceeds more rapidly, as amines act as stronger nucleophilic agents and organic bases that accelerate polymer chain degradation (Gupta et al., 2019). In this research, triethylenetetramine (TETA) was selected as the aminolysis reagent due to its high reactivity and multifunctional amine structure. The process was initiated by combining PET granules—used as the polymer feedstock in this study—with TETA in a weight ratio of 2:1 (PET:TETA). The mixture was introduced into a two-necked round-bottom flask equipped with a reflux condenser and magnetic stirrer. The aminolysis reaction was conducted at 140°C for 6 hours under a continuous nitrogen gas atmosphere to prevent oxidation and ensure reaction stability. Upon completion of the reaction, the system was subjected to vacuum conditions to facilitate the recovery of by-products such as low-molecular-weight polyamines and glycols. The residue remaining in the flask was a yellowish solid at room temperature, which was collected and designated as the PET-derived additive. After that this additive in dosages of 0%, 1% was blended with virgin asphalt binder by a low-shear mixer at 1000 rpm for 50 minutes at 140°C.

2.2.2. SCB samples

In this study, cylindrical specimens were fabricated according to each mixture type. A gyratory compactor was used to manufacture cylindrical specimens 150 mm in height and 150 mm in diameter with 7±0.5% air voids in accordance with the AASHTO TP124-16 specification. The air void content for each specimen was confirmed, using AASHTO T 166, to fall within the target range. The mean air void content for test specimens was 7%. To achieve this target range, 20 mm of the upper and 20 mm of the bottom section of the cylindrical specimen were cut, and the core of the cylindrical specimen was used to obtain semi-circular bending (SCB) specimens with 150 mm in diameter and 50 mm in thickness. after that, a notch, 2 mm wide and 15 mm deep, was made in the center of the SCB specimens.

2.2.3. Fracture toughness

Fracture toughness under Mode I loading is a critical parameter in fracture mechanics that characterizes a material's resistance to crack propagation under tensile stress conditions. Mode I, also referred to as the opening mode, occurs when the applied load acts perpendicular to the plane of the crack, causing the crack surfaces to separate. The Mode I fracture toughness is commonly denoted by the stress intensity factor K_{IC}. This parameter is essential for understanding the fracture performance of brittle or quasi-brittle materials, such as asphalt mixtures at low service temperatures. It reflects the material's ability to resist crack initiation and growth under tensile loading and is influenced by factors such as temperature, loading rate, and material heterogeneity. A higher value of Mode I fracture toughness indicates a greater resistance to crack growth, making it a key indicator for durability and long-term performance. The Mode I fracture toughness was calculated in this study using Equation (1) based on the observed test parameters.

$$K_{IC}(SCB) = \frac{F_{cr}}{2Rt}\sqrt{\pi a}\,Y_1\left(\frac{a}{D},\frac{2S}{D}\right) \quad (1)$$

In the context of fracture mechanics, Y_I represents the geometric shape factor for Mode I loading, while R and t denote the radius and thickness of the SCB specimen, respectively. The parameter a refers to the notch depth, and F_{cr} indicates the maximum load applied during the fracture test. The values of Y_I (for Mode I) is functions of the relative crack length a/D and the loading span ratio 2S/D, where D is the specimen diameter and S is the distance from the center of the specimen to each support. These geometric factors can be determined either through finite element analysis (FEM) or by referencing analytical plots developed by M.R. Ayatollahi and M.R.M. Aliha (Ayatollahi, M. R., & Aliha, M. R. M., 2007). Fig. 3 illustrates the specimen geometry and loading configuration for the SCB test under Mode I conditions. In this study, a loading rate of 2 mm/min was employed to evaluate the fracture behavior of different asphalt mixture types. Tests were conducted at low and intermediate temperatures (–10°C, 0°C, and +10°C) to simulate critical field conditions. As shown in Fig. 4, the loading configuration consists of a conventional three-point bending fixture, where the load F_{cr} is applied vertically at the top of the specimen, while the specimen is symmetrically supported by two bottom supports spaced at a distance S from the center crack, creating a stable bending setup for crack propagation analysis.

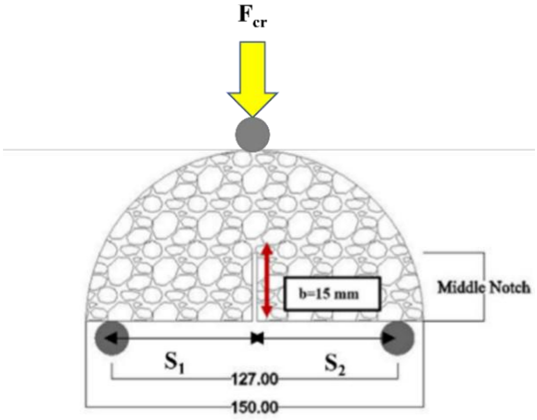

Fig. 3. Configuration of the three-point bending fixture and geometry of the SCB specimen

2.2.4. Fracture energy

Fracture energy is a fundamental parameter in characterizing the fracture behavior of materials within the framework of fracture mechanics. It represents the energy required to initiate and propagate a crack to failure and has been widely recognized as a reliable indicator for evaluating the crack resistance of various materials. Theoretically, fracture energy corresponds to the area under the load–displacement curve obtained from a fracture test, quantifying the total energy absorbed by the material during crack development—from initiation to complete separation. This energy metric is sensitive to changes in material composition, temperature, and other physical conditions, which directly influence the material's capacity to absorb and dissipate energy (Aliha et al., 2010; Razmi et al., 2018). In this study, fracture energy was determined using Equation (2).

