5. Conclusions

This study conducted a detailed experimental assessment of the compressive performance of concrete cylinders confined with Carbon Fibre-Reinforced Polymer (CFRP) and Steel Fibre-Reinforced Polymer (SFRP) jackets. Beyond conventional strength metrics, the research explored critical performance indicators, including dilation behaviour, confinement effectiveness, and ductility indices. The findings offer valuable insights into how different FRP systems influence the axial behaviour of confined concrete and provide a comparative foundation for material selection in structural applications. The main conclusions drawn from the study are as follows:

Biçimlendirilmiş: Aralık Önce: 0 nk, Satır aralığı: tek

Biçimlendirilmiş: Satır aralığı: tek

- CFRP confinement provides superior strength enhancement, with a higher confinement effectiveness coefficient (up to 4.08), attributed to its high tensile strength and stiffness. It is especially suitable for applications requiring high axial strength and stiffness under compressive loads.
- SFRP confinement significantly outperforms CFRP in strain and energy ductility, achieving up to 27.8 in strain ductility index and 139.0 in energy ductility index. These results underscore SFRP's ability to undergo larger deformations and absorb more energy due to its metallic fibre composition.
- Increasing the number of FRP layers enhances overall confinement performance for both CFRP and SFRP. However, the rate of improvement is more pronounced in SFRP-confined specimens, especially for strain-related metrics.
- Higher-strength concrete exhibits diminished confinement benefits, both in terms of strength and ductility enhancements, compared to lower-strength concrete due to its inherently lower ductility and stiffer core.
- Dilation behaviour analysis reveals distinct confinement mechanisms: CFRP effectively restricts dilation due to its stiffness, while SFRP accommodates greater volumetric strain, contributing to its enhanced energy dissipation capacity.
- From a performance efficiency standpoint, SFRP-confined systems offer a favourable balance between strength gain and enhanced ductility, making them more suitable for seismic or energy-dissipative applications, whereas CFRP remains optimal for stiffness-critical strengthening.

Acknowledgments
The author gratefully acknowledges SIKA Canada for generously donating the CFRP sheets and epoxy adhesive and Hardwire LLC for providing the SFRP sheets. Appreciation is also extended to the University of Calgary for its partial funding and support of this research.

Abstract. Enhancing the seismic performance of deficient reinforced concrete (RC) buildings through retrofitting significantly reduces potential of severe structural damage during earthquakes. With the increasing adoption of retrofitting techniques, shape memory alloy (SMA) bars have emerged as a promising alternative to traditional steel reinforcement in critical structural elements. SMAs with inherent superelastic behavior enable to regain the original shape after undergoing plastic deformations within specific strain limits. Therefore, residual displacements following seismic events can be minimized by incorporating SMA rebars. However, the high cost of SMA materials remains a challenge for their widespread application in retrofitting projects. A parametric study was conducted on SMA rebar with different configurations in the critical sections of first-story columns of a previously tested substandard RC frame. Using the lattice modeling technique in the OpenSees platform, the concrete and reinforcement elements of critical sections in RC frames were represented as truss elements with their corresponding material properties. Nonlinear time history analyses were performed on generated numerical models with different SMA rebar configurations,previously validated using pseudo-dynamic tests. The study compared peak and residual drifts at the first story, which has severely damaged columns and beam-column joints (BCJs), for each SMA rebar arrangement. Optimization analysis revealed that specific SMA rebar configuration in RC section effectively reduced both peak and residual drifts. The optimal SMA rebar layout provides a strategic balance between cost-effectiveness and enhanced seismic resilience in retrofitted RC structures.

1. Introduction

Local deficiencies, including the utilization of low-strength concrete, plain round bars, inadequate detailing in RC components, and unverified construction practices, negatively impact the seismic performance of structures within the current inventory of RC buildings (Yurdakul et al., 2021). Demolition and reconstruction of all these vulnerable structures is not feasible due to constraints related to time, cost, and application. Upgrading processes are essential for enhancing the structural performance of inadequate structures and mitigating the seismic risk in urban areas (Duran et al., 2019). Traditionally, upgrading procedures have depended on established methods (Yurdakul et al., 2023). A prevalent method is the application of local strengthening techniques to improve the load-bearing capacity of particular structural elements (Ciro et al., 2014; Yurdakul & Avşar, 2016; Del Zoppo et al., 2017; Lee et al., 2017; Teresa et al., 2020; Yurdakul et al., 2020, 2024). Alternatively, the implementation of supplementary support systems, structural walls, or other advanced mechanisms represents various approaches to enhance the overall performance of structures (Maheri et al., 2003; Elias et al., 2014; Cao et al., 2022; Cerè et al., 2022; Joseph et al., 2022).

In recent years, the concept of performance-based seismic design and assessment has gained traction and integrated into seismic design codes. In addition to prioritizing life safety, these codes place a growing emphasis on performance criteria that limit structural damage, even for severe earthquakes. The objective is to preserve building functionality while reducing both imposed and residual drifts. The increasing focus on enhanced structural performance has attracted significant attention in earthquake engineering research related to smart materials. SMAs are distinguished within the category of smart materials due to their exceptional characteristics, including superelasticity (SE) and the shape memory effect (SME). The inherent attributes of SMAs, such as their capacity to "remember" their original shape and geometry following deformation due to solid-to-solid phase

https://doi.org/10.31462/icearc2025_ce_eqe_911

golden light publishing

transformations, enable them to revert to their original shapes with minimal residual deformations once the load is removed (Desroches & Smith, 2004; Song et al., 2006).

The success of SMAs in enhancing the seismic performance of structures has been adequately demonstrated (Duran et al., 2019; Yurdakul et al., 2018; Ozbulut et al., 2011). SMAs have been utilized as an alternative to traditional materials for seismic retrofitting applications for the past twenty years. SMAs are applicable for retrofitting RC components using several techniques. These include internal reinforcement within RC structural members, near-surface mounted (NSM) reinforcement, embedded reinforcement within a shotcrete layer, and externally anchored reinforcement (Raza et al., 2022). Superelastic Nickel-Titanium (Ni-Ti) and Copper-based shape memory alloys (SMA) have been utilized as internal reinforcements in beams (Saiid et al., 2007; Abdulridha et al., 2013; Shrestha et al., 2013; Pareek et al., 2018; Azadpour & Maghsoudi, 2020), columns (Saiidi & Wang, 2006; Shin & Andrawes, 2011; Cruz Noguez & Saiidi, 2012; Hosseini et al., 2015; Tazarv & Saiid Saiidi, 2016), and BCJs (Youssef et al., 2008; Nehdi et al., 2010, 2011; Oudah & El-Hacha, 2017, 2018).

SMAs demonstrate potential as reinforcements for NSMs in existing RC structures, specifically in improving flexural strength and reducing post-inelastic displacements through their re-centering capabilities. Initially, grooves are created in the concrete cover. Following that, SMA rebars are installed within these grooves, which are then filled with either epoxy or cement mortar. Remarkable research has shown how well this method works to strengthen RC beams (Shahverdi et al., 2016; Rojob & El-Hacha, 2017, 2018; El-Hacha & Rojob, 2018; Hong et al., 2018). This method is effective for enhancing strength, helping crack healing, and minimizing residual displacements (Raza et al., 2022).

Based on the literature survey conducted, it is observed that while SMA bars have been employed to strengthen RC components in previous studies, there has been no optimization analysis utilizing numerical methods focused on the configuration of SMA rebars in RC components to reduce their quantity. Various approaches have been proposed in the literature for modeling substandard RC components. This study adopts the lattice modeling approach. The evaluation of the lattice modeling approach focuses on beam members's capacity to precisely reproduce the behavior of different RC components (Bowers, 2014; Lu & Panagiotou, 2014; Lu et al., 2016; Xing et al., 2018; Alvarez et al., 2019; Deng et al., 2021; Aydin et al., 2022; Demirtas et al., 2023). A numerical study was conducted together with an optimization strategy to evaluate the effectiveness of retrofitting techniques utilizing various SMA rebar configurations in the structural components of a sub-standard RC frame. One of the evaluated substandard RC frames exhibits a strong beam-weak column phenomenon along with inadequate BCJs. Additionally, the structure is composed of low-strength concrete and incorporates non-seismic transverse reinforcement details. Consequently, structural damage is primarily concentrated at the column ends and BCJs of the evaluated frame.

SMA bars presently exhibit a higher cost compared to conventional steel reinforcement bars. Due to the capacity of SMA materials to return to their original shape, they carry the potential to improve the seismic performance of structural systems when applied appropriately (Wilson & Wesolowsky, 2005). It is essential to establish the optimal quantity of SMA rebars required for retrofitting purposes. A study was conducted to address this issue within the scope of this research. A ½-scale, 3-story, 3-span substandard RC frame was subjected to laboratory testing under pseudo-dynamic conditions. The structure was modeled using the lattice modeling approach within the OpenSees platform (McKenna et al., 2016). Subsequent to this, nonlinear time history analyses were performed on both the retrofitted and reference RC frames, utilizing the ground motion recordings that were applied during the tests. The SMA rebar layout is subsequently optimized to identify the most efficient sections.

This study's originality exists in the identification of the optimal configuration of SMA rebars, aimed at enhancing the seismic response of the tested RC frame. NiTi and CuAlMn shape memory alloy rebars were utilized in various configurations exclusively within the column sections of the plastic hinge regions located in the first story. This method focused on reducing residual drifts while employing the minimum amount of SMA rebars necessary.

2. Test frame SP3

The lattice modeling approach was first confirmed using the results of pseudo-dynamic testing done by Mutlu (2012) on an RC frame called SP3. The nonlinear time history analyses were conducted utilizing the OpenSees program (McKenna et al., 2016). The specimen was constructed with minimal reinforcement features and constructed from plain round bars and low-strength concrete to illustrate the typical defects found in Turkish building stock. Table 1 and Fig. 1 present the primary characteristics of the SP3 specimen, along with the reinforcing details. Fig. 1 illustrates the geometric details and the dimensions of the cross-section. The cross-sections of all columns are aligned to work in their strong axes in accordance with the in-plane loading direction of the test frame. Column and beam sections utilized plain rebars with diameters of 8 mm and 10 mm, respectively. The yield strength of steel reinforcing bars with diameters of 8 mm and 10 mm is measured at 320 MPa and 355 MPa, respectively. The strains of the reinforcing steel are derived from TBEC (2018) The initial strain at the beginning of strain hardening is 0.008 mm/mm, whereas the strain associated with ultimate strength is 0.08 mm/mm. The elasticity modulus of reinforcing steel is estimated at 200 GPa in a average sense. The specimen consists of low-strength concrete, exhibiting an average compressive strength of 11.9 MPa. The axial load at the ground story is determined to be $0.23A_cf_c$ for the inner columns and $0.13A_cf_c$ for the outer columns, as a result of the vertical loads from the additional weights illustrated in Fig. 1. Additional information regarding the specimen is available in Sucuoglu et al. (2014).

Table 1. Main properties of the test specimen

Property	Value	
f_c (MPa)	11.9	
f_y (MPa)	320	
Type of longitudinal reinforcement	Plain	
Beam cross-section	175 x 150 mm	
Column cross-section	200 x 150 mm	
Beam longitudinal reinforcement ratio	Support region	Span region
	1.8%	1.1%
Column longitudinal reinforcement ratio	2%	
Transverse reinforcement in BCJ	N.A.	
Spacing of transverse reinforcement in column (mm)	Ø4/100	
Spacing of transverse reinforcement in beam (mm)	Support region	Span region
	Ø4/50	Ø4/80
Column axial load ratio, N_d/f_cA_c	Inner columns	Outer columns
	0.23	0.13
Application of displacement	At the floor level	
Loading type	Pseudo-Dynamic	
Failure mode	Damages at the member ends and BCJs	

Table 2 shows the ground motions employed for continuous pseudo-dynamic testing. The motions align with the earthquake design spectrum created for the specific location, taking into account various soil types, each presenting distinct probabilities of surpassing certain limits. Three acceleration time series, designated as D1, D2, and D3, were utilized in the pseudo-dynamic testing (Sucuoglu et al., 2014).

Fig. 2 illustrates the acceleration time series, their application sequence, and the response spectra of the associated ground motions. The damage mechanism of the reference test frame is primarily influenced by deformations and damages that occur at the column ends and BCJ regions, as indicated by experimental results and observations (Fig. 3). Structural damage is primarily observed at the ends of the columns, characterized by concrete crushing and significant cracking resulting from flexural demands (Fig. 3a). Shear cracks have been detected in the BCJ panel zone (refer to Fig. 3b).

Table 2. Ground motion properties used for the SP3 specimen

Earthquake	Exceedance Probability in 50 Years	Soil Type	PGA (g)
D1	50 %	Rock	0.254
D2	10 %	Rock	0.545
D3	10 %	Soft	0.604

3. Lattice modelling of the test frame

A numerical model of the test frame has been developed using the OpenSees platform (McKenna et al., 2016) to reproduce the results obtained from experiments. Factors such as computational effort, capabilities, and analysis time must be considered when evaluating various nonlinear modeling techniques available in the literature, which include lumped-parameter models and detailed finite-element models. The lattice modeling approach, combined with fiber-based distributed plasticity modeling, is identified as an appropriate selection for the designated test frame (Demirtas et al., 2023). The lattice modeling approach represents concrete, reinforcing steel, and bar slip elements of RC BCJs, along with certain sections of beam and column ends, as truss elements characterized by uniaxial material properties. The test frame is accurately modeled using the lattice modeling approach, which requires minimal computing efforts in comparison to more advanced modeling methods like finite element modeling. This study employs the diagonal, vertical, and horizontal components of the tension/compressive strut force transfer mechanisms to develop a nonlinear lattice structure. The springs characterized by zero-length sections connected to concrete and steel components illustrate the relationship between reinforcement bar slip. The nonlinear characteristics of concrete truss elements are described through a nonlinear concrete constitutive stress-strain model. In contrast, the behavior of steel truss elements is characterized by uniaxial stress-strain behavior specific to reinforcing steel.

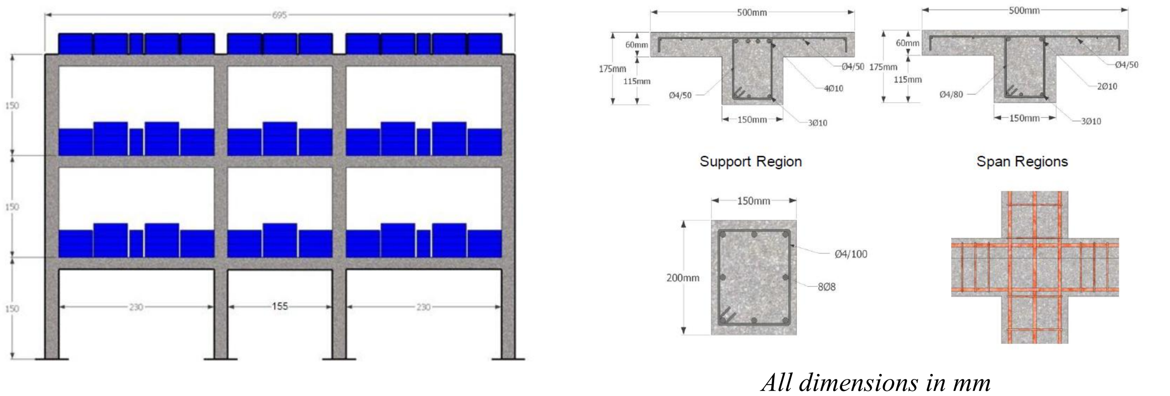

Fig. 1. Details of SP3 test specimen and elevation view (Sucuoglu et al., 2014)

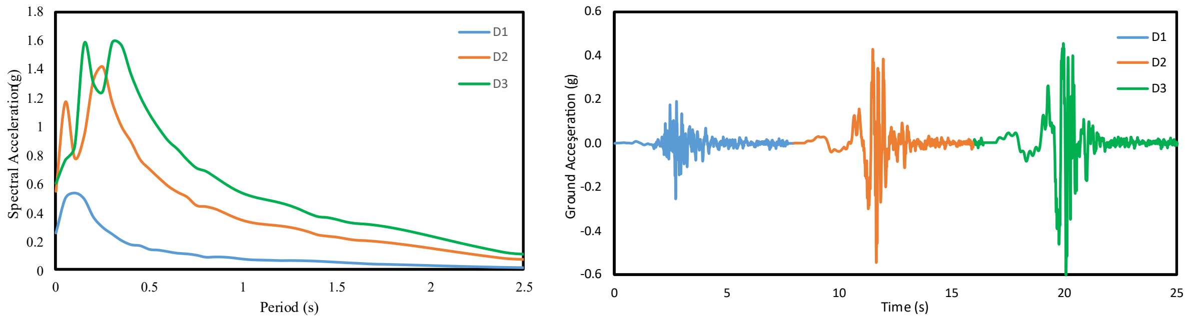

Fig. 2. Response spectra and acceleration time series of the ground motions (Sucuoglu et al., 2014)

(a)

(b)

Fig. 3. Structural damage observed in the first story of SP3 (a) column ends and (b) BCJs (Mutlu, 2012)

Fig. 4 illustrates the comprehensive configuration of the lattice model for RC beam-column joints, along with specific segments of the beam and column end sections. The model consists of concrete, reinforcement, bar slip, and rigid elements. A cell structure consists of vertical and horizontal concrete elements. The mesh size of the model is defined by the dimensions of each cell, which includes diagonal concrete struts. The diagonal elements serve the primary function of providing shear resistance, whereas the vertical and horizontal concrete elements, combined with reinforcing steel, enhance flexural resistance. Nonlinear zero-length springs that link the concrete and steel components illustrate the bar slip behavior.

Fig. 5 presents the cross-sectional areas of the concrete truss members. The calculation of the cross-sectional areas for the vertical and horizontal concrete truss members is carried out by multiplying the out-of-plane thickness by half of the tributary width, represented as *b/2*. The effective width of the diagonal concrete members is calculated using Equation (1), as proposed by Xing (2019). The calculation of the cross-sectional areas for diagonal members is carried out by multiplying the out-of-plane thickness by half of the effective width, represented as *b/2*. The use of half-width for all concrete truss members is attributed to the overlapping of their tributary widths (Demirtas, 2022; Salinas et al., 2022).

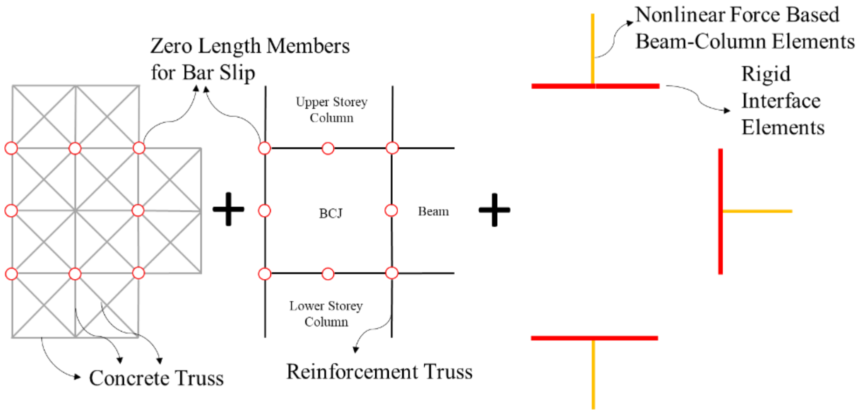

Fig. 4. Layout of the lattice model for BCJ (Demirtas et al., 2023)

(a) Tributary widths of the horizontal and vertical concrete truss members

(b) Tributary width of the diagonal concrete truss members

Fig. 5. Details of the cross-sectional areas of the concrete truss members (Demirtas, 2022)

$$b_{eff} = \frac{a \times b}{\sqrt{a^2+b^2}} \quad (1)$$

The amount of reinforcing steel in the model determines the cross-sectional areas of the reinforcement truss members, which are positioned at the edges of the sections. A rigid beam-column element is utilized to model the interaction between the BCJ and the neighboring beam or column. This guarantees that the cross-sections of beams and columns maintain their plane and perpendicular orientation relative to the deformed center of the frame member. Nodes at the truss members and rigid beam-column components are interconnected through EqualDof constraints in the x and y directions for the translational degree of freedom, thereby ensuring structural integrity at these locations.

3.1. Concrete model

The ConcretewBeta Material model, as presented in OpenSees (McKenna et al., 2016), is utilized to establish the constitutive model for both the compressive and tensile behavior of concrete. The specific characteristics of the trusses are established utilizing the constitutive model developed by Lu & Panagiotou (2014) within the OpenSees.

Fig. 6 shows the uniaxial stress-strain relationship for concrete. In this model, f_c represents the maximum compressive strength of concrete at a strain of ε_0, whereas ε_u indicates the ultimate strain of unconfined concrete. The parameters of the model are determined using the concrete's compressive strength. In this model, the value of ε_0 was set to 0.002. The ultimate strain ε_u of concrete is adjusted to incorporate mesh-size effects as outlined by

Demirtas et al., (2023). The ultimate tension strain of concrete is characterized by a significantly high value, for instance, 1.0, as demonstrated in Fig. 6, to prevent tensile failure of concrete and ensure computational stability.

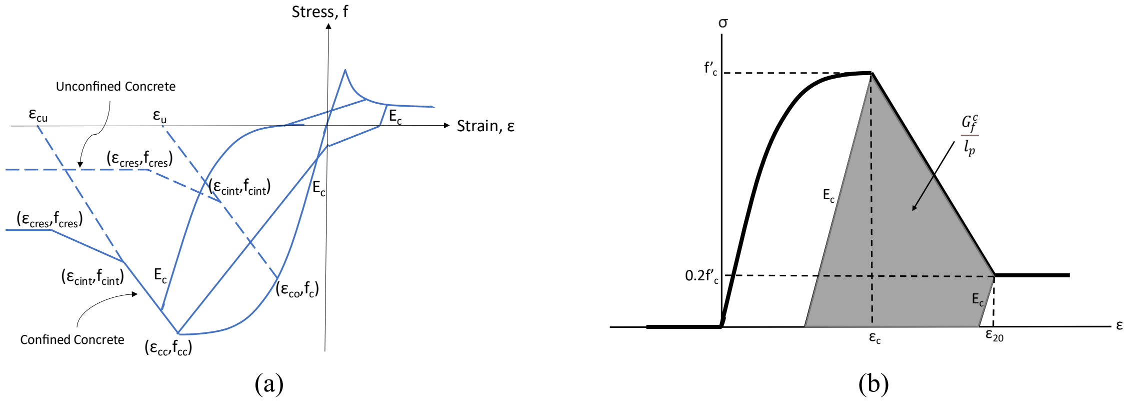

Fig. 6. (a) Uniaxial stress-strain relationship of concrete (Lu & Panagiotou, 2014) (b) Kent–Park concrete stress-strain model with fracture energy G_f^c in compression as shaded area (Scott & Fenves, 2006)

3.2. Reinforcement model

OpenSees' Reinforcing Steel material model, which is based on Chang and Mander (1994) uniaxial steel model, is used. Fig. 7 demonstrates the stress-strain behavior of the reinforcing bar, represented by the backbone curve. The initial strain at the beginning of strain hardening is defined as 0.008 mm/mm, while the strain associated with ultimate strength is established at 0.08 mm/mm.

The relationship between reinforcing bar slip is represented by zero-length springs that are connected to concrete and steel bars through the uniaxial material model BarSlip, which is available in OpenSees (Fig. 8). S_{lim}^C and S_{lim}^T represent the compression and tension slip limits, respectively. F_{lim}^C and F_{lim}^T denote the force limits for compression and tension, respectively. In OpenSees, the BarSlip material model is categorized as a uniaxial material model. It is defined utilizing the Pinching4 material model, which takes into account various parameters including the compressive strength of the concrete, the modulus of elasticity, the yield strength, and the ultimate strength of the reinforcing steel. Additionally, the diameter and quantity of reinforcing bars are considered to compute the backbone curve.

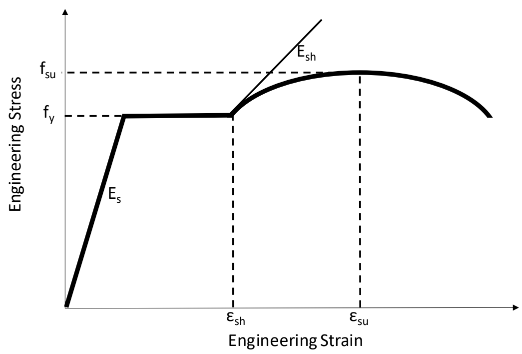

Fig. 7. Backbone curve of the Reinforcing Steel material (Chang & Mander, 1994)

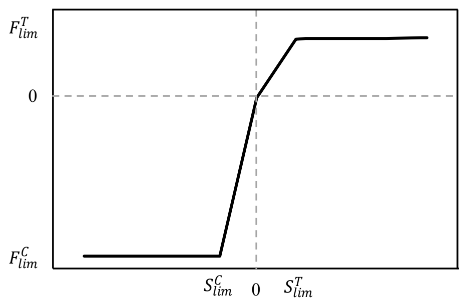

Fig. 8. Backbone curve of the BarSlip material (Demirtas, 2022)

3.3. Lattice model of the SP3 specimen

A lattice model featuring a grid size of 0.1 x 0.0875 m is implemented in OpenSees to simulate the essential components of the SP3 specimen. In addition to the BCJs, the columns experienced damage during the pseudo-dynamic testing process. The lattice structure is extended to the edges of the columns for a specified length to accurately capture the damage at the boundaries of the plastic hinge zone of the columns. Fig. 9 shows the overall configuration of the models incorporating a lattice structure alongside nonlinear force-based beam-column elements. The supplementary masses are allocated to the edges of the beams to accurately represent the masses and their correct positioning during dynamic analysis.

4. Retrofit study

SMAs are classified as metallic smart materials characterized by their ability to recover from significant deformations, attributed to their inherent shape-changing properties. In the past two decades, SMAs have emerged as an alternative to conventional materials for applications related to seismic strengthening. The effective use of SMAs in enhancing structural seismic performance has been successfully established (Yurdakul et al., 2018; Duran et al., 2019). SMA bars may be utilized as internal reinforcement within RC structural members for new constructions. SMA bars and plates are applicable in multiple techniques, including NSM reinforcement, embedded reinforcement within a shotcrete layer, and externally anchored reinforcement, for the rehabilitation and strengthening of existing structures (Fig. 10). This study employs a method similar to the NSM technique for the retrofitting of the SP3 specimen. Fig. 11 illustrates the replacement of steel reinforcement with SMA rebars in the plastic hinge region at the ends of the columns. The SMA replacement was not implemented in the reinforcements of the BCJ, which is susceptible to seismic damage primarily due to insufficient transverse reinforcement in the BCJ panel. Furthermore, within the current 3D structures, the existence of out-of-plane beams inhibits the replacement of longitudinal bars in the BCJ panel. SMA rebars and steel rebars are presumed to be interconnected via couplers within the plastic hinge region at the ends of the columns, consistent with the practical applications observed in the research conducted by Pareek et al. (2018).

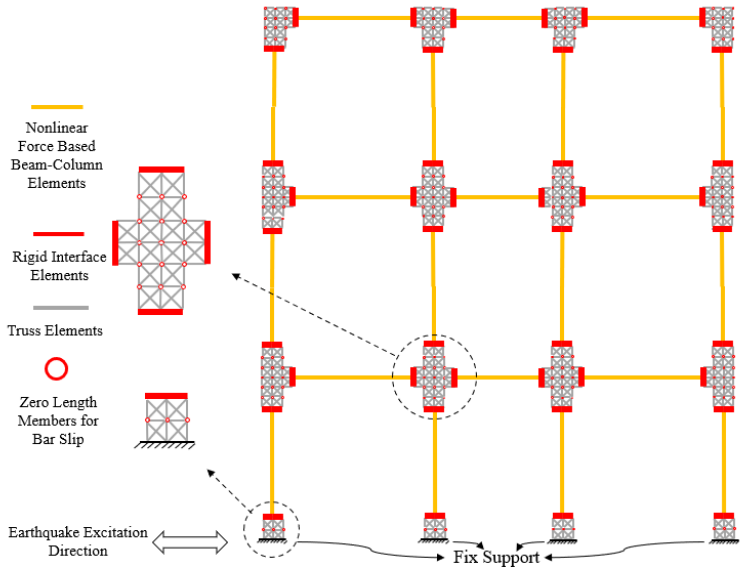

Fig. 9. General layout of the lattice model of SP3

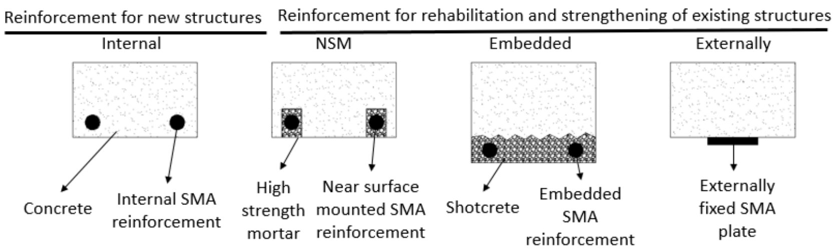

Fig. 10. Retrofitting techniques by SMA rebars (Raza et al., 2022)

Two categories of SMA materials, specifically CuAlMn and NiTi, are utilized as reinforcement materials across various cross-section configurations. In every configuration of the RC column section, the current steel rebars are replaced with the chosen SMA rebars within the plastic hinge region, as illustrated in Fig. 11. The SelfCentering material model implemented in OpenSees was utilized as the material model for the SMA rebars (Fig. 12). This model is predicated on the assumption that the SMA material exhibits an ideal re-centering capability. The numerical values for the modeling parameters of CuAlMn and NiTi materials, as illustrated in Fig. 12, are detailed in Table 3. The cost of SMA materials is still greater than that of traditional steel materials, even if their use in retrofitting existing buildings is growing (Molod et al., 2022). Therefore, optimizing the quantity of SMA material is crucial for attaining a cost-effective retrofitting solution. As illustrated in Fig. 13, SMA materials are implemented in various configurations specifically within the critical cross-sections of the first story columns, which experienced significant flexural damage during the pseudo-dynamic testing (Fig. 3a). In these cross-section configurations, variations are observed in both the quantity of SMA bars and their positioning. The longitudinal rebar layout remains consistent across all configurations (Fig. 13). Steel transverse reinforcement is utilized with consistent spacing and detailing across all reinforced concrete sections.

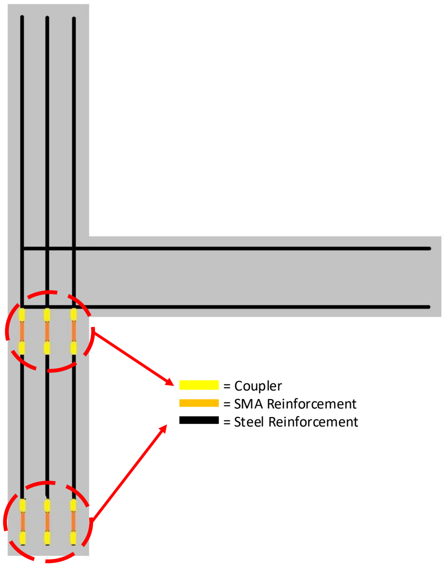

Fig. 11. Connection of SMA rebars to the existing steel rebars

E_2 (MPa)	5	372
f_y (MPa)	179.3	365
Beta (%)	10	59

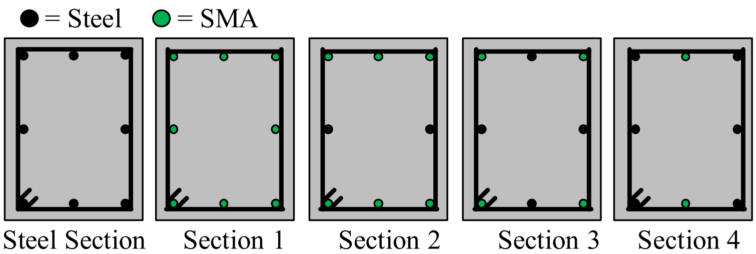

Fig. 13. Cross-section configurations

4.1. Results of nonlinear time history analyses

The SP3 specimen, with parameters detailed in Section 2, performed ground motion records during the pseudo-dynamic testing process. The interstory drift ratio and the residual displacement demands serve as critical metrics for assessing the seismic damage levels of structural and nonstructural components. The hysteretic behavior related to the first story shear force and interstory drift ratio for various column section configurations is illustrated in Fig. 14, as structural damage mostly exhibited in the first story of the tested frame. The reference section, which is fully reinforced with reinforcing steel, provided an accurate estimation of the peak story shear force and residual displacement derived from the experimental results. The first-story shear force is consistent across the configurations of CuAlMn and NiTi SMAs in both Section 3 and Section 4. However, compared to the steel reinforced section, the peak interstory drift ratio was much greater when SMA reinforcement was used throughout Section 1. However, the peak interstory drift ratios are more consistent with the steel reinforced section observed in Sections 2 and 4. Additionally, the residual displacements observed in Sections 1 and 2 are significantly lower than those recorded in the steel-reinforced section. In contrast, Sections 3 and 4 exhibit residual displacements that are comparable to or exceed those in the steel reinforced section. The steel reinforcement rebars in Sections 3 and

4 are the primary contributors to the structural response. The addition of SMA bars in these sections demonstrates reduced effectiveness compared to Sections 1 and 2 regarding residual displacements.

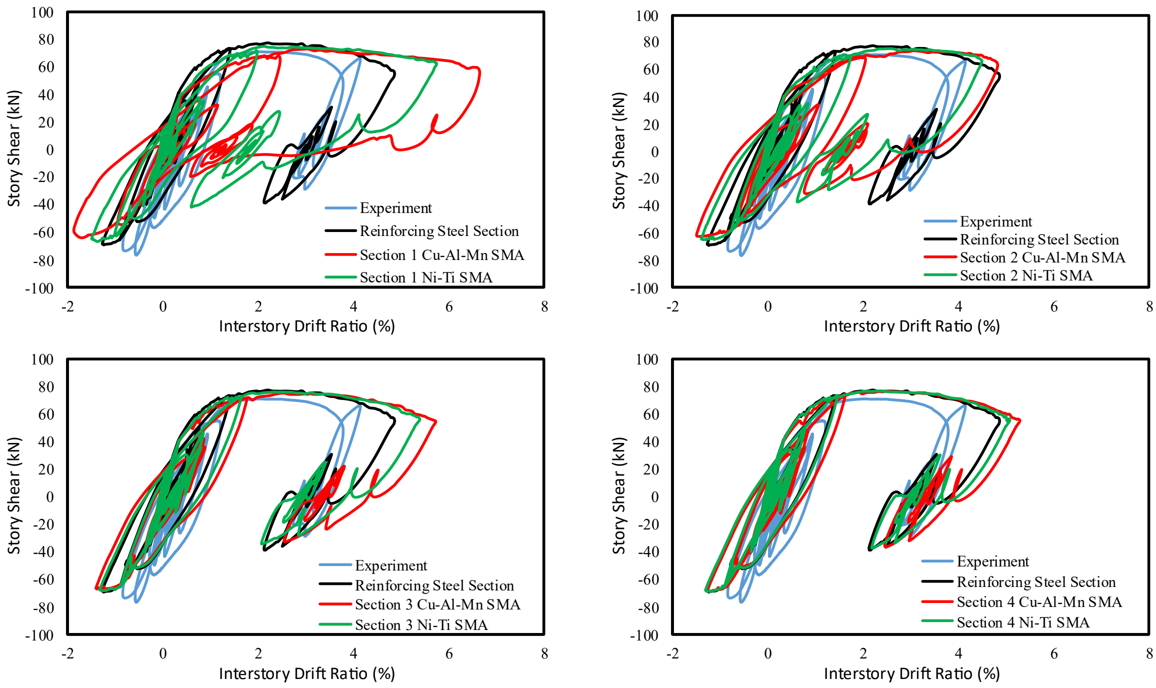

Fig. 14. Comparison of first story shear force versus interstory drift ratio between the experimental, steel, CuAlMn and NiTi lattice model results

The calculated peak values of the drift ratio and the residual drift at the first story are compared for the investigated cross-section configurations with the experimental response. The lattice model incorporating NiTi SMA reinforced column sections demonstrates a reduced peak interstory drift ratio compared to the lattice model utilizing CuAlMn SMA reinforced sections (Fig. 15). The same trend is observed for the residual drift ratio, with the exception of Section 1. Section 1 indicates that the peak drift ratio for the NiTi SMA reinforced model is 5.5%, whereas the peak drift ratio for the CuAlMn SMA reinforced section is 7.5%. The residual drift ratio of Section 1 is comparable for both SMA materials. The peak interstory drift ratio and residual drift ratio in Sections 3 and 4 exhibit similarities to those observed in the steel reinforced reference section. The peak drift ratio demands for Section 2, which includes both NiTi SMA reinforced and CuAlMn SMA reinforced sections, are identified as the lowest values within the analyzed sections, ranging from 4.5% to 5.0%. The residual drift ratio in Section 2 is calculated as 1.5%, which is significantly lower than that of the other sections, with the exception of Section 1. Upon comparison of Sections 1 and 2 regarding residual displacements, the negligible difference observed suggests that the implementation of SMA rebars throughout the entire longitudinal rebar configuration is unnecessary. An optimal layout for SMA rebar must be determined to ensure the most advantageous structural response regarding peak and residual displacements, while also reducing the quantity of SMA material utilized.

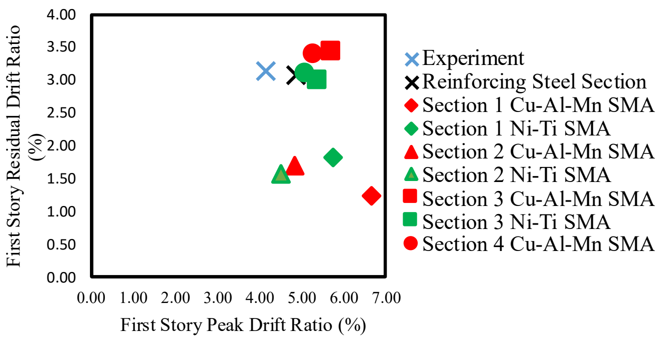

Fig. 15. Comparison of first story peak drift ratio versus residual drift ratio between the experimental at the end of the loading history D3, steel, CuAlMn and NiTi lattice model results

5. Conclusions

SMAs are increasingly utilized in the retrofitting of sub-standard RC buildings, owing to their essential superelastic properties, which enable them to revert to their original shape upon the removal of applied loads. Given that SMAs are not cost-effective materials, it is essential to utilize them in quantities that produce the best structural performance. This study employs NiTi and CuAlMn SMA rebars arranged in various layout configurations within the plastic hinge region of the first story columns of a three-story, three-span RC frame characterized by non-seismic detailing and substandard structural configuration. The response of the RC frame, which was subjected to experimental testing, was replicated in the OpenSees platform utilizing the lattice modeling approach. This technique involves modeling concrete and reinforcement elements located in the critical position of the RC frame as truss elements, utilizing their respective material properties. The developed models were subjected to nonlinear time history analysis utilizing the sequential ground motion records applied during the pseudo-dynamic testing. The analysis focused on the peak drift ratio and residual drift ratio of the first story across each developed numerical model, which evaluates the optimal configuration of SMA bars for improving seismic performance.
For the identical section configuration utilizing various SMA rebars, sections incorporating CuAlMn rebars exhibited a greater peak drift ratio compared to those with NiTi rebars. Because CuAlMn has a lower yield strength and post-yield behavior than NiTi, sections containing CuAlMn rebars may need more displacement, which might result in a greater dissipation of seismic energy.

- With the exception of Section 1, which utilizes a uniform rebar material for all longitudinal bars, sections incorporating CuAlMn rebar have demonstrated reduced residual displacements in comparison to those utilizing NiTi rebar. The variation in residual displacements between the two distinct SMA materials is less pronounced compared to the variation observed in peak displacements.
- Sections 1 and 2 achieve the smallest residual displacement demands. The use of SMA material for all longitudinal bars in the critical cross-section is unnecessary. Consequently, it is essential to identify an optimal layout for SMA rebar to attain the most advantageous structural response, characterized by peak and residual displacements, while also reducing the quantity of SMA material utilized.
- The inclusion of steel longitudinal rebars in both the top and bottom bar layers significantly influences the behavior of the cross-section. The SMA rebars exhibit inefficiency in Sections 3 and 4, leading to comparable residual displacements when compared to the original steel rebar configuration. In order to attain the required seismic response, it is essential to evaluate the performance of the cross-section to identify a cost-effective retrofit solution utilizing SMA materials as longitudinal reinforcing bars.

Abstract. In densely populated metropolitan areas, buildings are often constructed with insufficient gaps between them, increasing the risk of poundings during seismic events, which can cause damage to structural elements. Therefore, evaluating the seismic behavior of buildings subjected to the pounding effect is essential. This study investigates the structural pounding effects between a base-isolated and a fixed-base reinforced concrete building under seismic excitation. Both buildings were designed as four-story structures in accordance with the Türkiye Building Earthquake Code. Finite element models of the buildings were developed using the SAP2000 software. The interaction between these two structures was examined through nonlinear time-history analyses using eleven pairs of ground motion records. The separation distances between the base-isolated and fixed-base buildings are set at four different levels: 25%, 50%, 75%, and 100% of the total design displacement of isolators. The interaction and transfer of pounding forces between adjacent structures were simulated using nonlinear elastic spring model, specifically the Hertz contact model. The seismic behavior of both base-isolated and fixed-base buildings under the influence of pounding effects were evaluated by analyzing the structural response in terms of story accelerations, plastic rotations, and shear force demands. Story accelerations were analyzed to assess the amplification of inertial forces due to pounding. Impact forces generated during poundings were examined to determine their magnitude and effect on structural components. Plastic hinge rotations were evaluated to identify potential locations of excessive deformation and damage concentration, providing insights into the structural performance under repeated impact loading. The results demonstrate that reduced separation distances significantly amplify seismic demands. At 25% separation, plastic rotations in column elements—especially in the fixed-base building—frequently exceed the Collapse Prevention performance level. Conversely, at 100% separation, pounding is effectively mitigated, and structural responses are substantially reduced. It is observed that the highest pounding forces typically occur at the isolation level and upper stories, with non-uniform distribution along the height. Base-isolated buildings exhibit consistently lower plastic hinge demands compared to fixed-base buildings under identical conditions, particularly in columns. Moreover, beams located at the isolation level remain largely within elastic limits across all scenarios. Directional analyses reveal that structural elements aligned with the pounding direction experience significantly higher demands than those in the orthogonal direction. The findings confirm that inadequate separation distances severely compromise the efficiency of seismic isolation systems by increasing acceleration demands and structural deformations. Thus, ensuring sufficient clearance is critical for the optimal performance of base-isolated buildings during strong ground motions.

Keywords: Reinforced concrete building; Base isolation; Pounding; Separation distance; Damage evaluation

1. Introduction

Base isolation systems have been widely adopted as an effective strategy for enhancing the seismic resilience of structures by significantly reducing inertial demands transmitted to the superstructure (Komodromos et al., 2007; Domadzra et al., 2024). Despite their effectiveness, base-isolated structures are susceptible to large lateral displacements during seismic events, which can lead to pounding between adjacent buildings or between the superstructure and the surrounding moat wall (Pant & Wijeyewickrema, 2012). Seismic design codes prescribe minimum separation distances to avoid such poundings. However, several studies have shown that these provisions

* Corresponding author, E-mail: furkan.sen@giresun.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_915

may not always be sufficient under certain structural configurations or when subjected to extreme or near-fault ground motions (Rajaram & Kumar, 2012; Kamal & Inel, 2022; Altunışık et al., 2023).

While the literature has extensively examined the pounding between base-isolated buildings and moat walls (Komodromos, 2008; Masroor et al., 2012; Liu et al., 2014; Mavronicola et al., 2017), limited attention has been paid to pounding scenarios involving base-isolated and adjacent fixed-base buildings. These interactions can occur at the isolation level or story-to-story depending on the height and dynamic characteristics of the structures involved (Mavronicola et al., 2020; Sadeghi-Movahhed et al., 2024). Earlier numerical studies demonstrated that pounding-induced responses are sensitive to the base type, stiffness contrast, and separation distance (Mahmoud & Jankowski, 2010; Naderpour et al., 2019). Moreover, inadequate separation can significantly amplify seismic demands in both structures, sometimes resulting in localized damage or even collapse.

Another important aspect insufficiently addressed in prior studies is the effect of ground motion characteristics on pounding behavior. Most investigations rely on a limited number of records and often neglect the distinctions between near-fault and far-field ground motions. In particular, near-fault motions are known to contain velocity pulses, which can significantly increase displacement demands and consequently elevate the risk and severity of pounding (Kazemi et al., 2021; Ebrahimiyan et al., 2022).

In this context, the present study aims to investigate the seismic performance and behaviour of base-isolated and fixed-base reinforced concrete building subjected to pounding. For this purpose, four separation distances are analyzed, corresponding to 25%, 50%, 75%, and 100% of the total design displacement of the isolation system. Nonlinear time-history analyses are performed to comprehensively assess the influence of both separation on pounding-induced demands such as plastic hinge rotations, pounding forces, and story accelerations.