$$G_f = \frac{W_f}{A_{ligamnet}} \quad , \quad A_{ligamnet} = (R - a) \times t \tag{2}$$

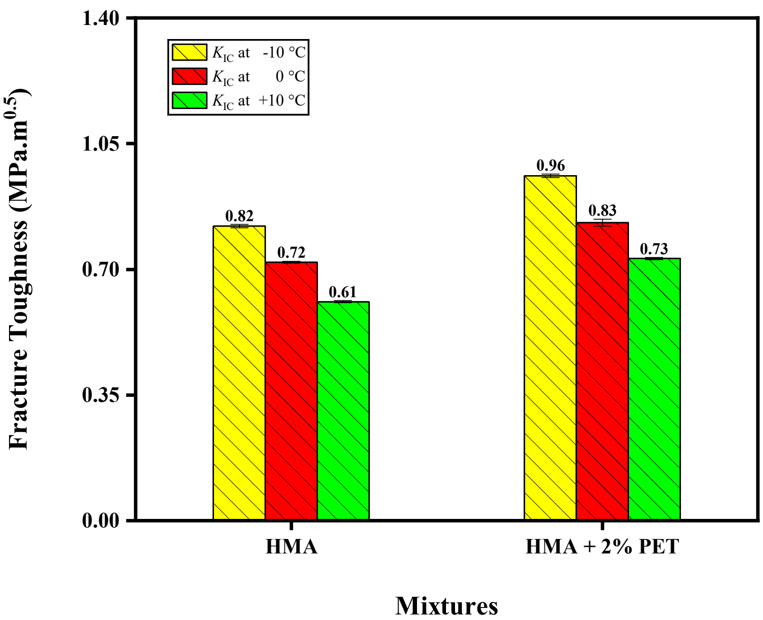

Fig. 4. Fracture Toughness (K_{IC}) values of mixtures at different temperatures

3. Results and discussions

3.1. Evaluation of fracture toughness

Fig. 4 illustrates the fracture toughness values of asphalt mixtures evaluated at three distinct temperatures -10°C, 0°C, and +10°C. The experimental results clearly demonstrate that incorporating a 2% additive derived from chemically recycled polyethylene terephthalate (PET) granules significantly improves the fracture toughness of hot mix asphalt (HMA) pavements across all tested conditions. Specifically, at –10°C, the fracture toughness of the PET-modified mixture increased by 17.1% compared to the unmodified control. Similarly, enhancements of 15.3% and 19.7% were observed at 0°C and +10°C, respectively. These findings underline the effectiveness of PET additives in enhancing the low-temperature cracking resistance of asphalt pavements, which is critical for maintaining performance in cold climates. According to the previous, The enhancement in asphalt mixture performance observed with the incorporation of polyethylene terephthalate (PET) additives can be fundamentally ascribed to complex chemical interactions between the PET molecules, asphalt binder, and mineral aggregates. At the molecular scale, the efficacy of PET additives is rooted in their unique chemical architecture, notably the presence of functional groups such as amines, which actively participate in chemical bonding with both binder constituents and aggregate surfaces.

These molecular interactions critically reinforce the cohesion and structural integrity of the asphalt composite. A key determinant of PET additive performance lies in the abundance and spatial configuration of these amine groups. Their reactive nature facilitates robust chemical linkages, and any variation in their number or orientation significantly modulates the additive's interaction dynamics with asphalt components, thereby influencing the overall mechanical properties of the mixture. Moreover, the balance between hydrocarbon chain length and the density of amine groups within the PET molecular framework further governs its performance characteristics. Longer hydrocarbon chains are hypothesized to enhance adhesive interactions with the binder matrix, while a higher concentration of amine groups promotes compatibility and chemical bonding within the asphalt system. Striking the optimal balance between these molecular features is pivotal for maximizing binder performance, particularly its resistance to stress-induced microcracking. Emerging research underscores that PET additives amplify key intermolecular forces within the asphalt matrix, such as hydrogen bonding and van der Waals interactions. These enhanced molecular forces contribute to improved cohesion and mechanical stability, fostering the formation of a more intricate and resilient molecular network. The interaction of amine groups within this network enhances critical mechanical properties, including elasticity, tensile strength, and ductility—essential for withstanding environmental stresses and repetitive traffic loading. Additionally, the incorporation of PET additives aligns with broader findings on amine-functionalized modifiers, which are known to augment the binder's capacity for mechanical energy absorption and dissipation. This mitigates crack initiation and propagation under cyclic loading conditions, thus prolonging pavement lifespan and enhancing reliability across diverse climatic and operational environments.

In conclusion, PET additives represent a highly promising approach for advancing asphalt mixture performance. By strategically engineering their molecular structure—optimizing the amine group density, spatial orientation, and hydrocarbon chain length—the reinforcing effects of PET can be fine-tuned to deliver superior durability and crack resistance. This positions PET additives as critical enablers in the formulation of next-generation, high-performance asphalt composites designed for long-term serviceability (Baradaran et al., 2025; Baradaran et al., 2024; Xu et al., 2022).