2. Modeling and design

2.1. Superstructure and pounding configuration

This study focuses on evaluating the influence of seismic pounding-occurring between base-isolated buildings and adjacent fixed-base buildings-on the plastic hinge rotations, pounding forces, and maximum story accelerations. To evaluate the influence of separation distance, the base-isolated building is assumed to be separated from the adjacent fixed-base building by varying clearance distances, denoted as d_g. The ratios of separation distance to the total maximum design displacement, $d_g/D_{T,max}$ are taken as 25%, 50%, 75%, and 100%. A four-story, four-bay by four-bay reinforced concrete structure is adopted as the representative fixed-base and base-isolated buildings. Each bay measures 6.0 meters in both longitudinal and transverse directions, with a uniform story height of 3.2 meters. Both the base-isolated and fixed-base buildings are assumed to be regular in plan and exhibit no vertical irregularities. The investigated pounding configuration is illustrated in Fig. 1.

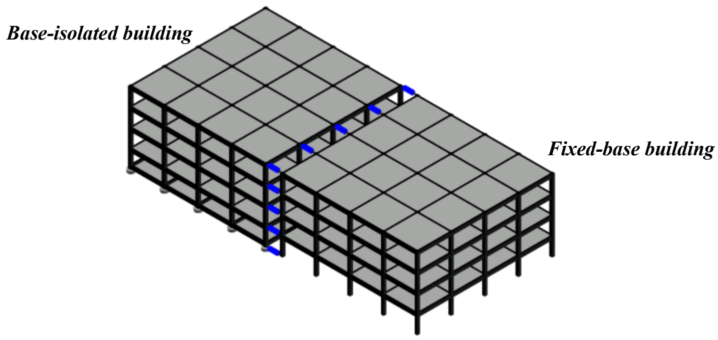

Fig. 1. The considered pounding configuration.

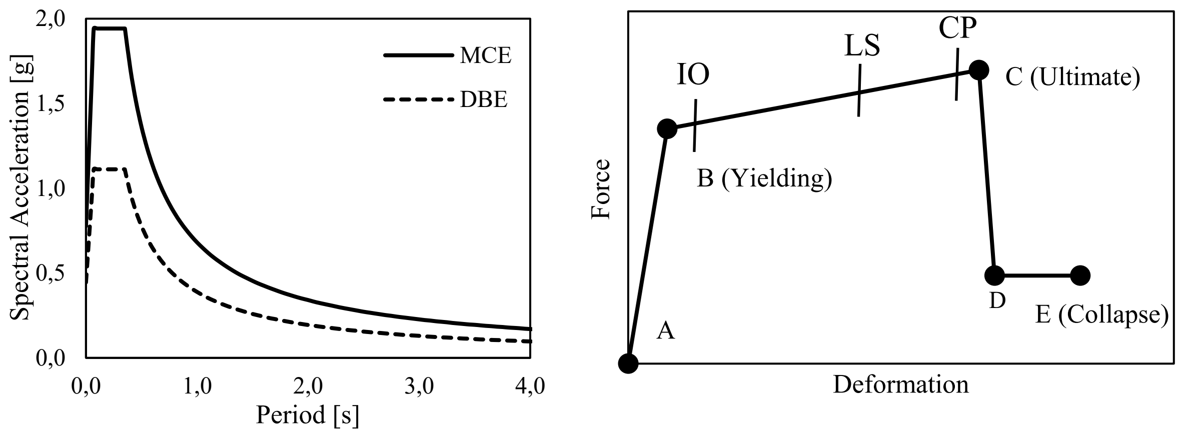
In the base-isolated building, column and beam cross-sections are 50×50 cm and 30×60 cm, respectively, while in the fixed-base building, columns are 60×60 cm with identical beam dimensions. Slab thickness is 15 cm in both buildings, except at the isolation interface where it is increased to 25 cm to ensure diaphragm effect. The concrete is C30 (f_{ck} = 30 MPa) and reinforcement is B420C (f_{yk} = 420 MPa). Nonlinear behavior of confined and unconfined concrete is modeled using the Mander model (Mander et al., 1988). The modulus of elasticity, Poisson's ratio, and unit weight of concrete are 31000 MPa, 0.2, and 25 kN/m³, respectively. For reinforcement, these values are 200000 MPa and 76.97 kN/m³. Fig. 2a presents the elastic design spectra corresponding to the Design Basis Earthquake (DBE) and Maximum Considered Earthquake (MCE), as defined in the Türkiye Seismic Hazard Map (TSHM, 2018). Finite Element (FE) models were developed using SAP2000 (2020). To represent nonlinear behavior in the superstructure, a concentrated plastic hinge model was adopted, with linear behavior assumed between hinge locations. These hinges were generated using SAP2000's default auto hinge properties in compliance with ASCE 41-17. The typical force–deformation behavior of plastic hinges is illustrated in Fig. 2b.

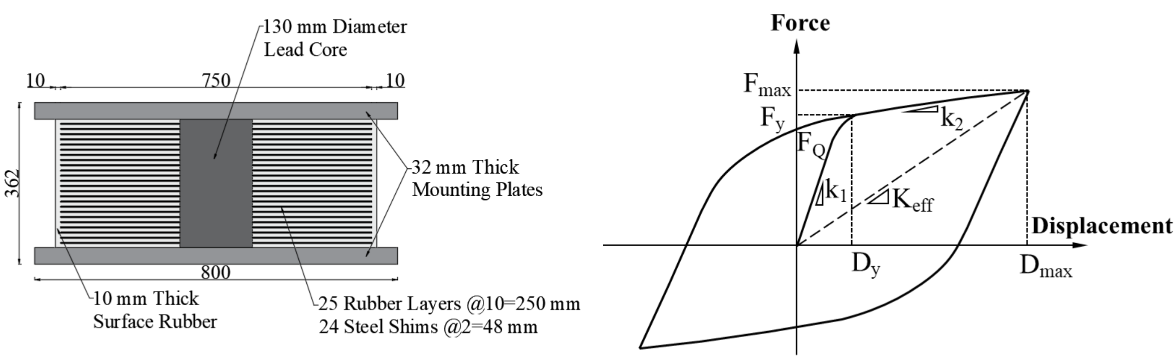


(a) (b)

Fig. 2. (a) Elastic design spectrum of selected location for DBE and MCE level (b) Force–deformation relationship for a typical plastic hinge

2.1. Superstructure and pounding configuration

Lead-Rubber Bearings (LRBs) were selected for the seismic isolation of the superstructure. To improve their energy dissipation capabilities, each was equipped with a lead plug at its core. This design feature notably enhances the efficiency of LRBs in absorbing energy, making them highly effective base isolation devices, as demonstrated by Kelly et al., (2010). The typical force-displacement behavior of LRBs is illustrated graphically in Fig. 3b. Plasticity model is based on hysteretic behavior introduced by Wen (1976); Park et al., (1986) and recommended for base-isolation analysis by Nagarajaiah et al., (1991). Several key parameters influence the force-displacement relationship, and the formulas for these parameters can be found in numerous codes (UBC, 1997; ACSE-41-17, 2017; TBEC, 2018) or publications (Naeim and Kelly, 1999). Fig. 3a presents the geometrical dimensions of the LRBs designed within the scope of Türkiye Building Earthquake Code (TBEC, 2018). The lower and upper bound properties of isolators are determined using property modification factors. Instead of using the post-yield stiffness k_2 and characteristic strength F_Q directly, lower bound values are obtained as $k_2\lambda_{low,k_2}$ and $F_Q\lambda_{low,F_Q}$, while upper bound values are calculated as $k_2\lambda_{up,k_2}$ and $F_Q\lambda_{up,F_Q}$ (TBEC, 2018). Design and performance checks are conducted using nominal, lower bound, and upper bound properties. For instance, maximum isolator displacement is checked using MCE and lower bound properties; the substructure is designed with MCE and upper bound properties; story accelerations are evaluated using DBE and nominal properties; and the superstructure design is based on DBE and upper bound properties (TBEC, 2018).



(a) (b)

Fig. 3. (a) The geometry and (b) horizontal force-displacement relationship of LRBs

The total design displacement of the isolation interface, $D_{T,max}$, is determined by adding torsional displacements from the superstructure and isolation system to the design displacement. Instead of using values from Eq. (1) alone, the greater of the calculated displacement and $1.1D_{max}$ is considered (TBEC, 2018). Eq. (1) accounts for eccentricity effects, where seismic force $K_{eff}D_{max}$ acts at the center of mass, offset by eccentricity from the center of stiffness. Table 1 presents the nominal, lower, and upper bound properties of the LRBs for both DBE and MCE levels.

$$D_{T,max} = D_{max}\left[1 + y\frac{12e}{b^2 + d^2}\right] \tag{1}$$

Table 1. The design parameters of LRBs

Parameter	Unit	Lower bound		Nominal		Upper bound	
		DBE	MCE	DBE	MCE	DBE	MCE
k_v	[kN/m]	975790.54					
k_2	[kN/m]	655.63		857.03		1569.54	
k_1	[kN/m]	6556.25		8570.26		15695.37	
F_Q	[kN]	78.98		132.73		213.32	
D_y	[mm]	13.38		17.21		15.10	
F_y	[kN]	87.75		147.48		237.02	
β_e	[%]	25.69	13.96	32.77	21.69	34.72	25.47
K_{eff}	[kN/m]	1074.39	821.20	1839.47	1263.99	3848.02	2556.11
D_{max}	[cm]	16.76	42.40	12.01	28.99	8.32	19.22
$D_{T,max}$	[cm]	18.44	46.64	13.21	31.89	9.15	21.41
η	[-]	0.571	0.726	0.535	0.612	0.535	0.573
T	[s]	2.328	2.663	1.779	2.146	1.230	1.509

Many codes (e.g., UBC, 1997; TBEC, 2018) recommend providing a gap at the isolation interface at least equal to the total design displacement calculated using MCE and the lower bound properties of isolators, as this yields the maximum displacement. Accordingly, to assess potential pounding between base-isolated buildings, nonlinear time-history analyses were conducted using MCE and lower bound isolator properties.

The interaction and transmission of pounding forces between neighboring structures was simulated using a nonlinear elastic spring model, specifically the Hertz model, which is widely referenced in the literature (Wang et al., 2009; Miari et al., 2019; Borekci et al., 2024). The nonlinear impact stiffness k_G, was set at 1.13×10^6 kN/m$^{3/2}$ for concrete-concrete interactions, as indicated by Jankowski (2005).

3. Ground motion selection

To investigate the effects of structural pounding between fixed-base and base-isolated buildings, a set of 11 near-fault ground motion records was employed. The selection and scaling procedures for these records were carried out in accordance with the provisions of the TBEC (2018). For each record, a resultant horizontal response spectrum was computed by taking the square root of the sum of the squares (SRSS) of the two orthogonal horizontal components. All ground motions were scaled such that the average resultant spectra complied with the spectral matching criteria prescribed by the code over the relevant period intervals.

For fixed-base structures, the response spectra were selected and scaled to ensure that the mean spectral amplitudes within the period range of $0.2T_P$ to $1.5T_P$ —where T_P denotes the fundamental period of the fixed-base building—were not less than 1.3 times the corresponding segment of the code-defined design spectrum.

In the case of base-isolated structures, the period range was adjusted in line with isolation-specific requirements defined in the TBEC. Accordingly, the average spectral amplitudes were scaled within the range of $0.5T_M$ (T_M is the effective period of vibration calculated based on the upper-bound values of the base-isolated building under the maximum displacement of the isolation system) to $1.25T_M$ (T_M is the effective period of vibration calculated based on the lower-bound values of the base-isolated building under the maximum displacement of the isolation system). As with the fixed-base case, the applied scale factor was uniformly used for both horizontal components of each record to preserve directional consistency and spectral shape.

Furthermore, in accordance with the same code, fixed-base residential buildings are intended to meet the performance objectives associated with the DBE. Therefore, the records employed for fixed-base models were scaled to match the DBE-level target spectrum within the specified period range. In contrast, the design of base-isolation systems is governed by the MCE level, and consequently, the corresponding records were scaled to match the MCE level target spectrum over the isolation-specific period range. This methodology ensures that the scaled ground motions appropriately reflect the seismic demand levels corresponding to the structural system type and its associated performance objectives. These ground motions were obtained from the Pacific Earthquake Engineering Research Center Ground Motion Database (PEER, 2019), and the acceleration response spectra for 5% damping ratio are presented in Fig. 4. Also, the properties of the selected ground motions were listed in Tables 2.

Table 2. Selected near-field ground motion records

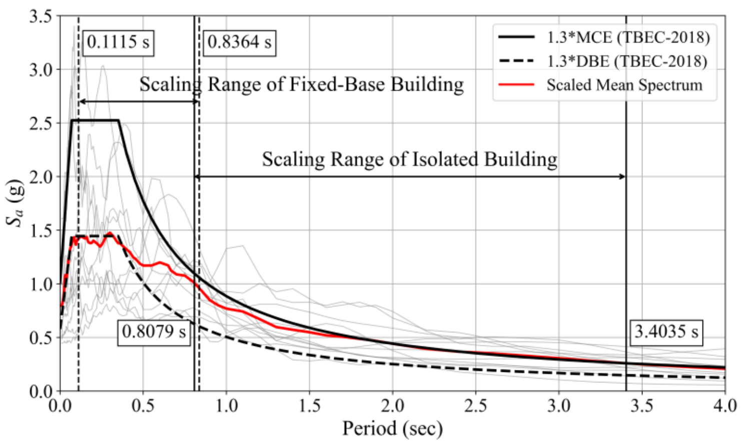

Fig. 4. The acceleration response spectra of selected ground motions for 5% damping ratio

4. Result and discussion

The nonlinear time-history analyses were conducted to evaluate the seismic pounding behavior between two adjacent buildings-one fixed-base and the other base-isolated-under various separation distances. The effects of separation distance on plastic hinge rotations were evaluated in detail. In addition to local member responses, inter-building maximum pounding forces and story accelerations were also assessed to evaluate dynamic interaction and the amplification of seismic demand due to pounding. Four separation scenarios were considered (25%, 50%, 75%, and 100% of the total design displacement of seismic isolators), and the resulting plastic rotations in columns and beams were compared against three performance levels: (i) Collapse Prevention (CP), (ii) Life Safety (LS), and (iii) Immediate Occupancy (IO). Box plots were employed to illustrate the distribution of plastic hinge rotations under 11 ground motion records for each separation distance. Special emphasis was placed on the directional response differences between the pounding direction (R3) and the orthogonal direction (R2). The results offer a comparative assessment of seismic responses in both buildings and directions and highlight the effectiveness of base isolation in mitigating pounding-induced damage.

Plastic hinge rotations for all structural members-beams and columns-are presented separately for each building (fixed-base and base-isolated) and for both directions (R3 and R2) in Fig. 5, under considered separation distances. The pounding analysis results indicate that decreasing the separation distance between the two buildings significantly amplifies plastic hinge rotations. At the smallest separation distance (25%), plastic rotations in both columns and beams reach their highest levels. Specifically, in the fixed-base building, the median plastic rotation in columns along the pounding direction (R3) is approximately 0.0157 radians, already exceeding the CP performance level, while the maximum value reaches about 0.027 radians—nearly twice this limit. At a 50% separation distance, the median plastic rotation reduces to approximately 0.0118 radians, falling below the CP threshold but slightly surpassing the LS threshold of 0.0109 radians. Although the damage potential is lower compared to the 25% case, plastic rotations remain considerably high, with maximum values reaching 0.018 radians, still above the CP performans level. At wider separations (75% and 100%), plastic hinge rotations are significantly reduced, with median values decreasing to around 0.0106 radians. Although occasional exceedances of the LS threshold persist, their frequency diminishes considerably. Similarly, increasing the seperation distance reduces plastic demands in beam elements. Particularly in the fixed-base building, where pounding occurs, the median beam plastic rotation at 25% separation is around 0.0158 radians, while at 100% separation it decreases to approximately 0.0107 radians. These findings confirm that insufficient separation increases plastic hinge demands and raises damage levels in structural elements, whereas adequate separation distances mitigate rotations and help maintain elements near their elastic limits.

A comparison between the fixed-base and base-isolated building elements reveal that columns and beams exhibit different behaviors during pounding. Overall, plastic hinge rotations in the base-isolated building elements are lower compared to those in the fixed-base building under the identical separation conditions. The influence of isolation is particularly evident in columns: in the base-isolated building, the median rotation at 25% separation distance remains around 0.0105 radians, with the majority of the values remaining below the LS performance level of 0.0115 radians. In contrast, in the fixed-base building under the same conditions, the median column rotation is approximately 0.0157 radians, with a significant portion of the columns exceeding the CP performance level. These observations suggest that base isolation can significantly reduce pounding effects and limit damage in column elements. A similar trend is observed for beams; however, the distinction is slightly less pronounced compared to columns. In the fixed-base building, beams exhibited a median plastic rotation of approximately 0.0155 radians at 25% seperation distance, and some cases exceeded the CP performance level of 0.0138 radians. Conversely, in the base-isolated building, the median beam rotation at the same separation is around 0.0115 radians—above the LS threshold of 0.0104 radians but generally remaining below the CP performance level. In both building types, the plastic rotations of beams were generally lower than those of columns. This difference is attributed to the structural role of columns, which play a more critical role in the load-bearing system of the frame and are subjected to greater demands during poundings. The isolation system effectively reduces the transmission of acceleration and shear forces to the superstructure, resulting in lower plastic demands in both beams and columns of the isolated building. At moderate to large separations, plastic hinge formation in the isolated building is substantially limited, and plastic rotations remain within elastic bounds. Moreover, no significant damage was observed in the beams located at the isolation level under any earthquake scenario, and maximum plastic rotations remained below the LS performance limit across all separation distances. However, in the fixed-base building, noticeable plastic rotation demands persist in certain elements even at these larger separations.

When plastic hinge rotations in the R3 and R2 directions are evaluated separately for column elements, the results demonstrate a clear directional disparity. Damage accumulation is significantly more pronounced in the R3 direction, while plastic demands in the R2 direction are relatively limited. For example, at 25% separation, columns in both the fixed-base and base-isolated buildings exhibit plastic rotations nearing or surpassing their deformation capacities in the R3 direction. In contrast, due to the absence of direct contact in the R2 direction, plastic rotations are markedly lower. In the fixed-base building, the median column rotation at 25% separation is approximately 0.0157 radians in R3, while it is only about 0.0083 radians in R2. Similarly, the base-isolated building shows a median column plastic rotation of approximately 0.0105 radians in R3, compared to about 0.003 radians in R2, which remains below the LS performance level, highlighting the directional dependence of damage due to seismic pounding and the effectiveness of base isolation in limiting out-of-pounding direction plastic demands.

The analysis of inter-story pounding forces between the fixed-base and base-isolated buildings, as illustrated in Fig. 6, reveals substantial variations depending on both the separation distance and the story level. The findings are evaluated considering the magnitude and distribution of pounding forces under 11 different ground motion records and four separation distances. A clear inverse relationship is observed between the separation distance and the magnitude of pounding forces. At 25% of the design separation distance, most of the earthquake records resulted in pounding forces exceeding 20,000 kN—with maximum values such as 25,902 kN (EQ ID: 825), 24,067 kN (EQ ID: 1086), and 22,208 kN (EQ ID: 828). As the separation distance increases, a consistent reduction in pounding intensity is evident. At 50% separation, forces at the isolation story drop to around 10,000–15,000 kN, and at 75%, they are generally below 5,000 kN. At 100% separation, pounding forces are effectively eliminated across all stories, confirming the adequacy of this clearance in preventing poundings. Nevertheless, for one ground motion record (EQ ID: 723), pounding still occurs at the 3rd and 4th story levels, indicating that while the total design displacement is effective at the isolation interface, upper-story interactions may still arise under certain excitation characteristics.

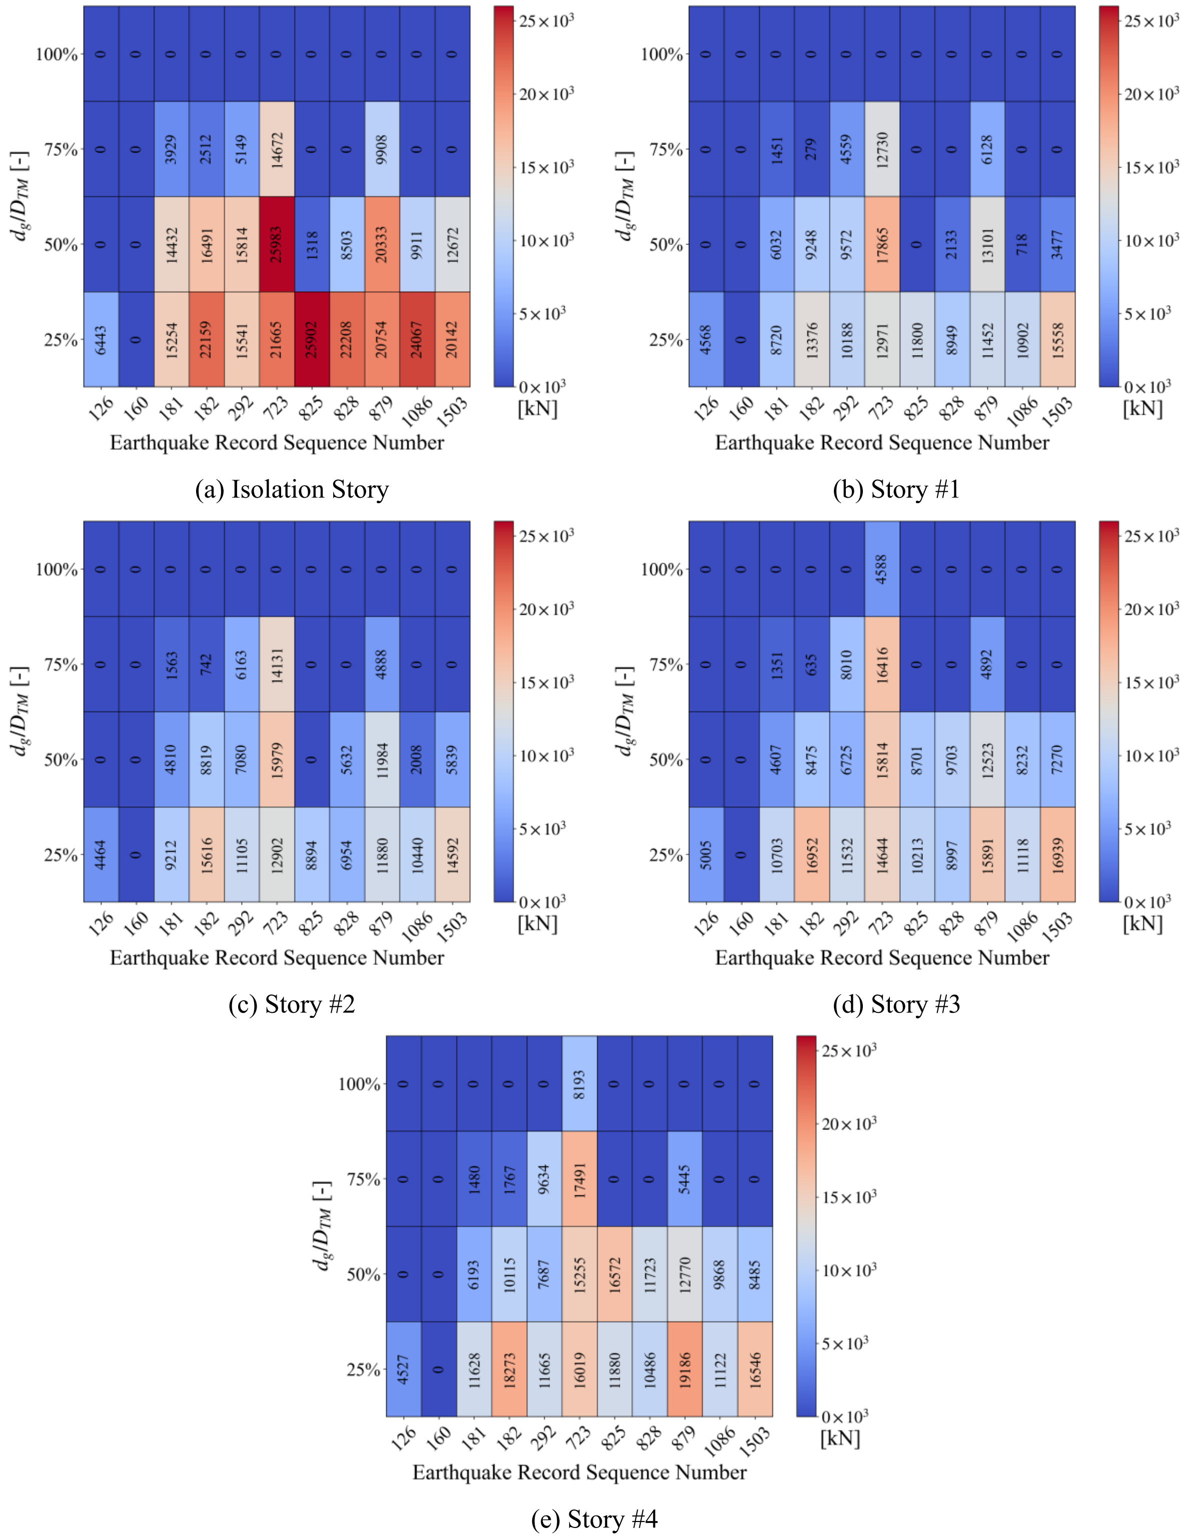

Fig. 6. Inter-story pounding forces at different separation distances for each story under multiple earthquake records

Among the upper stories, 1st and 2nd stories exhibit relatively lower average pounding forces (9,862 kN and 9,642 kN, respectively) when compared to the isolation story for the 25% seperation distance. In contrast, 3rd and 4th stories experience higher average forces, evaluated as 11,090 kN and 11,939 kN, respectively. Although these values are still lower than the maximum average force observed at the isolation story (17,648 kN), they clearly indicate that the pounding demand does not monotonically decrease with height. Instead, 3rd and 4th stories are subjected to greater average pounding forces than 1st and 2nd stories, highlighting that upper stories may also be critically affected by pounding, depending on structural and dynamic characteristics. Furthermore, in some earthquake records (e.g., EQ ID 723 and 825), pounding occurred in the upper stories while no impact was observed in the lower stories. This pounding pattern indicates that the relative motion between buildings during seismic excitation is not uniformly distributed across the height of the structure.

(g) F-B Building Story #3 (h) F-B Building Story #2 (i) F-B Building Story #1

Fig. 7. Radar charts of maximum story accelerations for each story of the base-isolated and fixed-base buildings

The analysis indicates that as the separation distance between the base-isolated (B-I) and fixed-base (F-B) buildings decreases, story accelerations in the both buildings increase markedly. When a 100% separation is provided, the isolation system demonstrates effective performance by substantially reducing story accelerations, with an maximum value of 0.391g. In contrast, the fixed-base building experiences significantly higher accelerations under the same separation condition, reaching an maximum of 0.745g, thereby confirming the critical role of adequate clearance in maximizing the efficiency of seismic isolation systems. As the separation distance is reduced to 75%, story accelerations in the base-isolated building increase moderately, reaching a maximum of 0.803g, yet remain lower than those observed in the fixed-base building, which records a peak of 0.960g. Notably, even at this reduced separation distance, the maximum story acceleration observed in the base-isolated building exceeds that of the fixed-base building at 100% separation, highlighting the adverse impact of insufficient clearance on the effectiveness of the isolation system. However, the disparity between the two buildings diminishes substantially at 50% separation, where accelerations in the base-isolated building surge to 1.690g, nearly equaling those in the fixed-base building, which reach 1.667g. At 25% separation, the displacement capacity of seismic isolators becomes critically constrained, and the accelerations in the base-isolated building escalate further, reaching up to 2.430g. The fixed-base building also shows high value of 2.062g, at this level of separation, the accelerations in the base-isolated system not only approach but even exceed those observed in the fixed-base building (Fig. 7). This finding confirms that the isolation system's effectiveness strongly depends on maintaining sufficient separation, and when that condition is compromised, impact effects and restrained isolator movement significantly amplify the dynamic response.

4. Conclusions

This study investigated the seismic pounding behavior between a fixed-base and a base-isolated building using nonlinear time-history analyses under 11 ground motions and four different separation distances (25%, 50%, 75%, and 100% of the total design displacement od isolators). Plastic hinge rotations, inter-story pounding forces, and story accelerations were comprehensively assessed. The analysis aimed to evaluate the influence of separation distance on the severity and distribution of seismic demands.

- Insufficient separation distance causes excessive plastic hinge rotations in both buildings, especially in columns along the pounding direction, frequently exceeding CP performance level.
- Adequate separation ensures the effectiveness of the isolation system by minimizing both accelerations and plastic deformations.
- The directional assessment of plastic rotations reveals that structural elements aligned with the pounding direction (R3) are subjected to considerably higher deformation demands than those in the orthogonal direction (R2), highlighting the directionality of damage mechanisms in pounding scenarios.
- At reduced separation distances, plastic hinge rotations in columns consistently exceeded those in beams, highlighting the greater susceptibility of columns to pounding-induced demands.
- Inter-story pounding forces reach critical levels at 25% separation, especially at the isolation and upper stories. These forces decrease markedly as separation increases and are eliminated at 100%, except for rare upper-story interactions.
- The pounding forces are highest at the isolation story; however, upper storys—particularly the third and fourth stories—tend to experience greater average forces than the lower storys, indicating a non-monotonic distribution of pounding demands along the building height.
- Story accelerations increase significantly in both base-isolated and fixed-base buildings as the separation distance between them decreases.
- Even 75% under separation distance, the maximum story acceleration in the base-isolated building surpasses the peak acceleration observed in the fixed-base building at full (100%) separation, clearly demonstrating how inadequate clearance can significantly impair the performance of the isolation system.
- Story accelerations in the base-isolated building dramatically increase under reduced separation. At 25%, isolator efficiency is severely compromised, with accelerations exceeding those of the fixed-base building, indicating the critical importance of maintaining adequate clearance for isolation systems to function properly.
- No significant damage was observed in beams located at the isolation level of the base-isolated building for any earthquake scenario, with all plastic hinge rotations remaining below the LS threshold, suggesting that isolation floor beams are less vulnerable under proper design conditions.

Semi-automatic detection of unusable roads after an earthquake

Ömer Canözü[1], Hayrettin Acar*[2]

[1] Sivas Technical Sciences Vocational School, Cartography and Cadastre, Architecture and Urban Planning, Sivas, Turkey
[2] Karadeniz Technical University, Department of Geomatics, 61080 Trabzon, Türkiye

Abstract. After an earthquake, there is often significant loss of life and property. To minimize the loss of life, it is crucial to quickly reach the affected buildings and individuals. The planning of search and rescue operations or the transit times of aid convoys can vary depending on the condition of the roads after the earthquake. In city centers, where major destruction may occur, it is especially important to rapidly determine which roads are usable after the earthquake. Roads often become unusable due to cracks or collapses in areas intersecting fault lines or debris from collapsed buildings blocking the road. In this study, roads blocked and unusable by building debris after an earthquake were identified using a semi-automatic method. Since it is impossible to predict where and when earthquakes will occur, obtaining precise 3D data for all areas prior to an earthquake is not feasible. In this study, single-period point cloud data obtained from unmanned aerial vehicles were combined with building vector data from cadastral maps. The vectorial road data from cadastral maps were adapted for 3D analysis through algorithms developed. Thus, without the need for two-period LiDAR data, unusable roads after an earthquake were identified using single-period point cloud data and cadastral maps through 3D analyses.

Keywords: Earthquake; Unusable roads; Point Cloud

1. Introduction

Earthquakes are unpredictable natural disasters that can cause severe destruction, particularly in regions with unplanned urban development. In such areas, the extent of damage is significantly greater, adversely affecting both human life and emergency response efforts. The damage caused by earthquakes is not limited to the collapse of buildings; debris from ruined structures often blocks roads, impeding access and delaying the arrival of search and rescue teams. For post-disaster response operations to be conducted effectively, it is essential to rapidly and accurately identify damaged infrastructure. In this context, information regarding whether roads are open or blocked plays a critical role in the planning and coordination of search and rescue missions. Remote sensing technologies have emerged as vital tools in disaster management, particularly for damage assessment following earthquakes. Commonly used data sources include satellite imagery, aerial photographs, orthophotos, SAR data, thermal imagery, LiDAR, and 3D point clouds. While multi-temporal analyses are prevalent in the literature, studies utilizing only single-epoch data for road blockage and damage detection remain limited. This gap underscores the necessity for the development of rapid and (semi-)automated systems, particularly in scenarios requiring urgent intervention.

This study focuses on the semi-automatic detection of earthquake-induced road blockages caused by collapsed building debris using single-epoch three-dimensional (3D) point cloud data. The proposed method aims to support the effective and timely deployment of search and rescue teams by facilitating the strategic planning of intervention routes. The literature demonstrates the widespread application of various technologies in identifying post-earthquake road blockages. These include deep learning, machine learning, image processing, LiDAR, radar, photogrammetry, and satellite imaging—all of which play significant roles in decision-making processes within disaster management. Notably, Hosseini et al. (2024) proposed a probabilistic model based on seismic parameters to assess road blockage and clearance time, while Muhammad et al. (2023) provided a comprehensive review of technologies used for detecting road obstacles post-disaster. Yu et al. (2022) introduced a Bayesian approach using data from the Haiti earthquake to estimate conditional probabilities of accessibility. Earthquake events critically reduce the functionality of urban road networks due to building collapses and infrastructure damage. Costa et al. (2020) analyzed pre-disaster road densities and post-disaster traffic impacts, emphasizing the importance of

* Corresponding author, E-mail: h_acar@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_916

promptly clearing critical routes. Argyroudis et al. (2015) evaluated the systemic risk posed by building and bridge collapses on road infrastructure. Similarly, Moya et al. (2020) statistically analyzed factors affecting debris spread and its correlation with road blockages. In their study, LiDAR and aerial imagery were utilized to assess obstructed roads. LiDAR data, in particular, has proven to be a valuable resource for conducting 3D analyses of post-collapse road blockages. Seydi et al. (2019) employed CNN and multilayer perceptron (MLP) models to detect debris areas from LiDAR point clouds, enabling precise identification of structural damage on road networks.

High-resolution satellite imagery has become prominent in deep learning-based automatic damage assessment. For instance, Zhang et al. (2024) achieved a 76.09% F1 score using their segmentation network, RDSeg, which outperformed CNN and transformer models. ViT-B and ResNet-18 integration allowed for pixel-based road damage detection. Doğan et al. (2022) proposed a CNN-based model for detecting road cracks on the Crack500 dataset, while Cheng et al. (2019) attained 94.89% accuracy using a CNN with the Gai-ReLU activation function. The integration of satellite imagery with vector data has also proven to be an effective strategy for detecting road damage. For example, Rastiveis et al. (2015) generated damage maps using WorldView II imagery and vector maps, and Zhao et al. (2022) applied the TLD algorithm for identifying damaged roads from remote sensing images. Chen et al. (2018) overlaid UAV images with vector roads, extracted buffered road zones, and applied object-based classification.

The use of autonomous systems and Edge AI technologies for real-time, automated road damage detection is becoming increasingly widespread. Bibi et al. (2021) developed a system for autonomous vehicles to detect and share road anomalies such as potholes, cracks, and speed bumps, achieving over 99% classification accuracy using ResNet-18 and VGG-11. Kizdarbekova et al. (2015) proposed a CNN-based method capable of detecting road damage under varying environmental conditions, highlighting the limitations of vision-only systems due to spectral variability and time constraints. Hence, the inclusion of sensor data such as LiDAR is suggested to enhance accuracy.

Deep learning and machine learning algorithms have achieved high accuracy in classifying road cracks. Reis et al. (2024) used ResNet152 for feature extraction from post-earthquake images, reaching 98.68% accuracy with SVM and EL classifiers. Alqethami et al. (2020) introduced the RoadNet CNN model, achieving 98.6% accuracy and outperforming AlexNet, VGG-16, and ResNet-34, although the study highlighted generalizability issues due to limited datasets. Optimized image processing and machine learning methods are employed to distinguish and classify different types of road cracks. Hoang et al. (2022) classified asphalt surface cracks with 91.33% and 92.83% accuracy using the Salp Swarm Algorithm and multi-class SVM. Fang et al. (2023) generated crack density maps using NSCT and classified them with SVM, achieving an F1 score above 85%. However, the cost and computational demands of high-resolution imagery were noted as challenges. The success of deep learning methods is highly dependent on data quality and accurate labeling. Rill-García et al. (2022) emphasized the impact of annotation errors on F1 scores and proposed the Syncrack dataset to address this issue. The U-VGG19 model highlighted the benefits of self-supervised learning and 5-neighbor voting techniques. In addition to AI systems, IoT sensors have also demonstrated efficacy in detecting road cracks post-earthquake. Ma et al. (2023) analyzed low-frequency vibration signals generated by vehicles, achieving 93.3%–96.7% accuracy using LR, SVM, and RFC classifiers.

Several studies have focused solely on detecting road damage using image data. These approaches aim to establish continuous monitoring mechanisms by identifying surface irregularities. However, their accuracy often varies depending on the study area, time frame, and data type. Image-based, deep learning approaches typically require extensive datasets, which makes training time-consuming for each new area of study.

In the proposed study, a novel approach focusing on 3D geometric deformations is introduced for detecting roads rendered unusable by earthquakes. By integrating cadastral data of collapsed buildings, a semi-automatic method has been developed to accurately identify roads affected by debris. The method relies on pre-disaster base maps and post-disaster 3D point cloud data, which can be rapidly acquired using UAV technologies. Through joint analysis of post-collapse 3D point clouds with vector data of roads and buildings, the extent and direction of debris spread are calculated, and obstructed road segments are identified. The resulting road damage map enables search and rescue teams to plan optimal intervention routes, shortening response times and enhancing the effectiveness of rescue operations. This method not only provides significant time and resource savings but also aims to reduce casualties, facilitate logistics, and improve coordination during crises. Moreover, it contributes to post-disaster urban planning, environmental impact assessments, and efforts to strengthen community resilience.

2. Materials and methods

In the proposed method, a semi-automatic approach is employed to determine whether debris from collapsed buildings after an earthquake has blocked the roads. To implement this method, cadastral polygon data of collapsed buildings, road network data, and a post-earthquake three-dimensional photogrammetric point cloud are required. The study area is selected as Antakya, a district of Hatay province in Turkey, which was severely affected by the major earthquake on February 6, 2023, and is visually presented in Fig. 1. The historical texture of Antakya and its dense, adjacent construction style have led to the prevalence of narrow streets. This condition significantly increases the risk of road blockage due to falling debris during the earthquake.

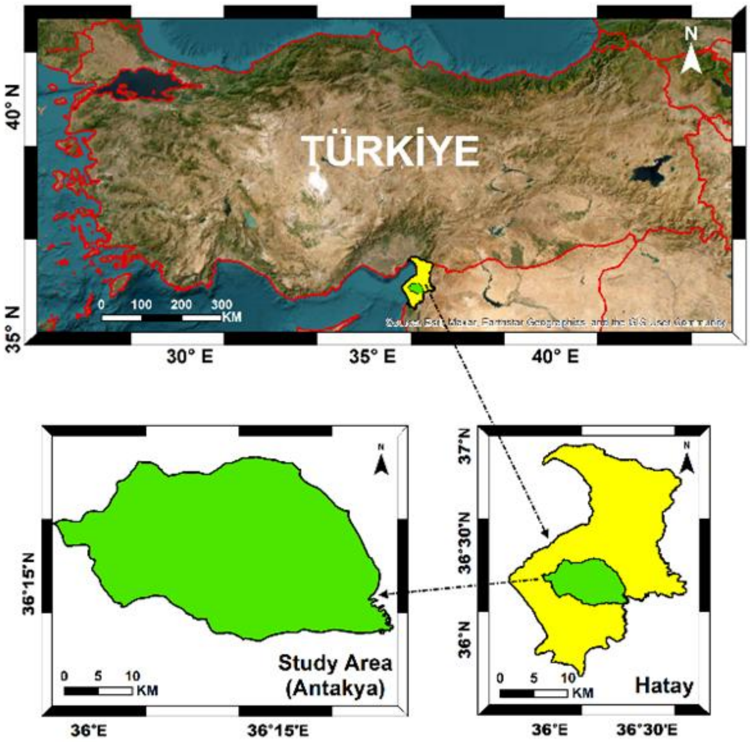

Fig. 1. Study area

The study area covers a 64-hectare region that includes roads of varying widths. This area contains a three-dimensional photogrammetric point cloud obtained via an unmanned aerial vehicle (UAV), with an average density of 8 points/m². Additionally, up-to-date vector road data for the earthquake-affected region were acquired from OpenStreetMap (OSM). Furthermore, cadastral polygon data of collapsed buildings are also available. Fig. 2 illustrates the orthophoto generated from UAV imagery of the test site, overlaid with the collapsed building polygons and vector road data.

Fig. 2. Visualization of collapsed building polygons and cadastral road data on the orthophoto

The effective management of post-earthquake disaster response processes depends on the rapid and accurate assessment of the extent of destruction. In particular, the condition of transportation infrastructure is critically important for the coordination of search, rescue, and relief operations. In this context, debris originating from collapsed buildings may scatter unpredictably depending on the direction of collapse, leading to road blockages and hindering emergency response efforts.

The main objective of this study is to identify roads blocked by debris by estimating both the amount and direction of debris generated by collapsed buildings. To this end, the amount of debris produced by a collapsed building was first determined. Simultaneously, the direction in which the debris was distributed and the spread width were also identified. Costa et al. (2020) developed a manually applied method to estimate how much debris a building could produce and the approximate extent of its spread. In this method, the debris spread width is calculated manually based solely on the total amount of debris a building could generate, without considering how many floors have collapsed.

In the proposed method, the varying collapse heights of individual buildings are taken into account. The corresponding values in the developed formula were automatically detected using software implemented in the MATLAB environment. The newly developed formula is presented in Equation (1).

$$\mathrm{Wd} = \sqrt{\bar{\mathrm{W}} - \frac{2*\mathrm{k_v}*\mathrm{Zh}}{\cot(\mathrm{c})}} - \bar{\mathrm{W}} \tag{1}$$

Wd = Debris spread width
Zh=Collapse height of the building
Zh=Collapse height of the building
$\bar{W}$=(W+L)/2
k_v=Collapsed volume ratio
c=Debris slope angle

The height loss (Zh) of each collapsed building was calculated by comparing the 3D building models derived from pre-earthquake cadastral data with post-earthquake point cloud data. The developed formula provided more accurate results by considering varying degrees of collapse for each building. The inclusion of Zh (collapse height) allowed for a more accurate calculation of the debris spread width by incorporating the collapsed portion rather than just the total building height. Additionally, the use of cot(c) models the debris spread width more realistically by taking the slope angle into account. As a result, Wd (debris spread width) was calculated to produce results that are consistent with physically meaningful field data. The final condition of a road completely blocked by debris from the collapse of two floors of a four-story building is shown in Fig. 3.

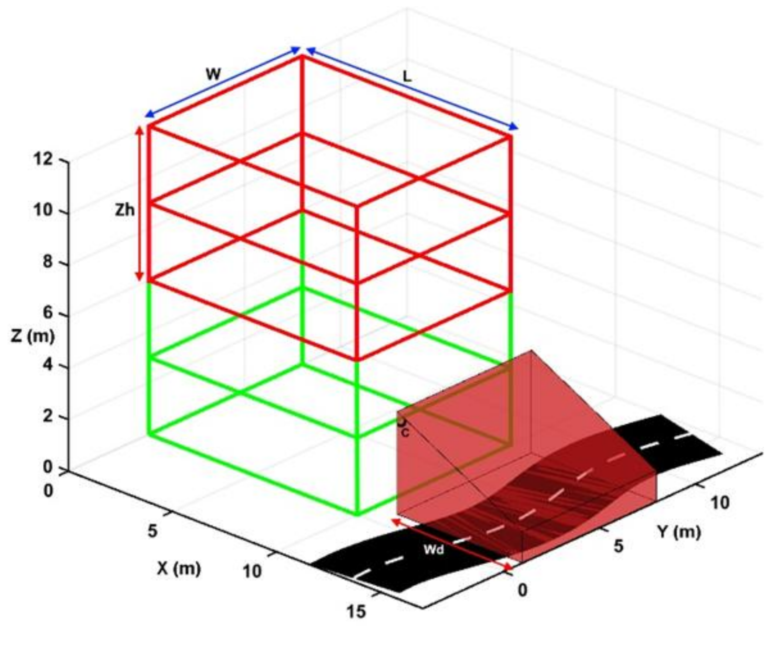

Fig. 3. Visualization of the debris spread width (Wd) of a building on the figure

Using the developed formula, the debris spread widths for each collapsed building in the study area were automatically calculated. This information is essential for detecting the direction of debris distribution and identifying the roads blocked by the debris. To determine the direction of debris distribution, three-dimensional buffer areas encompassing the polygon boundaries of the buildings were created. The 3D polygon buffer generated around a building's polygon boundary is shown in blue in Fig. 4. The building points concentrated within the buffer areas (in red) indicate the direction in which the debris has spread. Taking into account the debris distribution direction, the debris shift vector was automatically calculated. The 2D vector representing the debris spread direction for a collapsed building is shown with a yellow arrow in Figure 4. Thus, the direction of the debris spread from collapsed or heavily damaged buildings was determined.

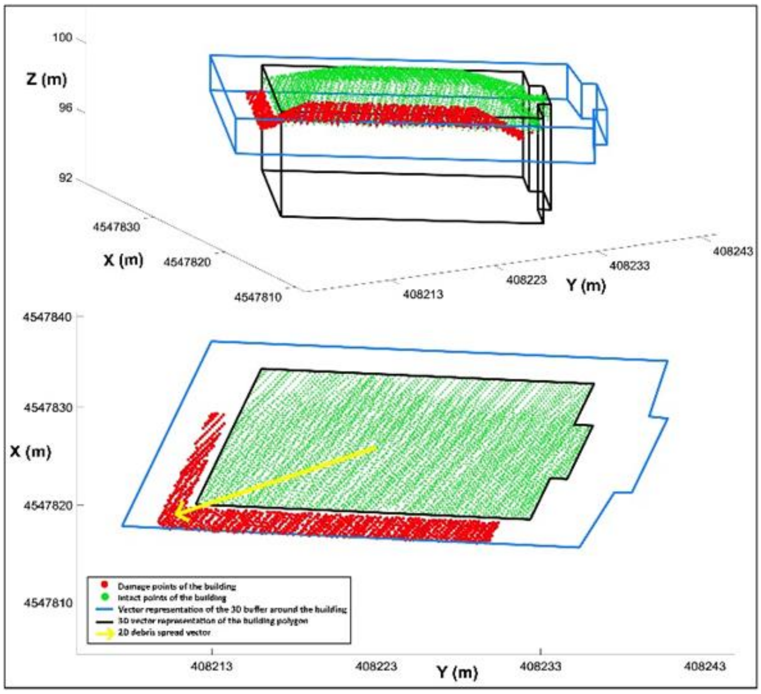

Fig. 4. 3D buffer generated around the building and the debris spread vector

The direction in which the debris from collapsed buildings after the earthquake spreads clearly shows the impact of the destruction on the surrounding area and the areas affected by the debris. Additionally, the total volume of the debris is as important as the direction of its spread. Based on the volume of debris, the spread width of the debris was calculated according to the values given in Equation 1. For each building, debris spread vectors were generated based on the direction and width of the spread. However, in some severely damaged buildings, the debris did not extend beyond the building polygon. In such cases, the magnitude of the debris spread vector was calculated as zero. The debris spread vectors, with non-zero magnitude, generated for each building in the study area are shown with yellow arrows in Fig. 5.

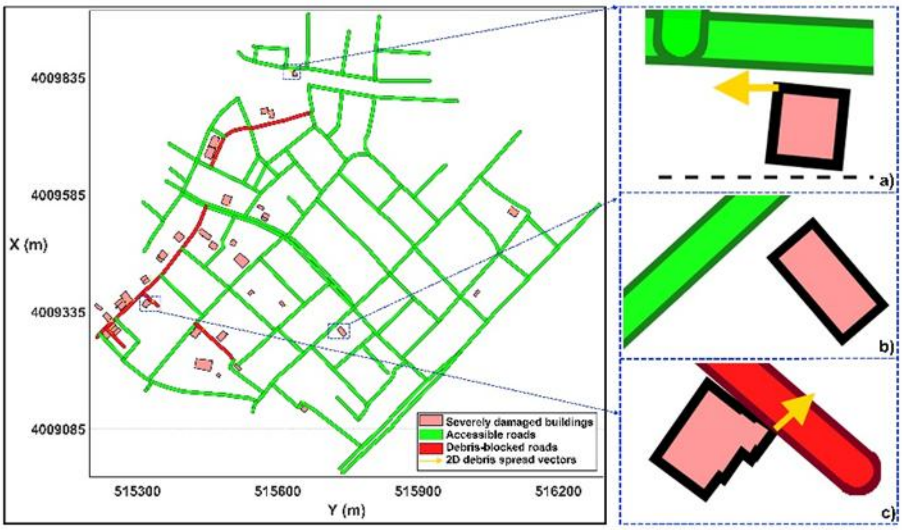

Fig. 5. Visualization of roads blocked by debris from collapsed buildings (red roads), **a)** Debris spread vector not overlapping with the road, **b)** Situation with zero-magnitude debris spread vector, **c)** Situation where debris vector blocks the road

In the study, debris spread vectors calculated for each building were combined with vector road data to analyze the road blockage due to debris. During the evaluation process, only building debris with a debris spread vector magnitude different from zero was considered. Additionally, cases where the debris spread vector did not intersect with roads providing access to the building prior to the earthquake were excluded from the analysis. This ensured that debris vectors from buildings that were located in the opposite direction of the road and did not have the possibility of intersecting with the road line were not included in the evaluation. For every building debris, excluding such cases, the potential for the debris vector to block the nearest road was first assessed. Once the road with the potential for blockage was identified, the level of road blockage was determined based on the length of the debris spread vector. In the study, points that obstruct road areas, based on cadastral polygons, were identified using a semi-automatic method. At these points, the spread of debris from the building along the road was examined, and road status analysis was performed considering the debris points along the road. In this way, roads that were fully, partially, or not blocked at all were classified, and road points completely blocked to traffic were detected semi-automatically with high spatial accuracy. These points were mapped in a geographic information system (GIS) environment, visualized, and made available for intervention planning.

3. Result and discussion

In the proposed study, road points blocked by the debris of collapsed buildings after the earthquake were identified using a semi-automatic method based on the direction and width of debris spread. This approach not only enhances the accuracy of spatial analyses but also provides significant contributions to search-and-rescue teams operating in the field. The pre-identification of areas that are inaccessible due to debris allows teams to quickly and effectively plan the most optimal intervention routes. This, in turn, provides a significant advantage in disaster response, where time is critical, ensuring faster access to survivors and contributing to the protection of human life.

During some stages of the study, various issues were encountered. One of these issues was the inclusion of objects outside the road when extracting the road area from the 3D point cloud due to the linear road data not fully reflecting the actual road centerline. This resulted in points outside the road being perceived as if they were on the road, leading to roads being incorrectly assessed as blocked. To overcome this issue, manual interventions were performed using updated satellite images to align certain road centerlines as closely as possible to the actual road centerline. In Fig. 6, the lines that incorrectly represented the road centerline are shown in red, while the correct road centerline is represented in blue. Thanks to the corrected road centerlines, the debris of collapsed structures on the roads after the earthquake was identified more accurately.

Fig. 6. Representation of the original road centerlines (red) and manual-corrected road centerlines (blue)

4. Conclusions

Rapid response and transportation in cities after a disaster are of great importance for the effectiveness of rescue operations. In natural disasters such as earthquakes, road closures can prevent rescue teams from reaching the affected areas in a timely and accurate manner. Especially, the rapid assessment of situations where debris from collapsed buildings causes road blockages is a critical requirement for effective intervention and rescue efforts.

In this context, the proposed study combines cadastral data and post-earthquake 3D point clouds to semi-automatically detect the road points blocked by the debris of collapsed buildings. For this study, post-disaster 3D point clouds of Antakya city center were used. The 3D point cloud produced from aerial images obtained by UAVs has RGB bands. In addition to this data, the study also integrated collapsed building polygons and linear road data into the algorithm. Using the developed algorithm, a debris spread vector was generated for each building. This vector shows the direction and magnitude of the debris from the collapsed building. Then, the presence of debris residue points on the road was detected according to the debris spread vectors. Finally, which road points would be blocked based on the direction and magnitude of the debris spread were semi-automatically detected. More accurate results will be obtained by improving the accuracy of linear road data or automatically correcting incorrect road centerline drawings. A road damage map was generated, showing the blocked roads due to 3D geometric changes after the earthquake. This map allows for the quick identification of areas where roads are impassable. The resulting map helps rescue teams determine the shortest and most optimal routes to reach the damaged and collapsed areas as quickly as possible.

Additionally, this data facilitates more effective and rapid planning of post-disaster intervention strategies, accelerating the rescue processes. Furthermore, determining preventive measures for future disasters provides an important foundation for minimizing potential damage. Such a map creation will be beneficial not only during the disaster but also in the post-disaster reconstruction and planning processes.

Abstract.

Purpose: This study aims to examine the historical development, current practices, and future improvement strategies of post-earthquake damage assessment forms used in Turkey. The purpose is to evaluate their role in disaster management and to provide recommendations for their digital transformation and standardization.Study design/methodology/approach: A qualitative document analysis was conducted, supported by an expert-based survey developed under a TÜBİTAK 1001 project. The study reviews national disaster experiences from 1999 to 2023, analyzes official forms issued by AFAD, and integrates insights from professionals who have actively participated in field damage assessments. Findings: The findings reveal that although standardized damage assessment forms have significantly contributed to improving disaster response, challenges such as limited digital integration, inconsistent interpretations, and lack of sufficient training persist. The study highlights the benefits of adopting digital tools, AI-supported analysis methods, and blockchain-based validation systems. A national damage database is proposed to enhance long-term resilience and urban planning efforts. Originality/value: This paper offers a comprehensive evaluation of Turkey's post-disaster form-based assessment system, bringing together technical analysis and field practitioner feedback for the first time. It contributes original recommendations for technological integration and policy-making in disaster risk reduction.

1. Introduction

Turkey is one of the countries with the highest earthquake risk in the world due to its location on active fault lines. Throughout history, major earthquakes have not only resulted in loss of life and property damage but have also necessitated the continuous review of disaster management systems and response tools. Damage assessment studies conducted immediately after earthquakes play a critical role in accurately evaluating the impact of the disaster, ensuring public safety, and initiating the reconstruction process (Akdemir & İnan Günaydın, 2025). The standardized damage assessment forms used in this process enable the rapid and systematic documentation of the condition of structures.

These forms are structured to include various technical details, ranging from building types and observed cracks to foundation systems and soil characteristics. They serve not only as tools for collecting technical data but also as official documents that form the basis for social assistance, evacuation, resettlement, and legal processes. However, although these forms are intended to guide technical personnel in the field, challenges encountered during their implementation—such as data integrity issues, interpretation discrepancies, and lack of digital integration—can limit their effectiveness. Therefore, it is important to examine the implementation of damage assessment forms from past to present and to develop future-oriented recommendations for digitalization and standardization (Talaslıoğlu & Soyluk, 2024). This study addresses the historical development of damage assessment forms in Turkey, their field applications, and their contributions to disaster management processes. It also aims to highlight why these forms have become indispensable tools and to outline what needs to be done for a more effective system.

2. History of damage assessment forms

The systematic implementation of damage assessment efforts in Turkey largely took shape after the 1999 Marmara Earthquake. This earthquake marked a turning point—not only due to the collapse of thousands of buildings but also because it exposed significant shortcomings in disaster management. Before 1999, damage assessments were typically carried out under the initiative of local authorities, often lacking sufficient technical standards and centralized coordination (Çatal, 2019). The forms used at that time were mostly non-standardized documents prepared by various institutions, containing data that was not comparable across regions or agencies (Özmen, 2023).

In the aftermath of the Marmara Earthquake, the use of standardized forms in damage assessment became mandatory. These forms were centrally regulated by institutions such as the Ministry of Environment and Urbanization and the Ministry of Public Works and Settlement (later AFAD). Definitions for damage classifications were also clarified, with four main categories established: minor damage, moderate damage, severe damage, and collapse. This classification enabled decisions on whether structures should be evacuated, reinforced, or demolished to be made on a more scientific basis. From the 2010s onward, various initiatives were introduced to digitize these forms so they could be filled out in the field using tablets or mobile devices (Maraş & Sarıyıldız, 2023). However, these digitalization efforts have not yet been widely and effectively adopted in all provinces. Nevertheless, this transition represents an important step toward collecting form data in centralized systems, enabling analysis, and building databases for future disasters. Finally, the earthquakes in Elazığ/2020 (Demirel et al., 2020), İzmir/2021, and Kahramanmaraş/2023 once again highlighted the critical role of damage assessment forms in the field (Avğın, Köse, & Özbek, 2024) (Aydoğdu Gürbüz & Aslan, 2023). Particularly in large-scale disasters, where thousands of buildings need to be evaluated simultaneously, the importance of standardization and a trained workforce has become even more evident.

3. Cuurent standards

Today, damage assessment efforts in Turkey are primarily conducted under the coordination of the Disaster and Emergency Management Authority (AFAD), and the forms used for these assessments are governed by specific standards. Technical teams deployed to the field immediately after an earthquake use these forms to systematically collect data on the overall condition of structures. These forms are critical for ensuring that damage classification and structural evaluations are carried out in a uniform and comparable manner across different regions. Fig. 1 illustrates the "Definitive Damage Assessment Form (Kesin Hasar Tespit Raporu)" currently in use by provincial AFAD directorates. The form includes detailed administrative information (e.g., GPS coordinates, building age, usage type), structural characteristics (e.g., construction system, material, number of stories), and observed damage categories (e.g., minor, moderate, severe, or collapsed).

Fig. 1. General view of the definitive damage assessment report (Form EK-3/b) used by AFAD.

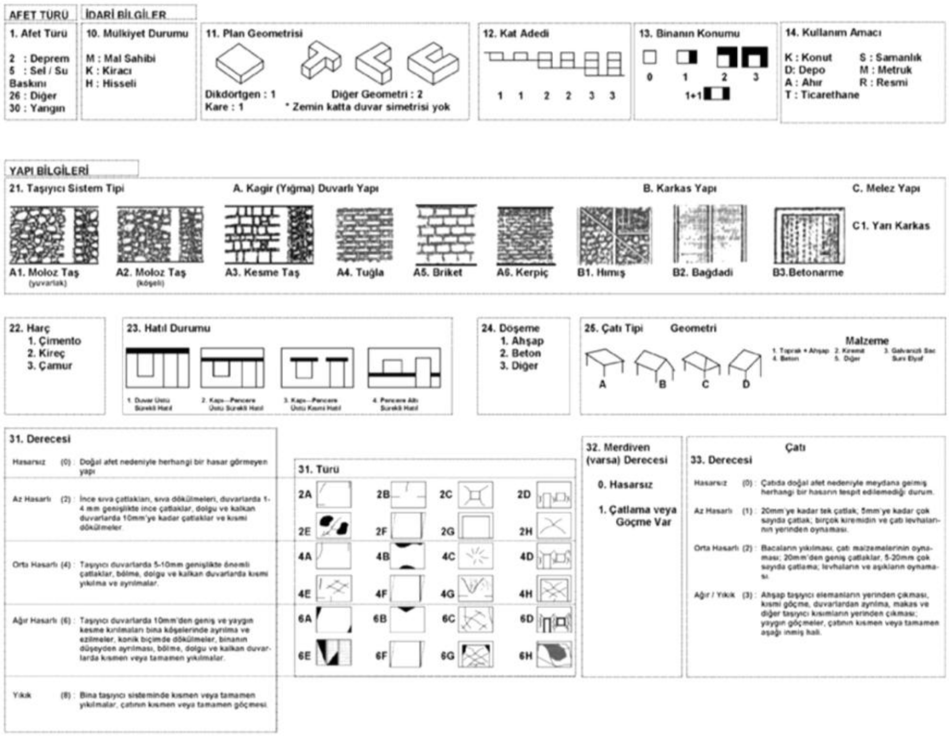

Fig. 2. Visual reference chart accompanying the damage assessment form, including symbols and classification guides.

Fig. 2 presents the visual legend and classification guide used to support the consistent and accurate completion of the damage form. It outlines key concepts such as structural systems (e.g., masonry, reinforced concrete, hybrid), damage severity levels, usage types, and roof/foundation configurations. These visual references help minimize interpretation differences among technical personnel working in the field and ensure that damage assessment decisions are made based on standardized criteria. The integration of such a standardized format with visual coding greatly contributes to the reliability of post-earthquake assessments and facilitates communication between technical teams and administrative decision-makers. The forms are completed based on on-site observations and are often accompanied by photographs and documentation. Once filled, the data is entered into digital systems and transferred to centralized databases (Özerol Özman, Arslan Selçuk, & Arslan, 2024).

The main data fields included in the damage assessment form are as follows:

- Building identification: Building address, structural type (reinforced concrete, masonry, timber, etc.), number of floors, usage type (residential, commercial, public building, etc.)
- Soil condition and foundation characteristics: Soil type, slope, signs of settlement
- Evaluation of structural damage: Cracks, separations, and crushing observed in load-bearing elements such as columns, beams, and shear walls
- Critical areas: Deformations in sensitive areas like stairwells, cantilevers, and soft stories
- Observational notes and photographs: Expert comments and visual documentation provided by the assessor

At the end of the form, the structure is classified according to the level of damage observed:

- Minor Damage: Damage that does not hinder usage and can be repaired with simple fixes
- Moderate Damage: Damage rendering the structure temporarily unusable but salvageable through strengthening
- Severe Damage: Damage posing a threat to life safety, requiring either demolition or comprehensive strengthening
- Collapsed: Complete structural failure or damage so extensive that reconstruction is required

These forms are typically completed in pairs by engineers in the field, submitted to local AFAD units, and then verified through a central system to be included in official decision-making processes. In recent years, completing these forms via mobile applications has significantly improved both the speed and accuracy of the process. Furthermore, the ability to instantly attach photos and automatically record GPS-based location data minimizes potential errors (Dondi et al., 2025). However, in some rural areas, paper-based forms are still preferred, leading to delays in data entry and challenges in data analysis. This situation highlights the need for the widespread adoption of digital systems across the entire country.

4. Challenges in practice and recommendations for improvement

Although post-earthquake damage assessment forms play a vital role in disaster management processes, various field challenges and systemic shortcomings sometimes limit their effectiveness (Feng et al., 2024). The issues encountered in practice manifest at different levels, including human resources, infrastructure, and operational processes.

- Insufficient and Irregularly Trained Personnel: In large-scale earthquakes, thousands of buildings must be assessed in a short period, and the number of engineers and technical staff available in the field is often inadequate. As a result, personnel are temporarily assigned from different institutions and cities; however, the lack of experience among these individuals in accurately and consistently completing damage assessment forms can lead to subjectivity and non-standard evaluations. Differences in knowledge and interpretation among teams may also result in varying damage classifications for the same building.
- Time Pressure and High Workload: The urgent need for rapid intervention immediately after a disaster forces field teams to work under significant time pressure. This can lead to evaluations being conducted without detailed inspection, increasing the risk of inaccurate decisions. Especially in rural areas or densely built-up zones with multi-story buildings, the need to assess multiple structures in a short time often results in superficial completion of the forms.
- Lack of Digitalization and Data Integration Issues: While mobile applications and digital systems have been introduced in some regions, these technologies have not yet become standardized across Turkey. The continued widespread use of paper forms leads to data loss, incorrect entries, and delays in processing data within centralized systems. Furthermore, the lack of full integration between form data and Geographic Information Systems (GIS) makes regional analyses more difficult.
- Lack of Supervision and Feedback: After the forms are completed in the field, there are not always sufficient mechanisms in place to verify the accuracy of the data through central units. This can result in erroneous assessments being detected too late or only after citizen complaints prompt a re-evaluation. Weak feedback processes also hinder the improvement and development of the teams working on-site.
- Citizen Appeals and Lack of Information: Inadequate communication with citizens regarding damage assessment results can lead to trust issues. Particularly in the classification of moderately and severely damaged buildings, the public's unfamiliarity with technical terms makes it difficult to understand the form content and contributes to an increase in objections. This, in turn, slows the process and adds extra burden on public institutions.

4.1. Recommendations for improvement

The integration of technological advancements into disaster management makes it possible to carry out post-earthquake processes more effectively, swiftly, and reliably. In this context, the digitalization of damage assessment forms is becoming one of the fundamental pillars of future disaster response efforts. Thanks to mobile applications developed in recent years, technical teams can directly enter structural information into the system using tablets or smartphones, and GPS-based location data and photos from the time of the event can be integrated into the form. Such digital systems facilitate the accurate and complete completion of the form while minimizing the risk of data loss. Moreover, since this data can be transmitted to central servers in real time, the overall scope of the disaster can be analyzed simultaneously, and intervention plans can be developed much more effectively. From a more advanced perspective, the automatic pre-analysis of damage-assessment photos using AI-supported image processing systems can reduce the workload of technical personnel and limit interpretation discrepancies. Additionally, recording damage assessment forms using blockchain-based systems would ensure both the immutability and the reliability of these documents—an aspect that is critically important for legal proceedings and insurance evaluations. Looking ahead, the creation of an integrated national damage assessment database across Turkey could enable past forms to be linked with geographic, structural, and demographic data. This would allow for both risk analyses and the maintenance of an up-to-date building inventory. Such an approach also holds the potential to guide urban transformation policies in a data-driven manner.

As part of this study, a survey is being conducted to enrich the findings with broader expert insights and to directly reflect the experiences of field practitioners. The survey in the Table 1 was developed under the TÜBİTAK 1001-funded project titled “Post-Disaster Damage Assessment Training Platform.” It aims to gather direct field feedback on the applicability, comprehensibility, and digital compatibility of current damage assessment forms.

Table 1. Summary of the Survey Questions for the Revision of Post-Earthquake Damage Assessment Forms

Question No.	Survey Question Summary
1	What is your professional background?
2	How many years have you participated in post-earthquake assessments?
3	How many assessments have you been involved in?
4	In which earthquakes have you conducted observational assessments?
5	Are the damage categories sufficient and clear?
6	Are HO and THO calculations practically applicable?
7	Is the HK2 coefficient calculation logical?
8	Which part of the form do you find most difficult?
9	Does using digital forms make your work easier?
10	Which features should be added to the digital forms?
11	Did you receive adequate training before using the forms?
12	What should training for proper use include?
13	Which area of the form should be revised most urgently?
14	What tools or equipment do you use and find most useful?
15	What are the top 3 challenges you face in the field?
16	How do you determine the critical floor in damage assessment?
17	How long does it take to assess a typical 5-story building?
18-20	Have you encountered issues in interpreting, processing, or receiving feedback on your assessments?
21	Rating of different aspects of the form (1–5 scale)
22	Others

5. Conclusions

Post-earthquake damage assessment forms are critical documents forming the foundation for both technical and administrative decisions in disaster management. These forms should be regarded as strategic tools that guide all aspects of life safety, social aid planning, legal processes, and reconstruction activities. Given Turkey's frequent exposure to major earthquakes, it is essential to continuously improve these forms in terms of both content and implementation. Accordingly, the following recommendations are presented as key takeaways from this study:

- The digitalization of damage assessment forms should be expanded nationwide and integrated with mobile applications.
- The training of technical personnel assigned to the field should be conducted regularly to enhance evaluation quality.
- Interpretation of forms should be standardized using AI-supported pre-analysis systems.
- Public information processes should be improved to strengthen public trust and increase transparency in appeal mechanisms.
- A national damage assessment database should be established to analyze data from past disasters and better predict future risks.

Expert opinions will provide significant contributions to improving the current form structure and aligning proposed digitalization processes with user needs. The findings will help ground our recommendations for making damage assessment processes more effective, transparent, and standardized. Ultimately, a well-designed and properly utilized damage assessment form is not just a sheet of paper—it is the cornerstone of critical decisions that directly affect the lives of thousands of people during a crisis. Therefore, these forms must be seen not merely as technical documents but as strategic guides in disaster management, and should be developed accordingly.

Abstract. Historical structures are not only architectural assets but also witnesses of past social and cultural heritage. These structures represent invaluable cultural values that must be preserved and transmitted to future generations. However, maintaining such structures without compromising their authenticity requires more than visual restoration; it also necessitates ensuring structural safety through engineering assessments. In this context, it is essential to determine whether restoration serves merely as an aesthetic intervention or provides actual structural improvement, which requires comprehensive engineering analyses. In this study, a three-dimensional finite element model of a registered timber building with a traditional bagdadi wall system, located within the urban conservation area of Alaçam District in Samsun, was developed. The structural performance of the building was evaluated under various loading scenarios, including live load, wind, snow, and seismic actions. Both ultimate limit state and serviceability limit state conditions were considered during the analysis, and the stress and displacement responses of the structural elements were assessed in accordance with standards. The results demonstrated that the structural components satisfy the required safety levels. This finding provides critical insight into the technical impact of restoration and guides necessary structural interventions. The study highlights the necessity of engineering analyses in the restoration process of historical structures and emphasizes the value of finite element modeling as a robust tool for evaluating the structural effectiveness of restoration efforts..

Keywords: Bağdadi wall; Cultural heritage; Finite element model; Timber structures; Urban conservation area

1. Introduction

Timber has historically held a prominent place in the construction of vernacular and monumental architecture due to its favorable mechanical properties, sustainability, and ease of workmanship. Especially in regions like Anatolia, the widespread availability of forests and the material's cultural compatibility have led to the development of diverse timber construction techniques, among which the bağdadi wall system stands out for its structural and architectural ingenuity. Timber buildings are not only examples of traditional building science but also represent living heritage, encapsulating the craftsmanship, social practices, and aesthetic preferences of their era (Cruz et al., 2015).

In the contemporary era, timber is also being revisited through the lens of sustainability. As a natural and renewable material with a low carbon footprint, timber structures are increasingly considered as part of climate-conscious design. Nevertheless, their organic nature makes them vulnerable to moisture, biological decay, temperature fluctuations, and most critically, to seismic and lateral forces over time. Historical timber buildings-many of which are protected under cultural heritage laws-require special attention in this regard. These structures often show signs of structural degradation such as deformation, loosening of joints, local collapses, and material fatigue due to prolonged exposure to environmental and mechanical loads (Riggio et al., 2018).

Restoration, in this context, becomes a critical tool not just for preserving the visual and historical identity of a structure, but also for ensuring its continued serviceability and safety. A well-executed restoration must not only reinstate damaged or missing architectural components but also provide an engineering basis to justify the building's static and dynamic stability. However, in practice, restoration projects are often dominated by architectural and material conservation concerns, while structural evaluation is either superficial or entirely overlooked. This discrepancy may lead to interventions that are aesthetically successful but structurally insufficient-posing future risks for users and the heritage asset itself.

golden light publishing

The literature includes various studies documenting the restoration of timber heritage buildings, often focusing on techniques of material conservation, detailing, and reuse of traditional joinery (Karacabeyli & Douglas, 2013). Yet relatively few of these works involve detailed structural modeling or computational analyses. Research has begun to emphasize the integration of numerical modeling in heritage conservation, underlining the need for advanced tools such as finite element analysis (FEA) to quantify the effectiveness of interventions (Altunışık et al., 2018; Altunışık et al., Kalkan Okur et al., 2021). These methodologies enable a more reliable assessment of existing structural performance and the impact of any restoration effort.

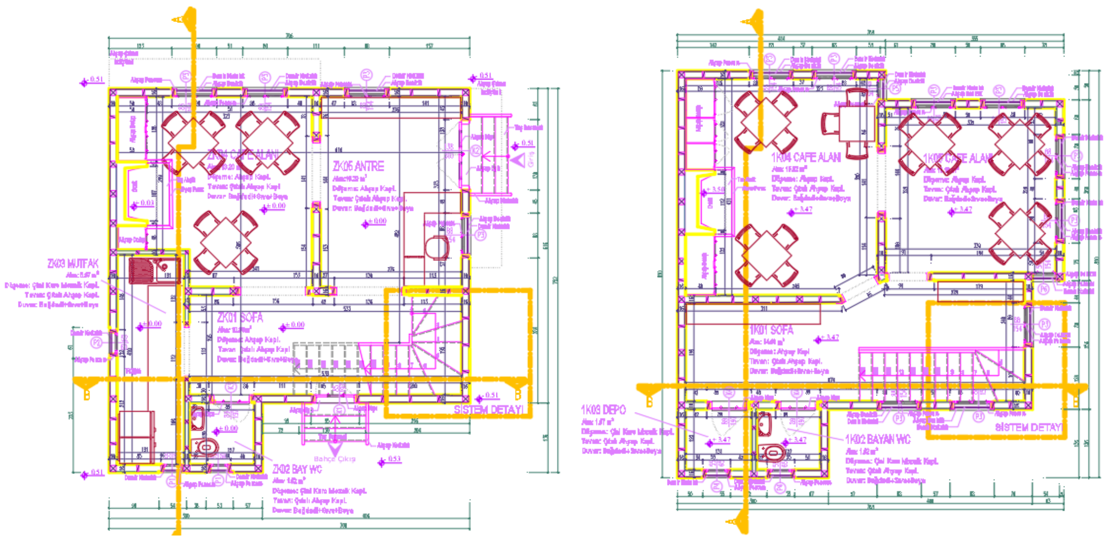
Motivated by this gap, the present study focuses on the structural analysis of a two-story registered timber building located in the urban conservation zone of Alaçam district in Samsun, Turkey. The building employs a bağdadi wall system composed of timber frames infilled with brick masonry, a typical Ottoman-era construction technique. A comprehensive three-dimensional finite element model of the structure was developed using SAP2000 software, in accordance with national (TBEC, 2018; Turkish Standards Institution, 2025) and international (TS EN 1995-1-1) codes. Structural behavior was assessed under vertical and lateral loads, including dead load, live load, snow, wind, and earthquake actions. Both ultimate limit state (ULS) and serviceability limit state (SLS) conditions were examined to evaluate element-level stresses, displacements, and structural adequacy.

This study not only provides a scientific basis for assessing the effectiveness of the ongoing restoration intervention but also contributes to the limited but growing body of literature on structural modeling of historical timber buildings. The results aim to guide future restorations by illustrating how engineering analyses can complement conservation decisions to achieve both heritage protection and structural resilience.

2. Timber structure with bagdadi wall system

2.1. Architectural properties

The historical timber structure slated for restoration is located in the district of Alaçam, Samsun, and consists of two floors constructed with the traditional bağdadi wall system. The ground floor accommodates a café area, entrance hall, central sofa space, kitchen, and restroom. The upper floor comprises two café spaces, a secondary sofa area, an additional restroom, and a storage room (Fig. 1). The rectangular plan of the structure measures 7.00 meters in width and 7.50 meters in length, with a floor area of 40.76 m² on the ground floor and 44.71 m² on the upper floor. The ground floor has a clear height of 3.3 meters, and the upper floor is 2.7 meters high, culminating in a total building height of +7.95 meters from the foundation to the ridge of the roof.



a) Ground floor plan

b) 1st floor plan

Fig. 1. Floor plans of timber structure

As shown in Fig. 2, the exterior elevations reflect the architectural identity of a typical bağdadi structure. The main load-bearing system is composed of solid timber vertical studs with cross-sectional dimensions of 4×12 cm and 12×12 cm, between which fired clay bricks (known as harman tuğlası) are infilled to form the bağdadi walls. These walls are further reinforced with 12×12 cm timber beams at both the top and bottom, ensuring horizontal continuity. Diagonal timber braces of the same dimensions are integrated within the wall cavities, providing additional stiffness by connecting the vertical members.

The interior partitions that separate the rooms are constructed from 2.5 cm thick timber planks, preserving the lightweight and modular character of the building. The flooring system consists of 4×12 cm timber joists spaced at 30 to 50 cm intervals, over which 2.5 cm thick timber decking is laid to form the finished surface. The roof employs a traditional timber hip-roof configuration, aligning with the building's historical typology. The structure rests on continuous strip footings beneath 12×12 cm timber foundation beams, ensuring proper load distribution to the ground.

Figure 3 illustrates a representative view of the proposed bağdadi wall detailing to be used during the restoration process, exemplifying both the material composition and the craftsmanship involved in traditional Anatolian timber architecture.

Fig. 3. Appearance of the bagdadi wall to be applied

2.2. Finite element model

The historical timber structure was modeled in three dimensions using the SAP2000 finite element software. In the model, key structural components such as timber foundation beams (hatıl), bağdadi wall studs, interior wall studs, main beams, secondary floor joists, and bağdadi-type diagonal members were represented as frame (bar) elements. All remaining wall infill and floor sheathing components were defined as shell (area) elements. All door and window openings observed in the architectural drawings were accurately reflected in the model geometry.

Given the structure's status as a registered cultural heritage asset, both the modeling and the analysis phases were carried out in accordance with the "Guidelines for Earthquake Risk Management for Historical Buildings" issued by the General Directorate of Foundations of Turkey. Section 6.4.5 of this guide, titled "Modeling Based on Construction Type," includes specific recommendations for timber structures. It emphasizes that vertical load-bearing elements in historic timber buildings typically consist of frames with studs and diagonals, while horizontal elements consist of beams and floor slabs. Furthermore, infill materials commonly used in timber walls-such as brick or adobe-should not be assumed to contribute to lateral load resistance. Therefore, only the timber members are considered in seismic analyses, and internal forces should be calculated based solely on the frame components. The adequacy of connection regions must also be assessed separately. Additionally, the guide allows for the use of simplified modeling approaches to facilitate structural assessment in complex historical systems.

In alignment with these principles, two separate models were developed for different loading scenarios. In the first model, both timber members and brick infill (harman tuğlası) were included. The infill material was modeled using shell elements to account for its contribution to vertical load distribution. This model was used to evaluate the structure's performance under gravity loads. For seismic analyses, a second model was created by excluding the shell elements representing the brick infill. This reduced model consisted only of timber studs, beams, and diagonal braces that form the core of the bağdadi structural system. To ensure mass continuity, the weight corresponding to the removed brick infill was distributed to the beams as additional line loads. Figures 4 and 5 illustrate the finite element representations of the first and second models, respectively.

To simplify the analysis of this complex historical structure, and as recommended by the aforementioned guideline, the intricate geometry of the roof system was not modeled in detail. Instead, the total weight of the roof elements, calculated based on their cross-sectional dimensions and material properties, was applied as equivalent loads to the supporting structural members. Structural verification of the roof system itself is beyond the scope of this report and was therefore not included in the modeling process.

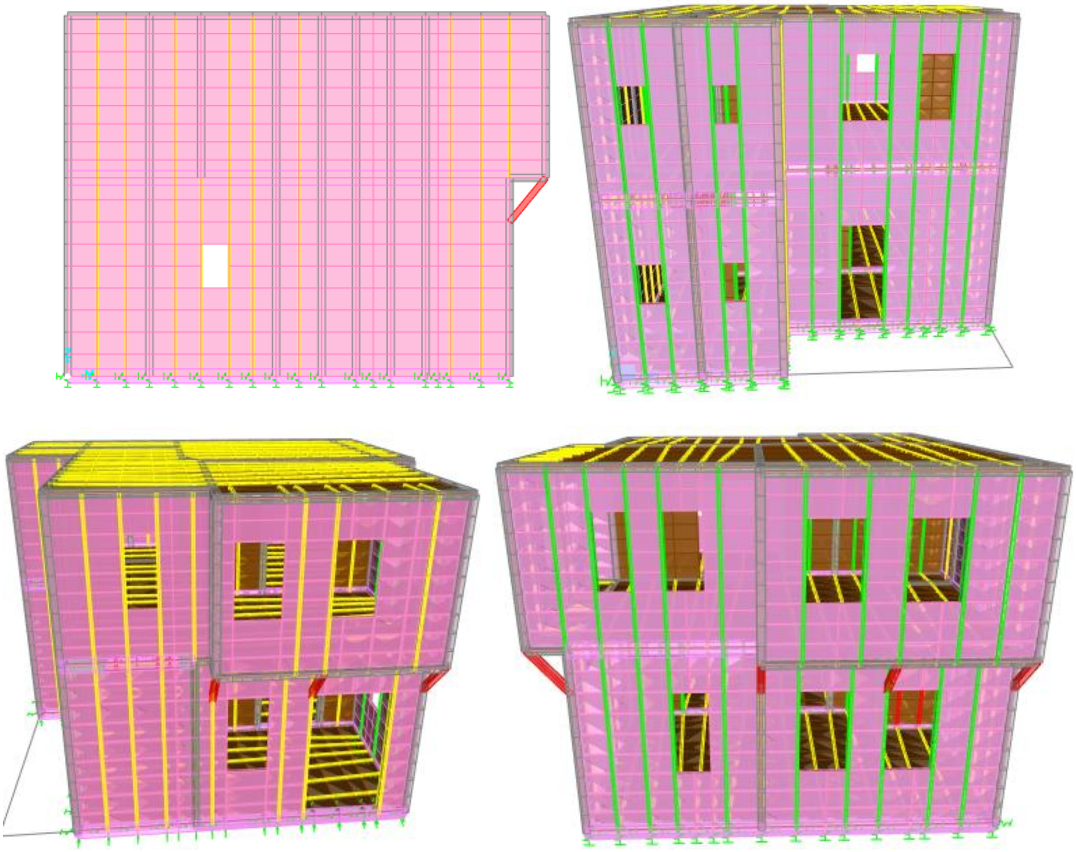

Fig. 4. Finite element model of the first model timber structure

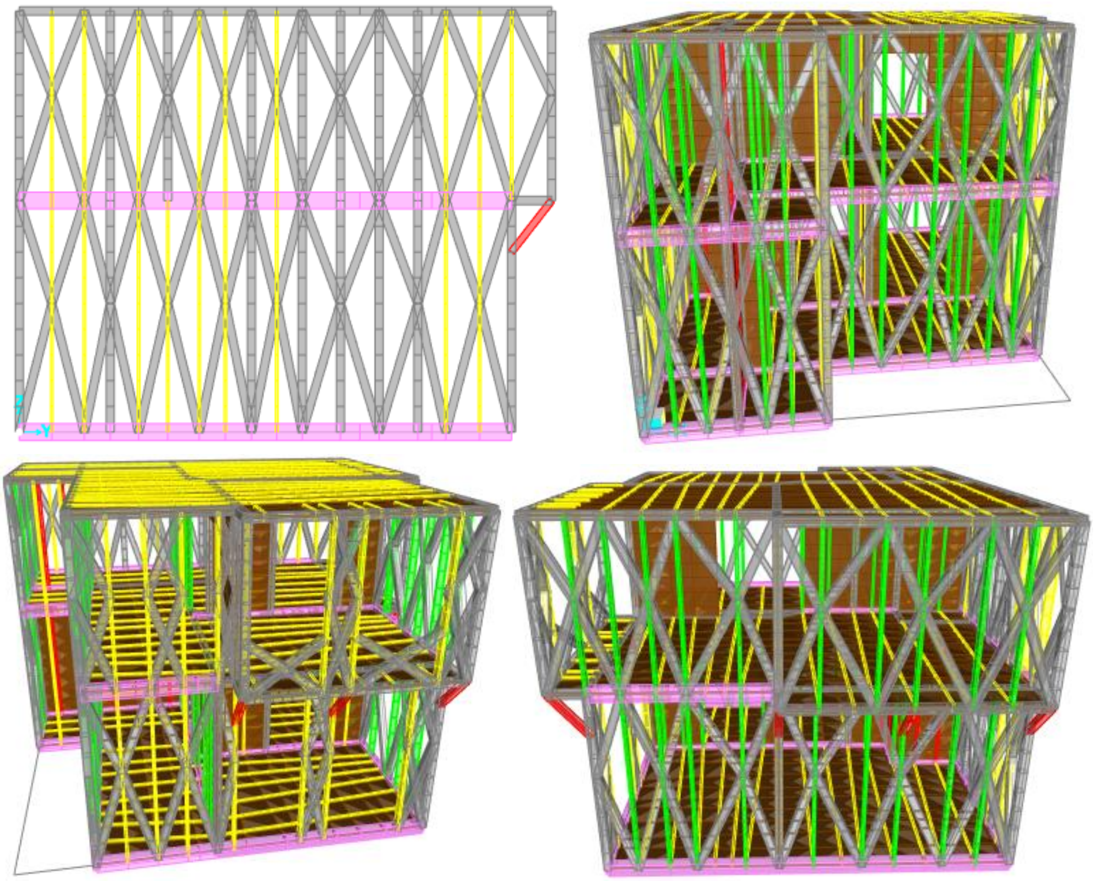

Fig. 5. Finite element model of the second model timber structure

2.3. Analysis parameters

Within the scope of the analysis, the strength classes and material properties of all structural timber elements were determined in accordance with the specifications outlined in TS EN 1995-1-1 (Eurocode 5). This standard classifies structural timber into two main groups and twenty distinct strength classes based on their mechanical performance. The classification is derived from a series of mechanical criteria, including bending strength, tensile strength parallel and perpendicular to the grain, compressive strength parallel and perpendicular to the grain, shear strength, modulus of elasticity parallel and perpendicular to the grain, shear modulus, and density.

Group C represents the softwood category, which includes commonly used species such as pine, fir, spruce, and cedar. Group D, on the other hand, consists of tropical hardwoods such as merbau, balau, and teak, typically found in Southeast Asia, Africa, and Australia.

For the purposes of this study, timber elements were modeled using the mechanical properties corresponding to the C22 strength class, which is suitable for softwood species commonly employed in traditional Anatolian timber structures. In SAP2000, these properties were assigned as an orthotropic material model to accurately simulate the anisotropic behavior of timber. All wooden members in the finite element model were assigned this C22 orthotropic material definition. In accordance with TS EN 1995-1-1, two primary limit states were considered in the structural design and evaluation process:

- Ultimate Limit State (ULS): Ensuring structural safety against collapse under maximum design loads.
- Serviceability Limit State (SLS): Verifying usability and limiting deformations under normal service loads.

Material properties were calculated separately for both limit states, and finite element analyses were conducted accordingly. Table 1 summarizes the material parameters used in the model under ULS and SLS design conditions.

Table 1. The material parameters for the model under ULS and SLS design conditions

Limit State	Design Elasticity Modulus (kN/mm^2)		Design Shear Modulus
	$E_{d//}$ (Parallel)	$E_{d\perp}$ (Perpendicular)	(G_d)
Ultimate	7.69	0.25	0.48
Serviceability	3.33	0.11	0.21

The determination of structural loads was carried out in accordance with the load calculation provisions of TS EN 1995-1-1, which governs the design of timber structures, and the EN 1991 series, which addresses environmental actions. According to TS EN 1995-1-1, the following Eurocode standards must be used to define the relevant loads and actions:

- EN 1991-1-1 (2025): Densities, self-weight, and imposed loads on structures
- EN 1991-1-3 (2007): Snow loads
- EN 1991-1-4 (2005): Wind actions

Seismic loading was determined based on the national standard TBDY 2018 (Turkish Building Earthquake Code 2018). The imposed roof load was taken as 1.25 kN/m², the live load as 5.00 kN/m², the snow load as 0.60 kN/m², and the wind load was calculated regionally based on wind directions, reaching a maximum of 0.98 kN/m². For the seismic load calculations, the design response spectrum was developed in compliance with TBDY 2018, using site-specific soil classification data provided in the geotechnical investigation report. The site was categorized as Soil Class ZD, and the spectrum parameters were obtained from the Turkish Earthquake Hazard Maps Interactive Web Application. Since the building is registered as a cultural heritage asset, the "Guidelines for Earthquake Risk Management for Historical Buildings" prepared by the General Directorate of Foundations was followed. Accordingly, the seismic action level was selected as DD-3, which corresponds to medium-intensity earthquake motion for Group II buildings with local cultural significance. Based on these parameters, the following design spectrum values were used:

- Short-period map spectral acceleration coefficient: SS = 0.154
- 1.0-second map spectral acceleration coefficient: S1 = 0.063
- Design spectral acceleration coefficient at short period: SDS = 0.246
- Design spectral acceleration coefficient at 1.0 second: SD1 = 0.151

In line with TBDY 2018 provisions, the structure was classified as follows:

- Building Height Class (BYS): 7
- Building Occupancy Class (BKS): 3
- Earthquake Design Class (DTS): 4
- Importance Factor (I): 1.0

Considering the structural configuration and lateral load-resisting system, the following response parameters were adopted:

- Structural Behavior Factor: $R_x = R_y = 4$
- Overstrength Factor: D = 2

Fig. 6 illustrates the applied load cases in the finite element model, while Fig. 7 presents detailed contour diagrams corresponding to the loading conditions applied during the analysis.

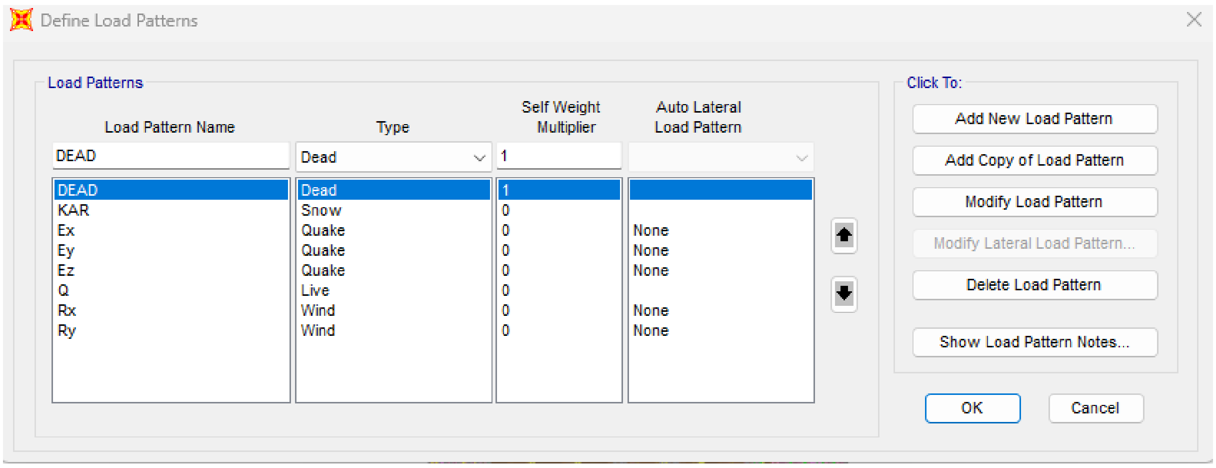

Fig. 5. Loading cases taken into account

Load combinations were generated in accordance with relevant standards for both ultimate limit state (ULS) and serviceability limit state (SLS) conditions, and these combinations were taken into account in the structural analyses under the applied loading scenarios.