3.2. Evaluation of fracture energy

The other important fracture parameter investigated in this study was fracture energy. Fracture energy value results for mixtures at -10°C, 0°C, and +10°C are shown in Fig. 5. Based on the results it can be seen adding PET additive can increase fracture energy of asphalt pavement which is indicated PET additive can improve cracking resistance of asphalt pavement. For instance, by adding 2% PET additive to the HMA mixture at +10°C, G_f value is increased by 43.4%. This improvement is observed at other temperatures. For example, at -10°C and 0°C G_f values are increased by 72.5% and 59.3%, respectively. The enhancement of fracture energy in asphalt pavements through the incorporation of recycled PET additives has been consistently validated by multiple studies (Baradaran et al., 2024; Ma & Hesp, 2022; Baradaran, Aliha, Maleki, & Underwood, 2024; Baradaran & Aliha, 2025; Saleh, Ahmed, Moghaddam, & Hashemian, 2024). These findings suggest that asphalt mixtures modified with PET-TETA additives require substantially more energy to propagate cracks, thereby improving the material's resistance to fracture. Several critical factors have been identified in previous research as significantly influencing the fracture energy and cracking behavior of asphalt mixtures.

One key factor is the optimal spatial arrangement of coarse aggregates within the ligament area. Proper distribution of aggregates ensures effective stress dispersion, reducing the likelihood of premature crack initiation and propagation (Stewart, Oputa, & Garcia, 2018; Airey, Hunter, & Collop, 2008). Another fundamental element is the cohesion within the soft asphalt matrix (SAM), the binder-rich zone that integrates the aggregates. The mechanical integrity of this matrix is essential for maintaining the mixture's structural strength and resistance to cracking (Aliha, Fazaeli, Aghajani, & Nejad, 2015). Additionally, the inclusion of various additives or binder modifiers has been shown to enhance both the chemical and physical properties of asphalt binders, thereby improving their fracture resistance (Pirmohammad, Amani, & Shokorlou, 2020; Pirmohammad, Shokorlou, & Amani, 2020; Alkuime, Tousif, Kassem, & Bayomy, 2020; Ghoroghi, Haghighatpour, Aliha, & Berto, 2023). Environmental conditions further impact the cracking performance of asphalt pavements. Processes such as freeze-thaw cycles and temperature-induced expansion and contraction subject the material to repeated stress, influencing its durability and long-term fracture behavior (Haghighatpour & Aliha, 2022; Ziari, Aliha, Moniri, & Saghafi, 2020). The current research focuses on the modification of asphalt binders using amine-functionalized compounds, particularly PET-TETA, derived from chemically recycled PET. Recent evidence indicates that PET-TETA significantly strengthens the bond between the asphalt binder and mineral aggregates (Baradaran et al., 2024; Baradaran & Aliha, 2025). This improvement is attributed to intensified intermolecular interactions within the binder matrix, particularly hydrogen bonding and van der Waals forces, which enhance cohesive strength and molecular stability. These interactions result in stronger adhesion at the binder–aggregate interface, promoting a more durable and resilient bond. The increased bonding strength provided by PET-TETA also leads to an improved elastic response in the asphalt mixture under mechanical loading. This enhanced elasticity translates into greater ductility, a critical factor for resisting crack initiation and propagation. Ductility improvements directly contribute to the elevation of fracture energy—a key parameter defining the material's capacity to absorb energy before failure. By augmenting the ductility and elastic properties of the asphalt mixture, PET-TETA facilitates higher fracture energy levels, making the material more resilient to cracking under mechanical and environmental stresses. This increase in fracture energy is a primary contributor to the superior cracking resistance observed in PET-TETA-modified asphalt mixtures, as corroborated by numerous studies (Baradaran et al., 2024; Ma & Hesp, 2022; Baradaran et al., 2024; Baradaran & Aliha, 2025; Xu et al., 2022). In conclusion, the integration of PET-TETA into asphalt formulations represents a promising strategy for enhancing pavement durability. Through the reinforcement of binder-aggregate interactions and the improvement of mechanical properties such as ductility and fracture energy, PET-TETA-modified mixtures exhibit superior performance in resisting cracking and sustaining long-term mechanical integrity.

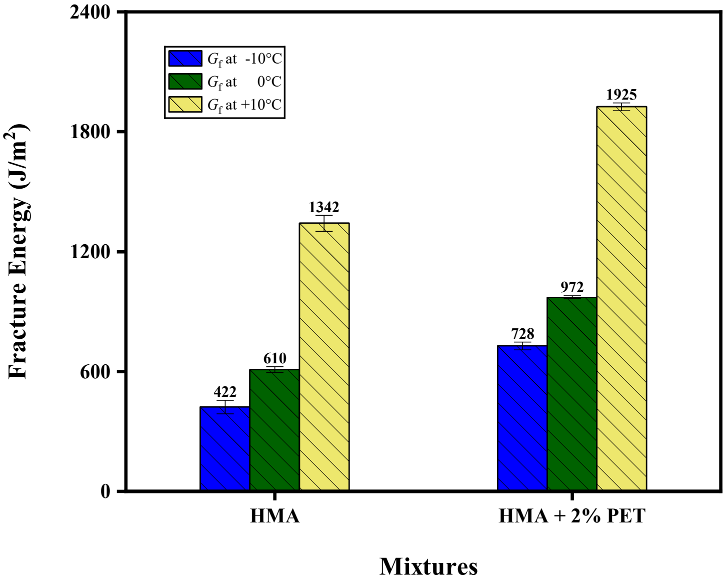

Fig. 5. Fracture Energy (G_f) values of mixtures at different temperatures

4. Conclusions

This study investigated the fracture resistance of asphalt mixtures modified with chemically recycled polyethylene terephthalate (PET) in granular form, focusing on enhancing performance at low and intermediate temperatures. The PET granules, processed via aminolysis into an amine-functionalized additive, were incorporated at a dosage of 2% by weight of bitumen to assess their influence on asphalt fracture behavior. The experimental findings clearly demonstrated that the inclusion of granular PET-derived additives significantly improved both fracture toughness (K_{IC}) and fracture energy (G_f) across the tested temperatures (-10°C, 0°C, +10°C). Enhancements of up to 19.7% in fracture toughness and 72.5% in fracture energy were observed, indicating superior resistance to crack initiation and propagation in the modified mixtures. These improvements are largely attributed to the amine-functional groups present in the chemically recycled PET additive, which enhance the binder-aggregate interaction and improve the mixture's elasticity and ductility. The research highlights the potential of chemically recycled PET granules as an effective modifier for asphalt pavements, offering not only enhanced mechanical performance but also contributing to environmental sustainability by repurposing plastic waste. Utilizing PET in granular form provides a practical and scalable method for integrating recycled materials into pavement construction.