2.4. Analysis

2.4.1. Modal Analysis

As a result of the modal analysis, the structural mode shapes and their corresponding natural frequencies were obtained. The mass participation ratios of the first 38 modes considered in the analysis are presented in Figure 7. The first mode, occurring in the Y-direction, has a period of 0.18 seconds (5.54 Hz) and a mass participation ratio of 34%. The second mode, in the X-direction, has a period of 0.16 seconds (6.24 Hz) with a 37% mass participation ratio. The third mode corresponds to a torsional mode with a period of 0.069 seconds (14.31 Hz) and contributes 28% to the total mass participation.

OutputCase	StepType Text	StepNum Unitless	Period Sec	UX Unitless	UY Unitless	UZ Unitless	SumUX Unitless	SumUY Unitless	SumUZ Unitless
MODAL	Mode	38	0,042409	3,779E-05	9,082E-05	2,085E-06	0,967	0,965	0,991
MODAL	Mode	35	0,046061	0,004962	0,014	0,001669	0,966	0,957	0,991
MODAL	Mode	36	0,044108	6,419E-05	0,005399	2,497E-05	0,966	0,962	0,991
MODAL	Mode	34	0,047128	0,086	0,016	0,001469	0,961	0,942	0,989

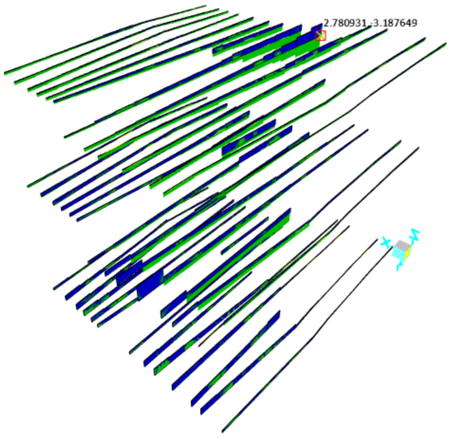
MODAL	Mode	31	0,049237	0,006967	0,055	0,0009411	0,841	0,824	0,986

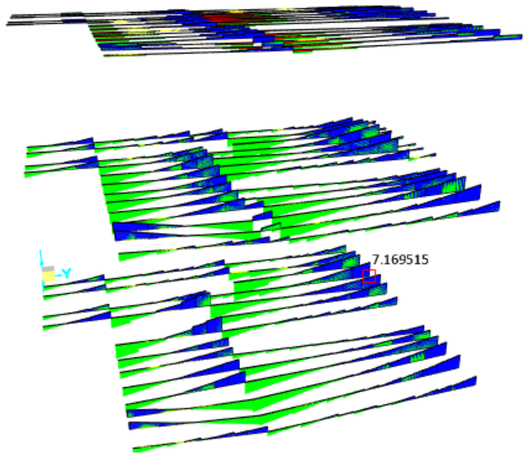
Fig. 7. The mass participation ratios of the first 38 modes

2.4.2. Static and dynamic analyses

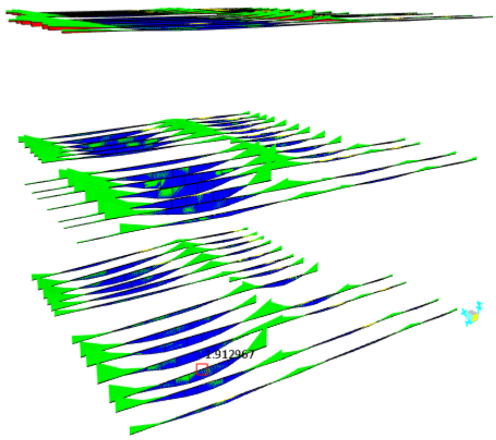
The finite element analyses are conducted separately under three distinct models corresponding to ultimate limit state (ULS) and serviceability limit state (SLS) conditions. For the seismic evaluation under ULS, the model excluding the bağdadi infill walls was utilized, in accordance with the relevant guidelines. Envelope combinations are generated for both ULS and SLS by superimposing the respective load combinations to obtain the critical structural responses. The global distribution of displacements and internal forces under the maximum effect conditions derived from these analyses are presented in Figures 8 and 9.



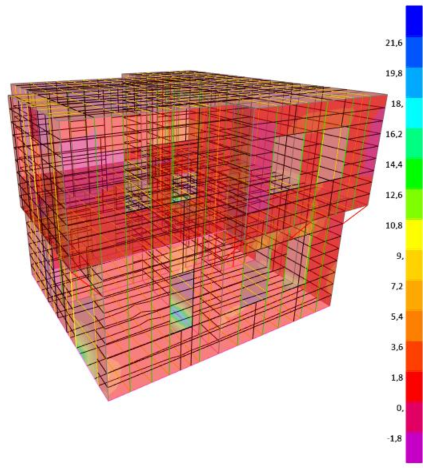
a) Normal forces in purlin elements (kN)



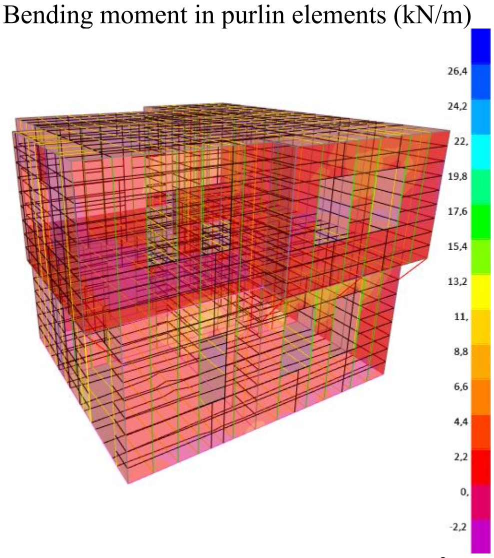
b) Shear forces in purlin elements (kN)



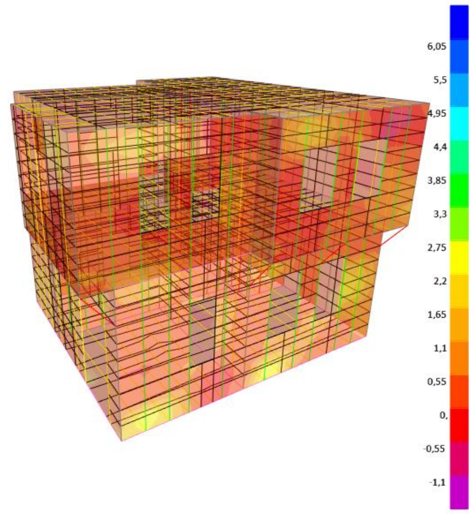
c) Bending moment in purlin elements (kN/m)



d) S11 stresses in area elements (N/mm^2)

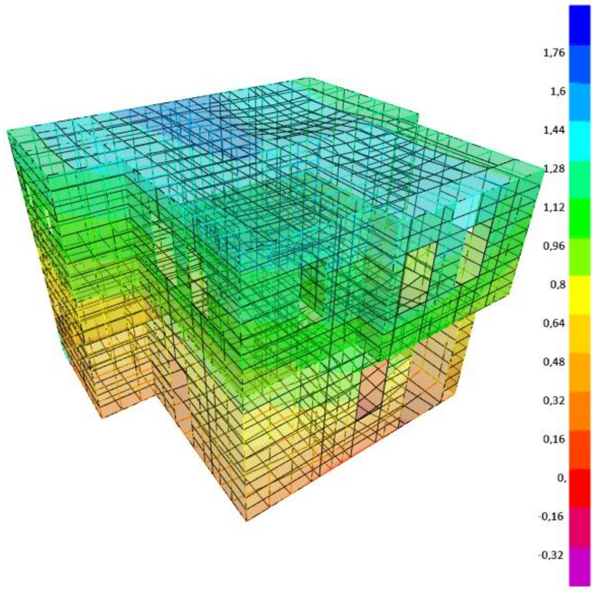


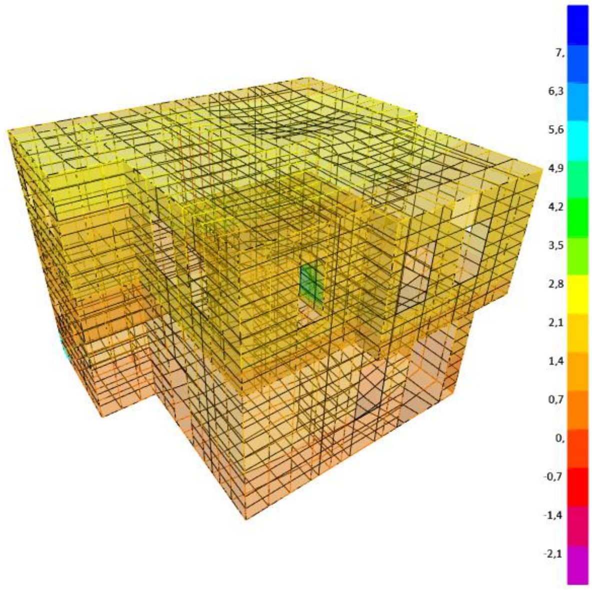
e) S11 stresses in area elements (N/mm^2)



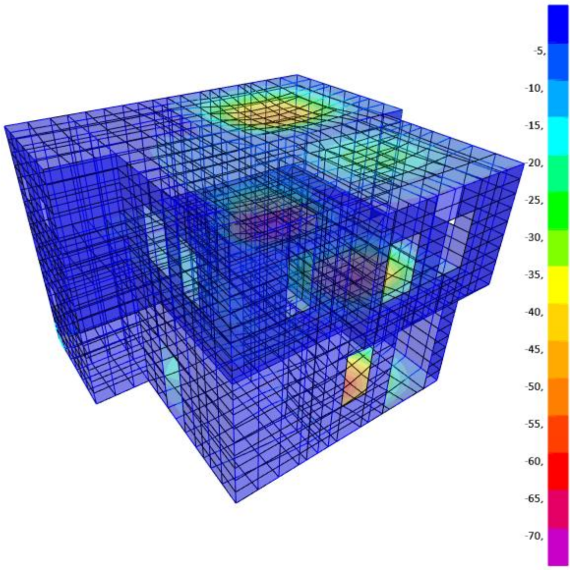
f) S11 stresses in area elements (N/mm^2)

Fig. 8. Analysis results of bearing capacity limit state





a) X direction displacement values (mm) b) Y direction displacement values (mm)



c) Z direction displacement values (mm)

Fig. 9. Analysis results of usability limit state

2.5. Verification

For the structural verification of the timber building, stress values obtained from the analysis were evaluated for key structural elements including columns (studs), beams, wall panels, and floor systems. These stress values were compared against the allowable design stresses of the selected C22 timber class, specifically for bending, tension (both parallel and perpendicular to the grain), compression (parallel and perpendicular to the grain), and shear. The maximum and minimum stress values observed in the shell (area) elements of the structure are comprehensively summarized in Table 2.

Table 2. Maximum and minimum stresses of area elements

Elements	Cross Section Area (mm)	Stresses occurring in Area Elements (N/mm^2)				
		S11	S22	S12	S13	S23
Interior Wall	25x100	1.70 / -1.76	0.25 / -0.28	0.90/ -1.31	0.03 / -0.03	0.005 / -0.002
Flooring	25x100	8.37 / -8.79	0.23 / -0.51	0.90 / -0.53	0.24 / -0.30	0.027 / -0.018

Table 2 presents the maximum and minimum stress values obtained from the structural analyses, considering all relevant load combinations. The maximum stress values generally occur under load cases involving live load, snow load, and wind actions. According to TS EN 1995-1-1, these effects are classified as short-term actions, and for solid timber elements, a modification factor k_{mod} of 0.7 is recommended for service class 3. For the C22 timber strength class, the allowable design stresses were obtained by multiplying the characteristic stresses by the corresponding k_{mod} factor. These adjusted design stress values, which were used for safety verification during the structural assessment, are summarized in Table 3.

Table 3. Alan elemanlara ait maksimum ve minimum gerilmeler

Timber Class	Bending	Tensile (Parallel to Fibers)	Tensile (Perpendicular to Fibers)	Compression (Parallel to Fibers)	Compression (Perpendicular to Fibers)	Shear
C22	15.4	9.1	0.28	14	1.68	2.66

The comparison of the obtained stresses with the allowable stresses is detailed in Tables 4 and 5.

Table 4. Verification of internal walls

Internal wall			Verification Result
S11	Tensile	1.70 < 9.1	Suitable
	Compression	1.76 < 14	Suitable
S22	Tensile	0.25< 0.28	Suitable
	Compression	0.28< 1.68	Suitable
S12 S13 S23	Tensile	0.90 < 2.66	Suitable
	Compression	1.31 < 2.66	Suitable

Table 5. Verification of floor

Internal wall			Verification Result
S11	Tensile	8.37 < 9.1	Suitable
	Compression	8.79 < 14	Suitable
S22	Tensile	0.23 < 0.28	Suitable
	Compression	0.51 < 1.68	Suitable
S12 S13 S23	Tensile	0.93 < 2.66	Suitable
	Compression	0.61 < 2.66	Suitable

In the finite element model, the timber studs, beams, and purlins modeled as frame elements were assessed through structural verification based on bending, shear force, and combined bending-stress calculations. The results of these checks indicated that all members satisfy the required safety criteria and exhibit adequate structural performance under the applied loading conditions.

3. Conclusions

This study presents a detailed structural assessment of a registered two-story timber building featuring a traditional bağdadi wall system, located within an urban conservation area in Samsun, Turkey. Through the development of a comprehensive three-dimensional finite element model and the application of various static and dynamic analyses, the study investigates the structural performance of the building under multiple loading scenarios, including gravity, snow, wind, and seismic effects.

- The analyses were carried out in accordance with national and international standards, particularly TS EN 1995-1-1 and TBEC 2018, and took into account both the Ultimate Limit State (ULS) and Serviceability Limit State (SLS) conditions.
- The results clearly indicate that the structural elements of the building possess sufficient strength and stiffness under all considered load combinations.
- These findings confirm that the restoration project not only contributes to the architectural preservation of the heritage asset but also ensures its structural reliability for future use.
- This underscores the critical role of engineering analysis in restoration processes, shifting the perception of such efforts from purely aesthetic interventions to technically reinforcements.

In conclusion, finite element modeling proves to be an essential tool for validating the effectiveness of restoration interventions in historical timber structures. The methodology and findings presented in this study may serve as a reference for similar heritage conservation projects, promoting a more integrated and performance-based approach in architectural preservation efforts.

Investigation of infill wall effects on structural behavior of RC buildings: a case study of collapsed building after the 2023 Kahramanmaraş Earthquakes

Abstract. During the design phase of structures and the evaluation of their seismic performance, it is commonly assumed that all loads acting on the structure are resisted by the primary structural elements, such as shear walls, columns, and beams. The contributions of non-structural elements, such as infill walls, to load resistance are generally neglected. However, research conducted on the structural behavior of RC buildings has demonstrated that infill walls play a critical role in key parameters such as stiffness, energy dissipation capacity, and seismic performance, thereby enhancing the overall load-carrying capacity. Neglecting the influence of infill walls on lateral stiffness and considering them merely as vertical loads during structural analysis may result in unexpected structural behavior under seismic loading. Therefore, in order to accurately evaluate the structural behavior of buildings, infill walls should be considered during the design and analysis phases. In this study, the nonlinear analyses of a RC building that collapsed during the 2023 Kahramanmaraş earthquakes were comparatively investigated for cases where the infill walls were considered and not considered. The finite element (FE) model of the building was created using the SAP2000 software. As a result of the analyses, the extent to which infill walls affected the structural behavior and structural responses (such as interstory drift ratios, modal parameters, base shear forces, and performance levels) of the collapsed building was investigated.

Keywords: RC building; Infill wall; Kahramanmaraş earthquakes; Nonlinear time history analysis (NTHA)

1. Introduction

During the design of structures and the evaluation of their seismic performance, it is generally assumed that all loads acting on the structure are resisted by structural system elements such as shear walls, columns, and beams. The contribution of non-structural elements, such as infill walls, to load resistance is often neglected, and the interaction between the structural system and the infill walls is not considered (Abdelaziz et al., 2019; Çavdar et al., 2020; Murty et al., 2000; Köse Sunca, 2019; Öztürkoğlu et al., 2017; Sattar et al., 2010; Tan et al., 2025; Wang et al., 2021). In addition, in the currently used structural design software packages, infill walls are considered only as vertical loads. Ignoring the contribution of infill walls to lateral stiffness may lead to unexpected damage and irregularities within the structure (Köse et al., 2007).

The results of recent studies have revealed that a significant portion of the loss of life and property during major earthquakes is caused by unexpected damage to infill walls (Smilordo et al., 2023). Therefore, in order to accurately determine the actual behavior of structures, infill walls must be considered during the design and analysis phases of buildings (Yakut et al., 2013; Köse Sunca, 2019). In the literature, there are numerous analytical and experimental studies investigating the interaction between the structural system and infill walls. Hashemi and Mosalam (2006), it was demonstrated that the presence of infill walls reduces both the natural period and the lateral displacements of the structure. Hasemi (2007) experimentally investigated the seismic performance of RC structures and revealed that the presence of infill walls is one of the most critical factors affecting performance. Kadysiewski and Mosalam (2009), through their analytical studies, demonstrated that infill walls not only increase the stiffness of the structural system but also enhance its damping capacity.

Sattar and Liel (2010) conducted a study comparing the collapse probabilities of frames with and without infill walls using nonlinear analysis methods, and found that frames containing infill walls exhibited greater lateral stiffness and improved seismic performance. Hermanns et al. (2013), based on observational studies conducted on

* Corresponding author, E-mail: senndoga@gmail.com

https://doi.org/10.31462/icearc2025_ce_eqe_946

two different buildings with varying numbers of stories following the 2011 Lorca earthquake, identified that infill walls, which are neglected during design, can lead to the formation of short columns in structures, resulting in sudden collapses. Ning et al. (2017) investigated the collapse mechanism of infill walls using different modeling approaches through static pushover tests. The analyses revealed that the presence of infill walls affects the locations of plastic hinges in structural elements. Öztürkoğlu et al. (2017) analytically examined the seismic performance of frames with and without infill walls, having different span lengths and numbers of stories, using nonlinear analyses. The results of the study demonstrated that the presence of infill walls significantly alters the behavior of the system. Baghi et al. (2018) compared the behaviors of RC frames with and without infill walls under static loading and demonstrated that infill walls significantly increase the load-carrying capacities. Özkaya (2018) investigated the effect of infill walls on the soft-story irregularity in buildings using different modeling approaches. As a result of the analyses, it was determined that soft-story irregularity occurred in the building modeled without infill walls, leading to the conclusion that infill wall design should not be neglected in structural analyses. Köse Sunca (2019) investigated the effects of infill walls placed at different ratios and configurations on seismic performance using the NTHA method. The study results indicated that increasing the proportion of infill walls substantially enhanced the structural stiffness, highlighting the necessity of accounting for the influence of infill walls on both vertical load resistance and lateral load-bearing capacity. Abdelaziz et al. (2019) investigated the seismic behavior of reinforced concrete buildings with varying story numbers through NTHA, focusing on different infill wall configurations. Their findings indicated that the presence of infill walls notably improved lateral stiffness and seismic performance. However, the removal of infill walls at the ground story created a discontinuity in stiffness, resulting in a soft-story irregularity that could critically compromise structural safety during earthquakes. Wang et al. (2021), in their experimental study, subjected bare and infilled frames to cyclic pushover tests. The experimental results demonstrated that infill walls increased the lateral load-carrying capacity and stiffness of the frame, while also enhancing its energy dissipation capacity; however, they were found to reduce the deformation performance. Usta et al. (2023) investigated the effect of infill walls on RC buildings under seismic loading by analyzing a model of a building that collapsed during the 2020 Düzce earthquake, both with and without infill walls. The analyses revealed that infill walls positively influenced characteristics such as the period of the structure, base shear force at the ground story, column load-carrying capacity, interstory drift ratio, and base shear force at the ground story, and that they increased the base shear force. Akbaş and Çalışkan (2024) evaluated the impact of infill walls on the stiffness, strength, and energy dissipation capacity of the structural system, emphasizing that this contribution is at a level that cannot be neglected, particularly under seismic loading. They also suggested that neglecting infill walls during the design and analysis process may lead to the formation of irregularities such as short columns, weak stories, and soft-story mechanisms within the structure. Tan et al. (2025) investigated the performance of a building that sustained severe damage during the 2023 Kahramanmaraş earthquake. In the study, NTHA were conducted using two different FE models, one with infill walls and one without. The analyses revealed that infill walls significantly affected the seismic performance.

In this study, the nonlinear analyses of a RC building that collapsed during the 2023 Kahramanmaraş earthquakes were comparatively investigated for cases where infill walls were considered and not considered. The FE model of the building was created using the SAP2000 software. In the NTHA, real ground motion records obtained from the station closest to the building were utilized. The infill walls was represented using the equivalent diagonal strut approach, which is commonly preferred in numerical modeling. As a result of the analyses, the extent to which infill walls affected the structural behavior and structural responses (such as interstory drift ratios, modal parameters, base shear forces, and performance levels) of the collapsed building was investigated.

2. Description of selected building

Within the scope of this study, a RC building that collapsed during the February 6, 2023 earthquake was selected for investigation. The ground floor and mezzanine of the building were used for commercial purposes, while the upper floors were used for residential purposes. The location and pre-collapse condition of the building are presented in Fig. 1.

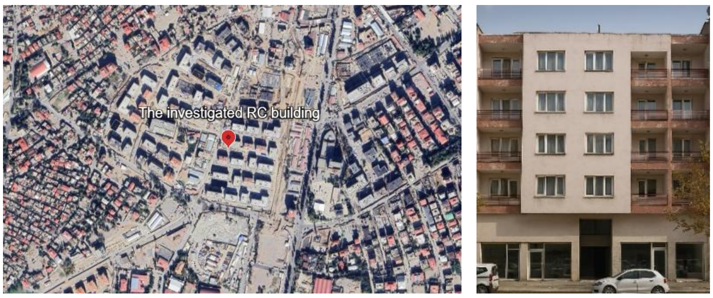

Fig 1. The location and pre-collapse condition of the investigated building

The load-bearing system of the investigated building consists of RC frames. The building, which has a total of six stories, has a height of 17.5m. The story heights are 2.75 meters for the ground floor and clerestorey, and 3.00m for the normal floors. The general characteristics of the building, the dimensions of the structural elements, and the analysis parameters are presented in Table 1, while the plan of a typical floor is shown in Fig. 2.

Table 1. General characteristics and analysis parameters of the RC building

General characteristics of the building	
Building height	17.5m
Story heights	Ground floor and clerestorey: 2.75m Normal floor: 3.00m
Properties of structural elements	
Column	25×25cm, 25×30cm, 25×40cm, 25×50cm
Beam	20×40 cm, 20×50cm, 20×60cm
Slab thickness	12 cm-14 cm
Material properties	
Concrete material	C14 (f_{ck} = 14MPa)
Steel material	S220 (f_{yk} = 220MPa)
Soil classification	ZC
Considered loads	
Slab dead loads	1.5 kN/m^2
Slab live loads	Rooms: 2.0 kN/m^2 Stairs: 3.5 kN/m^2 Balconies: 5.0 kN/m^2
Infill wall	
Wall type	Brick wall

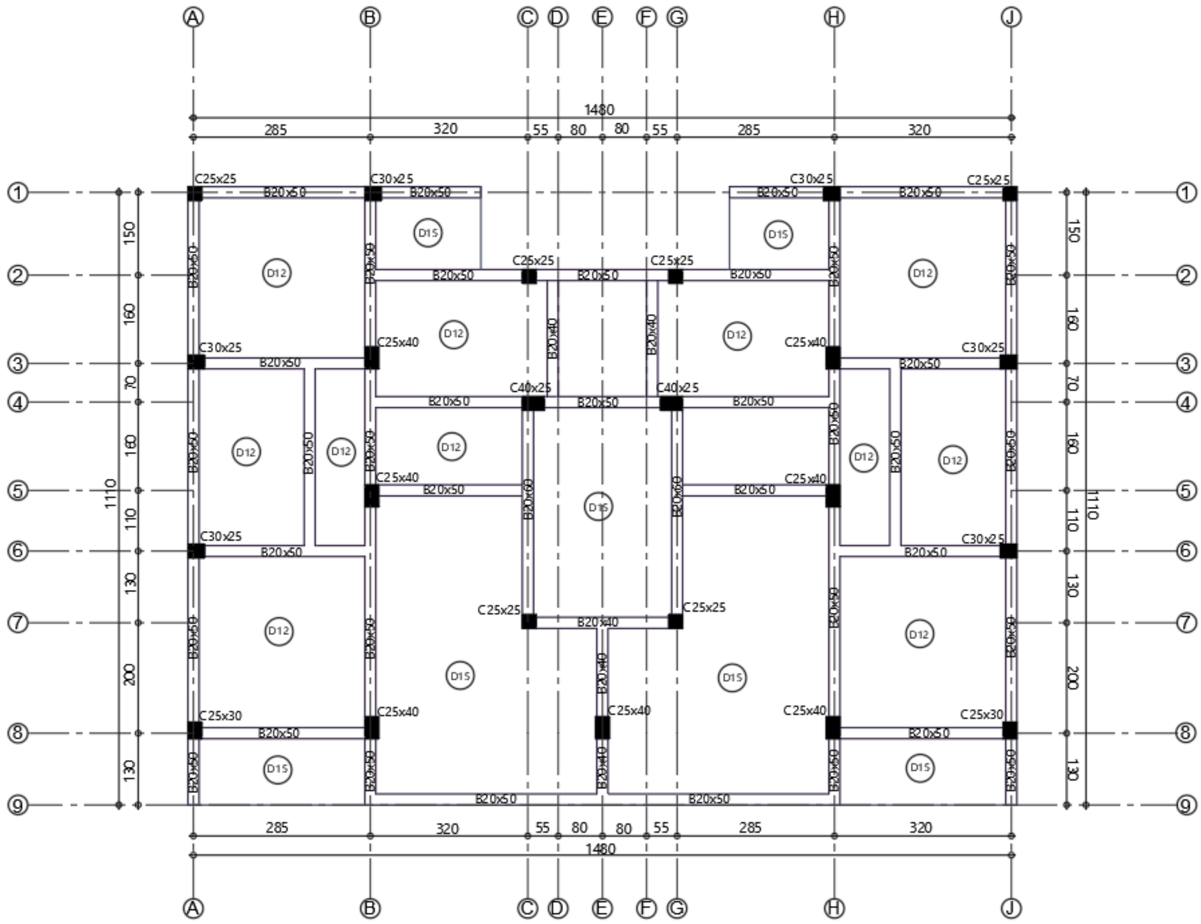

Fig 2. Plan view of a typical floor of the building

3. Ground motion selection

The Turkish Strong Motion Database and Analysis System (AFAD-TADAS) of the Disaster and Emergency Management Authority (AFAD) was used to determine the ground motion to be applied to the structure. Acceleration data from six different stations located in the Onikişubat district, where the structure is situated, were examined, and it was aimed to select the acceleration records from the station closest to the structure. The acceleration records from station TK4620, located nearly 2.50 km away from the structure, were used in the analyses. The locations of the relevant stations and the selected station are presented in Fig. 3.

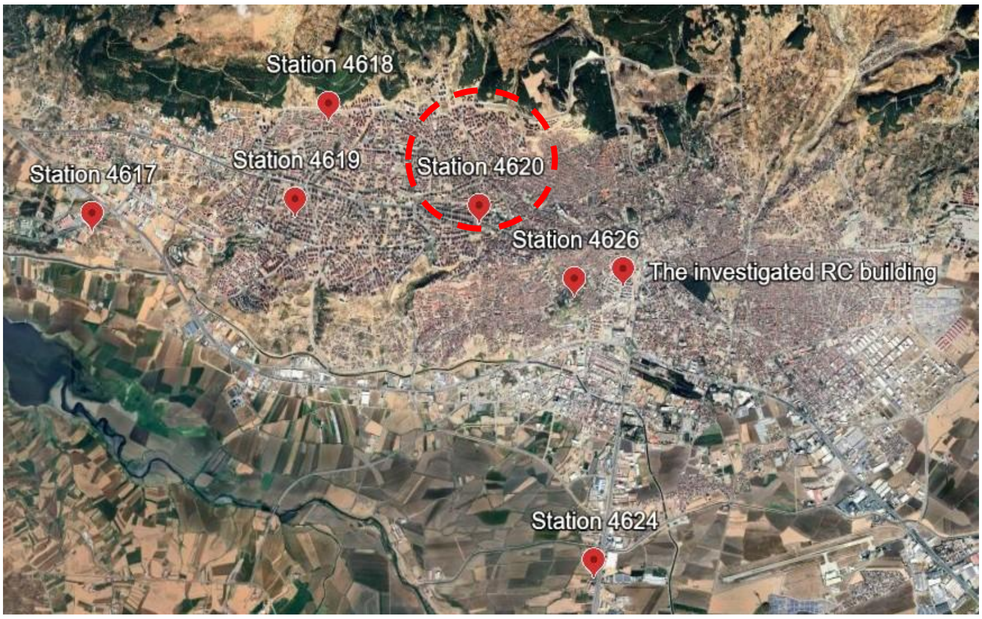

Fig 3. The locations the selected building and station

For use in structural analyses, the acceleration records of two horizontal components (E and N) obtained from the station coded TK4620 were considered. The Peak Ground Acceleration (PGA) values corresponding to these records were determined as 0.327 g and 0.306 g. The acceleration-time histories generated from the data obtained in both directions are presented in Fig. 4, while the comparison between the response spectra of the horizontal components recorded at the TK4620 station and the design spectra defined by the Turkish Building Earthquake Code (TBEC) is presented in Fig. 5.

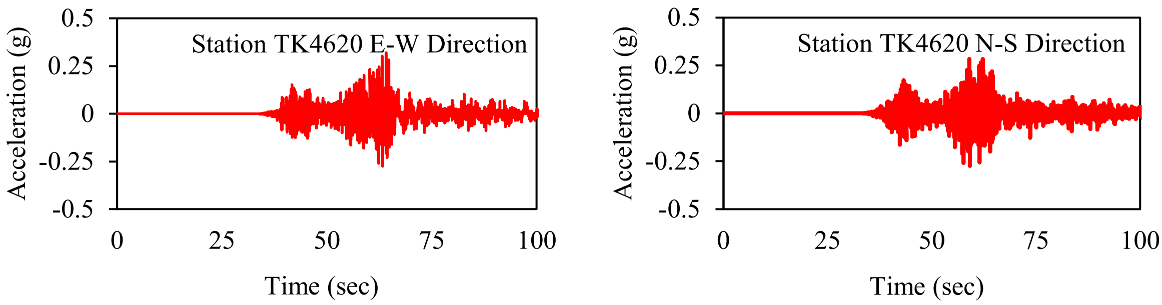

Fig 4. Acceleration-time graphs of selected ground motions

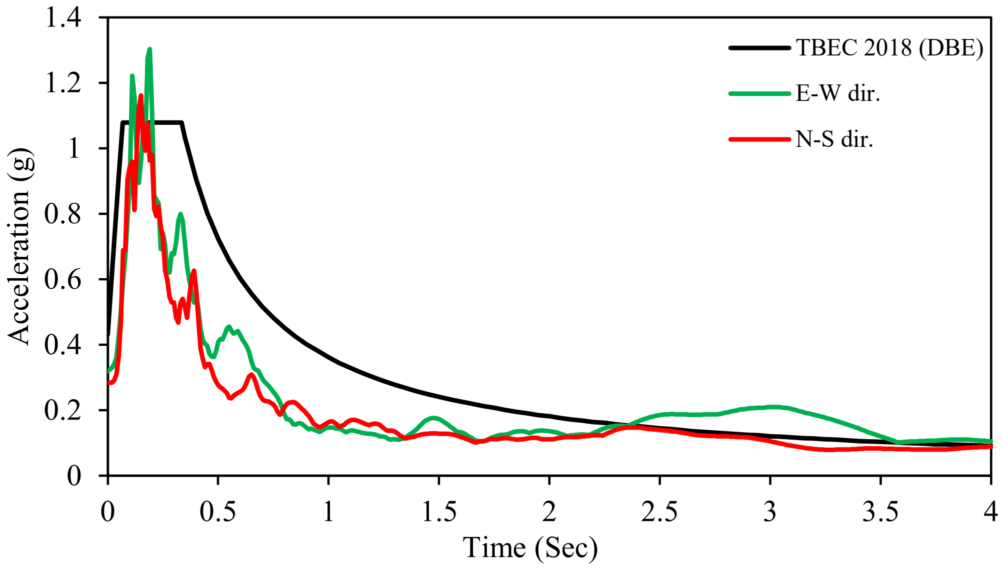

Fig 5. Comparison of the design spectrum and the station-specific spectra

4. Numerical modelling

Within the scope of the study, two different analytical models were developed to evaluate the structural behavior of the building under seismic effects. In the first model, the contribution of infill walls to the structural behavior was neglected, and only the primary structural elements (columns and beams) were considered. In the second model, the infill walls were incorporated into the model using strut elements.

NTHA were conducted using the SAP2000 v25 software. In the analyses, in order to realistically represent the nonlinear structural behavior, the confined concrete model developed by Mander et al. (1988) was adopted for the concrete material. The properties of concrete and reinforcement materials were defined based on the provisions specified in Annex 5A of the Turkish Building Earthquake Code (TBEC-2018). The Stress-Strain relationships of the concrete and steel material models are presented in Fig. 6. In the three-dimensional FE models, columns and beams were modeled as frame elements, while slabs were modeled as shell éléments. Three-dimensional views of the FE models are provided in Fig. 7.

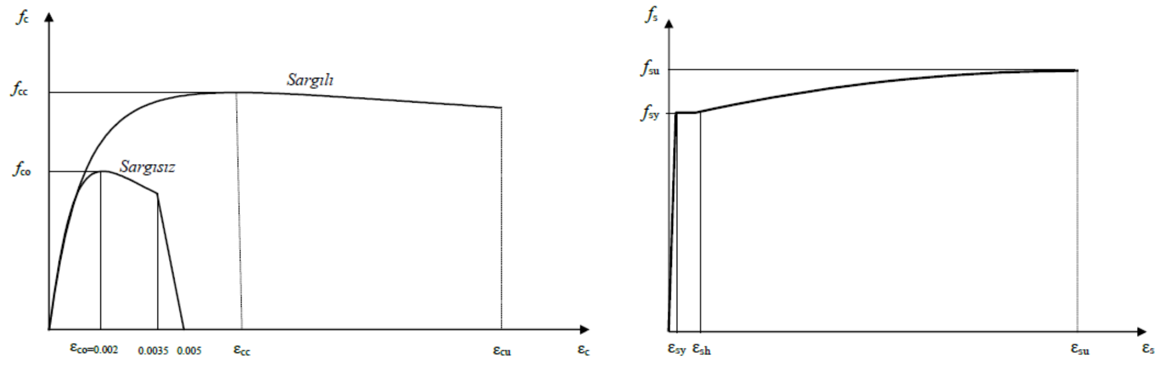

Fig 6. Concrete and steel material model

Without infill wall ***With infill wall***

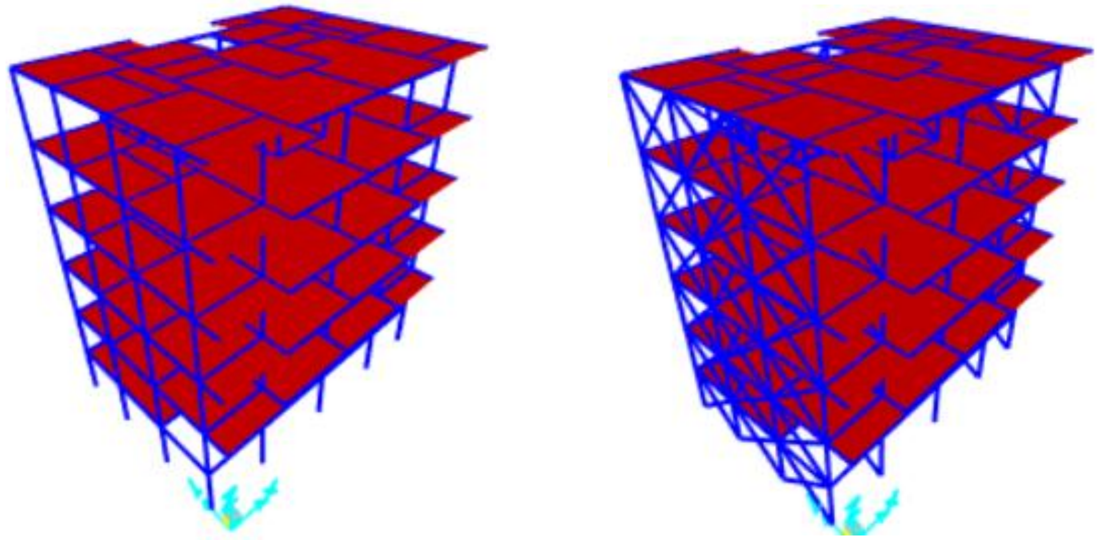

Fig 7. 3D FE models of the investigated building

In the representation of nonlinear behavior, a distributed plasticity model was employed, which is based on the assumption that plastic deformations are continuously distributed along the cross-section and allows for a more realistic simulation of the nonlinear behavior of structural elements. In this approach, the cross-sections of structural elements are subdivided into fiber elements, enabling the prediction of distributed nonlinear behavior both within the section and along the element length (Yön and Calayır, 2013). In the three-dimensional FE models, in order to monitor strain values of load-bearing elements, Fiber P-M2-M3 hinges were assigned at the ends of the column and beam éléments.

In the FE models, infill walls were represented using the equivalent diagonal strut approach, which is commonly adopted in the literature and frequently employed in numerical modeling studies. The first comprehensive investigations into the modeling of infill walls and their structural behavior were conducted by Polyakov (1956). In his study, infill walls can be represented as diagonal struts that transmit forces through compression zones within the structural frame. (Al Chaar et al., 2002). The equivalent diagonal strut method offers a simplified yet effective approach for evaluating frame-infill wall interaction and is currently recognized and utilized by numerous design codes (Köse and Karslıoğlu, 2007; Öztürkoğlu et al., 2016; Köse Sunca, 2019; Çavdar et al., 2020). The thickness and material properties of the compression struts were assumed to be the same as those of the infill wall material (Yakut et al., 2013; Öztürkoğlu, 2016). In calculating the width of the equivalent struts, the modulus of elasticity and compressive strength values obtained from an experimental study conducted by Kaltakçı et al. (2003) were adopted.

In the analyses, the orientation of the struts was adjusted based on the direction of the applied lateral loads; considering the possibility of load direction reversal during seismic events, two diagonally placed equivalent compression struts were defined for each opening to represent this behavior (Öztürkoğlu, 2016). To ensure that the struts carried only axial loads, both end nodes were defined as pinned connections. The axial load capacities of the struts were calculated, and axial load hinges were assigned at the midpoints of each strut to ensure load transfer consistent with these capacities (Özkaya, 2018). In the definition of the axial load hinges, the tensile strength of the wall was considered to be 10% of its compressive strength.

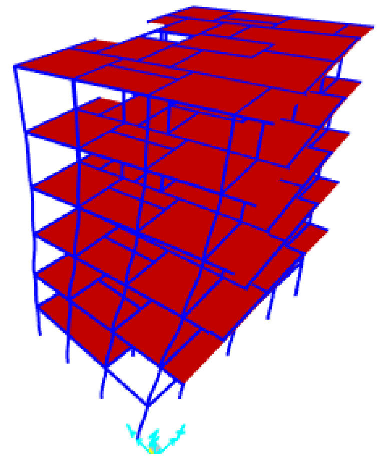
5. Results and discussion

In this section, the findings obtained from the NTHA are presented. The analysis results were comparatively evaluated in terms of modal parameters, story shear forces, interstory drifts, and strain values.

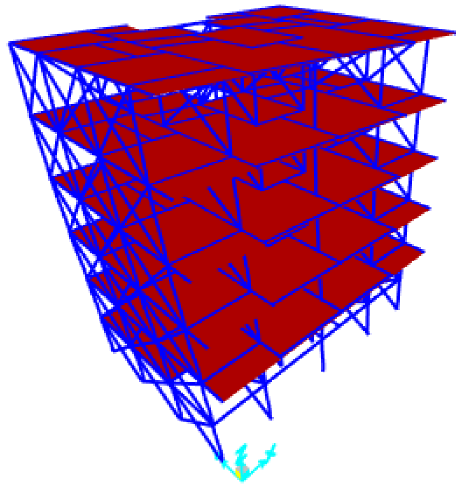
5.1. Modal analysis results

The mode shapes and natural vibration periods corresponding to the first three modes of the FE models with and without infill walls are presented in Fig. 8. The analysis results revealed that the presence of infill walls significantly reduced the period values of the structure. This finding indicates that infill walls can substantially change the dynamic behavior of the structure by increasing the stiffness of the structural system.

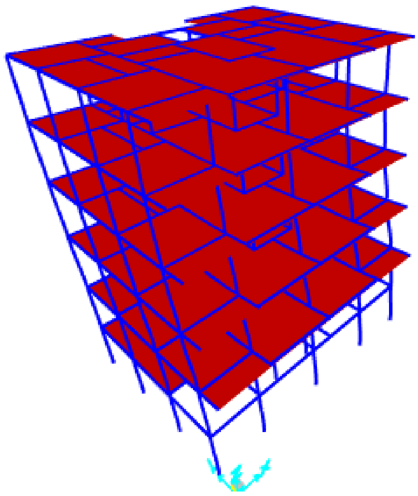
Without infill wall | ***With infill wall***



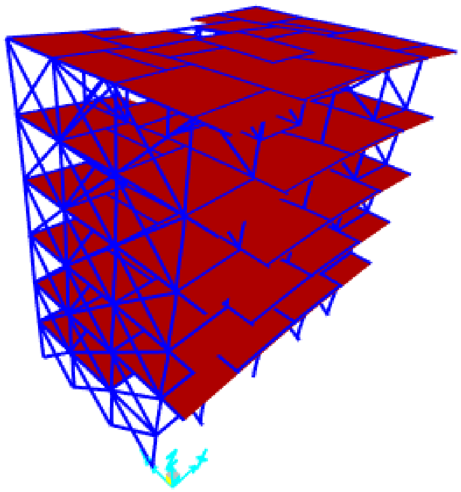
T_1 (x_1) = 1.00s



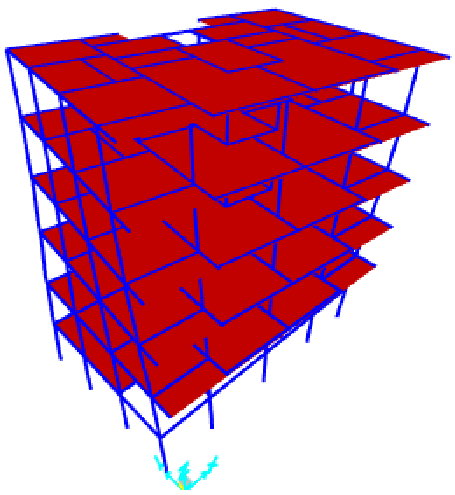
T_1 (x_1) = 0.64s



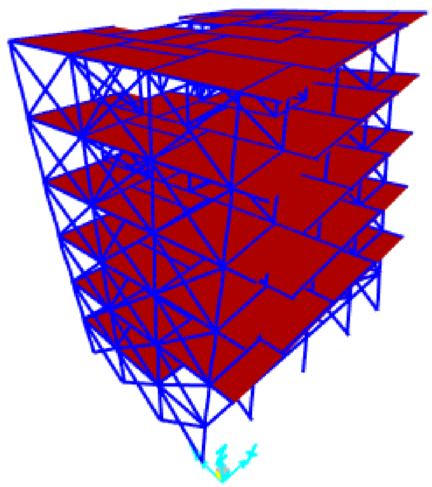
T_2 (y_1) = 0.85s



T_2 (y_1) = 0.36s



T_3 (r_1) = 0.81s



T_3 (r_1)= 0.33s

Fig 8 Comparisons of modal parameters of selected RC building

5.2. Interstory drift results

As a result of the analyses, interstory drifts were calculated for both directions and compared for the models with and without infill walls (Fig. 9). It was determined that the interstory drifts of the model with infill walls were significantly reduced compared to the bare frame model. However, it was observed that the reduction in drift in the X-direction was more limited, due to the lower number of infill walls placed along the X-axis compared to the Y-axis. This finding demonstrates that the density and distribution of infill walls have a direct influence on the lateral stiffness of the structure.

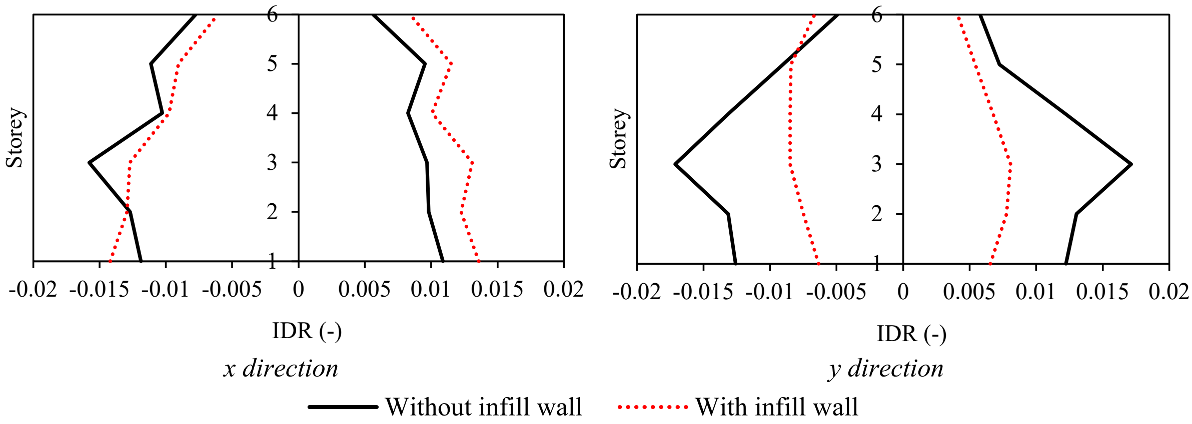


Fig 9. Comparisons of IDRs of selected RC building

5.3. Base shear forces

The base shear forces of the FE models with and without infill walls is comparatively presented in Fig. 10. The results indicate that the base shear forces in the model with infill walls are significantly higher compared to the bare frame model, demonstrating that the presence of infill walls increases the structural stiffness and consequently leads to the development of greater base shear forces under seismic effects. Furthermore, Fig. 10 shows that higher base shear forces occurred in the Y-direction. This observation is attributed to the higher density of infill walls along the Y-axis, which enhances the lateral stiffness of the structure and thus results in greater shear force demands during seismic loading.

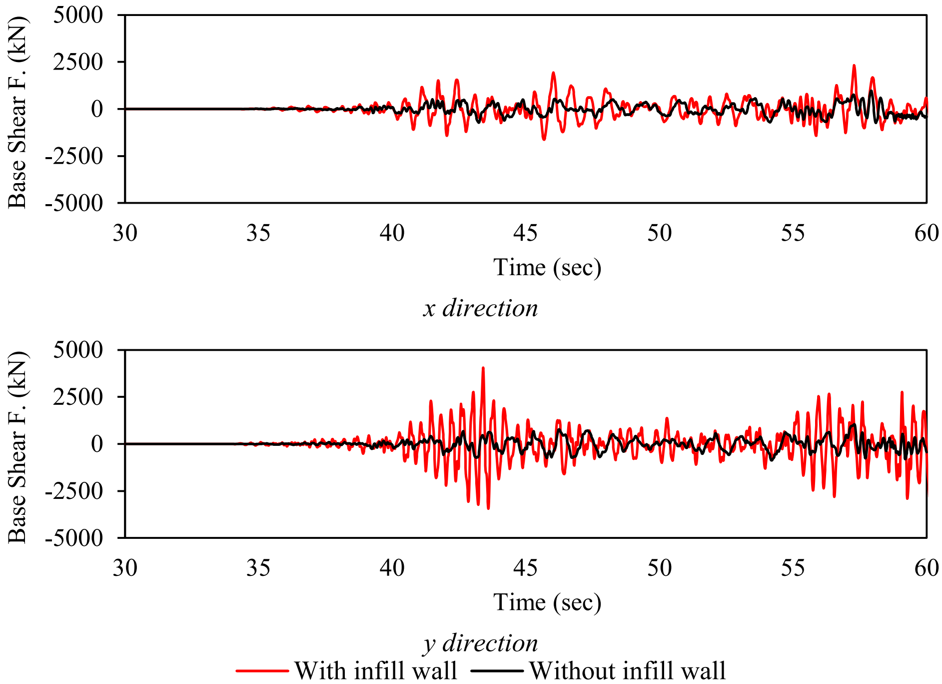

Fig 10. Comparisons of base shear forces of selected RC building

5.4. Performance level of load-bearing elements

As a result of the analyses, the plastic hinge formations in the structural elements are presented in Fig. 11. An examination of the plastic hinge distribution in the bare frame model reveals that extensive plastic deformations occurred in the structural elements, with a significant number of hinges reaching the Collapse Prevention (CP) performance level. This indicates that in the absence of infill walls, the lower lateral stiffness of the structure led to larger plastic deformations in the primary structural members. In contrast, the model with infill walls exhibited a significant reduction in both the formation and severity of plastic hinges.

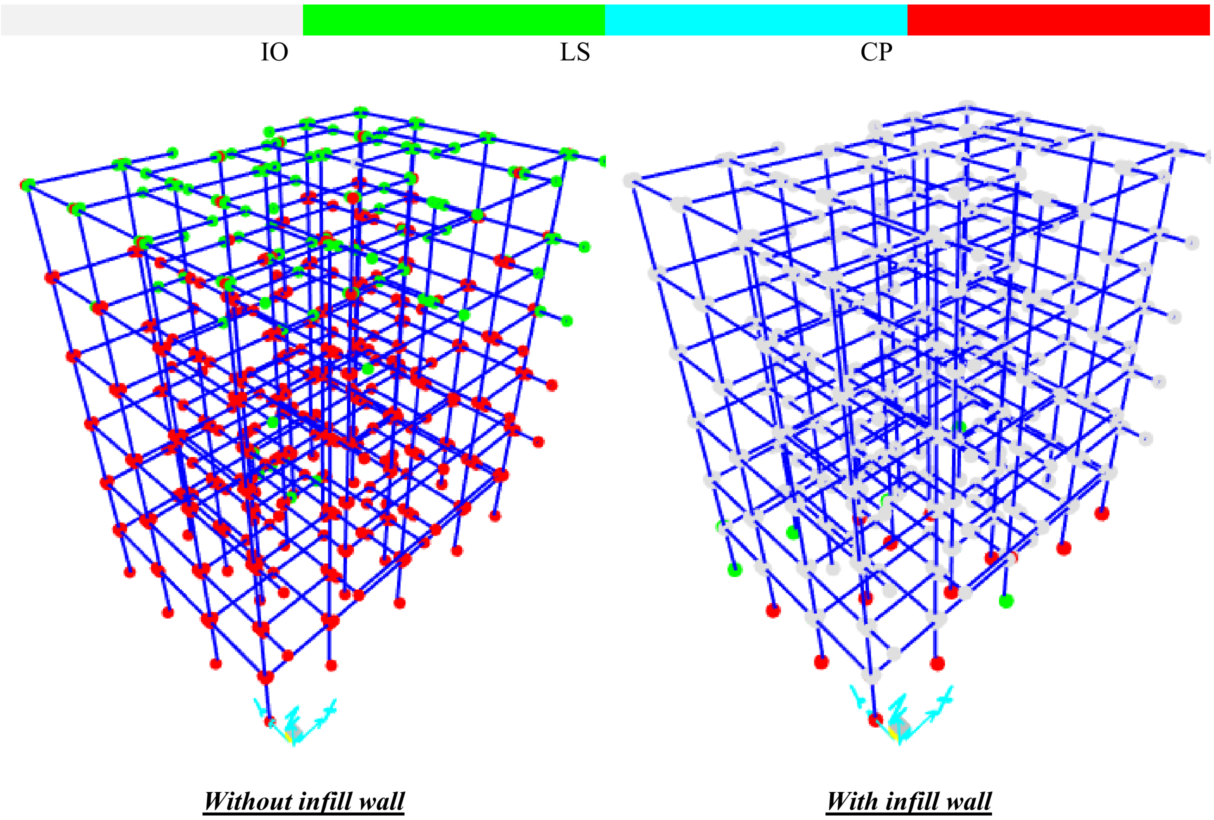

Fig 11. Comparisons of performance level of load-bearing elements

6. Conclusion

The aim of this study is to investigate the effects of infill walls on the structural behavior of a RC building that collapsed during the 2023 Kahramanmaraş Earthquake, through NTHA utilizing real ground motion records obtained from a station located near the building. Within the scope of the study, two different FE models were developed: one including infill walls and one excluding them. The key results derived from the analyses are summarized below:

- As a result of the modal analysis, it was observed that the presence of infill walls led to reductions of 36%, 57.65%, and 59.29% in the natural vibration periods for the first three modes, respectively. These results indicate that infill walls significantly enhance the lateral stiffness of the structure.
- With the inclusion of infill walls, reductions in interstory drifts were observed in both directions. However, the lower density of infill walls in the X-direction compared to the Y-direction limited the extent of the reduction in that direction. This finding highlights that the density of infill walls has a direct influence on the lateral stiffness of the structure.
- In the model with infill walls, a significant reduction in the formation of plastic hinges and damage was observed compared to the bare frame model, and the plastic deformation demands on the structural elements were effectively limited.

Abstract. After the devastating earthquakes on the Eastern Anatolia Fault zone on February 6, 2023, earthquakes are still occurring in the region. One of these earthquakes occurred on October 16, 2024 at 10:46 local time at the epicenter of Akuşağı-Kale (Malatya). The instrumental magnitude of this earthquake was reported as M_L 5.9 - M_W 6.0. It was a shallow focused earthquake (focal depth 6.8 km) and was strongly felt in Malatya and Elazığ provinces. The subject of this study is to analyze the some characteristics of this earthquake and to investigate its effects on the building stock. Within the scope of the study, various parameters of some strong ground motions recorded at seismic stations operated by AFAD are analyzed considering the directional effect. The acceleration velocity and response spectrum values given in the Türkiye Earthquake Hazard Map for the characteristics of the earthquake were compared and evaluated. At the end of the study, the effects of the earthquake on the building stock are presented.

Keywords: Eastern Anatolia fault zone; October 16, 2024 Akuşağı-Kale (Malatya) earthquake; Seismic characteristics; Building stock; Directionalty effect

1. Introduction

Earthquakes are natural disasters that occur with the release of large amounts of energy as a result of tectonic movements in the earth's crust. These natural disasters have serious impacts on settlements around the world and deeply affect the lives of human communities. As a result of earthquakes, especially damages to superstructures, loss of life and property occur. Additionally, earthquake-induced infrastructure damage disrupts societies by collapsing transport and communication networks. Earthquakes in regions located on active fault lines threaten not only physical structures but also social and economic order. The social effects can be said to be psychological traumas, stress and anxiety disorders in individuals in the long term, and permanent scars on the social fabric. On the other hand, economic effects are the stoppage of production processes in earthquake zones, labor force losses and reconstruction costs, and significant deterioration in the economic structures of countries. In this context, evaluating earthquakes solely within a geoscientific framework is not sufficient. For this reason, earthquakes create a comprehensive crisis situation in humanitarian and socioeconomic terms, and the management of these crises is of critical importance for the resilience of societies.

To minimize the negative impacts of earthquakes, a comprehensive planning and preparation process is required before, during, and after disasters. Seismic risks should be considered in the construction of settlements, and earthquake-resistant structures should be provided. In addition, strengthening social awareness-raising activities is of enormous importance in terms of learning how to behave against disasters. However, all these measures are not sufficient to prevent the destruction caused by earthquakes. By establishing a long-term resilience strategy, we can ensure that societies become more resilient against disasters. Thus, losses caused by earthquakes can be minimized, and societies can cope with such disasters in a more sustainable way.

Turkey, as a country located in the earthquake zone, is obliged to be constantly prepared and take precautions against such disasters. For this reason, seismic risks should be considered in the construction of residential areas, and earthquake-resistant structures should be provided. Construction measures are especially urgent in regions located on active faults like the North Anatolian Fault Zone (NAFZ) and the East Anatolian Fault Zone (EAFZ). Although all precautions should be taken before earthquakes, painful social experiences also contribute to the rapid implementation of the measures to be taken. Because the mobility in these fault lines and the painful experiences since the beginning of the 21st century are the biggest triggers of this urgency.

* Corresponding author, E-mail: iozgur.dedeoglu@batman.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_957

The 1999 Gölcük and Düzce earthquakes that occurred in the NAFZ at the beginning of the 21st century resulted in the loss of approximately 20,000 lives. The magnitudes of these earthquakes were 7.4 and 7.2 respectively. The mobility of the NAFZ continued over the years. The Düzce-Gölyaka earthquake in 2022 demonstrated this continued mobility. For the EAFZ, it is possible to say that this mobility is higher. In the 21st century, some of the earthquakes that occurred in the EAFZ are the 2003 Bingöl, 2010 Karakoçan-Elazığ, and 2020 Sivrice-Elazığ earthquakes. In addition to these earthquakes, many medium-sized earthquakes occurred in the region. However, the Kahramanmaraş earthquakes that occurred in 2023 and directly affected the region have gone down in history as the largest earthquakes of the last century. Unfortunately, these earthquakes did not go down in history, only in terms of their magnitude. The uniqueness of these earthquakes lies in the significant losses they caused in Turkey.

The 2023 Kahramanmaras earthquakes, in particular, are often interpreted using data such as magnitude, PGA, and PGV. Usually, these data are used to reveal the damage relationship between earthquakes and structures, to create earthquake hazard maps, and to determine the performance of existing structures under the effect of possible earthquakes. These data consider two horizontal components and one vertical component of the earthquake. However, when such an evaluation is made, the directional effect of earthquake loads, the effects of the interaction between the components of the earthquake ground motion on the structural behavior, torsional effects due to some structural irregularities (mass, stiffness, and strength, etc.), and the effects arising in non-orthogonal buildings are not directly taken into account. The evaluations made by ignoring these effects may lead to structural damage in some cases.

To determine the effects of earthquakes more realistically, the effects of the earthquake ground motion in the principal axis directions as well as the intermediate directions in the plan should be considered. However, the structural behavior analyses of buildings under the earthquake hazard level determined depending on the predicted performance target are performed in the principal axis directions in the plan without considering the characteristic features of the building. However, it is known that the directions of the horizontal components of the earthquake ground motion are variable. The probability of the earthquake effect from the principal axis (X and Y) directions in the plan of the building is the same as the probability of the earthquake effect from any intermediate direction. For this reason, the designed/existing buildings are required to fulfill the prescribed performance targets for the intermediate earthquake directions as well as the principal directions. This study examines how earthquake ground motion is affected by direction. The earthquake that occurred on 16 October 2024 in Akuşağı-Kale (Malatya) is selected as a case study. The focal depth of this earthquake was 6.8 km, and its magnitude was M_L=5.9-M_W=6.0. The study evaluated the characteristics of this earthquake, considering the directional effect. The study took into account the acceleration, velocity, and response spectrum values provided in the Earthquake Hazard Map of Turkey. The study concludes with a discussion of the earthquake's effects on the building stock.

2. Tectonics and seismicity of the region

Malatya province and its districts are located within the I.-III. Degree Earthquake Zone in the Earthquake Zones Map published by the Ministry of Public Works and Settlement, General Directorate of Disaster Affairs in 1996 (Fig. 1a). The Turkiye Earthquake Zones Map (TEZM, 1996) was renewed by the AFAD Earthquake Department and entered into force on 1 January 2019. Unlike the previous map, the new one displays maximum ground acceleration values (PGA) instead of earthquake zones. The Turkiye Earthquake Hazard Map (TEHM, (2019)) shows that for Malatya province, the maximum acceleration value (PGA) at Earthquake Level 2 (design earthquake, return period 475 years) ranges from 0.2 to 0.7 g (Fig. 1b). This indicates that the earthquake hazard of the region has changed relatively and is very high.

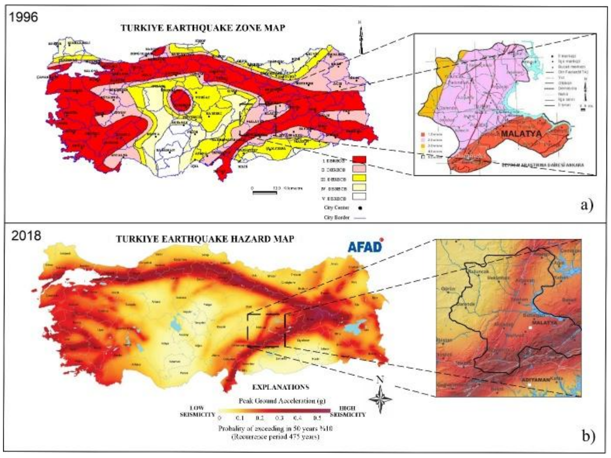

Fig. 1. Earthquake hazard map of Malatya province a) 1996 b) 2018

The south-southeast of Malatya province borders are generally under the influence of the EAFZ. As can be seen in the Active Fault Map of Türkiye prepared by MTA (Mineral Research and Exploration General Directorate) in 2011, Doğanşehir-Sürgü Faults in the south, the part of the Eastern Anatolian Fault Zone passing through Pütürge-Doğanyol and Malatya Fault are important tectonic structures in the region (Fig. 2).

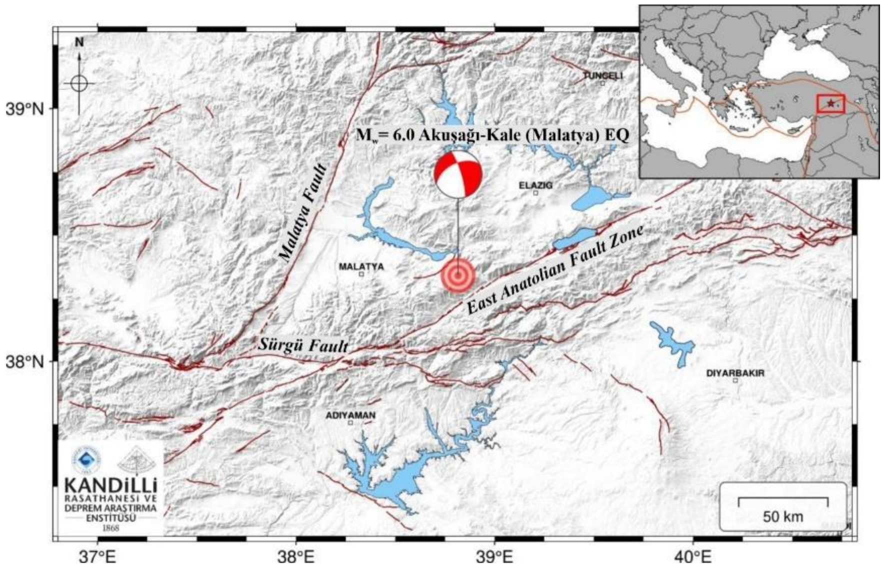

Fig. 2. M_w=6.0 Akuşağı-Kale (Malatya) earthquake epicenter and active fault structure of the region (adapted from KOERİ Report, 2024)

During the Instrumental Period (A.D. 1900-2024; magnitude M≥4.0 KOERI Earthquake Catalogue), the Gaziantep (M=7.7) and Kahramanmaraş (M=7.6) earthquakes that occurred on 06 February 2023 caused intense aftershock activity throughout the region. The earthquakes that occurred closest to the city center recently are the 1964 Aksu-Sincik (Adıyaman) and 2020 Sivrice (Elazığ) earthquakes (Fig. 3).

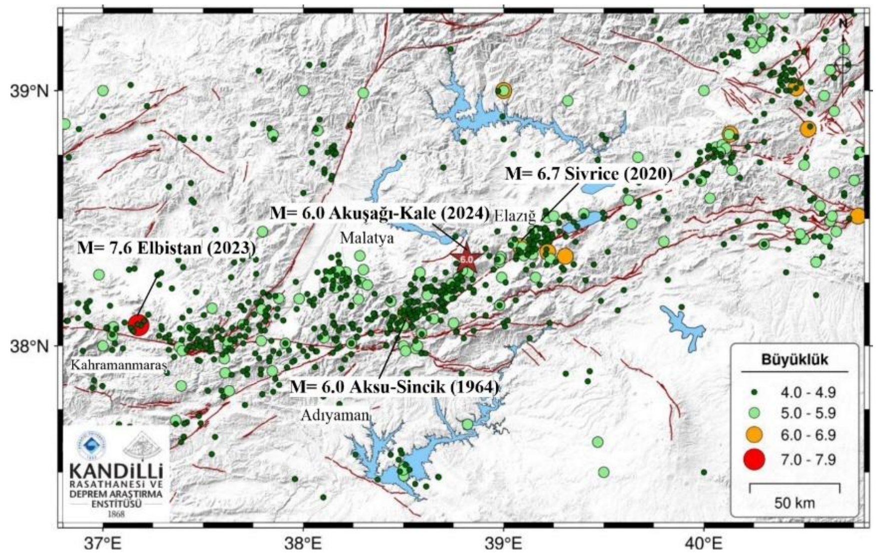

Fig. 3. Earthquake map of the region (1900-2024, M≥4.0 KOERI Earthquake Catalogue) (adapted from KOERİ Report, 2024)

3. Characteristics of earthquake

On 16 October 2024, a strong earthquake with an instrumental magnitude of ML 5.9-Mw 6.0 occurred at 10:46 local time at the epicenter of Akuşağı-Kale (Malatya) (38.3410 N 38.8155 E). The focal depth of the earthquake was 6.5 km; it was a shallow-focused earthquake. The distances of the epicenter of the earthquake to the settlements are given in Table 1.

The earthquake occurred on the EAFZ. The statement indicates that it was an aftershock from the consecutive earthquakes in Kahramanmaraş on February 6, 2023. Despite being an aftershock, the region where it occurred felt its impact strongly. The maximum acceleration magnitudes of the earthquake measured at various stations are given in Table 2. The maximum ground acceleration of the earthquake was recorded as 0.61 g in the horizontal direction and 0.35 g in the vertical direction at station 4414 (Kale/Malatya). The acceleration-time history record of this station is shown in Fig. 4.

Table 1. The distances of the epicenter of the earthquake to the settlements (KOERİ Report, 2024)

Province	District	Distance (km)	Province	Distance (km)
Malatya	Kale	9.23	Malatya	42.56
Malatya	Pütürge	16.28	Elazığ	49.81
Malatya	Doğanyol	19.49	Adıyaman	80.55
Elazığ	Baskil	26.01	Tunceli	105.32
Adıyaman	Sincik	38.19	Diyarbakır	130.93

Table 2. Ground motion characteristics of the October 16, 2024 Akuşağı-Kale (Malatya) earthquake, as recorded by some accelerometer stations (AFAD, 2024)

Province	District	Station Code	Latitude (°)	Longitude (°)	PGA (g)			R_{JB} (km)	R_{rup} (km)	R_{epi} (km)
					N-S	E-W	U-D			
Malatya	Kale	4414	38.7541	38.4069	0.428	0.608	0.351	2.65	7.90	6.59
Malatya	Pütürge	4404	38.8738	38.1958	0.103	0.065	0.036	13.33	15.49	19.74
Malatya	Doğanyol	4413	39.0393	38.3135	0.137	0.118	0.078	17.84	21.24	20.95
Adıyaman	Sincik	0218	38.6333	38.0300	0.010	0.009	0.008	34.61	28.15	40.35
Elazığ	Merkez	2311	39.1520	38.6442	0.030	0.018	0.022	38.92	41.18	43.03
Elazığ	Sivrice	2308	39.3102	38.4506	0.059	0.061	0.031	45.80	44.71	45.92

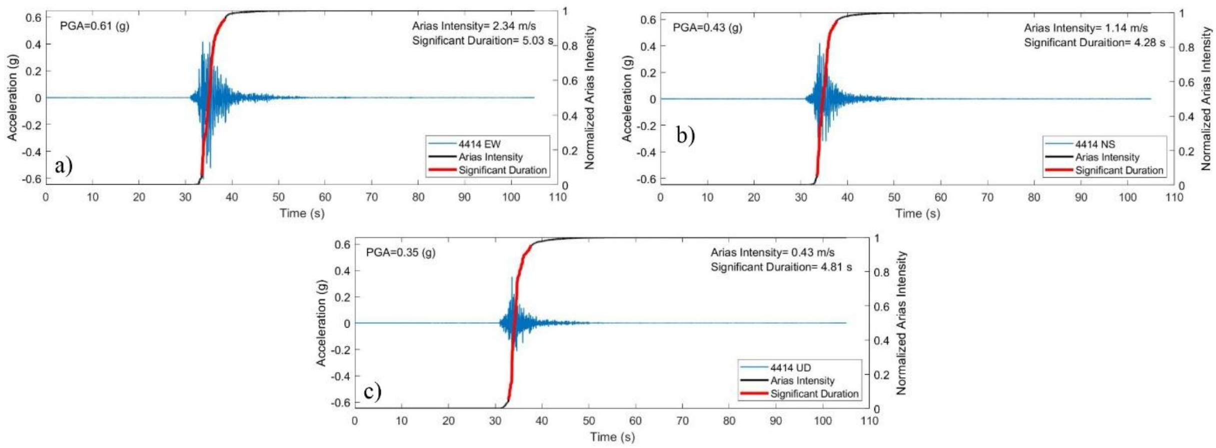

Fig. 4. Acceleration time history, Arias intensity and effective time parameters for station 4414 during M_w=6.0 Akuşağı-Kale (Malatya) earthquake

4. Investigation of the directionalty effect

Earthquakes are recorded in three perpendicular directions by seismic stations in the region where they occur. Various methods incorporate the obtained strong ground motions into earthquake-resistant building design. However, the earthquake propagates as waves at the focal point. Earthquakes may have a different magnitude in a different direction (angle) than the recorded directions. In this study, the records of station 4414, where the largest ground accelerations of the Akuşağı-Kale (Malatya) earthquake that occurred on 16 October 2024, will be discussed in terms of directional effect.

Using the E-W and N-S acceleration records of 4414 stations, acceleration records were obtained for each angle (with 1° angle intervals from 0° to 360°), and then the maximum acceleration and velocity magnitudes in each direction were determined from the acceleration records obtained for each direction. In Fig. 5, the PGA and PGV values for each direction from station 4414 are displayed alongside the PGA and PGV values set in the TBEC (2018) earthquake code for the station's location during the DD1 and DD2 earthquake levels.

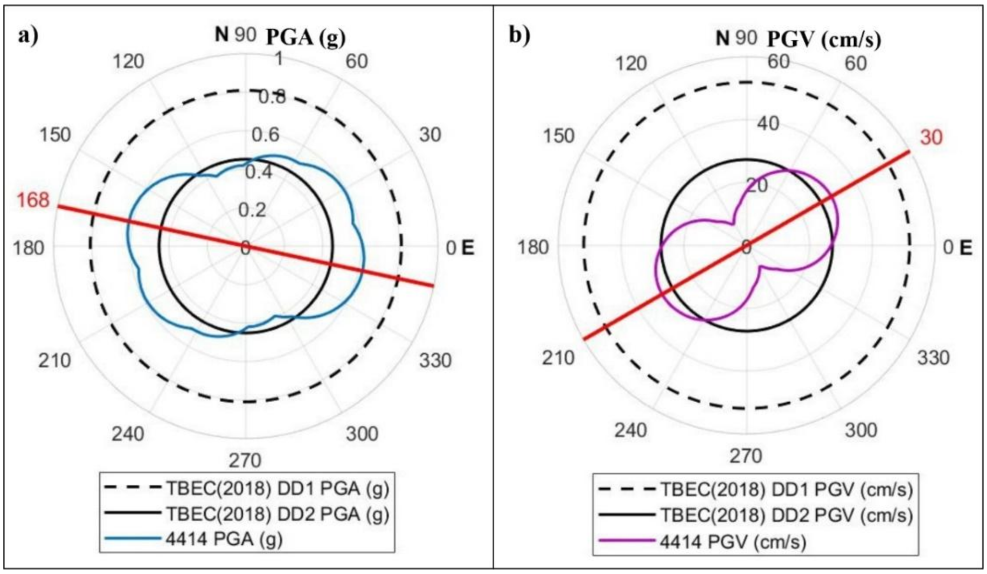

Fig. 5. a) PGA and b) PGV magnitudes of the acceleration records obtained from the horizontal directional acceleration records of station 4414 depending on the direction during M_w=6.0 Akuşağı-Kale (Malatya) earthquake

When Fig. 5. is analyzed, the maximum PGA and PGV values of the strong ground motion recorded at station 4414 were measured as 0.621 g and 31.1 cm/s in different directions from E-W and N-S directions, respectively. The largest PGA and PGV values occurred at angles of 168° and 30° with respect to the east direction, respectively.

Acceleration response spectra are highly utilized in the determination of earthquake loads in earthquake-resistant building design. Therefore, acceleration response spectra of strong ground motions are of significant importance. In Fig.6., the acceleration response spectra obtained for various periods of acceleration records obtained for each direction of station 4414 are shown together with the values determined for DD1 and DD2 levels in TBEC (2018) regulations. When Figure 6 is analyzed, it is obvious that the direction effect affects the response magnitude.

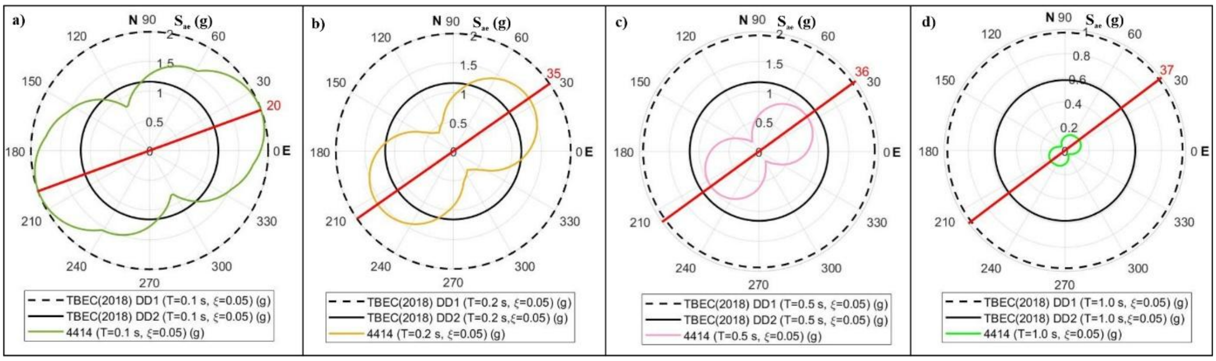

Fig. 6. Acceleration response magnitudes at various periods of acceleration records obtained for each direction from the horizontal direction records of station 4414 a) T=0.1 s, b) T=0.2 s, b) T=0.5 s, b) T=1.0 s for M_w=6.0 Akuşağı-Kale (Malatya) earthquake

For the strong ground motion belonging to station number 4414, the acceleration response spectrum was obtained by taking into account the maximum values of the acceleration response values obtained in all directions for all period values at 0.02 s intervals from T = 0.02 s to T = 1.00 s. The acceleration response spectrum obtained is presented together with the acceleration response spectra of the E-W and N-S direction records and the acceleration response spectra determined for DD1 and DD2 in the TBEC (2018) earthquake code for the location of the station (Fig. 7).

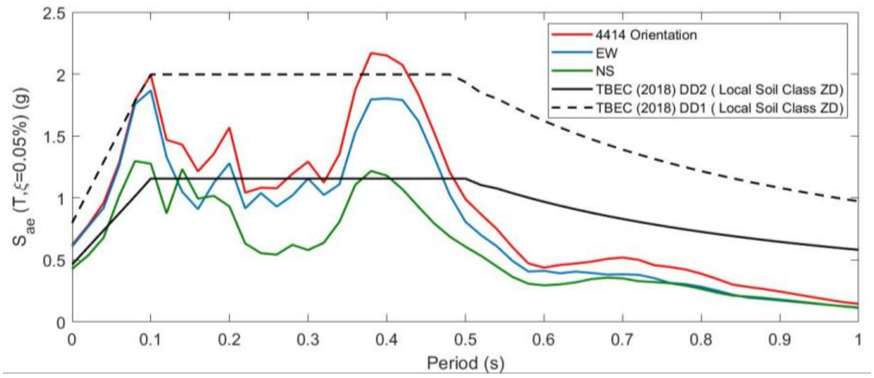

Fig. 7. Acceleration response magnitudes at various periods of acceleration records obtained for each direction from the horizontal direction records of station 4414 a) T=0.1 s, b) T=0.2 s, b) T=0.5 s, b) T=1.0 s for M_w=6.0 Akuşağı-Kale (Malatya) earthquake

The ratio of the acceleration response spectrum obtained depending on the direction to the acceleration response spectrum belonging to the E-W direction was calculated as the minimum 1.01 and the maximum 1.44. When we calculated this ratio for the N-S direction, the minimum was determined as 1.16 and the maximum was determined as 2.23.

5. Conclusions

On October 16, 2024, an earthquake with a moment magnitude of Mw=6 occurred in southeastern Türkiye, with its epicenter near the Kale district of Malatya province. This earthquake was reported as an aftershock of the February 6, 2023 Kahramanmaraş sequential earthquake. First, the tectonics and seismicity of the region were overviewed, and then the earthquake's general features were discussed. The acceleration records of station 4414 (Kale/Malatya), where the highest ground acceleration of the earthquake in the horizontal direction was recorded, were examined in terms of directionality effect. The results obtained are listed below:

- The peak ground acceleration of the earthquake was measured as 0.608 g in the E-W direction and 0.428 g in the N-S direction at station 4414 (Kale/Malatya). When the acceleration record of the station was examined in all directions, the peak ground acceleration value was determined as 0.621 g in the 168° angle with the East direction.
- The peak ground acceleration of the earthquake was measured as 26.88 cm/s in the E-W direction and 17.33 cm/s in the N-S direction at station 4414 (Kale/Malatya). When the acceleration record of the station was examined in all directions, the peak ground acceleration value was determined as 0.621 g in the 30° angle with the East direction.
- When the response spectra of the acceleration records of station 4414 (Kale/Malatya) obtained in all directions were examined, it was generally obtained in a direction different from the E-W and N-S directions in all periods (T=0.02-1.00 s). However, it was observed that in some directions in short-period values, the spectral acceleration values of TBEC (2018) DD2 exceeded and even approached the spectral values of TBEC (2018) DD1.
- The ratio of the acceleration response spectrum, depending on the direction, to the horizontal directions' (E-W and N-S) acceleration response spectra was calculated as a minimum of 1.01 and a maximum of 2.23. These ratios show the importance of the direction effect.
- When we look at the acceleration data from earthquake station number 4414 regarding directional effects, we found that although there was no major difference in the PGA and PGV values, the directional effect was clearly seen in the acceleration response spectra.

Abstract. The damages of the 2023 Kahramanmaraş Earthquakes are modeled through various supervised and unsupervised machine learning techniques by variables ground condition parameters, including Vs_{30}, engineering bedrock depth (EBd), predominant frequency (f_0), horizontal to vertical spectral ratio value (A_0). The supervised approaches achieved recall scores of 94% for damage conditions and 92% for no-damage conditions under optimal circumstances, with an overall damage status prediction accuracy of 93%. The minimum observed accuracy for supervised methods was 80%. In comparison, unsupervised methods demonstrated a maximum accuracy of 90%, with a minimum accuracy of 86%. The outcomes definitively designate EBd as the most crucial parameter to its role in building damage occurrence within the study area. In contrast, significance values were determined as 24%, 18%, and 6% for f_0, Vs_{30} and A_0 respectively in supervised cases. Among the parameters, the EBd and f_0 demonstrate the ability to establish a discernible demarcation by manifesting distinguishable clustering patterns in unsupervised methods. These findings underscore the importance of demonstrating that initial damage estimation in high seismic hazard zones can be effectively carried out using machine learning approaches through seismic-based local site parameters.

1. Introduction

Urban regions located in seismically active zones face a growing need for resilient infrastructure, particularly as population densities rise and previously unexamined building stocks age under outdated regulations. While modern seismic codes such as Eurocode 8 (EN, 2004), NEHRP (BSSC, 2020), and TBDY (AFAD, 2018) guide the construction of new buildings, many existing structures remain vulnerable due to poor design, material degradation, or suboptimal local site conditions. These vulnerabilities are typically revealed during strong earthquakes, where soil-structure interaction plays a pivotal role in the extent and spatial distribution of structural damage.

From a seismic risk assessment standpoint, damage can be interpreted as a manifestation of structural frailty and site-specific amplification effects triggered by earthquakes of varying intensities (Tien et al., 2012; Brando et al., 2020). Thus, estimating building damage necessitates consideration of both structural characteristics and geotechnical site parameters, such as Vs_{30}, f_0 (fundamental frequency), A_0 (HVSR ratio), and engineering bedrock depth (EBd or VsD_{760}) (Mori et al., 2020; Pontrelli et al., 2023; Petrescu et al., 2023). While traditional vulnerability assessments rely on rule-based frameworks like EMS98, FEMA P-154, and JBDPA, these methods require comprehensive in-situ data and may not effectively capture nonlinear interactions or spatial damage patterns, especially in large-scale applications (Rainer et al., 1993; FEMA, 2015; Aydogdu et al., 2023).

Recent advances in machine learning (ML) offer complementary pathways for seismic risk evaluation through both supervised and unsupervised approaches. Supervised algorithms (e.g., Random Forest, SVM, MLP, Logistic Regression) can be trained to estimate damage grades by learning from labeled datasets containing post-earthquake damage outcomes and associated geotechnical parameters. Such models not only identify the dominant features influencing structural failure but also facilitate early damage prediction in regions lacking detailed structural inventories by extrapolating from available site data (Harirchian et al., 2021; Zhang et al.,

*Corresponding author, E-mail: mustafasenkaya@uludag.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_986

2023a). Conversely, unsupervised learning techniques—particularly clustering algorithms—enable the discovery of latent patterns in seismic site behavior without requiring predefined labels. This is especially beneficial for regional-scale assessments where uniform construction practices may lead to similar structural behavior under shared geotechnical conditions (Meyers-Angulo et al., 2023; Chiaradonna et al., 2023).

This study adopts a hybrid methodology integrating both supervised and unsupervised machine learning strategies to evaluate building damage resulting from the Mw 7.8 Pazarcık and Mw 7.5 Elbistan earthquakes that struck southeastern Türkiye on February 6, 2023. These twin events caused catastrophic losses across eleven provinces, with Hatay, Kahramanmaraş, and Gaziantep experiencing especially severe impacts (Görüm et al., 2023; Mavroulis et al., 2023). In the supervised modeling phase, various ML classifiers are trained on damage data correlated with seismic site parameters obtained from AFAD strong-motion stations and the Turkish Damage Assessment Inquiry system. In parallel, unsupervised clustering techniques are employed to group sites based solely on their seismic characteristics, enabling the exploration of potential site-induced damage patterns and their implications for future regional risk assessments.

Through the combined application of supervised and unsupervised modeling techniques, the proposed framework not only enables accurate and scalable damage prediction but also enhances understanding of the complex interplay between local soil conditions and structural performance. This dual approach is particularly suited for informing pre-earthquake risk mitigation strategies and supports the development of efficient, data-driven policies for urban resilience planning in earthquake-prone regions.

2. Data collection and pre-processing

The dataset comprises input parameters, Vs_{30}, f_0, A_0, and EBd, which represent localized site conditions, with damage status serving as the target variable (Table 1). The site condition parameters were derived from the TADAS database (https://tadas.afad.gov.tr/), which provides seismic datasets for the AFAD stations considered in this study (AFAD, 2024). This repository includes multichannel active/passive surface wave data and microtremor measurements acquired directly at the station locations by AFAD teams.

The Vs_{30} parameter, indicating the average shear wave velocity in the upper 30 meters, was primarily derived from 1D Vs-depth profiles obtained through inversion of dispersion curves (Park et al., 1999). Parameters f_0 and A_0 correspond to the site's fundamental frequency and amplitude of the Horizontal-to-Vertical Spectral Ratio (HVSR), respectively. These were obtained by analyzing microtremor data using the HVSR method (Nakamura, 1989), based on the observation that the spectral ratio of horizontal to vertical components of ambient seismic noise. The resulting HVSR curves help determine dominant subsurface frequencies (f_0) and presents an aspect for impedance contrast of layered sub-surface (A_0). The EBd parameter, indicative of deeper subsurface characteristics, is best captured through extended Vs-depth profiles—especially in areas with deep sedimentary deposits. In this study, EBd values were estimated from inversion of HVSR curve (Piña-Flores et al., 2017).

The damage status for each AFAD station location was determined by assessing the condition of neighboring structures according to the EMS-98 damage scale (Grünthal et al., 1998). This scale categorizes structural damage from DG0 (no damage) to DG5 (total collapse), and accounts for differences in structural typologies such as masonry and reinforced concrete (Aktas et al., 2022; Whitworth et al., 2022). Data on adjacent buildings surrounding each station were retrieved from the official Damage Assessment Inquiry System managed by the Ministry of Environment, Urbanization, and Climate Change of Türkiye (https://hasartespit.csb.gov.tr/). In this study, a location was labeled as "Damage" if at least 50% of the buildings in adjacent directions had a DG3 or higher rating, signifying moderate to severe structural damage. Conversely, the "No-Damage" label was assigned if at least 50% of neighboring structures were classified as DG2 or lower, indicating minor or no structural damage.

Exploratory Data Analysis (EDA), introduced by Tukey (1977), is essential for detecting outliers and unwanted patterns, serving as the first step in any data analysis (Páez and Boisjoly, 2022). An initial check revealed no missing data. Additionally, feature reduction was applied during the preparation of input parameters. As a result, Station ID, longitude, and latitude from Table 1 were excluded, as they are not used in the FCM and SC methods.

Following the removal of irrelevant features, normalization was performed to ensure all parameters shared a consistent scale. This helps reduce model bias and accelerates learning by stabilizing internal variable behavior (Singh and Singh, 2020). The process employed the MinMaxScaler function from Scikit-learn, which maintains similarity between data points and is especially suitable for distance-based algorithms like clustering (Cao et al., 2016).

Table 1. The details of dataset

Location ID	Station Number	Longitude	Latitude	f_0 (Hz)	A_0	Vs_{30} (m/s)	VsD_{760} (m)	Building damage status

Before modeling, input correlations were examined using Spearman's rank correlation via Seaborn's heatmap. This nonparametric measure assesses variable relationships without assuming linearity (Zhang and Wang, 2023). Fig. 1 displays these correlations, independent of clustering or accuracy. A value of 1 indicates strong positive correlation, -1 indicates strong negative. Highly correlated variables often contain redundant information, allowing one to be removed without affecting clustering outcomes (Yu and Liu, 2004). Determining a correlation threshold is critical in feature selection and often informed by prior studies. A threshold of ±0.85 was chosen here to retain as many features as possible given the dataset's limited size (Gu et al., 2019; Ozsagir et al., 2022). However, no variables exceeded this threshold, with the highest correlation being -0.82 between VsD_{760} and f_0, so no further reduction was required.

3. Methods

During modeling two unsupervised, Fuzzy C-means (FCM) and Spectral Clustering (SC), and three supervised, Random Forest (RF), K-nearest Neighbor (KNN) and Stochastic Gradient Descent (SGD), methods were employed. Also, performance metrics were determined through several well-known criteria based on the confusion matrix, including accuracy, precision, recall, and f-score.

FCM algorithm is an unsupervised clustering method rooted in fuzzy logic, which allows each data point to belong to multiple clusters with varying degrees of membership (Nayak et al., 2015). Unlike hard clustering methods that assign each point to a single cluster, FCM assigns soft membership values, enabling a more nuanced classification. The algorithm minimizes an objective function based on the Euclidean distance between data points and cluster centers, iteratively updating membership values and centers until convergence (Li et al., 2018; Naghi et al., 2023). These updates are conducted through defined equations involving Lagrange multipliers. FCM was implemented using the cluster.cmeans function from the Scikit-Fuzzy library. The iterative process continues until either a minimum objective function value is achieved or changes in membership fall below a set threshold (Hashemi et al., 2023).

SC is a graph-based clustering algorithm that identifies clusters using the eigenvalues and eigenvectors of a similarity matrix derived from the dataset (von Luxburg, 2007; Lee et al., 2022). The method begins by constructing a similarity graph and computing its unnormalized Laplacian matrix. It then solves the generalized eigenvalue problem to extract the top eigenvectors, which serve as a reduced representation of the data. These vectors are then clustered using the k-means algorithm, enabling the identification of complex, non-linearly separable patterns (Shi and Malik, 2000). SC was applied using the SpectralClustering function from the Scikit-learn library, making it especially suitable for data with intricate relationships not easily captured by traditional distance-based methods.

RF is an ensemble learning method that constructs multiple decision trees during training and aggregates their outputs, typically via majority voting, to make final predictions (Breiman, 2001). This approach reduces the risk of overfitting associated with individual decision trees by leveraging their independence and diversity. Unlike boosting methods, Random Forest doesn't sequentially modify the training set but instead introduces randomness through feature selection and data sampling. Its robust performance in classification tasks, especially on small datasets, has been demonstrated in various studies (Li et al., 2022; Luan et al., 2020). A positive correlation between the trees tends to enhance the algorithm's accuracy further (Chang et al., 2023).