Abstract. Juniperus species are globally significant due to their extractive components and applications in medicine and pharmacology. Juniperus trees, widely distributed in Turkey, provide essential oils that are traditionally used as antiseptics, anti-inflammatory agents, and antibacterial remedies. However, large quantities of juniper seeds are discarded as waste after oil extraction. This study investigates the potential of using juniper seed waste as lightweight aggregate in SCM-based cementitious composites to reduce the unit weight of mixtures. The juniper seeds (JSA) were volumetrically replaced with No.1 aggregates at 10%, 20% and 30% levels, while 40% level was found to be unstable. Two experimental groups were prepared with cement partially replaced by 70% fly ash (FA) or ground granulated blast furnace slag (GBFS). Tests were conducted to assess fresh, physical and mechanical properties. FA-based mixtures showed lower fluidity at higher JSA content compared to GBFS-based ones. Due to the high JSA porosity, water absorption increased from 1.23% to 15.83% at 30% replacement. The dry unit weight decreased by up to 35%, 10% JSA replacement reducing the weight to 1.83 g/cm³ and 1.63 g/cm³ in FA and GBFS mixtures, respectively. The mechanical performance declined as JSA content increased, due to the lower strength of JSA compared to conventional aggregates. However, a 10% JSA replacement maintained moderate performance, achieving splitting tensile strengths of 1.22 MPa and 1.00 MPa and compressive strengths of 18.40 MPa and 13.22 MPa for FA and GBFS, respectively. The results suggest that a 10% JSA replacement is optimal for lightweight concrete applications.

Keywords: Juniperus seed waste, Lightweight concrete, Waste management, Mineral addition, Water absorption

1. Introduction

Concrete is the most widely used material in the world after water due to its advantages, such as easy production, low cost, abundance of raw materials, ease of access, and modification of performance properties (Celik et al., 2024). Thus, it is known that 60% of the materials used in the construction of a building come from concrete (Aytekin & Mardani-Aghabaglou, 2022). According to the U.S. Geological Survey published in January 2025, 4.0 Gt of cement is produced globally (Geological Survey, 2025). This amount of Portland cement (PC) is assumed to be combined with over 26 Gt of concrete, approximately 19 Gt of aggregates, and 2-3 Gt of fresh water (J. Li et al., 2019; Vahidi et al., 2024). Although concrete's raw materials are essentially natural, it is responsible for approximately 7-8% of global CO_2 emissions because of the extreme consumption of cement-related products. Therefore, the global cement and concrete sector published Net zero progress report in 2025 committing to produce net zero concrete by 2050 (Cement Industry Net Zero Progress Report, 2025). However, the production and consumption of cement are expected to increase by 43–72% by 2050, with rising demand concentrated in economically-developing regions such as India, Africa, Southeast Asia and Latin America (Fry, 2013). Reducing the number of raw materials used in concrete production is crucial for minimizing environmental impact and promoting the efficient use of natural resources. One of the key strategies for reducing the environmental impact of concrete is to decrease the amount of PC used in its composition. The incorporation of supplementary cementitious materials (SCMs) is an effective approach to achieve this. A range of materials, including fly ash (FA), ground granulated blast furnace slag (GBFS), rice husk ash, silica fume, metakaolin, red mud, bottom ash, and agricultural waste ashes, are employed as supplementary cementitious materials (SCMs). Among these, FA and GGBFS are especially preferred due to their significant availability as industrial by-products(Çelik et al., 2023; Demircan et al., 2021; Yahyaee Nojoukambari et al., 2023). FA, one of the commonly used SCMs, is a by-product

* Corresponding author, E-mail: damlanur.celik@gazi.edu.tr

https://doi.org/10.31462/icearc2025_ce_was_871

of coal-fired thermal power plants, with an estimated global annual production of approximately 750 million tons (Wang et al., 2025). GBFS is another widely used SCM, produced as a by-product of iron and steel manufacturing, with around 394 million tons generated annually worldwide (L. Li et al., 2023). In addition to their high production volumes, FA and GBFS can replace up to 50% of PC in cementitious systems without compromising performance (Mehta & Monteiro, 2006). Research studies have demonstrated that the replacement of PC with FA and GGBFS enhances both the fresh and hardened properties of concrete. These SCMs chemically react with the hydration products of cement, particularly calcium hydroxide (CH), thereby refining and densifying the microstructure (Demircan et al., 2021; Naresh & Saravanan, 2022). In addition to the microstructural improvements, the use of SCMs enhances mechanical performance and significantly reduces the risk of durability-related issues such as sulfate attack, alkali-silica reaction (ASR), and chloride ion penetration, especially at higher replacement levels. Furthermore, SCMs contribute to lower overall production costs, improved long-term performance, and a notable reduction in carbon emissions (Berryman et al., 2005; Ifzaznah et al., 2024; Wang et al., 2025).