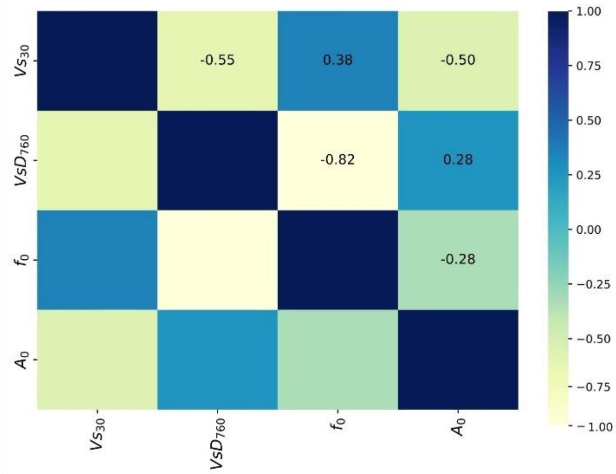

Fig. 1. The correlation relationship among the input parameters

KNN is a non-parametric and instance-based learning algorithm, often referred to as a lazy learner since it doesn't build a model explicitly but classifies based on the proximity of training samples. The classification of a new instance is determined by the majority class among its 'k' closest neighbors (Cover & Hart, 1967). Its appeal lies in the intuitive statistical relationship it forms between observed and target classes and its flexibility in handling data without assuming any prior distribution (Belattmania et al., 2023).

SGD is an optimization technique frequently used in training large-scale machine learning models. Unlike traditional gradient descent, which processes the entire dataset per iteration, SGD updates model parameters incrementally using one data point at a time, making it computationally efficient for online learning (Sharma, 2018). Its effectiveness depends on appropriate learning rates and convergence criteria to avoid overfitting and ensure stable learning.

4. Results

Performance of learning algorithms are given in Table 2. The RF model achieved the highest test accuracy during cross-validation, recording a value of 0.90, alongside a training accuracy of 0.97. It also exhibited strong performance across additional evaluation metrics, including precision, recall, and F1-score. Notably, the precision values for the 'No Damage' and 'Damage' classes were 0.89 and 0.96, respectively, suggesting a low rate of false positives. Similarly, the recall scores—reflecting the model's capability to identify true positives—were also high, with 0.94 for the 'No Damage' class and 0.92 for the 'Damage' class. The balanced F1-scores further underscore the model's ability to maintain an effective trade-off between precision and recall, thereby affirming its robustness in classifying both damaged and undamaged cases. Although a slight decrease in accuracy was observed on the test set, the RF model maintained strong and consistent performance across all major evaluation metrics. In contrast, while the KNN model demonstrated consistent and balanced accuracies on both the training and test sets, the SGD model showed a marked decline in precision and recall for the 'Damage' class, despite achieving moderate overall accuracy.

The relative importance of each feature in predicting building damage is quantitatively assessed and presented in Fig. 2, with the Random Forest (RF) model identified as the most effective classifier. Among the evaluated parameters, EBd emerged as the most influential, accounting for approximately 52% of the total feature importance in relation to building damage within the study area. In comparison, the features f_0, Vs_{30} and A_0 contributed 24%, 18%, and 6%, respectively. These findings highlight the dominant role of EBd in damage prediction and reinforce its critical significance in assessing structural vulnerability.

Table 2. Performance metrics of supervised learning algorithms

	Accuracy			Precision		Recall		F1-score	
	Train	Test	All	No Damage	Damage	No Damage	Damage	No Damage	Damage
RF	0.97	0.90	0.93	0.89	0.96	0.94	0.92	0.92	0.94
KNN	0.97	0.89	0.91	0.89	0.92	0.89	0.92	0.89	0.92
SGD	0.91	0.89	0.93	0.84	0.92	0.89	0.88	0.86	0.90

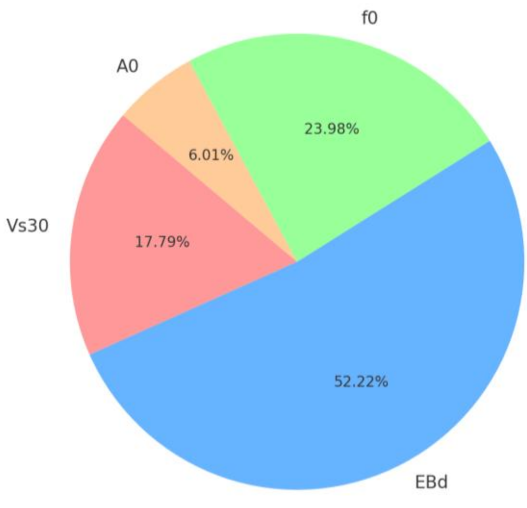

Fig. 2. Importance of features for the best classifier (RF)

Fig. 3a and 3b illustrate the performance of the Fuzzy C-Means (FCM) and Spectral Clustering (SC) methods, respectively, through confusion matrices that highlight the number of correct and incorrect predictions. The FCM approach demonstrates a relatively higher classification accuracy for the "No Damage" class, with only 2 misclassifications out of 18 instances. In contrast, the SC method registers 4 misclassifications for the same class. Both clustering methods yield identical performance in identifying the "Damage" class, correctly classifying 24 out of 26 cases. These results suggest that while both methods are comparably effective in detecting damaged structures, FCM offers a slight advantage in accurately identifying undamaged cases.

Table 3 summarizes the overall performance metrics for the Fuzzy C-Means (FCM) and Spectral Clustering (SC) algorithms. The FCM method outperforms SC in overall classification accuracy, achieving 90% compared to SC's 86%. In terms of specificity, which reflects the ability to correctly classify negative instances, FCM attains 88%, whereas SC demonstrates a slightly lower value of 77%. The precision metric, indicative of the correctness of positive predictions, is markedly high for FCM at 92%, surpassing SC's 85%. Both algorithms exhibit a strong recall rate of 92%, indicating effective identification of true positive instances. Furthermore, the F1 score, which provides a harmonic balance between precision and recall, is highest for FCM at 92%, with SC following at 88%. These results collectively underscore the superior performance of the FCM algorithm in unsupervised classification tasks within the given context.

5. Conclusions

This study presents an integrated approach to assessing the seismic vulnerability of structures by employing both supervised and unsupervised machine learning (ML) techniques, using local seismic parameters such as Vs_{30}, f_0, A_0, and EBd. Data collected from 44 locations affected by the February 2023 earthquakes in Hatay, Kahramanmaraş, and Gaziantep were analyzed to establish correlations between ground conditions and observed structural damage.

In the supervised learning framework, Random Forest (RF), K-Nearest Neighbors (KNN), and Stochastic Gradient Descent (SGD) classifiers were evaluated using five-fold cross-validation to mitigate overfitting from the limited dataset. Among these, the RF model demonstrated the highest predictive accuracy (93%) and exhibited strong performance across all key evaluation metrics. Feature importance analysis identified EBd as the most influential parameter (52%), followed by f_0, Vs_{30}, and A_0, highlighting the practical significance of seismic site parameters in damage prediction. Particularly, the ease of acquiring f_0 and EBd through microtremor measurements makes them valuable for conducting large-scale vulnerability assessments.

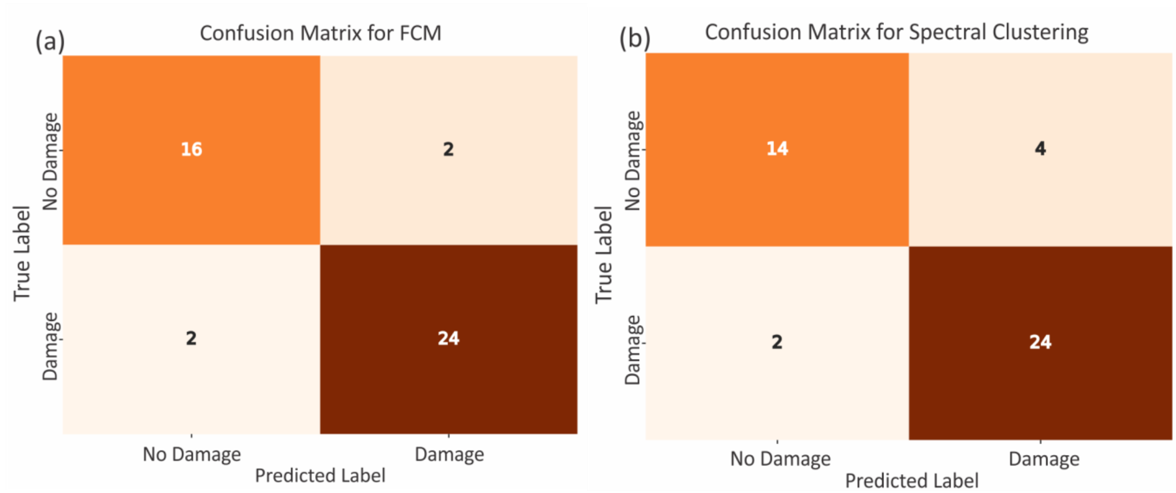

Fig. 3. a) and b) confusion matrix for FCM and SC

Table 3. Performance metrics of unsupersived algorithms

	FCM	SC
Accuracy	0.90	0.86
Specificity	0.88	0.77
Precision	0.92	0.85
Recall	0.92	0.92
F1Score	0.92	0.88

In parallel, unsupervised learning methods—specifically Fuzzy C-Means (FCM) and Spectral Clustering (SC)—were applied to identify damage patterns without the need for detailed structural information. Both clustering algorithms achieved high levels of agreement with observed damage states, correctly identifying 38 out of 44 sites. ROC-based evaluations indicated an average accuracy of 91%, reinforcing the potential of these techniques for pre-earthquake damage prediction using only seismic site parameters.

The dual application of supervised and unsupervised models demonstrates a robust, scalable framework for seismic risk assessment. These methods enable efficient prioritization of at-risk areas and can support decision-making in other regions with comparable seismic hazards and geological settings—such as Bursa, Sakarya, Adapazarı, and Erzincan. The approach also offers a cost-effective alternative to conventional assessments, optimizing time and resource allocation in both regional planning and emergency preparedness.

Abstract. In the analysis of structural systems, it is traditionally assumed that the structure founds on an undeformable rigid base and the interaction between the structure and the foundation/soil system is neglected. This approach may not be valid for the structures built on the soils (clay, sand, weathered rocks, etc.) other than the rigid rock soils depending on the structural properties. The importance of the soil-structure interaction (SSI) effects on buildings under seismic loading has been shown in many studies. Furthermore, the slenderness of the structure, its dimensions, the building material and the variation of the mechanical properties of the soil reveal significant differences in the dynamic responses of the structure. In this study, the SSI effects on the seismic response of an 8-story building structure are evaluated for different subsoil conditions. The SSI is considered through massless foundation approach. First, the finite element models of the considered structure with fixed and flexible bases are created using ANSYS software. Then, the analytical models of the structure with fixed and flexible bases are constituted, and the modal periods of the numerical and analytical systems are compared. Finally, the time history analyses of the SSI systems are carried out through numerical models, and the computed lateral displacements and stresses are discussed. The results show that the soil properties have a significant effect on the time-dependent responses under earthquake loads, and the SSI effects should not be ignored in the seismic design.

Keywords: Analytical model; Ansys; Finite element model; Seismic response; Soil-structure interaction

1. Introduction

In structural analysis, buildings are often assumed to rest on a rigid soil that does not change shape. However, this approach may not be valid, especially for structures located on soft or medium-hard soils (e.g. clay, sand or weathered rock). In reality, the interaction between the structure and the foundation soil - the soil-structure interaction (SSI) - can significantly affect the behavior of the structure during dynamic events such as earthquakes. Therefore, ignoring the effects of SSI can lead to inadequate assessment of structure performance and potential safety issues. As well as the geometrical characteristics of the structure (height, slenderness ratio, dimensions) and material diversity, the mechanical properties of the soil directly affect the dynamic response. These effects become evident in basic parameters such as the period of natural vibration, the amount of horizontal displacement and internal stress distributions. Neglecting SSI in seismic design may lead to underestimation of displacement and internal force values, thus jeopardizing the safety of the structure against earthquakes.

Many studies on SSI in the literature have investigated the effects of this interaction on the behavior of the structure under different scenarios. For example, Menglin et al. (2011) investigated the effects of SSI in adjacent buildings in depth and summarized the research on this topic with its historical development. Li et al. (2011) determined the dynamic parameters of the soil-structure interaction system by means of shaking table tests performed under hard soil conditions. The results showed a strong agreement between numerical modeling and experimental data and demonstrated that this approach can be reliably used in SSI analysis. Jaya et al. (2012) analyzed the dynamic response of deeply buried chimneys and showed that the peak acceleration and displacement values decrease as the depth of burial increases. Priyanka et al. (2012) evaluated the seismic response of multistory buildings under different soil conditions. Roesset (2013) reviewed the early work on SSI and discussed the debates and developments, especially in the seismic design of nuclear power plants. The advantages of direct and substructure approaches, the evolution of dynamic foundation stiffnesses and the effects of inertial and kinematic interactions on structural response are discussed in detail. Cakir (2014) analyzed the flexibility of anchored retaining walls and the effect of soil type on seismic behavior using three-dimensional finite element models. Masaeli et al. (2015) revealed that SSI has significant effects on the seismic performance of thin and tall buildings.

Yeganeh et al. (2015) evaluated the behavior of tall buildings adjacent to deep excavation areas under earthquake effects in the context of SSI. As a result of the analyses performed with FLAC2D software, significant differences between static and dynamic responses were observed, indicating that SSI plays a significant role in the structural response. Li et al. (2017) investigated the collision effects in the context of structural soil-structure-ground interaction (SSSI) in adjacent buildings using ANSYS software and found that this interaction increases the collision severity. The study also found that the building spacing prescribed in Chinese standards is generally inadequate for such interactions. Mortezaie and Rezaie (2018) developed a three-dimensional performance-based plastic design (PBPD) approach for high-rise reinforced concrete structures considering SSI effects. The results show that the mechanical properties of the soil play a decisive role in the dynamic behavior of the structure. Gao et al. (2020) confirmed that the response spectrum method (RSM) is effective in evaluating the effects of SSI in their analysis of structures with shallow foundations and emphasized that the interaction between horizontal motion and rocking is a critical factor, especially in tall buildings located on soft soils. Scarfone et al. (2020) performed three-dimensional, nonlinear dynamic analyses to evaluate the effects of SSI in high-rise buildings. As a result of these analyses, it was determined that foundation deformation reduces the base shear forces, but does not make a significant difference on the displacements. Similarly, Bahuguna and Firoj (2021) investigated the nonlinear seismic behavior of nuclear structures with SSI and concrete damage plasticity (CDP) model and showed that buried foundations provide significant reductions in moment and displacement demands. Gao et al. (2021) proposed a generalized response spectrum method using viscous-spring artificial boundaries (VSAB) to improve the accuracy of seismic analysis for underground structures. Kamal and Inel (2021) analyzed the relationship between ground motion parameters and displacement demands by considering SSI effects in mid-rise reinforced concrete buildings and found that velocity-based parameters such as Housner Intensity (HI) can reliably represent the potential for structural damage. Ozgur and Bozdogan (2022) investigated the effects of SSI on period elongation and seismic design parameters of reinforced concrete buildings and showed that the seismic performance of rigid structures changes significantly under soft ground conditions. Araz et al. (2022) evaluated the effect of frequency content on tuned mass dampers (TMD) in multistory buildings and found that these parameters vary significantly with frequency content. Similarly, Araz (2022) developed an optimization strategy for TMDI systems used in high-rise buildings by considering SSI effects. Bapir et al. (2023) presented a comprehensive literature review on SSI modeling techniques and their effects on seismic response of the structure and emphasized that SSI should be considered in engineering design processes. Araz et al. (2023) investigated the effect of foundation embedment depth and soil properties on the optimum TMD design and revealed that these two parameters significantly affect the damper performance. Rostami Heshmat Abad et al. (2024) analyzed the effect of SSI on the torsional behavior of asymmetric steel moment frame structures resting on masonry-raft foundation system and showed that SSI causes critical torsional irregularities by increasing the maximum story rotation angles Bapir and Abrahamczyk (2024) compared different simplified SSI modeling techniques and reported that these methods give different results in terms of accuracy and practical applicability. In the same year, Bapir et al. investigated the SSI-induced seismic behavior of reinforced concrete structural systems and different foundation sizes and found that the stiffness of the foundation and the type of structure are determinants of the structural response. Vicencio and Alexander (2024) evaluated the Site-City Interaction (SCI) effects between city blocks and showed that this effect can enhance or weaken the structural seismic response depending on building placement and ground resonance. Wang et al. (2024) analyzed the performance of semi-active tunable mass dampers (STMD) under SSI effects in tall buildings and found that these systems provide more effective control compared to conventional TMD systems by simultaneously optimizing frequency and damping ratios. Araz (2025) investigated the effect of SSI parameters on seismic control performance in structures equipped with optimized TMD systems and found that the structure-ground stiffness ratio and structure slenderness ratio significantly affect TMD efficiency. Hwang et al. (2025) investigated the seismic ground pressures on the basement walls of buildings with 1g shake table experiments and observed significant differences in the distribution of these pressures depending on the basement stiffness and building height Finally, Ozturk (2025) analyzed the effects of main shock-aftershock sequences on the dynamic behavior of natural gas pipelines in the context of soil-pipe interaction (SNGPI) and showed that the reduction in soil stiffness significantly increases the peak stress and displacement values of pipelines.

This study investigates the seismic behavior of an 8-storey structure under different soil types in the context of SSI. A massless foundation approach is adopted to represent the SSI, and structural models with rigid and flexible foundation conditions are generated using ANSYS software. In addition, analytical models corresponding to these systems are developed and the natural periods obtained are compared by numerical and analytical methods. The horizontal displacement and stress behavior of the structure under seismic effects were evaluated by time domain analysis. The obtained results clearly reveal the determinant role of the soil on the dynamic response and demonstrate once again the necessity of considering SSI effects in seismic design processes.

2. Methodology

2.1. Structure and soil model

In this section, the numerical model for the soil and structure is presented in Fig.1. For the structure, an 8-storey building model with column dimensions of 30x60 cm and beam dimensions of 30x50 cm is considered. The model has a total length of 12 m with 3 spans in x and y directions horizontally and the storey height is 3 m. The compressive strength, modulus of elasticity, Poisson's ratio and unit density values of all structural elements are 25 MPa, 30GPa, 0.2 and 2500 kg/m3 respectively. The dimensions of the soil medium affect the modal properties and dynamic response of the soil-structure system. The dimensions of the numerical model for the soil were chosen seven times (84 m) the width of the structure in the x-y direction horizontally and three times (36 m) in the z-direction vertically, considering the studies in the literature (Rayhani and El Naggar, 2008; Torabi and Rayhani, 2014; Kabtamu et al., 2018). The selected soil properties are given in Table 1. The numerical models were obtained with ANSYS software (ANSYS, 2015) using 3D finite elements. SOLID45 and SOLID65 element types were used for the soil and structure, respectively. The SOLID45 element type including plasticity, creep, swelling, strain hardening, and large deformations. On the other hand, the SOLID65 element is specifically designed to model concrete materials, with features that allow it to simulate cracking under tension and crushing under compression, even without reinforcement.

Table 1. The properties of the soil material

Soil type	E (N/m^2)	G (N/m^2)	v	ρ (kg/m^3)	v_s (m/sn)	v_p (m/sn)
S1	3.00 x 10^8	11 x 10^7	0.35	1900	241.83	503.40
S2	1.50 x 10^8	5.56 x 10^7	0.35	1900	171.00	355.96
S3	0.75 x 10^8	2.68 x 10^7	0.40	1800	121.99	298.81

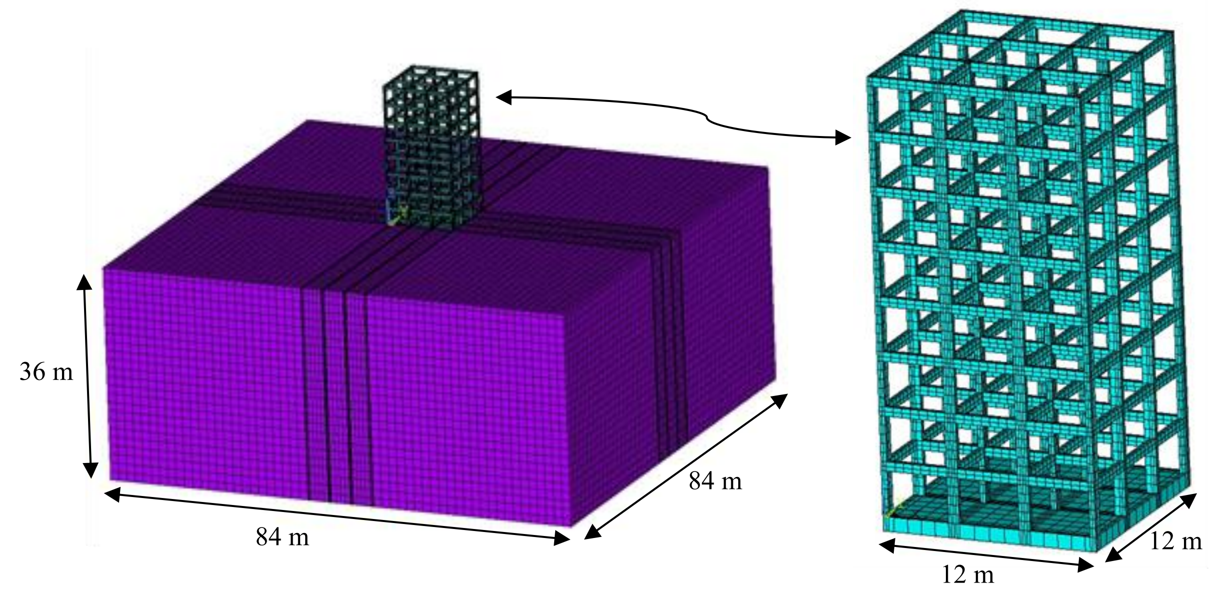

Fig. 1. Numerical model for SSI

The modes with higher modal participation factors have a greater influence on the structural response (Cakir and Livaoglu, 2013) Table 2 presents the first three natural periods, selected based on effective modal masses, for both fixed-base and flexible-base conditions. As shown in the table, SSI leads to an increase in the natural periods, with the longest periods observed in structures founded on S3 soil type.

Table 2. The periods of the structural system (s)

Soil type / Model	Fixed	S1	S2	S3
1	0.71	0.76	0.80	0.87
2	0.24	0.24	0.24	0.25
3	0.14	0.14	0.14	0.15

2.2. Analytical solutions and comparison of modal analysis results

In this section, the modal analysis results obtained from the numerical models are evaluated by comparing them with the results of the proposed analytical models. The analytical model equations, called F-1, are given below (Eqs. 1-4).

$$M\ddot{x}(t) + Kx(t) = f(t) \tag{1}$$

Here, M denotes the mass matrix and K represents the stiffness matrix. The vector $f(t)$ corresponds to the external force applied to the system, while $x(t)$ denotes the displacement vector describing the system's response over time.

$$M = \begin{bmatrix} m_1 & & & & m_1 & m_1 z_1 \\ & m_2 & & & m_2 & m_2 z_2 \\ & & \ddots & & \vdots & \vdots \\ & & & m_N & m_N & m_N z_N \\ m_1 & m_2 & \cdots & m_N & m_0 + \sum_{i=1}^{N} m_i & \sum_{i=1}^{N} m_i z_i \\ m_1 z_1 & m_2 z_2 & \cdots & m_N z_N & \sum_{i=1}^{N} m_i z_i & \sum_{i=1}^{N} (m_i z_i^2 + I_i) + I_0 \end{bmatrix} \tag{2}$$

$$K = \begin{bmatrix} k_1 + k_2 & -k_2 & 0 & 0 & 0 & 0 \\ -k_2 & k_2 + k_3 & -k_3 & \cdots & 0 & 0 \\ & \cdots & \cdots & \cdots & \cdots & \cdots \\ sym & & -k_N & k_N & 0 & 0 \\ 0 & 0 & \cdots & 0 & k_s & 0 \\ 0 & 0 & \cdots & 0 & 0 & k_r \end{bmatrix} \tag{3}$$

$$x(t) = \begin{bmatrix} x_1 & x_2 & \cdots & x_N & x_0 & x_\theta \end{bmatrix}^T \tag{4}$$

Eqs. (2–4) define the parameters m_i, k_i, I_i, and as the mass, lateral stiffness, mass moment of inertia, and lateral displacement of the ith story, respectively. The foundation is characterized by its mass m_0 and mass moment of inertia I_0. The SSI is represented through the swaying stiffness k_s and rocking stiffness k_r of the supporting soil. Furthermore, x_0 and x_θ denote the horizontal displacement and rotational degree of freedom of the foundation, respectively.

The soil parameters associated with a rigid square foundation are determined using Eq. (5) (Wolf, 1994). In this context, G and v represent the shear modulus and Poisson's ratio of the soil, respectively. The terms A_0 and I_{0b} denote the contact area and the mass moment of inertia of the foundation about its side b. Parameters a and b correspond to half the width and half the length of the foundation, respectively.

$$k_s = \frac{2Ga}{2-v}\left[2 + 2.5\left(\frac{A_0}{4a^2}\right)^{0.85}\right], \; k_r = \frac{2.9G}{1-v}\left[I_{0b}^{0.75}\left(\frac{a}{b}\right)^{0.15}\right] \tag{5}$$

In the analytical solution referred to as F-2, the stiffness period of each story, denoted by k_i has been utilized in Eq. (6) to derive the overall lateral stiffness period of the structure, k_x. The rocking stiffness k_r, which varies with the height of the structure, has been reformulated to obtain the modified rotational stiffness k_r'. Subsequently, the equivalent stiffness K_{eqm} has been considered in Eq. (7) to carry out the analytical evaluation.

$$\frac{1}{k_x} = \sum_{i=1}^{N} \frac{1}{k_i} \tag{6}$$

$$k_r' = \frac{k_r}{h_s^2}, \; K_{eqm} = \frac{k_x k_r' k_s}{k_x k_s + k_x k_r' + k_r' k_s} \tag{7}$$

The analytical model equations, called F-3, are given below (Eq. 8).

$$M = \begin{bmatrix} m_s & 0 & 0 & 0 \\ 0 & m_f & 0 & 0 \\ 0 & 0 & I_s + I_f + m_\varphi & 0 \\ 0 & 0 & 0 & m_\theta \end{bmatrix}, \; K = \begin{bmatrix} k_x & -k_x & -k_x h_s & 0 \\ -k_x & k_s + h_s & k_x h_s & 0 \\ -k_x h_s & k_x h_s & k_x h_s^2 + k_r & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{8}$$

Where m_θ is the mass moment of inertia assigned to the rotational degree of freedom. In the case of $v>1/3$, the mass moment of inertia m_φ is added to the rotational degree of freedom, and the value $2v_s$ is taken instead of v_p (Song et al., 2021). v_p and v_s are the dilatational wave velocity and shear wave velocity of soil, respectively.

$$m_\theta = \frac{9}{128}\left[(1-\nu)\pi^2 \rho r^5 \left(\frac{v_p}{v_s}\right)^2\right], \quad m_\varphi = 0.3\left(\nu - \frac{1}{3}\right)\pi \rho r^5 \tag{9}$$

The modal analysis results of the numerical models obtained under fixed and flexible soil conditions are compared with the analytical solutions F-1, F-2, and F-3 in Table 3. When the difference values in Table 3 are examined, they are observed to range between 9.76% and 44.59%. Among the analytical solutions, the F-1 results showed lower differences compared to F-2 and F-3. Additionally, the largest differences were observed in the F-2 analytical solution.

Table.3. Comparison of first mode periods fixed and flexible base structures (s)

3. The SSI system responses

For the evaluation of displacement and acceleration responses in the numerically modeled eight-story soil-structure system, nodes have been selected at each floor level along the exterior face of the building. Additionally, for the assessment of stress response, a node located at the beam–column that recognized as a structurally critical region, has been selected for analysis (Fig. 2).

The 1999 Düzce Earthquake is selected for SSI. The earthquake component is DUZCE/BOL000, station is Bolu, magnitude is 7.1 and PGA is 0.739 g.

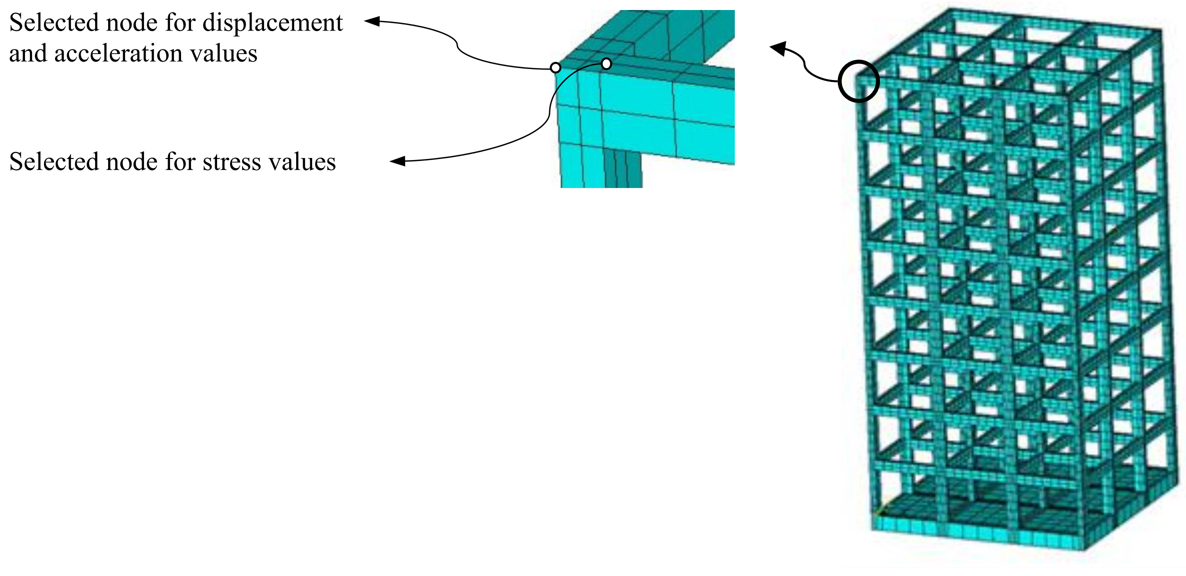

Fig. 2. Selected nodes on the structures for dynamic responses

Peak values of displacement, stress and acceleration dynamic responses depending over height and soil type are given in Table 4-6. As shown in Table 4, peak displacement values obtained under the effect of the Düzce earthquake are compared based on different floor levels and soil types. These displacement values are evaluated relatively, taking the bottom level of the foundation as the reference point. It is observed that the peak displacement values and their occurrence times vary depending on the floor level and the type of soil. Table 5 presents the peak stress values corresponding to different floor levels and soil types. When Table 5 is examined, it is observed that the stress values occur under both tensile and compressive effects. Similarly, Table 6 provides the peak acceleration values for various floor levels and soil types. A more detailed comparison of these findings is provided in Section 3.1.

3.1. Height-dependent variation of dynamic responses

In Fig. 3, the lateral displacement values of an eight-storey building at different floor levels under the effect of Düzce earthquake are presented comparatively for four different soil types (Fixed, S1, S2, S3). It is observed that the displacement values increase with the number of storeys for all soil types. The fixed base has the lowest lateral displacement values at all floor levels. It is observed that the structure is subjected to larger displacement values in soil types S1, S2 and especially S3. From soil type S1 to S3, the displacement values at the top floors increase significantly.

In Fig. 4, the stress values of an eight-storey building at different floor levels under the effect of Düzce earthquake are presented comparatively for four different soil types (Fixed, S1, S2, S3). Stress values reach a maximum at the second storey levels and show a decreasing trend towards the top of the structure. The highest stress values (see Table 4) were obtained for soil types S1, Fixed, S2 and S3 in descending order. This clearly shows the effect of soil properties on the internal forces in the structure.

In Fig. 5, the acceleration values of an eight-storey building at different floor levels under the effect of Düzce earthquake are presented comparatively for four different soil types (Fixed, S1, S2, S3). In general, it is observed that the acceleration values increase with the number of storeys. It is observed that the acceleration values obtained for S1 and S2 soil types follow a course very close to the fixed base condition. S3 soil type exhibited a different behavior: During the first four stories, the highest acceleration values were observed in the S3 soil, but after this level, the acceleration values decreased and reached the lowest level compared to all other soil types, especially at the eighth storey. At the top storey level, the highest acceleration value was obtained for the fixed base condition and the lowest acceleration value was obtained for the S3 soil. This indicates the complex nature of the SSI on the dynamic effects.

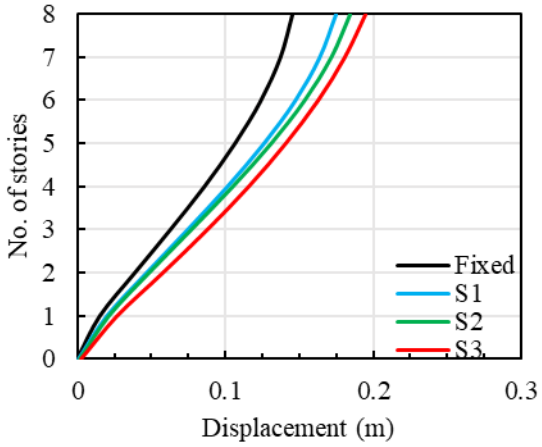

Fig. 3. Displacements depending no. of stories

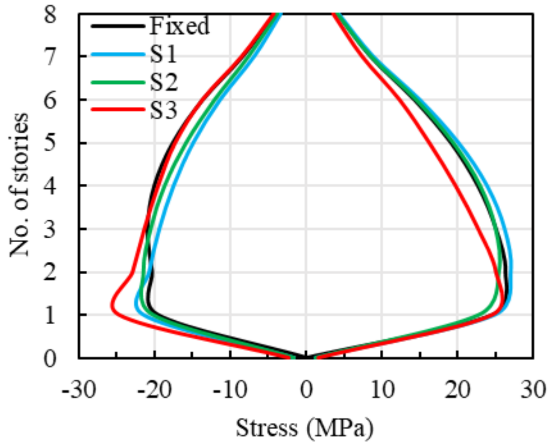

Fig. 4. Stresses depending no. of stories

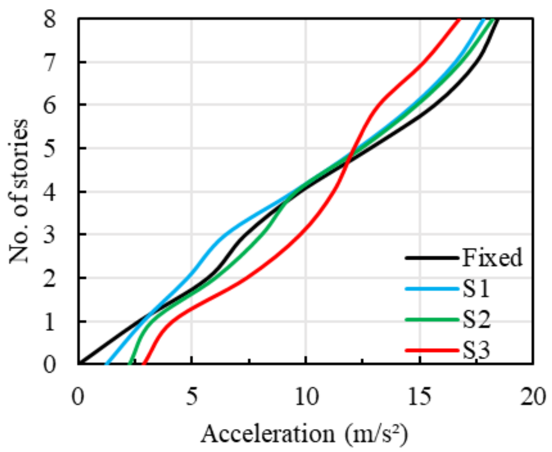

Fig. 5. Accelerations depending no. of stories

3.2. Time-history variation of dynamic responses

In Fig. 6, the peak lateral displacement values of an eight-story building under the effect of Düzce earthquake are presented for four different soil types (Fixed, S1, S2, S3) with time-history comparison. The peak displacement value obtained for the fixed base case is 0.1456 m. Compared to this value, the amount of displacement increased when the SSI was taken into account. For soil S1, this increase was 19.92% and the displacement increased to 0.1746 m. In S2 soil, the displacement increased by 26.72% to 0.1845 m and in S3 soil, the displacement increased by 33.79% to 0.1948 m. As can be seen, the peak displacement values increased as the soil softened. This is evidence that the lateral displacements on the structure are affected by the dynamic properties of the soil.

In Fig. 7, the peak stress values obtained from time-history analysis for the same building model and soil conditions. While the peak stress value was 26.3043 MPa in tensile effect on the fixed base, 26.9928 MPa was obtained in tensile with an increase of 2.62% in S1 soil compared to the fixed base, 25.4576 MPa in tensile with a decrease of 3.22% in S2 soil and 25.0101 MPa in tensile with a decrease of 4.92% in S3 soil. The comparison reveals that stress increases in S1 soil compared to the fixed base, whereas it decreases in S2 and S3 soils. In this case, it is understood that the structure encounters higher internal forces in stiff soils.

Fig. 8 shows, the peak acceleration values of an eight-story building under the effect of Düzce earthquake are presented for four different soil types (Fixed, S1, S2, S3) with time-history comparison. The peak acceleration value obtained under the fixed base condition is 18.4020 m/s². Compared to fixed base, a decrease of 3.27% is observed in S1 soil, resulting in an acceleration of 17.8010 m/s². In S2 soil, the acceleration decreases by 1.18% to 18.1850 m/s², while in S3 soil, a more significant reduction of 8.95% is observed, with an acceleration value of 16.7550 m/s². These outcomes underline the complex influence of SSI on structural dynamics.

4. Conclusions

In this study, an 8-story building was subjected to three-dimensional (3D) numerical analysis for different soil types under the 1999 Düzce Earthquake. Dynamic responses of the structure such as horizontal displacement, stress and acceleration are obtained and SSI effects are evaluated. In addition, the numerical model is subjected to modal analysis and the results obtained are compared with three different analytical solution methods.

- The modal analysis results of the numerical model were compared with three different analytical solution methods (F-1, F-2 and F-3). As a result of this comparison, the F-1 method produced lower natural period values compared to the other two analytical solutions.
- When examining the dynamic response of lateral displacements with respect to the number of stories and soil type, it is observed that the difference between the curves increases as the number of stories rises. This indicates that the effects of SSI become more pronounced with building height. Therefore, soil flexibility must be taken into account, especially in the seismic analysis of mid- and high-rise structures.
- The dynamic response of stresses reaches peak values particularly at the lower story levels, especially around the second story. Throughout the building height, the stress distribution varies depending on the soil type in both tension and compression directions. In tension, the S1 soil type is dominant, whereas in compression, the S3 soil type plays a more significant role.
- The dynamic response of accelerations generally exhibits an increasing trend along the building height. While acceleration growth is relatively steady in Fixed, S1, and S2 soil types, higher acceleration values are observed in the lower and middle stories for the S3 soil type. This demonstrates that SSI effects significantly alter the acceleration spectrum. Peak acceleration values are achieved at the top story level, particularly for the fixed-base case.
- These evaluations clearly demonstrate that soil properties are too critical to be neglected in engineering projects. Especially in regions with high seismic risk, it is not sufficient to focus solely on the structural system; the dynamic behavior of the soil during an earthquake must also be considered. Analyses based on

a fixed-base assumption often fail to accurately reflect the true seismic performance of a structure, which may compromise its safety. Therefore, accurately modeling the interaction between the structure and the soil, and addressing it specifically for each project, is essential for achieving safe and resilient designs.

A new approach in the design of mechanically stabilized earth walls, MSE-W

Mustafa Aytekin*[1]

[1] *University of Bahrain, Department of Civl Engineering, 973, Sakher, Kingdom of Bahrain*

Abstract. In this research, it has been focused on the design philosophy of mechanically stabilized earth walls (MSE-W). As a proverb says that very small changes, sometimes can make a huge difference so that a small change on the design philosophy of MSE-W has been made in this study. A correctly designed MSE-W supports itself as a coherent body. The inclusion of reinforcement within the soil tends to restrain the soil deformation which, in turn, increases the strength of the soil and the stability of the composite material. One of the earth reinforcements used in a backfill of MSE-W is the steel strip. These reinforcements are smooth or ribbed steel strips. The streps are placed layer by layer in to the backfill and each layer is compacted. The strips are placed as unidirectional positions. The steel strips are usually galvanized or may be epoxy coated. In this study, the linear unidirectional steel strips are replaced by bidirectional steel strips adding a ninety degree hook at the end of the strips in the backfill. Once the new approach was implimented in to the design procedure, an excel spreadsheet has been developed. Using the excel spreadsheet, many examples of MSE-W have been analized. In the analyses, the amount of reinforcement (galvenized steel strips) is compared with the approach in which, the unidirectional steel strips are used. Because of this small modification on the steel strips, the savings on the reinforcement for a particular MSE-W might be considered as huge. Also, the effect of several design parameters such as unit weight, internal friction angle, vertical space between the strips, etc, and geometry of MSE-W have been investigated and included in the paper.

Keywords: Bidirectional strips; Economical design; MSE-W; MSE-W design spreadsheet

1. Introduction

The use of MSE walls with a height of more than 25m is proliferating worldwide because of increasing restrictions of right of way, wetlands, and other limitations, Stuedlein, et al (2010). Thus, the importance of design and construction of MSE walls is increasing. MSE-W consist of several components. These components are prefabricated moduler units (face units of MSE-W), reinforcement (steel strips, geotextiles and/or geomembranes), drainage fill, backfill (reinforced soil mass), retained soil, leveling pad, subgrade (natural soil), surface load, etc, as seen in Fig. 1. MSE walls are analysed by geotechnical and structural engineering methods. The assumptions that are made in the analyses can be listed as mode of failure, earth pressure theory, ground water and hdroststic pressure, width of reinforced soil mass, the zone of maximum stress for internal stability. A typical model of MSE-W is seen in Fig.1. Some details of coneecting reinforcement and the face elemens are seen in Fig. 2a. The backfill surface could be inclinided too as seen in Fig. 2b, AASHTO (2004). The maximum friction angle used to calculate the horizontal forces in the reinforced soil mass shall be assumed to be 34° unless results from triaxial or direct shear tests methods. AASHTO T 234 (1974), and AASHTO T 236 (1972) specifies a higher friction angle, and it should never be more than 40°, Castellenos, B. A (2010). The usage of steel according to the existing design codes are making that the MSE walls are designed with more steel than what is needed, Castellenos, B. A (2010). In a particular MSE-W design with a height of 46m, it was pointed out that even if the evaluations indicated shorter reinforcing strips length could be considered in many portions of the MSE-W; the AASHTO criterion for minimum length was followed because of the critical nature (46m tall) of the structure, Stuedlein, et all (2010). Also, similar conclusions have been reached in this study. In reference, Castellenos, B. A (2010), the author conducted a MSc. thesis research to reduce the amount of steel bars employed in MSE-W by the current methods. The author has concluded that if crimped steel bars seen in Fig. 3 are used within the backfill as the reinforcement in place of straight steel bars, there would be a big benefit in terms of the volume of reinforcement as seen in Fig. 4.

2. Design procedure of MSE-W

The idea of a mechanically stabilized soil mass is not a new concept. Inserting a non-soil element in to a soil mass to improve the soil properties has been used for thousands of years, Berg, et al (2009). Nowadays, the idea on how MSE walls achieve their strength, in its simplest form, is based on the addition of a soil reinforcement such as steel, high strength plastic grids (geogrids) or woven plastic sheets, to a soil mass. The fill material mechanically stabilized and locked behind the face unit of a MSE-W is called retained backfill Berg, et al (2009). In the design of MSE-W several reinforcement for the backfill are used such as geogrids as described in Almohd et al (2014).