Another important strategy to reduce the environmental impact of concrete is to minimize the number of conventional aggregates used in its composition. A very effective approach to achieve this is the replacement of recycled aggregates with conventional ones. The use of recycled aggregates reduces the need for waste disposal, conserves natural resources and lowers the overall cost of concrete mixtures (Cheng & Khasani, 2024). Recycled concrete, recycled plastic, and recycled ceramic are the predominant types of recycled aggregates, mainly due to their high availability as construction by-products. In addition to these materials, various other waste materials have also been investigated for potential use as aggregates in concrete mixtures (Abbas & Qureshi, 2025; Cheng & Khasani, 2024; Huang et al., 2025). Juniper seed is one of the alternative waste materials used as aggregate in concrete. Juniperus species are globally recognized for their bioactive extractive components and are widely utilized in the fields of medicine and pharmacology. Juniper trees and their primary product, juniper seeds, are broadly distributed in Turkey and valued for their essential oils, which have traditionally been employed for their antiseptic, anti-inflammatory, and antibacterial properties (Ayşegül, 2018; Güvendiren, 2015; Judžentienė, 2019). Following oil extraction, large quantities of juniper seeds are discarded as waste, creating potential for their utilization in two distinct applications within concrete mixtures: as recycled aggregates and as supplementary cementitious materials. Once the oil is extracted, the residual juniper seed can be directly used as a lightweight aggregate due to its low density. Alternatively, when used as a biofuel, the resulting ash can serve as a SCM, contributing to sustainable concrete production. However, juniper seed has been rarely used in the construction sector in the literature. Celik et al. (2023) investigated the use of juniper seed ash as a SCM to obtain high-strength mortars. The performance of the mixtures was compared with the conventional SCMs. SCMs replaced cement at a ratio (wt%) of 7.5%, 12.5% and 17.5%. According to experimental results, JSA improved the flowability of the mortar mixture and reduced the unit weight due to its low density and porous structure. In terms of mechanical performance, a small amount of JSA slightly reduced the compressive strength of the mortar. However, long-term compressive strength results were higher than those of RHA-modified mortars (Celik et al., 2023). To date, the use of juniper seeds as a lightweight aggregate has not been reported in the literature. This study aims to investigate the feasibility of using juniper seeds as a partial replacement for No.1 coarse aggregates in concrete mixtures at varying replacement levels. The fresh, physical and mechanical properties of mixtures were evaluated. Additionally, the economic and environmental benefits of concretes incorporating juniper seed aggregates (JSA) were assessed and compared with those of conventional concrete.

2. Materials and method

2.1. Materials

In mixtures, CEM I 52.5 R type cement was used as main binder, which concordant with both EN 197-1 (EN 197-1, 2012) and ASTM C150 (ASTM C150, 2010) standards. To reduce PC usage, FA and GBFS were preferred as SCMs. F class FA was selected in line with the ASTM C618 standard (ASTM C618-22, 2025). GBFS was chosen which concordant with ASTM C989 standard (ASTM C989, 2024). The physical properties and chemical compositions of binders are given in Table 1.

Table 1. The physical properties of aggregate types

Properties	Coarse aggregate			Fine aggregate
Gradation	No.2	No.1	Juniper seed aggregate	Crushed-sand
Specific gravity	2.66	2.64	0.65	2.77
Fineness modulus	-	-	-	3.36

Fig. 1. Juniper seed particles

For concrete mix design, No.1 and No.2 type coarse aggregate and crushed-sand type fine aggregate were preferred. In order to reduce the amount of coarse aggregate and lower the weight of the concrete, the juniper seed aggregate was replaced with No.1 type coarse aggregates (Fig. 1). The physical properties of the aggregates are given in Table 1. The particle size distribution of the various types of aggregates is shown in Fig. 2.

2.2. Mixture proportions and preparation

The mixture proportions of cementitious composites used in this study are given in Table 3. The mix design of cementitious composites was completed according to TS EN 802 standard (TS EN 802, 2016). Two groups of mixtures were prepared with cement partially replaced by 70% FA or GBFS. SCMs are replaced with PC at 70% by weight of cement in mixtures. The w/c ratio was kept at 0.40 for all mixtures. In order to investigate the potential use of juniper seed waste as a lightweight aggregate in SCMs-based cementitious composites, JSA were volumetrically replaced with No.1 type aggregates at ratios of 10%, 20%, and 30% with a 40% replacement proving unstable.

A total of 8 mixtures were produced in this study, including two reference mixtures containing only FA and GBFS. In order to obtain cementitious composites, aggregate types except for JSA were first mixed for 3 minutes. Afterwards, the total amount of binder (cement + SCMs) was added to the mixture within 1 minute and mixing continued for 3 minutes. Then, total amount of mixing water was added to the mixture within 1 minute and mixing continued for 5 minutes until a homogenous mixture obtained. Finally, the total amount of JSA was added to the mixture and mixed for 1 minute to avoid damaging juniper seed aggregate particle, resulting in the final mixture. As a result of the procedure, the fresh mixture was placed into oiled molds without the application of vibration. The samples were removed from their molds after 24 hours. All samples were air-dried for 7 days, followed by moist curing for 21 days. The samples were coded as shown constituents of mixture. For instance, the mixture coded as "FA-20% JSA" was produced using fly ash as the cement replacement material and 20% JSA replaced with No1.type aggregate.

Table 3. Quantities of materials used in mixtures (kg/m^3)

Mix ID	Cement	FA	GBFS	No.2	No.1	JSA	Crushed-sand	Water
FA-reference	1580	3700	0	1170	3120	0	3510	2100
FA-10% JSA	1580	3700	0	820	1640	550	2460	2100
FA-20% JSA	2260	5280	0	900	1200	1200	2710	3000
FA-30% JSA	2260	5280	0	730	490	1470	2200	3000
GBFS-reference	1580	0	3700	1180	3150	0	3550	2100
GBFS-10% JSA	1580	0	5280	1180	2370	790	3550	2100
GBFS-20% JSA	2260	0	5280	910	1210	1210	2730	3000
GBFS-30% JSA	2260	0	5280	740	490	1480	2220	3000

2.3. Tests

The fresh, mechanical, and physical properties were evaluated for the performance of SCMs-based cementitious composites. Each test results was obtained by averaging at least three samples.

2.3.1. Fresh properties

In order to determine the consistency of the developed composites, flow diameters of mixtures were measured according to ASTM C1437 standard (ASTM C1437, 2020).

2.3.2. Mechanical properties

The mechanical performance of the proposed composites was evaluated by measuring splitting tensile strength and compressive strength after 28d of curing. The splitting tensile strength test was conducted according to ASTM C496 standard from Q100*200mm cylindrical samples (ASTM C496, 2017). The compressive strength test was applied according to ASTM C39 standard from 100*100*100mm cube samples (ASTM C39-05, 2005).

2.3.3. Physical properties

The water absorption and hardened unit weight tests were conducted in compliance with ASTM C642 standard (ASTM C642, 2022). The physical properties were then determined on cube samples with an edge length of 100 mm after 28 days.

2.3.4. Transport properties

Capillary water absorption was measured according to EN 1015-18 standard (EN 1015-18, 2002). The transport properties were then tested using 100*100*100mm cube samples after 28d of curing.

3. Results and discussion

3.1.1. Fresh properties

The effect of the JSA replacement in SCMs-based cementitious composites on fluidity is shown in Fig. 3. According to the test results, the flow diameter of reference samples varied based on the type of SCM. In FA-group samples, a larger flow diameter was observed than in the GBFS-group. One of the main reasons is the spherical structure of FA particles, which creates a ball effect and improves fluidity. Additionally, the structure of FA reduces friction between fine aggregates (Banerjee & Chakraborty, 2016; Memphis, 1996). Replacing 70% of the cement with FA significantly affected fluidity. The beneficial effect of FA on fluidity was observed at higher levels in comparison to GBFS. Increasing the replacement ratio of JSA with No.1 type aggregates negatively affected flowability. One of the main reasons for this is the high-water absorption capacity of JSA (Demircan et al., 2021). Although the water content in the mixture was adjusted in the design according to the water absorption capacity of JSA, a higher replacement content negatively affected the flow diameters, regardless of the SCM type. Interestingly, the GBFS-reference mixture had a lower flow diameter than the JSA utilized at different ratios. This is due to the improvement of fluidity due to the reduction of frictional forces between GBFS and the aggregates. Among the JSA-used mixtures, the best results were obtained in the FA-10 and GBFS-10 samples with 19 cm and 20 cm, respectively.

3.1.2. Mechanical properties

The effect of the JSA replacement in SCMs-based cementitious composites on compressive strength and splitting tensile strength is shown in Fig. 4. The 28-day strength results indicated that different strength values were measured for the reference samples depending on the SCM type. The FA-reference mixture exhibited the highest compressive strength at 56.85 MPa, while the GBFS-reference mixture recorded a compressive strength of 37.05 MPa. The results for splitting tensile strength were also similar to those for compressive strength. As the JSA replacement ratio increased, the splitting tensile and compressive strengths of the mixtures were significantly negatively affected. The compressive strength decreased by 75% with 30% of JSA replacement compared to the reference mixtures. This decrease can be explained by the low density and high porous structure of the JSA particles. The strength results indicate that the strength of JSAs is lower than that of conventional aggregates. In the FA-group, a moderate compressive strength of 18.40 MPa was achieved with the replacement of 10% JSA.