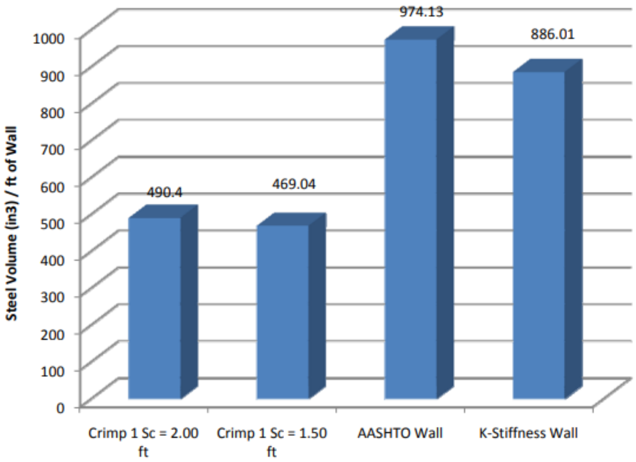

Fig. 4. Comparison of steel volumes needed for the same MSE-W among the AASHTO method, K-Stiffness wall and two different spaces of crimped steels strips, Castellenos (2010)

First of all, a project requirements and parameters must be established like the face panels and their connections with the reinforcement. Second, the embedment depth and the length of the reinforcement are estimated. Finally, internal and external stabilities are evaluated. In this study, it is focused on the estimation of length of the reinforcements which have been considered as inextensible steel strip. Inextensible reinforcement is manufactured from a material that deforms considerably less than the surrounding soil at failure. The required length of staraight steel reinforcements versus the the required length length of ninty degree hooked steel reinforcement. Design Steps can be listed as follows

a. The height (H) of the MSE-W, type of facing unit, leveling pad, properties such as internal friction angle, cohesion, unit weight of backfill material and the natural soil, type and size of reinforcement (in this case, galvinized steel strip), should be determined. Backfill material should be a cohesionles (gravel and/or sand) soil for the drainage purpose.
b. Initial vertical and lateral distances (Sv and SH) between the strips should be selected, later on several iterations can be performed to see the most economical (or optimum) distances.
c. Lateral active earth pressure distribution with depth should be determined as well.
d. Also, additional vertical and lateral earth pressures should be considered if a surface load (q) is applied on the backfill. The distance of surface load to the face unit, shape and size of loaded area, and the intensity of the load (q) should be known.
e. Calculations of L_r and L_e seen in Fig. 5:

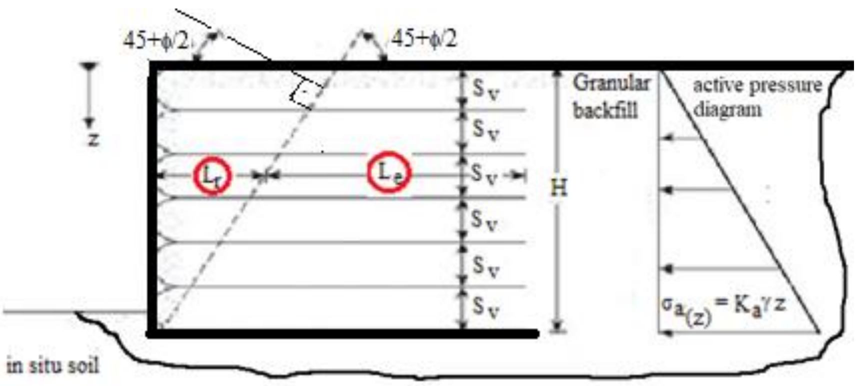

Fig. 5. Elements of a MSE-W

L_r is the length of steel bar within the Rankine failure zone (Fig. 5). Then, Eq.(1) can be written as follows;

$$\tan\left(45+\frac{\varphi}{2}\right)=\frac{L_r}{H-z} \quad (1)$$

Thus,
$$L_r=\frac{H-z}{\tan\left(45+\frac{\varphi}{2}\right)} \quad (2)$$

The applied tension force, T_{app}, to the reinforcement by the face unit of MSE-W due to the active pressure of the backfill at the level under consideration (z) can be writen as follows:

$$T_{app}=\sigma_{a(z)}\, S_H S_V \quad (3)$$

The tension force, T_f, that can be carried by the strip at its failure can be;

$$T_f=A_s f_y' \quad (4)$$

Where A_s, and f_y' are the surface area, and the characterictics yield strength of the steel strip, respectively. L_e is the effective length that will resist the applied force, T_{app}, (pullout force) with the friction between the surrounding backfill material and its surface area.

It is obvious that a safety factor, FS_B, must be considered againt the breaking (failure) of the steel strip. This safety factor is generaly take as 2.5 to 3.0 in practical applications.

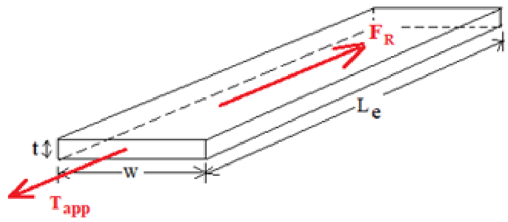

Fig. 6. Dimensions of reinforcement (strip) and forces applied

On the calculation of surface area of the strip, the thickness, t, is ignored mostly since it is tiny compared to the other dimensions. Thus, the frictional force, F_R, can be written as seen in Eq. (5) when there is no hook at end of the strip

$$F_R=2L_e\, w\sigma_{v(z)}tan(\varphi_u) \quad (5)$$

Where w: width, t: thickness, $\sigma_{v(z)}$: vertical effective stress, φ_u: internal friction angle betweenbackfill material and the strip. It can be approximated as $2/3\,\varphi$ To have a safe design friction resistant F_R, must be more than the pull out force of T_{app}. Thus; Eq. (6) must be satisfied:

$$F_R=FS_P\, T_{app} \quad (6)$$

FS_P is the safety factor against pullout. It can be taken as 1.5 to 3. Eq. (3) and Eq. (5) can be placed in Eq. (6) and ended up Eq. (7)

$$L_e=\frac{FS_P\sigma_{a(z)}S_V S_H}{2w\sigma_{v(z)}tan(\varphi_u)} \quad (7)$$

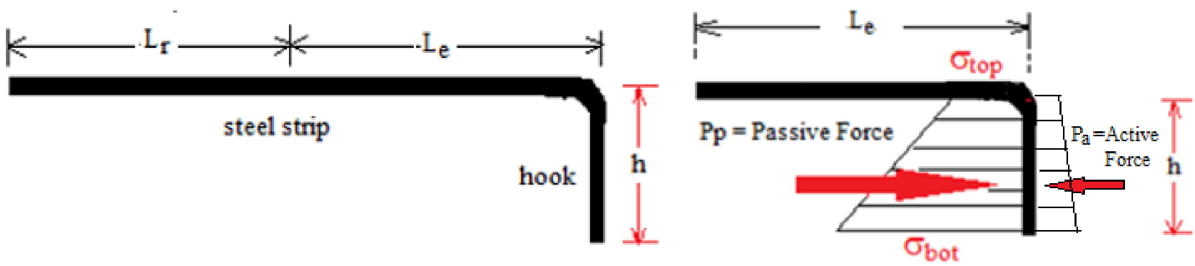
Unlike the strip with no hook at its end, the hooked strip as seen in Fig. 7a should have extra resistance due to the passive force that would be generated in front of the hook as seen in Fig. 7b. The passive force and active force can be determined from these equations:

$$P_p=\frac{h}{2}\left(\sigma_{top(p)}+\sigma_{bot(p)}\right)w \quad (8)$$

$$P_a=\frac{h}{2}\left(\sigma_{top(a)}+\sigma_{bot(a)}\right)w \quad (9)$$

Then, a net force the difference between Eq. (8) and Eq. (9) is considered as the contribution of hook to the polling strength of the strips.

$$P_{net}=P_p-P_a \quad (10)$$



(a) (b)

Fig. 7. (a) Hooked strip (b) Passive pressure distribution with the length of hooked portion

When the hook is employed at the end of strips, the calculation of effective length would be different from the calculation of effective length with no hook. First, the summation of passive net force by Eq. (10) generated in front of the hook plus the surface friction around the effective length must be more than the pullout force, T_{app}, Eq. (3), with a safety factor of FS_P.

$$L_{e-hooked} = \frac{(T_{app}-P_{net})FS_P}{2w\sigma_{v(z)}tan(\varphi_u)} \tag{11}$$

Second, there must be enough bacfill materal shear resistance against the sliding of the strip at the bottom end of the hook.

$$L_{e-hooked-min} = \frac{FS_P\, P_{net}}{w\sigma_{v(z)}tan\,\varphi} \tag{12}$$

Where φ: internal friction angle of backfill material. The highest value of effective length from Eq. (11) and Eq. (12) would be taken as the L_e value. Then, the total length of a strip is determined as the summation of L_e and L_r as seen Eq. (13).

$$L_{total} = L_r + L_e \tag{13}$$

Moreover, there is one point that is requested by some sources that says the bending angle of the strips should not be more than 15 degree, Castellenos (2010).

3. Hypothetical cases

In several hypothetical cases MSE-Walls are considered with the following data and some conclusions have been drown.

- Bacfill internal friction angle, $\varphi = (20 - 25 - 30 - 32 - 34, and\ 42\ degrees)$
- Unit weight of backfill material, $\gamma_b = 16.6kN/m^3$ (constant)
- Height of MSE-W, H=4m, 8m, 16m, and 32m.
- The characteristic yield strength of the steel strip, $f_y' = 240000kN/m^2$
- Factor of safety against pullout, $FS_P = 1.5$
- Factor of safety against break, $FS_B = 1.5$
- Width of the strip, $w = 100mm$
- Thickness of the stript, $t = 5mm$
- Lateral distance between the steel strips, $S_H = 1m$
- Vertical distance between the steel strips, $S_V = 1m$, 0.75m, and 0.50m.

The newly prepared excel spread-sheet that takes into account both strips with no hooks, and with hooks at their ends in the design of MSE-W has been employed on the calculations. As seen in Fig.8, and Table 1, the ratio of the optimum length, h_{opt} of the hook to the vertical distance between the steel strips, S_V, are varying with the internal friction angle of the backfill. However, these values are not affected much by S_v. In this study, the range of the internal friction angle, φ, is taken 20 to 40 degree since in the practical works, the backfill materials for the MSE-W construction must be a granular material with no cohesion. Thus, the author believes that this range of internal friction angle covers the material that would be used in the construction. Fig. 8, shows that there is no significant differebce on $\frac{h_{opt}}{S_V}$ ratio for the values of S_v from 0.5m to 1.0m. Engineers who work in the industry can easily determined the optimum hook length from Fig. 8. Initially, the internal friction angle of the bacfill material should be known. Then, the may select the vertical distance between the layers of reinforcement strips. Finally, they may get the ratio of optmum length of hook to the the vertical distance between the layers of reinforcement strips as a function of the internal friction angle of the backfill material.

In this study, the total length of the steel strips for both with hooks, and without hooks are determined. There is a considerable amount of savings on the total lengths of strips with hook agains the strips with no hooks. As it is seen in Fig. 9, the highest saving will be in low internal friction angles. Then, it would be reduced when the internal friction angles are increased. The highest saving would be 28.38% at $S_V = 1m$, and $\varphi = 20°$ whereas the lowest saving would be 17.19% at $S_V = 0.5m$, and $\varphi = 40°$ for the numerical values used in this study.

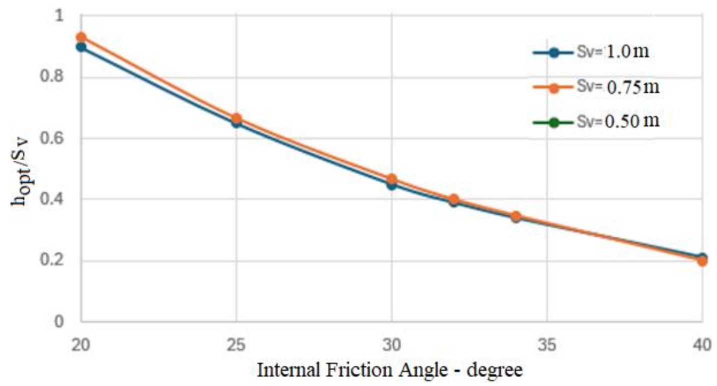


Fig. 8. The variation of optimum hook length to the vertical distance between reinforcement with internal friction angles

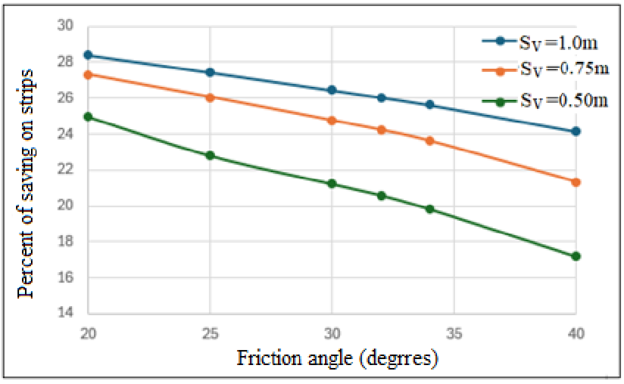

Fig. 9. Percent of savings on reinforcement with internal friction angle

Fig. 10 shows that the height, H, of a MSE-W does not effect significantly the optimum length of the hook at the internal friction angle of more than approximately 30 degree. Ihe smalest length of the hook needed is 20% Sv at an internal friction angle of 40 degree independent on the MSE-W height from 4 m to 32m. On the other hand, when the friction angle is 20 degree, the optimum length of the hook is 76% of Sv at the height of the wall is 4m. wheres of it is about 99% if Sv at H=32.

Table 1. Optimum hook lengths and percent of savings against the strips with bo hooks

	Sv=1 (m)			Sv=0.75m			Sv=0.50m		
φ (degree)	hopt (m)	Saving%	hopt/Sv	hopt (m)	Saving%	hopt/Sv	hopt (m)	Saving%	hopt/Sv
20	0.90	28.38	0.9	0.70	27.29	0.93	0.48	24.95	0.96
25	0.65	27.42	0.65	0.50	26.04	0.67	0.34	22.79	0.68

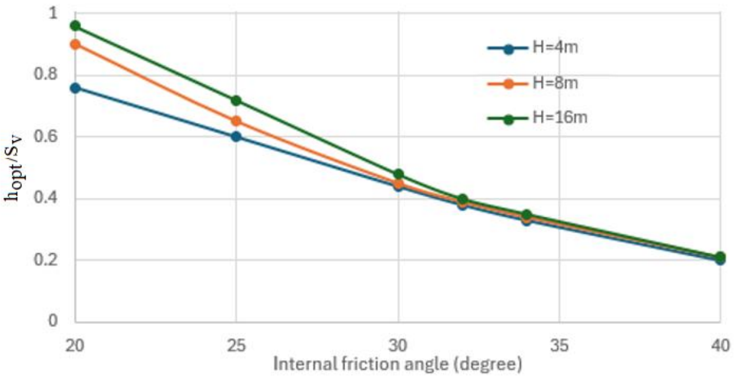

Fig. 10. Effect of MSE-W height on the ratio of hook length/Sv ratio

4. Conclusions and recommendations

The following conclusions can be drawn from this numerical modeling in this study.

1. A numerical modeling of MSE-W with hooks at the end of the steel strips and wth no hooks could be done. Thus, a comparison should be perfomed in terms of which type of steel strips are superior to the other type of steel strips.
2. It is concluded that to employ hooks at the end of the steel strips is beneficial. Thus, there would be a saving on the effective length, L_e, of the strips about 40% against the reinforcement used with no hooks.
3. The saving on the total length, $L = L_r + L_e$, of the strips would be more than 28%. The length of the steel strips, L_r, will remain same in the failure zone of the backfill as expected.
4. The savigs on usage of steel reinforcement are decreasing when a high quality of backfill material that have an internal friction angle of more than 30 degrees is placed. For this purpose Fig. 8 can be used for the purpose of determination of the optimum hook length.
5. There is an optimum length of the hook for different properties of the elements of a MSE-W. Thus, for each MSE-W, an optimum hook length should be determined.
6. The height of the MSE-W can be consider as if it has no effect on the length of the hook especially a backfill with an internal friction angle of 30 degrees or more.
7. It might be recommended that the effect of strip's width, w, in addition to its legth, h, should be investigated on the optimum length of hook as well as the effective length of the reinforcement so that the practitioners may consider these effects when they design a MSE-W.
8. The author believes that unit weight of the backfill material has an significant role on the effective length of the reinforcement. This effect should be investigated too.

Abstract. The performance of the subgrade layer is important to the pavement system. The quality of the subgrade material and other layers impact on the road's service life and long-term performance. The main objective of this study is to determine a suitable method to improve the strength of weak soil for use in the subgrade layer. Various mixtures of RAP-geopolymer material were used to enhance the physical and mechanical properties of sandy silt soil. RAP particles were added to the soil in several percentages (10%, 20%, 30%, 40%, and 50%) as an inert material in order to improve the mixture's stiffness and strength. An alkali solution of the NaOH at 8M and Na_2SiO_3 liquid, at 1.5 ratio of the NaOH: Na_2SiO_3 was prepared to be used an ctivaitor with flay ash for developing geopolymer. The results showed a significant improvement in the strength of the soil in terms of unconfined compressive strength (UCS) and indirect tensile strength (ITS). The optimal RAP content with the soil was found to be 40% without geopolymer material, while the optimal content was 20% with soil-geopolymer mixtures. The CBR index was determined under soaked conditions for both natural and treated soil at the optimal mixtures determined from the UCS and ITS tests. Using RAP alone increased the CBR index of natural soil from 3.8% to 9.6% with 40% RAP content. The CBR index increased significantly with RAP-kaolinite geopolymer mixtures, achieving a remarkable increase by 230%. In contrast, specimens stabilized with RAP-fly ash geopolymer showed great resistance to penetration, reaching the maximum capacity of the testing machine.

1. Introduction

The subgrade layer is the in situ soil or the natural soil, where the pavement layers are constructed upon. The subgrade soil provides the primary support to the top layers of the pavement system. The quality of soil in this layer significantly affects pavement design, performance, and service life. The subgrade layer is susceptible to environmental conditions and axle load repetitions. The role of the subgrade layer can be summarized as mitigating the negative effects of the environment and the dynamic and static stresses of traffic by supporting the upper layers without permanent distress (Schaefer, White, Ceylan, & Stevens, 2008). Therefore, the weak subgrade should be improved to provide a foundation that can resist the traffic loads transmitted from the upper layers. Moreover, improved subgrade layer provides a practical approach to decrease the thicknesses of the surface layer and the other layers of the pavement by increasing the strength and load-bearing capacity of the soil (Chilukwa & Lungu, 2019). This leads to a high reduction in pavement construction cost. Soil stabilization is the process of modifying the soil properties to match the standards specifications of the different engineering applications.There are several methods of soil stabilization, for example, the mechanical method such as the compaction and the chemical method by chemical agents such as cement or lime stabilization (Jones, Rahim, Saadeh, & Harvey, 2011); therefore, selection of stabilization technique depends mainly on soil type and properties. Last decades, inviromental issue became one of the main problem facing the world, one of these problems related to the wast materials, in this regrds Recycled Asphalt Pavement (RAP) one of the road construction wast materials that can be defined as a pavement material that has been removed during pavement rehabilitation or reconstruction. RAP consists of well-graded aggregates coated by asphalt binder and produced by milling or scarifying the surface course during pavement renovation or reconstruction, or by full depth replacement (Mahdi, Abd, & Ahmed, 2020; Thakur, Han, Pokharel, & Parsons, 2012). The aged asphalt that exists in the RAP has undesirable physical properties that make it inappropriate for reusing without enhancement

* Corresponding author, E-mail: ahm1973ed@uoanbar.edu.iq

https://doi.org/10.31462/icearc2025_ce_geo_056

(Chen, Huang, Chu, & Lin, 2007). This property will lead to huge quantities of waste RAP, which are harmful environmentally. RAP provides a resource material that can be utilized in civil engineering applications especially roads construction. In other words it can be considered as sustainability issue. Fly ash (FA) is the residue of coal material combustion, especially in power stations (Keyte, 2009). The chemical composition of coal fly ash and the fine particle size, as well as the low cost gave the fly ash excellent features can be utilized in concrete production as a cementitious material. The fly ash effect enhances the workability and increase the compressive strength as well as reduces CO_2 emissions by reducing the need for cement in concrete (Huang & Wang, 2024). Furthermore, fly ash can be considered as a waste material and this reduces the cost of concrete by utilizing cheaper material than cement. Kaolinite (Kao) is a clay mineral and produced naturally through weathering or by hydrothermal process of aluminosilicates-rich rocks such as granite. Kaolinite as a clay mineral is generally composed of $Al_2Si_2O_5(OH)_4$. the white color and the fine particles distinguish the kaolin from the other types of clay because it is rich material by aluminum and silicates (Bloodworth, Highley, & Mitchell, 1993). the kaolinite may considered as a suitable material in geopolymer syntheses where the geopolymer is made primarily from alumino-silicates materials. Geopolymers can broadly be defined as inorganic polymers mainly synthesized by activating materials rich in alumina and silica in an alkali or acidic medium (Kriven et al., 2024). The prefix "geo" is attached to indicate the geological origin of the prime material, which commonly encompasses fly ash, blast furnace slag, metakaolin, and others (Davidovits, 2017). In this filed geopolymer was used in a veritay of civil enginiring applications, for enstant; Singhi, et al., (2016) used fly ash, slag, and their blends as a precursor for the synthesis of geopolymer binder to stabilize a clayey soil, the investigation showed a signifecnt improvement in terms of unconfined compression strength (UCS) for slag-based geopolymer-soil mixtures compared to FA-based geopolymer-soil mixtures (Singhi, Laskar, & Ahmed, 2016). Adhikari, et al., (2018) studied the inclusion of RAP in addition to geopolymer binder to stabilize two types of soils (CL and MH), results showed that, the UCS increased by increasing RAP and FA content to 25% for both with an optimum NaOH molarity was 8M for both soils, while the optimum sodium silicate content varied based on soil type (Adhikari, Khattak, & Adhikari, 2020). Kwad, et al., (2020) investigated that a geopolymer based on fly ash affected the strength of weak soil in order to satisfy the requirements of the pavement structure's subgrade layer. The study used low plasticity sandy silt that was stabilized with various percentages of fly ash (5, 10, 15, 20, 25, and 30%); the addition of FA-based geopolymer improved UCS and indirect tensile strength (ITS) significantly, at 20% FA (Nawfal Farooq Kwad, Abdulkareem, & Ahmed, 2020). In further works. In other study, the effect of wetting – dry cycles on durability of silt-sand soil modified by fly ash based geopolymer with and without RAP were evaluated in terms of weight loss, the results ravealed that the weight loss and volume changes were less than 10% and 2% respectively (Nawfal F Kwad, Abdulkareem, & Ahmed, 2024). The efficiency of kaolinite based geopolymer material for stabilizing sandy silt soil, where different proportions of the kaolinite (5, 10, 15, 20, 25, and 30%) by weight alkaline activaitor solution consists of the NaOH at 8M and Na2SiO3 liquid, at 1.5 ratio of the $NaOH:Na_2SiO_3$ were used for creating the geopolymer. The investigation showed there are an improvement in: compaction charectersistics in terms of dry density, unconfined compressive strength and the indirect tensile strength; and the best improvement was at kaolinite content 15% (Abdulkareem, Ahmed, & Kwad, 2023). In further works, the resilience properties of a clayey soil modified with a fly ash-based geopolymer and RAP for unpaved road material were investigated using repeated-load California bearing ratio (CBR) testing method to evaluate recoverable and permanent deformations; the results showed that the geopolymer binder significantly increased the stiffness of the mixtures at optimum ratio of 25% FA and 30% RAP (Abdulwahed, Aljanabi, & Abdulkareem, 2024). In the filed of asphalt mixtuers, a qualitative leap was achieved by adding fly ash based geopolymer was incorporated to emulsified cold mix asphalt, a significant achievement was improved in the mechanical propertis in terms of Marshall stability, indirect tensile strength and perminant deformation compared to the reference cold mix. However, volumetric proberties was still with out improvement due to the nature of asphalt emulsion which is reach with water (Ali & Ahmed, 2024; Ahmed M Ibrahim & Ahmed, 2024; Ahmed Mahdi Ibrahim, Ahmed, & Ahmed, 2024).

The study aims to investigate the strength of soils in the subgrade layer after the incorporation of RAP-geopolymer mixture. The main interest of the study is the incorporation of a chemical stabilizing agent and recycled asphalt pavement (RAP) with the soil. This may produce high-quality material that can be used as a roadbed or stiff foundation for the road. This is applicable by achieving better properties and long-term performance for civil engineering applications that require high-quality soil.

2. Materials and methods

2.1. Soil

One type of soil was used in this study collected from Msheheeda quarry in Ramadi city. The soil was classified as low plasticity sandy silt soil according to the USCS system. The physical and chemical properties of soil presented in Table 1 and 2, respectively. The chemical composition shows that the soil is composed mainly of silicon, aluminum, and calcium oxide. Figure 1 shows soil under normal and scanning electron microscope (SEM) images, indicating that the soil has a lamellar composition and exhibited loosely structure.

Table 1. Geotechnical properties of soil

LL (%)	PL (%)	PI (%)	G_s	AASHTO	USCS	Description	OMC (%)	MDD (gm/cm^3)
38	27	11	2.66	A-6	ML	Sandy silt	15.5	1.73

Table 2. Chemical composition of soil, fly ash and kaolinite

Element	SiO_2	Al_2O_3	CaO	Fe_2O_3	MgO	Na_2O	K_2O	SO_3	MnO
Soil	37.64	6.50	23.43	4.06	3.90	1.30	1.10	0.70	0.10
Fly Ash	53.23	25.91	4.95	6.46	1.2	0.10	1.40	0.78	0.16
Kaolinite	51.40	26.23	5.38	5.64	2.41	1.28	1.20	-	-

Fig. 1. (a) Dried soil (b) SEM image of soil

2.2 Fly ash (FA)

One type of FA was used in this study to produce the geopolymer as shown in Figure 2. Class F is characterized as a low calcium content as per (ASTM C618-2012). The low calcium fly ash is preferred in geopolymer synthesis because it produces higher strength and showed a better response in sodium-based geopolymerization reactions. The chemical composition of fly ash was determined by the X-ray Fluorescence (XRF) test as listed in Table 2. The specific gravity of the fly ash is 2.14. The chemical composition shows that the silica is the dominant element in the fly ash followed by aluminum oxide and these are considered as the main two components required in the raw material to produce geopolymer bonds. The particle size analysis showed that 89 % of fly ash particles passed No.200 sieve (0.075 mm).

2.3 Kaolinite (kao)

Kaolinite is a clay mineral was used in this study as a source of alumina-silicate material to produce the geopolymer. It was dried at ambient temperature before use as shown in Figure 2. More than 71% of kaolinite particles passed No.200 sieve. The chemical composition through the X-Ray Fluorescence test is listed in Table 2. The specific gravity of the kaolinite is 2.35. The chemical analysis shows that the amount of silica is high, as well as, the alumina, while it has a low content of CaO.

2.4 Recycled asphalt pavement (RAP)

large amounts of RAP were observed as a waste material, especially in the destructive bridges and roads. In this study, RAP was collected from the removed asphaltic pavement layer for University of Anbar Bridge, which constructed before 20 years ago. It was heated and sieved on 10 mm sieve size as shown in Figure 2 to exclude the large particles and to satisfy the requirements of the unconfined compressive strength test (ASTM D4219-2008), which requires that the maximum size of the RAP particle should be smaller than the mold's diameter by 10 times. RAP consists of 98% coarse granular particles coated with aged asphalt binder.

2.5 Alkaline solution

The alkaline activator solution consists of 99% pure sodium hydroxide (NaOH) pellets and sodium silicate (Na_2SiO_3). The concentration of NaOH was 8 molar, and 40 g / mole is the molecular weight. The liquid form of sodium silicate (Na_2SiO_3) contains 32.5% of SiO_2, 13.4% of Na_2O, and 54% of water. The NaOH: Na_2SiO_3 ratio of 60:40 was used to activate kaolinite and soil particles. The molarity of NaOH and the NaOH: Na_2SiO_3 ratio were selected based on preliminary testing to ensure sufficient UCS of the Soil-Geopolymer and Soil-RAP - Geopolymer.

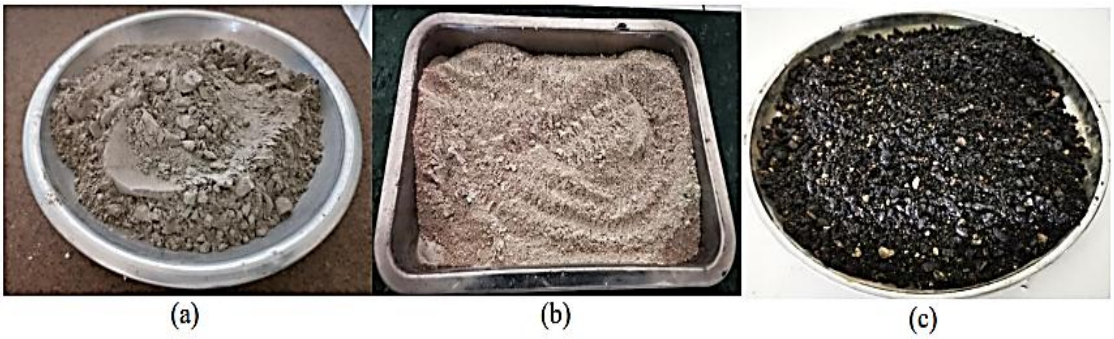

Fig. 2. (a)Fly ash (b) Kaolinite (c)RAP passed on 10mm sieve size.

2.6 Cement

Ordinary Portland cement (MASS brand) was used in this study as a standard stabilization additive. This type of cement with the soil was used as a reference mixture in comparing the mechanical properties with the soil-geopolymer and soil-RAP-geopolymer mixtures. The OPC with 6% and 12% content by weight of soil was used.

2.7 Preparing of mixtures

The soil was dried in the oven for 24 hours at 105°C, the dried soil and other additives were mixed using a mechanical mixer to ensure a homogeneous mixture. Soil with fly ash and soil with kaolinite mixtures were mixed thoroughly before adding the alkaline solution. The alkali content corresponds to the optimum moisture content of the mixture as estimated by the compaction test. Extra weight of the alkali liquid was added to the blend to compensate the dissolved NaOH weight in the solution which is 30% approximately at 8M concentration of NaOH (Adhikari, 2017). In the UCS and ITS tests, fly ash or kaolinite percentages were 5, 10, 15, 20, 25, and 30% by weight of soil, while RAP percentages were 10, 20, 30, 40, and 50 by weight of soil. The optimum percentages of the kaolinite, fly ash, and the RAP in the UCS test results were used in the CBR test. Fly ash and kaolinite percentages were 20 and 15% respectively. The optimum content of RAP, i.e. 40% was used in the soil-RAP mixtures. Soil-cement and soil-RAP blends were thoroughly mixed with water at the OMC of the mixtures. Dry mixing for 3 minutes by hand followed by a mechanical mixing for 7 minutes. The time of mixing was selected to ensure the effectual distribution and participation of mixture components with the alkaline solution in geopolymer mixtures. Long time mixing is not preferable to avoid the drying of the alkaline solution or the water prior to the required reactions of the geopolymer material. The specimens were cured for 48 hours in drying oven at 65^{o}c then the test was performed directly after the samples been cooled at ambient temperature.

3. Result and discussion

3.1. Compaction properties of natural and treated soil mixtures

Figure 3 shows the relationships between the dry density and the moisture content for soil-FA mixtures at various fly ash percentages (5, 10, 15, 20, 25, and 30%). It can be noticed that the maximum dry density of soil-fly ash mixtures exhibited increasing trend from 1.73 g/cm^3 of the natural soil to the MDD of 1.78 g/cm^3 at 30% of fly ash content. While there was a reduction in the optimum water content of soil-FA mixtures from 15.5% for the natural soil to 13.5% for soil+30% of fly ash mixture and it can be observed that this mixture has the MDD among other fly ash percentages. However, this increase in the MDD was observed beyond 15% of fly ash addition as the lower content of fly ash did not affect the MDD significantly.

The compaction curves of soil-kaolinite blends are presented in Figure 4. A general increasing trend was observed in the MDD values up to 1.93 g/cm^3 at 30% of the kaolinite content with the soil. The same mixture has the lowest OMC by 13%. Figure 4 shows that there was a noticeable increase in the MDD of the soil at the various kaolinite percentages and obvious decrease in the OMC at the same percentages. The clear trend of compaction curves reveals that adding more kaolinite to the soil leads to higher MDD and less OMC. The higher MDD may be attributed to the role of the fine particles of kaolinite which are likely to fill the pore spaces in the soil as a filler material resulting in a denser state in the soil under the impact of the compaction energy (Ayininuola & Adekitan, 2017).

The moisture-density curves of the soil-RAP mixtures are shown in Figure 5. The OMC decreases with the gradual increase in the RAP content from 10 to 50%. The MDD was 1.95 g/cm^3 and the OMC was 8.9 % and observed at 50% of RAP content with the soil. There was a noticeable decrease in the OMC for the various RAP contents. This reduction in the OMC may also be ascribed to the water-holding capacity of the RAP aggregate which is less than the silty soil (Akinwumi, 2014). In addition, the large size particles of the RAP that replaced the fine particles of the soil reduce the surface area of soil mixture and lead to a reduction in the water of the mixture (Edeh, Eberemu, & Agnes, 2012).

The moisture-density relationship of the soil and cement mixtures are shown Figure 6. Both of the MDD and the OMC are reduced due to the cement addition. The compaction test was performed to investigate the combined effect of the RAP-geopolymer on soil density and water affinity.

The compaction tests were performed using the optimum percentages in the soil-RAP-geopolymer mixture at 20% of RAP, 15% of kaolinite, and 20% of fly ash. The OMC and MDD of the optimum mixtures are listed in Table 3. The results showed that there was a noticeable increase in the MDD and a decrease in the OMC of the various mixtures of RAP-fly ash geopolymer and RAP-kaolinite geopolymer mixtures.

3.2. Unconfined compressive strength (UCS) test

The incorporation of RAP particles improved the compressive strength of the soil as presented in Figure 7 for various soil-RAP blends. Noticeable increase in the UCS of the soil with the high contents of the RAP was observed. The optimum percentage of the RAP was 40% which achieved the highest strength by 1.45 MPa. By inspecting Figure 7, an increase in the UCS was observed especially at the low contents and there is no considerable variation in the UCS for the various RAP proportions. In comparison with the cement stabilization results, the RAP did not achieve a significant increase in the UCS of the soil like the OPC, where 6 and 12% of cement achieved higher UCS than the optimum content of the RAP. In addition, the RAP incorporation results did not fulfill the Iraqi standards (SORB) of the stabilized subgrade which requires the minimum compressive strength of the stabilized subgrade to be 2.5 MPa for the cement-stabilized subgrade. The UCS results affirms that the RAP content affected the strength of the sandy silt soil to a specific limit. The slight increase in the UCS of the soil with RAP may be due to the nature of the RAP particles which coated by the bitumen material. In addition, the RAP particles with the soil and water acted as inert aggregate filling spaces in the mixture without any effects (Mustapha, Jibrin, Etsuworo, & Alhassan, 2014).

Table 3. OMC and MDD of the soil-RAP-geopolymer

Mixture	MDD (g/cm^3)	OMC (%)
Soil+20% RAP+20% Fly ash	2.02	9.1
Soil+20% RAP+15% Kaolinite	1.98	9.3

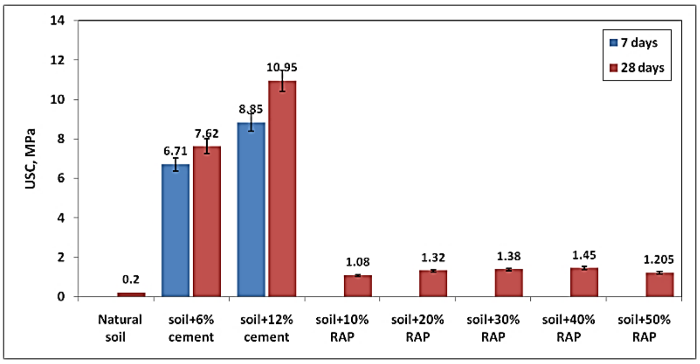

Fig. 7. Effect of soil–RAP mixtures on UCS test.

The UCS values of the soil-RAP-fly ash geopolymer mixture are listed in Figure 8. The maximum UCS values were 20.51 MPa and 22.56 MPa at 7 and 28 days of curing time respectively. Various proportions of the RAP were used to produce soil-RAP-fly ash geopolymer mixture. 20% of the fly ash was the optimum content that enhanced the UCS of the soil significantly when it incorporated with the alkaline solution in soil-fly ash geopolymer mixtures. The increase in the RAP content decreased the UCS from 22.56 MPa at 20% of RAP to 11.52 MPa at 50% of the RAP content. The obvious decrease in the UCS at the high content of the RAP highlights the role of the fly ash-based geopolymer with RAP particles. Despite of the nature of RAP particles, the surface area of RAP exposed to the pozzolanic reactions with the fly ash-based geopolymer as found by (Saride, Avirneni, & Challapalli, 2016) and the strength affected by the range of the exposed area.

The UCS test was conducted on 7 and 28 days cured specimens of soil+RAP+kaolinite geopolymer mixtures. Figure 9 presents the estimated strength results of the stabilized soil with various proportions of the RAP and 15% of kaolinite. Obvious increase in the compressive strength of the soil was observed with the initial increase in the RAP content. The results of 7 and 28 days cured specimens indicate that the optimum content of the RAP was 20% by weight of the soil when the kaolinite content remains constant at 15%. The maximum compressive strength was observed in the soil samples treated with this content and activated by 8M of NaOH and 60:40 of NaOH:Na_2SiO_3 ratio. Any further increase in the RAP content led to strength reduction irrespective of curing time. In addition, it can be observed that there was a slight increase in the strength after the first 7 days of curing and there is no big variation in the strength between 7 and 28 days cured specimens except at 20% of the RAP content. The heat-curing is responsible for the strength gain in the early ages of curing in the geopolymer paste (Rangan, B. ,2009). The optimum percentage of the RAP was found to be different from the soil-RAP mixture result, as the optimum content of the RAP was 40% with soil and water without the alkaline solution. This indicates that the high content of the RAP has a negative impact in soil stabilization by the geopolymer, as the RAP is inert material with the soil and the geopolymer. However, the bitumen coating the RAP particles may affect the geopolymerzation development by the reaction with the alkali solution and producing pozzolanic products on the RAP particles surfaces (Saride, Avirneni, & Challapalli, 2016).

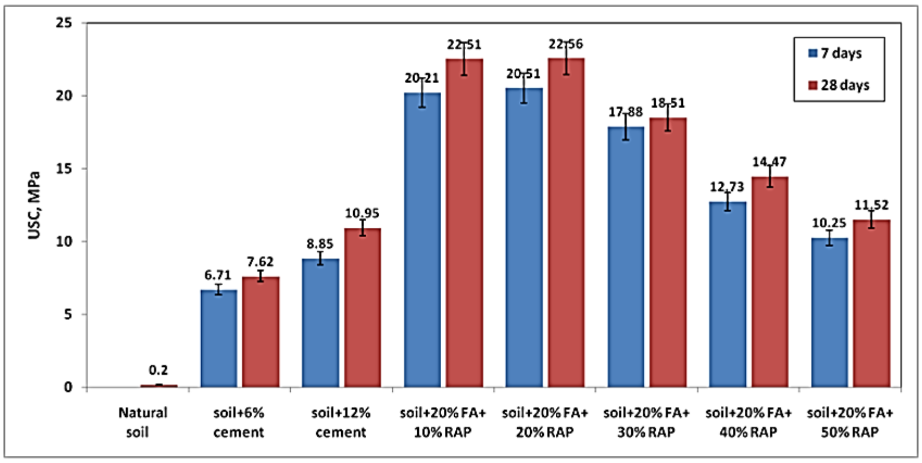

Fig. 8. Effect of soil-RAP-20% FA geopolymer mixtures on UCS test.

golden light publishing®

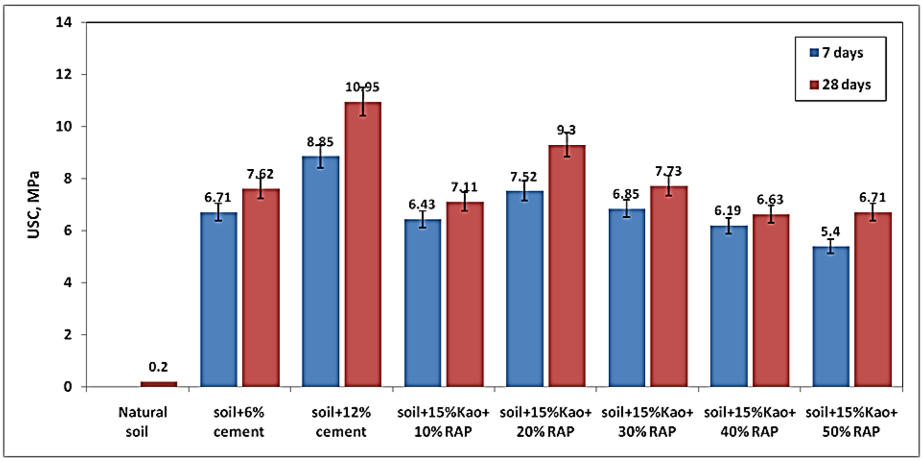

Fig. 9. Effect of soil-RAP-15% Kao geopolymer mixtures on UCS test.

3.3 Indirect tensile strength (ITS) test

The ITS test results alongside the specimens densities are shown in Fig. 10. It was obvious that the tensile strength of the soil increased by 7 times after adding 40% of the RAP by weight and it was the highest tensile strength among the other proportions of the RAP. The same trend was observed in the UCS strength as the optimum percentage of the RAP was 40% as well. The RAP was well-graded material and this property improves the interlocking between the RAP and the soil which leads to increase cohesion and friction capacity ,in turn, increase the strength of the mixture (Mahasneh, 2016). However, the addition of 8 and 12% of the OPC to the soil developed a tensile strength surpasses all soil-RAP mixtures after 7 and 28 days of curing at the ambient temperature. The reduction in the tensile strength occurred at 50% of the RAP content and this indicates that the high content of the RAP is not proper for the soil stabilization. It is obvious that the soil-RAP mixtures have significant densities especially at the high contents of the RAP. The high density may be attributed to the well-graded aggregates of the RAP which increase the density of the soil to a specific limit.

The combined effect of RAP and fly ash geopolymer on the tensile strength of the sandy silty soil is presented in shown Figure 11 for 7 and 28-day cured specimens. It is obvious that the stabilized soil developed a significant tensile strength at all RAP percentages with the constant ratio of the fly ash (20%) activated by 8M of the NaOH and 60:40 of NaOH:Na_2SiO_3. However, 20% of the RAP addition achieved the highest tensile strength irrespective of the curing period as shown in Figure 11. Other proportions developed high tensile strength in comparison with soil-cement mixtures. The stabilized soil by 10% of the RAP and 20% of the activated fly ash achieved considerable ITS by 2.16 MPa at 28 days of curing period. This result can be considered as a significant improvement in the tensile strength. By inspecting Figure 11, a reduction in the tensile strength occurs after increasing the RAP content to more than 20%. This reduction may be attributed to increasing the large particles of the RAP and non-uniform distribution of the RAP particles with the fly ash that may lead to weak areas in the soil structures.

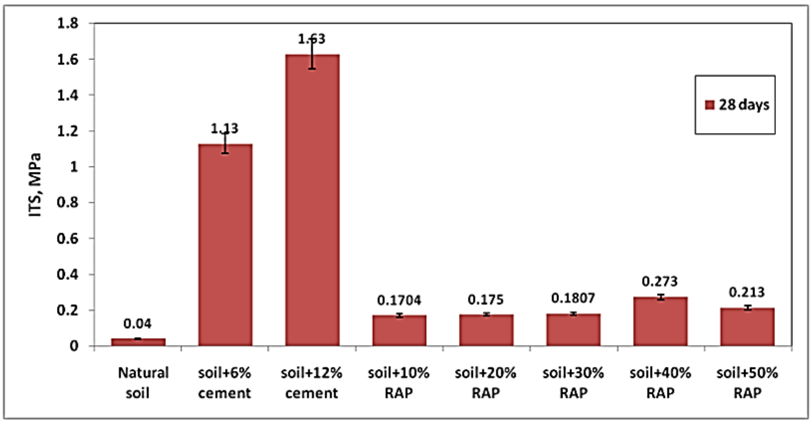

Fig. 10. Effect of RAP on ITS test with curing period at 28 days.

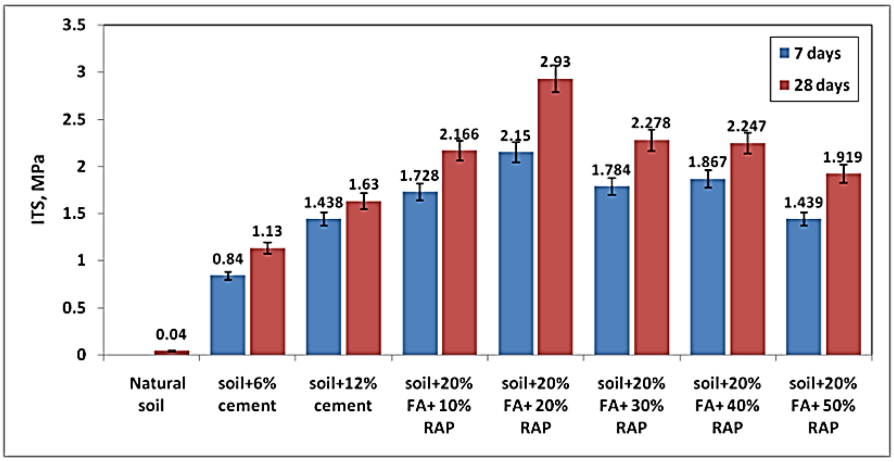

Fig. 11. Effect of soil-RAP-20% FA geopolymer mixtures on ITS test.

The results of the ITS test of soil-RAP-Kao geopolymer mixtures is presented in Figure 12. The optimum mixture was found at 15% of the kaolinite and 20% of the RAP by weight of the soil irrespective of curing time. This blend achieved the maximum tensile strength up to 1.35 MPa at 28 days of curing time. The other mixtures developed a considerable tensile strength at the low contents of the RAP particles while the kaolinite content remained constant at 15% by weight as found in the UCS and ITS of the soil+kaolinite geopolymer mixture. In the high-RAP content mixtures, the tensile strength exhibited a noticeable reduction especially at 40 and 50% of the RAP content by weight. The minimum tensile strength was recorded at the alkali-activated mixture that contains 50% of the RAP and 15% of the kaolinite by weight of the soil. This indicates the high content of the RAP negatively affects the strength in the geopolymer stabilized soil as was observed in the RAP-fly ash geopolymer stabilized samples.

The soil-cement mixture exhibited better tensile strength in comparison with the RAP-kaolinite geopolymer mixture, where 12% of the OPC has better tensile properties at both 7 and 28 days of curing period while 6% of the OPC achieved convergent results to the RAP-kaolinite based geopolymer. Figure 13 shows the ITS test specimen of the soil+50% RAP+15% kaolinite geopolymer after conducting the test. It is clear that the RAP particles did not lose the bitumen cover after 28 days of geopolymer reactions and this was opposite to the fly ash-based geopolymer, where the RAP was highly exposed to the chemical effects from the fly ash and the alkaline solution.