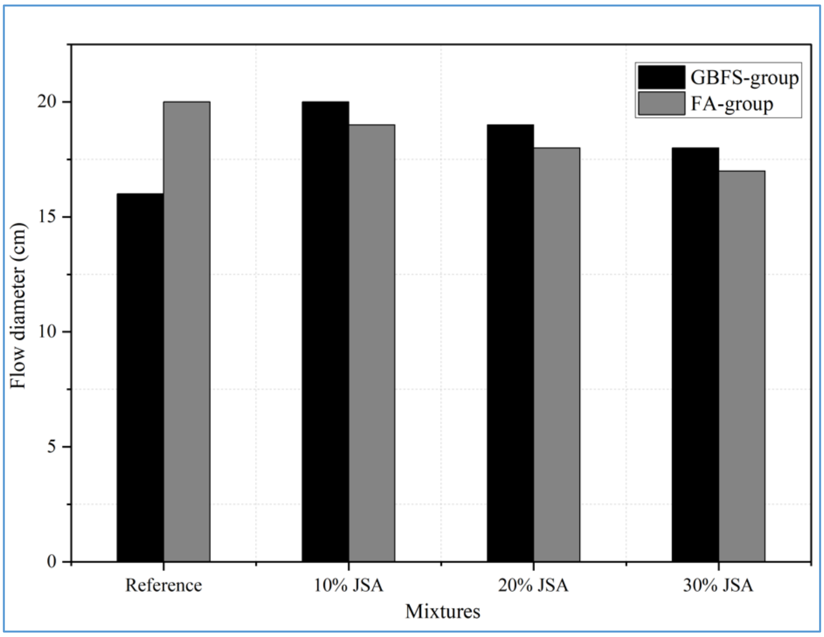

Fig. 3. Flow diameters of mixtures

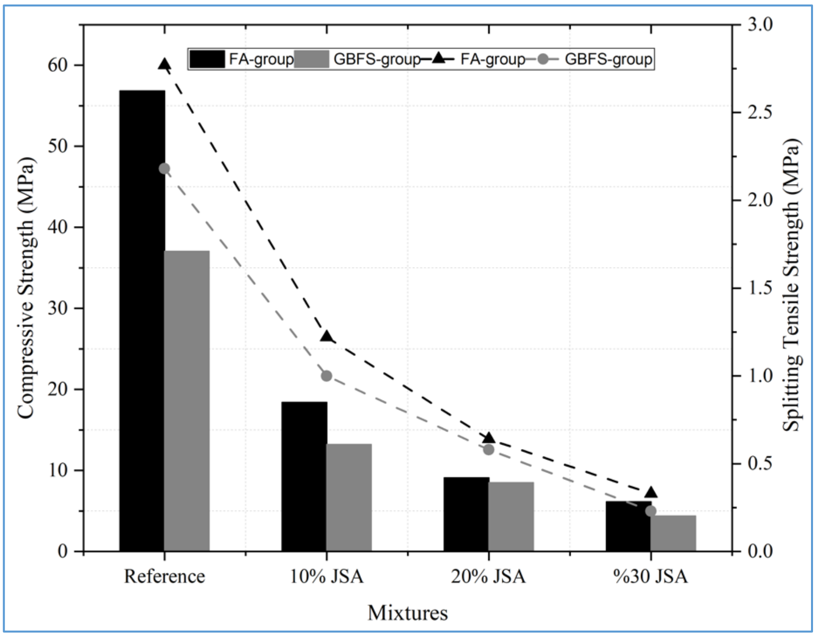

Fig 4. Mechanical properties of mixtures

3.1.3. Physical and transport properties

The effect of the JSA replacement in SCMs-based cementitious composites on physical properties is shown in Fig. 5. According to the test results, similar dry unit weight values were measured among SCM types. Fig. 5-a shows the highest dry unit weights were measured from reference samples. The dry unit weights decreased significantly with the higher JSA content. In the mixtures with the highest JSA replacement level, the dry unit weight decreased by 30% in the FA-group and by 35% in the GBFS-group. The differences arose from the low density of JSA compared to conventional aggregates. With a 10% replacement of JSA, dry unit weights were measured at 1.83 g/cm³ for the FA group and 1.63 g/cm³ for the GBFS group, respectively. Fig. 5-b shows the similar water absorption values for reference samples. The use of SCM resulted in a denser microstructure, whereby the water absorption level of the reference mixtures remained at 1.3%. However, the values for water absorption increased parabolically with the higher JSA content in both groups. Water absorption increased by up to 15 times with the 30% addition of JSA in the FA group, while it increased by 12 times in the GBFS group with the same JSA content. The reason for this increase is that JSAs have a higher level of water absorption compared to conventional aggregates. The lowest water absorption was observed with 10% JSA replacement, recorded as 3% for the FA group and 6% for the GBFS group, respectively.

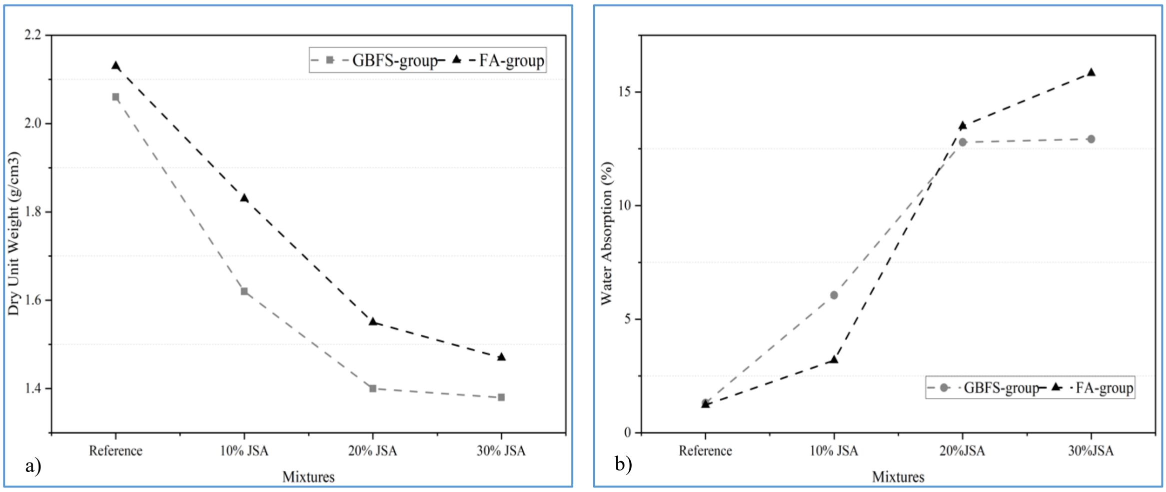

Fig 5. The physical properties of mixtures a) Dry unit weights b) Water absorption

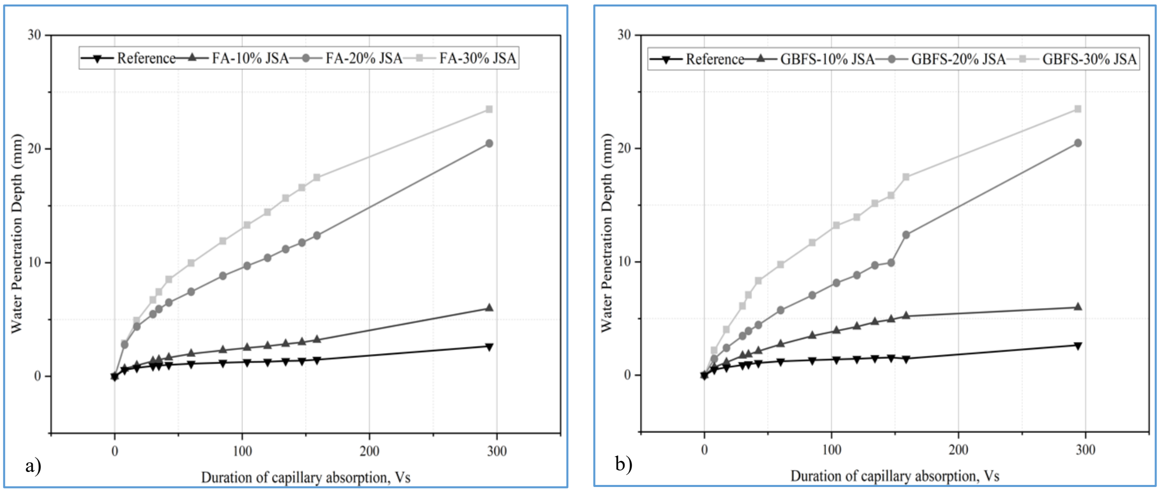

Fig 6. The water penetration depth of mixtures a) FA-group b) GBFS-group

The effect of the JSA replacement in SCMs-based cementitious composites on transport properties is illustrated in Fig. 6. The results of 2-day test, the water absorption depths were measured at 2.66 and 2.71 mm for FA and GBFS-reference mixtures, respectively. The water absorption depths increased continuously with the higher JSA content in both groups. With 30% of the JSA replacement, the water absorption depth increased up to 8 times regardless of the SCM type. Among the mixtures, the water absorption depth increased by 2 to 3 times with a 10% addition of JSA compared to the reference mixture, but it remains the most optimal rate among the other displacement ratios. The main reason for the high-water absorption depth in a short time is the high porous structure and significant water absorption capacity of JSAs.

4. Conclusion

This study investigates the use of juniper seed waste as a lightweight aggregate in SCM-based cementitious composites. The fresh properties, mechanical properties and physical properties are examined in relation to the JSA replacement ratio with natural coarse aggregate. Based on the results and discussion, the main conclusions are as follows:

- Increasing the replacement ratio of JSA with No.1 type aggregates negatively affected flowability due to the high-water absorption capacity of JSA. Among the JSA-used mixtures, the best results were obtained in the FA-10 and GBFS-10 samples with 19 cm and 20 cm, respectively.
- In terms of mechanical strength, the FA-reference mixture exhibited the highest compressive strength at 56.85 MPa, while the GBFS-reference mixture recorded a compressive strength of 37.05 MPa.
- Due to the low density and high porous structure of the JSA particles, the splitting tensile and compressive strengths of the mixtures were significantly negatively affected with increasing the JSA replacement ratio. Moderate strength was obtained with a 10% of JSA usage in the FA-group.
- The dry unit weights significantly decreased with the higher JSA content. In the mixtures with the highest JSA replacement level, the dry unit weight decreased by 30% in the FA-group and by 35% in the GBFS-group. With a 10% JSA replacement, the dry unit weight was measured as 1.83 g/cm^3 in the FA mixture and 1.63 g/cm^3 in the GBFS mixture, respectively.
- Water absorption values increased parabolically with the higher JSA content in both groups.
- With 30% of the JSA replacement, the water absorption depth increased by up to 8 times regardless of the SCM type. The replacement of 10% JSA resulted in water absorption of 3% in the FA group and 6% in the GBFS group, indicating the most favorable performance among all replacement ratios.

In conclusion, optimum fluidity and mechanical properties were obtained when 10% by volume of No.1 type aggregates were replaced with JSA, regardless of the SCM type. However, the water absorption values of the mixtures were 2 to 3 times higher than those of reference mixtures due to the high-water absorption capacity of JSA. On the other hand, the significant reduction in the dry unit weight of mixtures indicates the possible use of JSA as a lightweight aggregate.

Acknowledgments

The authors would like to express their sincere gratitude to Zekai Yıldızlı for his valuable insights, constructive suggestions, and support in providing materials for this study.

The Proceedings of the 4th International Civil Engineering and Architecture Conference includes all the accepted and presented papers, compiled in two volumes:

Volume 1: Civil Engineering, comprising 303 papers under major categories such as Structural Mechanics, Earthquake Engineering, Hydraulics & Fluid Mechanics, Geotechnics & Soil Mechanics, Transportation, Structural Materials, Hydrology & Water Resources, Construction Management, and Waste Management.

Volume 2: Architecture, featuring 118 papers grouped under topics such as Architectural Philosophy, Design & Practice, Architecture, Conservation & Restoration, Urban Planning & Landscape, Architectural Engineering, and Interior Design.

We are sincerely grateful to all authors for their valuable contributions. The papers included in these volumes were rigorously reviewed by field experts, and only those that were accepted and presented at the conference have been published. We extend our deepest appreciation to the reviewers for their meticulous evaluations, which significantly contributed to the quality of this publication.