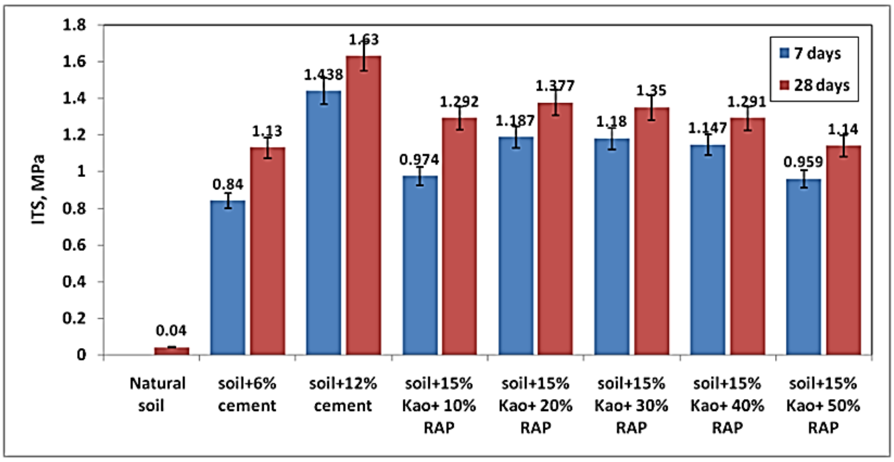

Fig. 12. Effect of soil-RAP-15% Kao geopolymer mixtures on ITS test.

Fig. 13 . ITS test specimen failure of soil +50% RAP +15% kaolinite geopolymer.

3.4 California bearing ratio (CBR) test

The CBR test was conducted on soaked specimens to investigate the contribution of RAP particles to the CBR value of the sandy silt soil. The CBR index of the natural soil is 3.8% for the soaked condition. One percentage (40%) of the RAP was added to the soil as an optimum proportion estimated from the UCS and ITS tests. The load-penetration curve of the soil+40% mixture is shown in Fig. 14. The CBR value was calculated from the stresses corresponding to both 2.54 mm and 5.08 mm of penetration depth and found to be 8.5% and 9.6% respectively. Since the CBR value at 5.08 mm was greater than the one at 2.54 mm, the test was conducted again to check the value and it was the same as the first test. According to (ASTM D1883-2014), the CBR value of the mixture is the one at 5.08 mm which was 9.6%. The CBR value increased about 2 times the CBR of the natural soil approximately. The considerable increase in the CBR index enhanced the soil to be a suitable material in the subgrade layer as it satisfies the Iraqi standards for the subgrade material, which indicates that the CBR index must be more than 4%. There was a big variation in the CBR index between the soil-RAP and soil-cement. The cement-treated soil achieved a significant CBR index corresponding to 230%. However, the RAP addition to the soil satisfies the Iraq standards for the subgrade material as the CBR index was more than 4% (Iraqi General Specifications for Roads and Bridges, 2003). In addition, the RAP was a waste material and there is no clear approach to recycle this material in transportation applications and soil stabilization.

Fig. 15 shows the CBR test result of the stabilized soil by 20% of the fly ash and 20% of the RAP by weight. It can be observed that the stabilized soil has showed a considerable resistance to penetration, however, the plunger of the CBR machine penetrated the soil surface to 1.6 mm at the maximum capacity of the machine as shown in Figure 16. The high resistance to penetration confirms that the stabilized soil strongly bonded by the new products and there was no considerable water absorption that may affect the soil by the leaching of the new binder in the soil. The main effect that enhanced the strength of the soil in terms of the CBR is the fly ash geopolymer binder. The strong bonds of the geopolymer highly affected the resistance of the soil and improved the bonding of the soil particles (Dungca, & Codilla, 2018). In the mixture of the soil+RAP+fly ash geopolymer, there was no swelling in the soil surface along the 4 days of soaking in the water. The swelling of the soil was 0% after adding the geopolymer which was another positive indicator of the stabilization efficiency.

The CBR test result of the stabilized soil by RAP-kaolinite geopolymer mixture is shown in Figure 17. The addition of the RAP with the kaolinite geopolymer has improved the CBR index significantly. The CBR value of soil+15% kaolinite+20% RAP approaches from the result of the soil+12% cement mixture which was 230%. The significant increase in the CBR index after adding the RAP confirms the important role of the RAP in resisting the penetration into the soil.

4. Conclusions

The study was performed to find out the influence of the geopolymer and recycled asphalt material on the physical, and mechanical properties of the subgrade soil. The study proved the efficiency of RAP-geopolymer mixtures in soil stabilization as a road subgrade material. The following conclusions are drawn:

- The MDD of the soil increased with the increase in the RAP content, on the other hand, the OMC decreased at the same proportions. The RAP has a significant impact on the MDD and the OMC. The high content of the RAP (50%) increased the MDD from 1.73 g/cm^3 of the natural soil to 1.95 g/cm^3.
- By 8M of the NaOH and 1.5 ratio of the NaOH:Na_2SiO_3 solution , the UCS strength of the stabilized soil was improved significantly at the optimum content RAP compared to the natural soil and soil-cement blends. The stabilized soil by the activated additives exhibited high compressive strength at both 7 and 28 days of curing time at 20% of the fly ash, 15% of the kaolinite, 40% of the RAP, and 20% of the RAP when used with the fly ash and kaolinite geopolymer mixtures. The mixtures were compacted by the modified effort method and cured initially at 65°C for 48 hours.
- The tensile strength of the stabilized soil increased significantly by RAP-geopolymer additives. The RAP aggregates increased the tensile strength of the soil from 0.04 MPa of the natural soil to 0.273 MPa at 40% of the RAP content. When the geopolymer was mixed with soil, 20% of the RAP has achieved the maximum tensile strength with the fly ash and kaolinite contents irrespective of the curing time.
- For the stabilized soil by various mixtures of the RAP-geopolymer mixture, the CBR index was highly improved after the incorporation of the additives. The specimens were tested after heat-curing at 65°C for 48 hours and soaked in the water for 96 hours prior to the test. The specimens stabilized RAP-fly ash geopolymer mixture has shown great resistance to penetration. The piston of the CBR machine could not be able to penetrate the specimen to the required depth (2.54 or 5.08mm) due to the high strength of the stabilized soil. While the specimens stabilized by 230% at the RAP-kaolinite geopolymer stabilized specimen. There was no indicator on swelling or water absorption in the specimens during the immersion period in the water.

Abstract. The low bearing capacity and high compressibility of bentonite-type clays, particularly under dynamic loads like earthquakes, make them unfavorable in terms of geotechnical properties. On the other hand, their extremely low permeability makes them advantageous. The adsorbed pore fluid regulates the engineering behavior of the clay. In experimental studies, distilled water—also known as adsorbed water—is typically utilized as the pore fluid. Atterberg limits, shear strength, and compaction parameters are all significantly impacted in this situation by variations in the salinity and viscosity of the water. This study used the Casagrande and fall cone tests with water containing 0 %, 1 %, 2 %, 3 %, 4 %, 5 %, and 10 % salt to calculate the Atterberg limits, and undrained shear strengths of bentonite type clay. Standard proctor test was also conducted to obtain the optimum water content and maximum dry density values. Furthermore, the water content-penetration depth relationship was established in over 30 steps by gradually increasing the fall cone experiments from a very low water content. The water content corresponding to 2 mm penetration was recognized as the plastic limit within the parameters of the study, and the water content corresponding to 20 mm penetration was identified as the liquid limit. This led to an experimental determination of the impact of salt content on bentonite clay. According to the findings, bentonite clay's plastic limit and liquid limit both decrease with increasing salt content. The maximum dry density of bentonite clay decreases as the salt content increases, while the clay's optimum water content increases, according to standard compaction results.

Keywords: Salt content; Fallcone test; Undrained shear strength; Atterberg Limits

1. Introduction

In coarse-grained soils, the soil is considered as an isotropic medium and geotechnical parameters are determined by the contact forces between the grains, while in fine-grained soils such as silt and clay, geotechnical parameters are obtained by the movements of surface forces due to the fact that the grain sizes are at micron levels and have a larger specific surface area.In fine-grained soils such as clay, where pore fluid properties are different, chemical interaction should be taken into account in classical soil mechanics calculations (Mitchell & Soga, 2005).

The geotechnical parameters of clays with different mineralogical properties are highly influenced by shear resistance, friction of grains, as well as chemical interaction due to van der Waals bonds. Many geotechnical parameters such as Atterberg limits and compaction properties of fine-grained soils are also affected by the properties of the pore fluid (Sridharan, 2002). For bentonite type clays, geotechnical parameters are influenced by the Double Diffuse Layer (DDL), while for kaolinite type clays, geotechnical parameters are influenced by the interparticle shear resistance.

The mechanical properties of fine-grained soils such as clay and silt are strongly influenced by changes in the chemical properties of the pore fluid (Santamarina et al., 2002). Mitchell and Soga (2005) showed that properties &such as dielectric constant and electrolyte concentration have a decisive influence on the bearing capacity and settlement properties of fine-grained soils.

The effect of pH in the pore fluid of fine-grained soils on geotechnical properties has been studied by many researchers (Santamarina et al., 2007; Gori, 1994;Gajo & Maines, 2007; Gratchev & Sasa, 2009; Spagnoli et al., 2012). Gori (1994) investigated the change of liquid limit and plastic limit values of kaolin clay depending on the pH in the pore fluid. According to the results of his experimental study, he concluded that pH value has no effect on liquid limit and plastic limit because kaolin clay is not bilayer. However, Di Maio (1996), Gajo and Maines (2007) and Yukselen-Aksoy et al., (2008) found the opposite result in their experimental studies.

The change of geotechnical properties of saline-water mixtures on fine-grained soils has been investigated by many researchers from past to present with laboratory experiments. For example, Rao et al., (1993) investigated the changes in interparticle forces in bentonite clay as a result of the long-term effect of artificial seawater. Their experimental results showed that the long-term effect of artificial seawater on bentonite clay did not cause any mineralogical changes in the clay samples. They observed an increase in liquid limits when the salt content in bentonite samples decreased from 42 g/L to 1.1 g/L. In another study, Di Maio (1996) showed that exposure of bentonite samples to saturated NaCl, KCl or $CaCl_2$ solutions caused residual shear strength increases. Di Maio et al., (2004) carried out oedometer tests on Ponza bentonite, a commercial kaolin, the Bisaccia and the Marino clays. They showed that artificial mixtures reconstituted with distilled water were strongly affected by the mineral composition. They concluded that an increase in the pore solution concentration leads to a decrease in the compressibility of the materials and an increase in the consolidation coefficients.

Sridharan et al., (2002) concluded that based on the results of fallcone and veyn tests, the liquid limit of Isahaya clay increases with increasing salt concentration, while a marginal decrease is observed for Kubota and Kawazoe clays. For Isahaya clay, the factors responsible for the increase in the level of flocculation and attractive forces resulted in higher undrained strength, while for Kubota and Kawazoe clays, they showed that for Kubota and Kawazoe clays, the expansion of the diffuse double layer thickness would result in higher viscous resistance and increase the undrained shear strength.

The main objective of this study is to investigate the changes in Atterberg limits of bentonite clay with salt water mixtures having different salt ratios. In addition, the effect of salt content on the undrained shear strength values obtained from Fallcone experiments was also investigated. For this purpose, a series of laboratory experiments were carried out by creating brine mixtures at 7 different salt ratios ranging from 0% to 10%. For this purpose, Casagrande, Fallcone and plastic limit tests were performed using 6 different salt-content mixtures.

2. Materials and methods

The behavior of clay minerals towards water is one of the main factors in the classification of these minerals. Bentonites are mainly classified in three main groups: Na-bentonites that swell in water; intermediate type bentonites containing balanced calcium and sodium, which have this property less; Ca-bentonites that do not swell in water. Na-bentonites with swelling properties have the ability to absorb approximately 1-15 times more water. When mixed with water, these clays show colloidal properties and swell in volume in water and some organic liquids. Ca-bentonites, which are called non-swelling clays, contain calcium in ions that can vary between layers.

Fig. 1 shows the bentonite clay obtained from ESAN company and its scanning electron microscope (SEM) image. Table 1 shows the chemical properties of bentonite clay. Bentonite clay-water mixtures were prepared by thoroughly mixing clay powders with distilled water and salt solutions. The clay-water mixtures were kept in a sealed plastic container for 24 hours to ensure proper homogeneity of the clay-water mixture. After 24 hours, the clay-water mixtures were re-mixed and used to determine the liquid limits using a fall cone test device. Mixtures were prepared using bentonite clay and water containing 0%, 1%, 2%, 3%, 4%, 5% and 10% salt. The mixtures were tested according to BS 1377-9 (1990) using a fall cone test device with a 30° apex angle and a conical tip with a mass of 80 g. The 55 mm diameter and 40 mm height sample container was filled with no air pockets, brought into contact with the cone and then penetrated under its own weight for five seconds and the penetration value was measured automatically. For the accuracy of the experimental results, the water content-penetration depth relationship was determined by conducting more than 30 steps, starting from 6% water content in frequent steps and proceeding with 3% water content increments. In this study, plastic limit values corresponding to 2 mm penetration as a result of the fall cone test were accepted as plastic limits and plastic limit values were also calculated by the conventional method.

Casagrande test is performed by filling soil samples prepared at different water contents into a Casagrande cup, opening a standard sized crack in this sample and dropping the cup many times from a height of 1 cm by turning the instrument handle at a standard speed. The relationship between the number of drops that cause the 1.25 cm long part of the opening to close and the soil water content is determined experimentally and the water content value corresponding to this much closure of the gap in 25 drops is accepted as the liquid limit of the soil.

If a fine-grained soil can be given the desired shape by kneading without causing fractures, it can be considered to have a plastic consistency. In order to determine the plastic limit of a soil experimentally, a moist sample is tried to be rolled into round thin cylinders on a smooth surface. The water content at which the soil is rolled into a cylinder about 3 mm thick without breaking is considered the plastic limit.

Table 1. Chemical properties of bentonite

Chemical Properties	SiO_2 (%)	Al_2O_3 (%)	Fe_2O_3 (%)	MgO (%)	CaO (%)	Na_2O	K_2O (%)
(%)	64	21	3.5	2.3	0.5	2.6	0.4

3. Results and discussions

In this study, the salt content dependent changes of bentonite clay samples prepared with salt water solutions with different salt concentrations were investigated in the laboratory by Casagrande, Fallcone and conventional plastic limit tests.

3.1. Casagrande test results

The Casagrande test apparatus, which is the most widely used method worldwide for soil classification in fine-grained soils, was used in accordance with ASTM D4318-17e1 (2018) standard. The experiments were first performed with distilled water. Then, the experiments were carried out at 6 different salt contents from 1% to 5% with 1% increase and 10% in total. For example, in the experiments, 5 g of salt was added to every 100 ml of distilled water for 5% salt content, mixed until completely dissolved and then used in the experiment.

First, the number of blows versus water content on a semi-logarithmic scale is given in Figure 2. As seen in Fig. 2, the water content corresponding to 25 blows was determined as the liquid limit. In order to obtain the liquid limit value much more accurately in the experiments, the test were carried out in 20-22 steps starting from 15%-20% initial water contents and up to 350% water content at the end of the experiment.

Table 2 shows the equations obtained using Fig. 2, the root mean square error values and the liquid limit values obtained using the casagrande test apparatus. The results in Table 2 and Figure 2 show that the liquid limit values of bentonite clay decreased with increasing salt content. For example, while the liquid limit value of bentonite clay was 222.90% at 1% salt content, the liquid limit value decreased to 195.79% when the salt content increased to 5%.

Table 2. Liquid limit and plasticity index for casagrande

Salt Content (%)	Equation	R^2		PL_{con}(%)	PI_{cas}
0	LL_{cas}=-22.83×ln(25)+293.17	0.995	219.68	47.62	172.06
1	LL_{cas}=-26.78×ln(25)+309.	0.969	222.90	54.11	168.79
2	LL_{cas}=-14.90×ln(25)+269.49	0.956	221.53	53.85	167.68
3	LL_{cas}=-23.93×ln(25)+279.64	0.989	202.61	54.55	148.99
4	LL_{cas}=-25.61×ln(25)+284.23	0.979	201.79	56.82	144.97
5	LL_{cas}=-23.30×ln(25)+270.79	0.963	195.79	58.62	137.17
10	LL_{cas}=-8.562×ln(25)+196.71	0.945	169.15	60.61	108.54

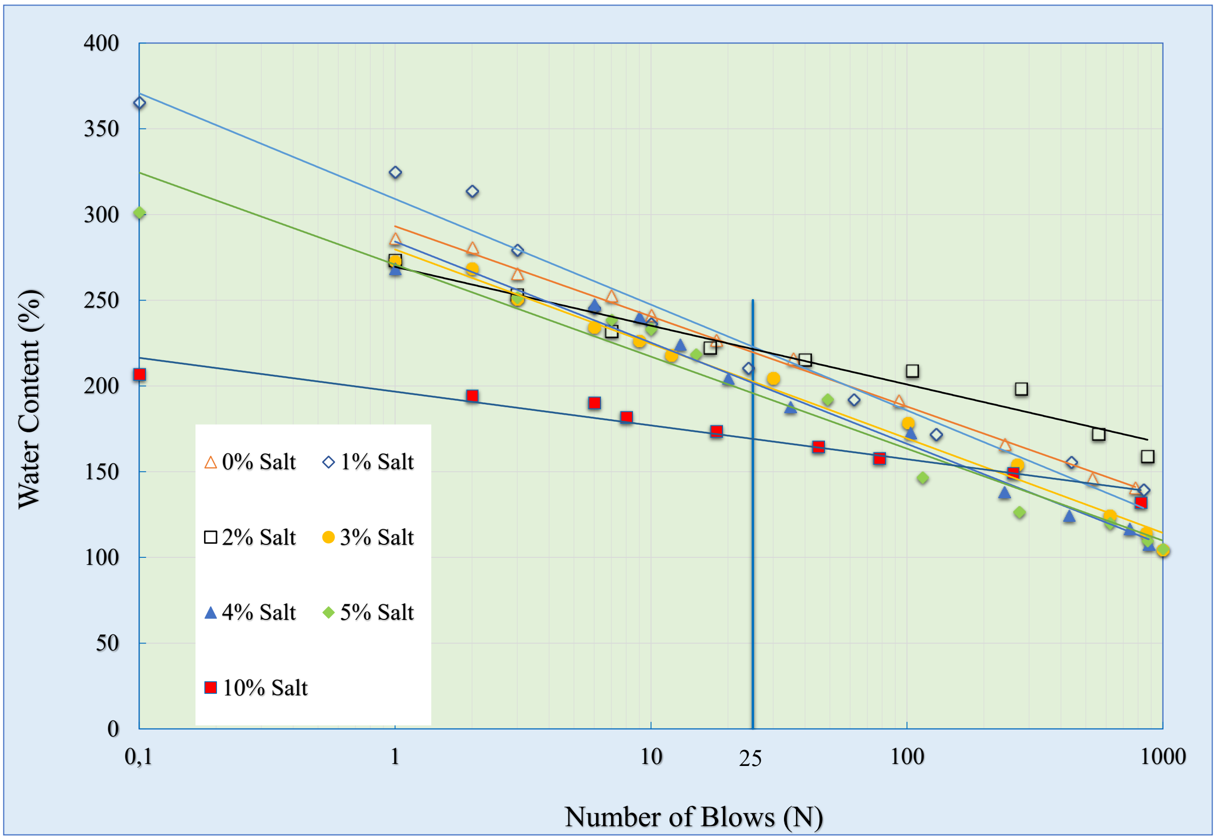

Fig. 2. Water content number of blows

Another parameter that determines the consistency of soils is the liquidity index. The liquidity index (I_L) is given in Equation 1. When the liquidity index is less than zero, the consistency of the soil is semi-solid or solid, when the liquidity index is between zero and one, the consistency of the soil is plastic and when the liquidity index is greater than one, the consistency of the soil is liquid. When the liquidity index is zero, it takes the plastic limit value, and when it is one, it takes the liquid limit value.

$$LI = I_L = \frac{w-PL}{PI} = \frac{w-PL}{LL-PL} \tag{1}$$

where, w=natural water content of the soil, LL=liquid limit, PL=plastic limit and PI=plasticity index.

Fig. 3 shows the number of drops corresponding to the liquidity index values obtained using the Casagrande test results. The liquidity index values obtained for 25 blows are also given in Fig. 3. The LI=0 line was determined as the value separating semi-solid from plastic state, while the LI=1 line was determined as the boundary separating plastic from liquid state. When Figure 3 is analyzed, firstly, at low water contents, the LI is less than zero and the soil is solid or semi-solid and the number of blows is very low. With increasing water content, the liquidity index increases above zero and the corresponding number of blows increases considerably. Then, if the water content continues to increase, the number of blows decreases and the liquidity index approaches one. If the water content continues to increase in the test, the liquidity index takes values greater than one and the number of blows decreases considerably.

Fig. 4 shows the variation of water content ratio with the number of blows for 6 different salt contents as a result of Casagrande test. When the natural water content of the soil is equal to the liquid limit value, the water content ratio becomes one. The results show that for the given number of strokes (N=25), soils with lower salt content have a higher water content ratio.

Finally, the variation of the liquidity index with water content is given in Fig. 5. For all data, the variation of the plasticity ratio (R_p=PL/LL) was analyzed for values of 0.2, 0.4 and 0.6. It is seen that for all salt contents, the data are concentrated in the region between 0.2 and 0.4 for different water contents and liquidity index values. In Fig. 5, the water content ratios vary between 0.05 and 1.6, while the corresponding liquidity index varies between -0.033 and 1.84.

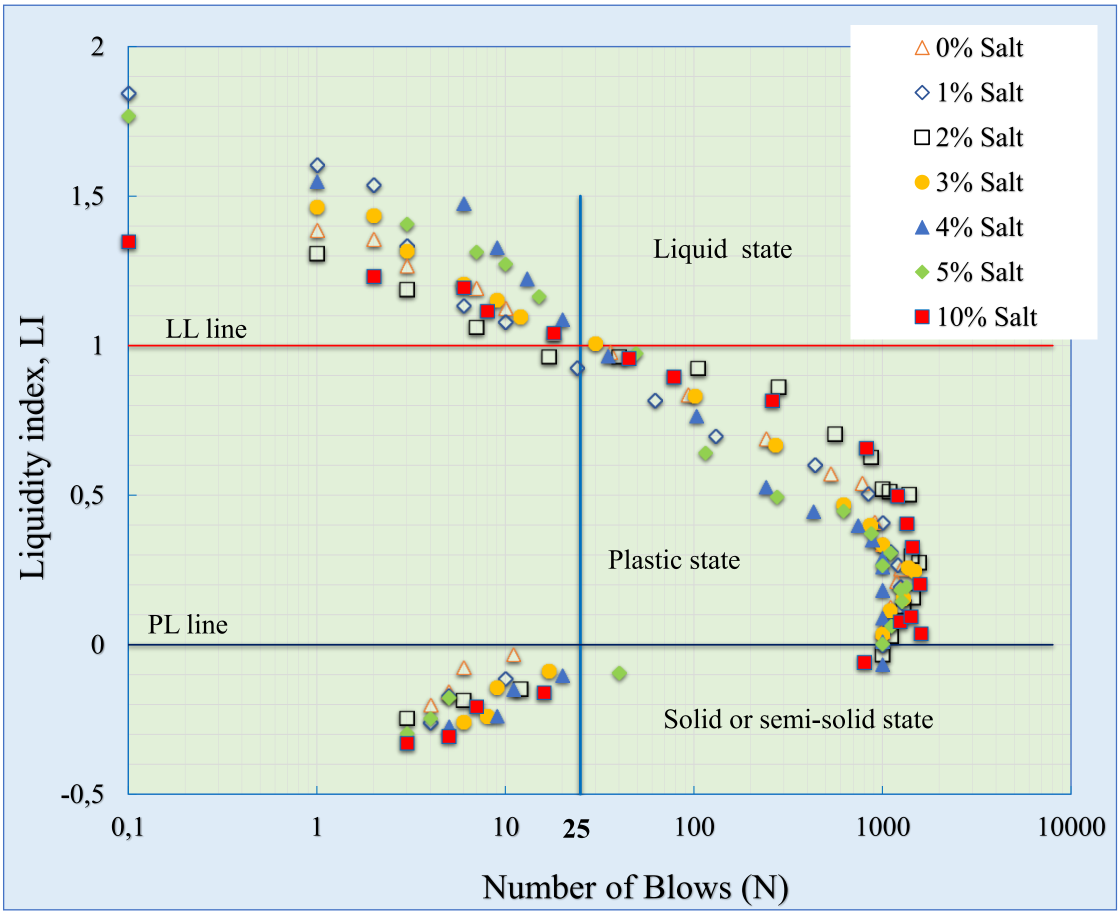

Fig. 3. Liquidity index number of blows

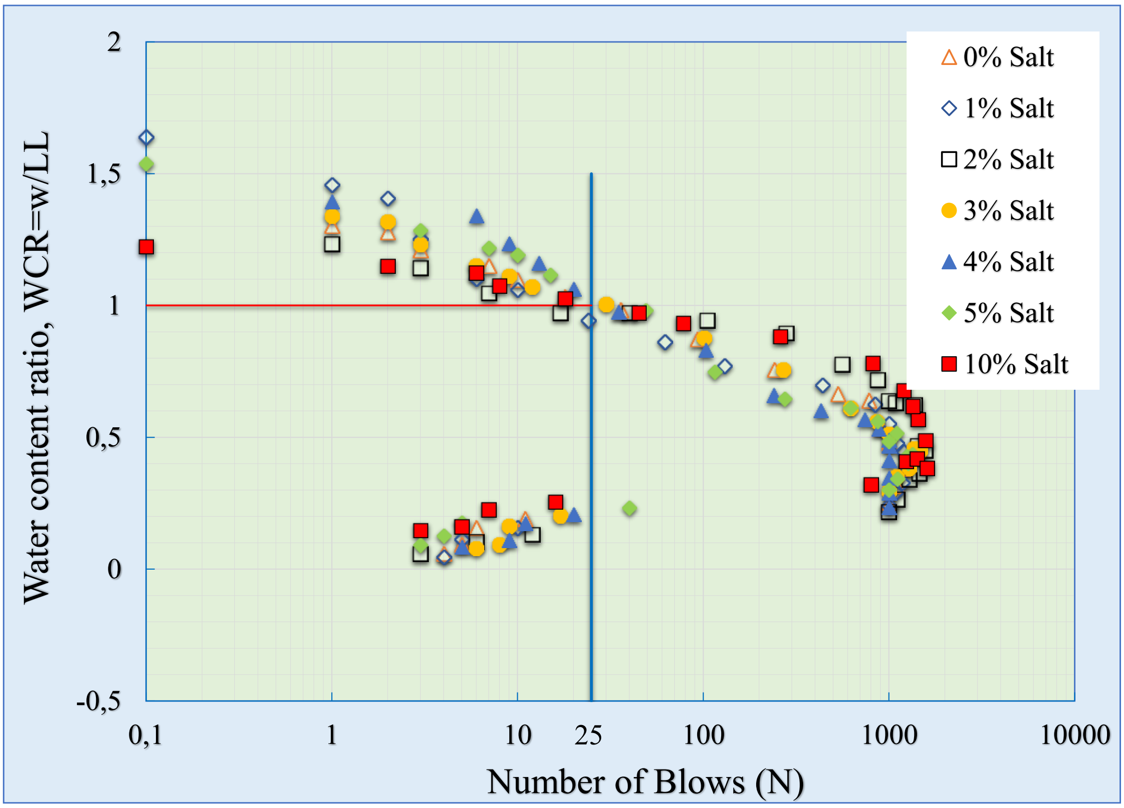

Fig. 4. Water content ratio number of blows

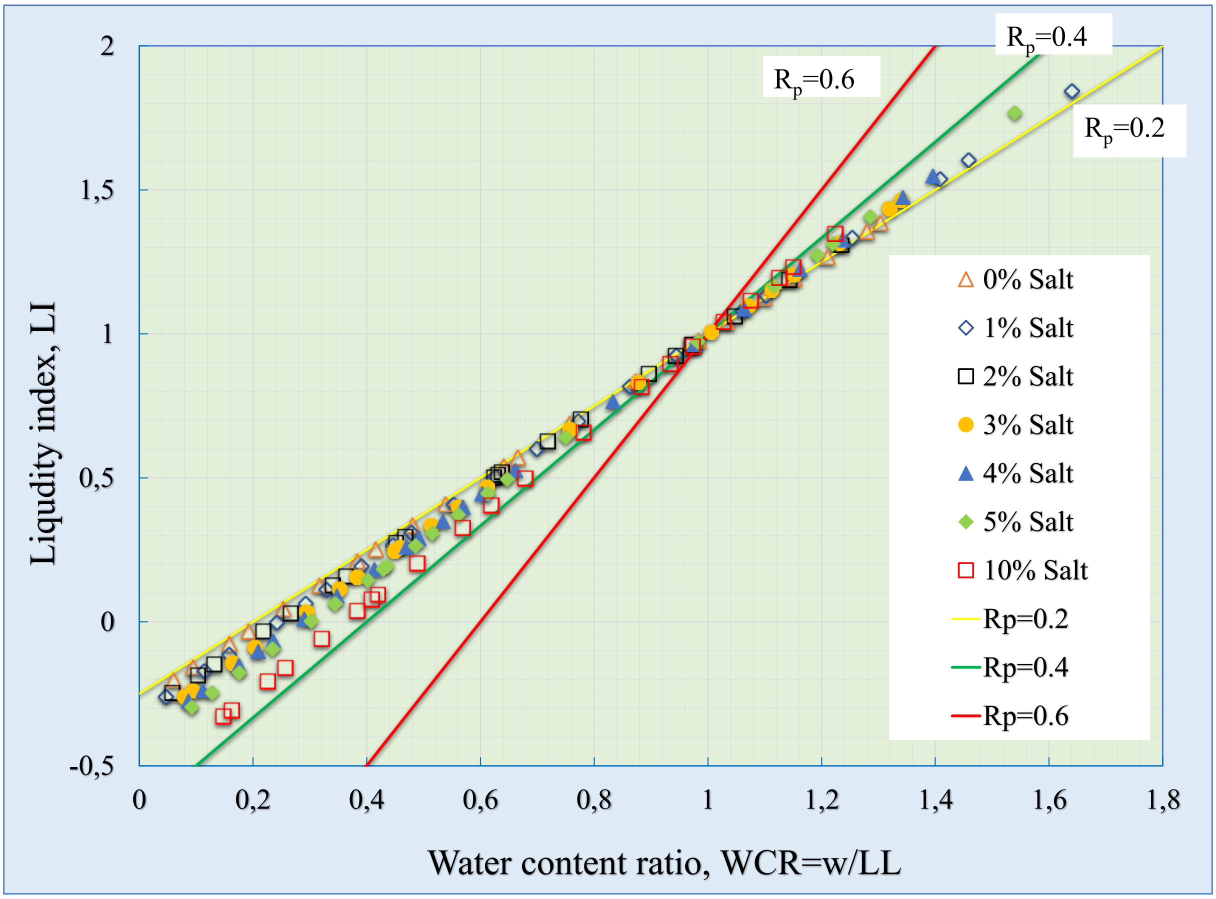

Fig. 5. Liquidity index water content ratio for Casagrande test

3.2. Fallcone test results

Within the scope of the study, fallcone experiments were carried out in accordance with BS 1377-9 (1990) standard at a total of 6 different salt concentrations on bentonite clay with distilled water, 1% to 5% with increasing 1% and 10% salt water mixtures.

The cone penetration water content relationship for the first 7 tests is shown in Fig. 6. At the beginning of the test, the experiment was started with 4-5% water content. Penetration values of 38-39 mm were obtained at very low water contents. Then, by gradually increasing the water content in the brine mixtures, the cone penetration amounts corresponding to each water content were also found. For different salt water concentrations, the cone penetration amounts decreased gradually. For a total of 7 different sets of experiments, minimum cone penetration amounts were obtained when the water contents were between 44% and 62%. For example, in the solution with 2% salt content, the water content was 44.3% and the corresponding cone penetration was only 0.88 mm. When the salt content in the solution was 4%, the cone penetration amount corresponding to 61.60% water content was found to be 1.19 mm. Thereafter, cone penetration continued to increase with increasing water content in all mixtures. After a limit water content, adding more salt water does not change the amount of cone penetration as it reaches the highest limit.

The experimental results shown in Figure 6 were given for all salt-water mixtures in order to describe the behavior and to present the results of the tests consisting of 25 steps in each experiment. In Fig. 7, the variation of cone penetration with water content is transformed into a data set consisting of the part of the data obtained during the experiment after the cone tip reaches its minimum penetration value and the cone penetration value increases with increasing water content. In this case, a linear relationship was obtained between cone penetration and water content. In the experiments, the part of the cone penetration value corresponding to 2 mm was defined as plastic limit, while the part corresponding to 20 mm was expressed as liquid limit.

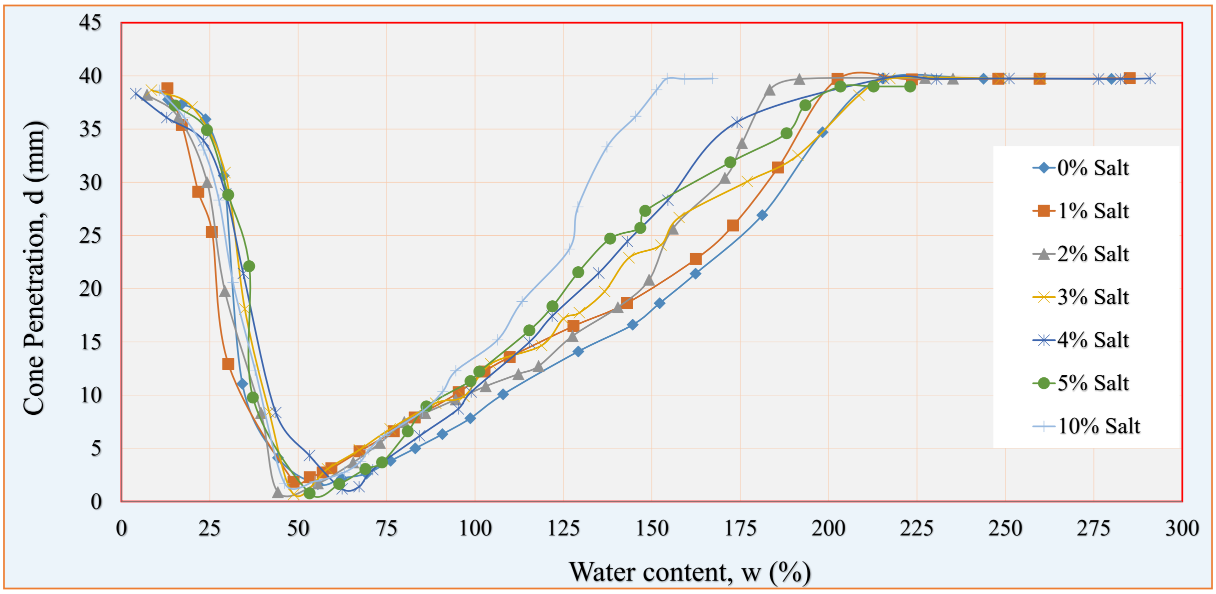

Fig. 6. Cone penetration water content

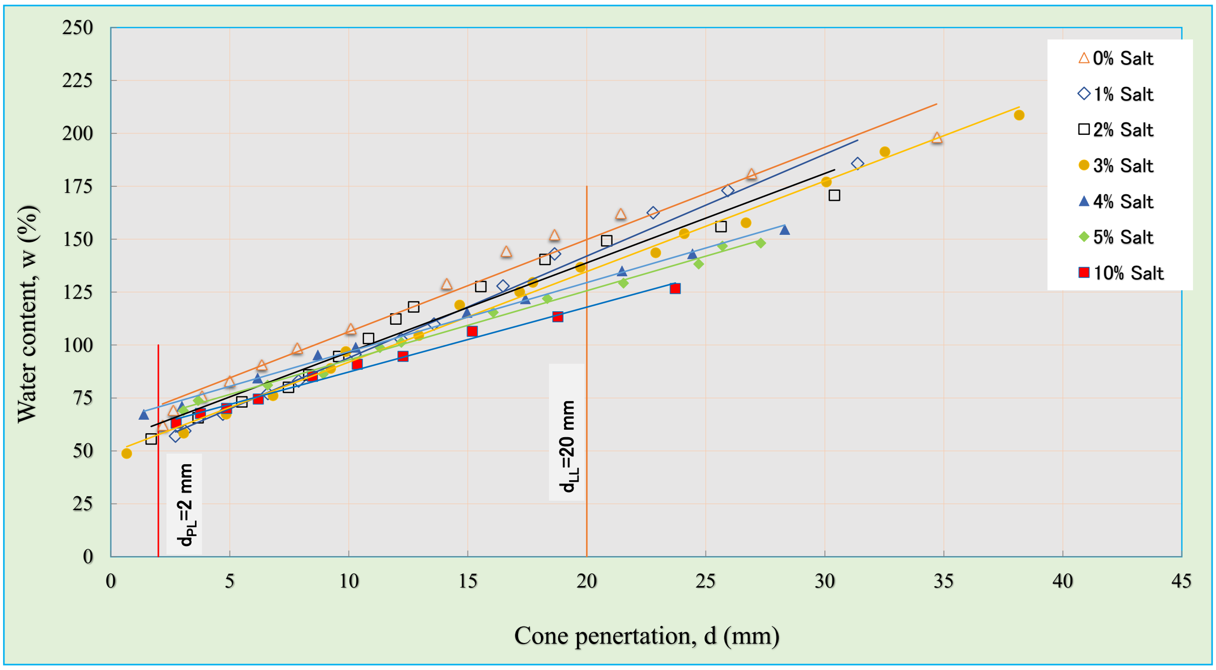

Fig. 7. Water content cone penetration relationship

In Table 3, liquid limit and plastic limit values are calculated and presented for different salt contents as a result of the fallcone test. The liquid limit values obtained in Table 3 are calculated as the water content corresponding to 20 mm penetration, while the water content value corresponding to 2 mm penetration is calculated as the plastic limit. When the results obtained are examined, while the fallcone liquid limit was 149.82% for 0% salt-water mixture, the liquid limit decreased to 117.92% in the experiment performed for 10% salt-water mixture. In this case, a regular decrease in the liquid limit of bentonite clay was observed as the salt concentration increased. When the plastic limit values were examined in the same experiment, there was no regular decrease with increasing salt content. While calculating the plasticity index values in the Fallcone experiment, the plastic limit values obtained by the conventional method were used for the plastic limit value. It was observed that the plasticity index values decreased as the salt content increased.

Table 3. Liquid limit, plastic limit and plasticity index for fallcone device

Salt Content (%)	Equation	R^2	LL_{FC} (%)	PL_{FC}(%)	PL_{con}(%)	PI_{FC}
0	LL_{FC}=4.357×d+62.679	0.975	149.82	71.39	47.62	102.20
1	LL_{FC}=4.8093×d+45.85	0.989	142.04	55.47	54.11	87.93
2	LL_{FC}=4.2232×d+54.374	0.960	138.84	62.82	53.85	84.99
3	LL_{FC}=4.2782×d+49.14	0.994	134.70	57.70	54.55	80.15
4	LL_{FC}=3.2679×d+64.171	0.996	129.53	70.71	56.82	72.89
5	LL_{FC}=3.265×d+60.334	0.995	125.63	66.86	58.62	67.01
10	LL_{FC}=3.066×d+56.601	0.990	117.92	62.73	60.61	57.31

Fig. 8 shows the variation of undrained shear strengths with water content for all salt-water mixtures. The undrained shear strengths of soils in Fallcone tests were calculated by Hansbo (1957) using Equation 2.

$$S_u = \frac{K \times W}{d^2} \quad (2)$$

In Equation 2, K=constant (0.85) related to the angle of the cone tip used in the Fallcone test, W is equal to the product of the mass of the cone tip (80 g) and the acceleration of gravity. d represents the amount of the cone penetration depth and its unit is mm. When the general behavior is analyzed, it is seen that the undrained shear strength increases with increasing water content, then reaches a peak value, and gradually decreases and stabilizes if the water content continues to increase. When the effect of salt is examined, for the undrained shear strength of the sample of 10 kpa, the samples prepared with 10% salt water solution have 81% water content, while the same undrained shear strength is reached at 99% water content in the experiments with distilled water. This indicates that for a constant value of undrained shear strength, lower water content is obtained at higher salt concentrations. At the end of the test, all solutions were stabilized at an undrained shear strength of 0.4 kPa but at different water contents. For example, 10% salt water solution has 154% water content, 5% salt water solution has 203.39% water content, 4% salt water solution has 212% water content, 3% salt water solution has 220% water content, 2% salt water solution has 223% water content, 1% salt water solution has 248% water content and 0% salt water solution has 251% water content.

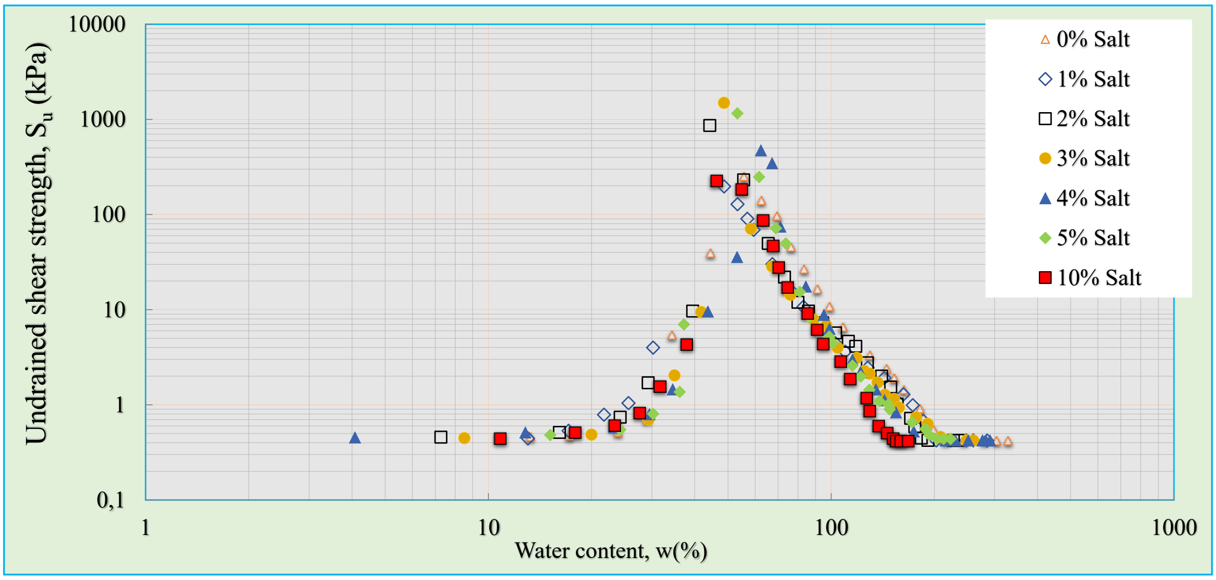

Fig. 8. Undrained shear strength water content relationship

The liquidity index cone penetration relationship obtained from Fallcone test results is given in Fig. 9. In addition, liquid limit lines are added in case the liquidity index is 1 and plastic limit lines are added in case the liquidity index is zero. In this case it is divided into 3 parts: solid or semi-solid state, plastic state and liquid state. In the solid or semi-solid state the liquidity index is less than zero. In this case, the liquidity index decreases from -1 to zero and the cone penetration values decrease from 40 mm to 1 mm. Then the liquidity index goes from zero to one and the cone penetration values increase again. When the liquidity index reaches 1.6, cone penetration values are obtained around 40 mm and after that, cone penetration values are fixed at 40 mm even if the liquidity index increases.

The liquidity index undrained shear strength relationship obtained by using the results of fallcone tests on mixtures with different salt concentrations is shown in Fig. 10. The initial undrained shear strengths started with values between 0.4-0.5 kPa when the liquid index is less than zero. When the liquidity index was around zero, the undrained shear strengths reached maximum values. For example, while the liquidity index was -0.10 for 184.78 kPa undrained shear strength at 10% salt water mixture, the liquidity index was -0.113 for 861.45 kPa undrained shear strength at 2% salt water mixture, and the liquidity index was 0.077 for 471.07 kPa undrained shear strength at 4% salt water mixture. As the liquidity index approached one, the undrained shear strengths decreased again. While the undrained shear strength of salt water mixtures is around 2 kPa, their liquidity index is around 1. As the liquidity index increased up to 1.5, the undrained shear strengths of salt water mixtures decreased and reached the range of 0.4-0.5 kPa. Increasing the liquidity index from 1.5 to 3 did not cause any change in the undrained shear strength of salt water mixtures. Because if the liquidity index is greater than 1.5, it means that the natural water content of salt-water mixtures is at least over 130% in the case of bentonite clay.

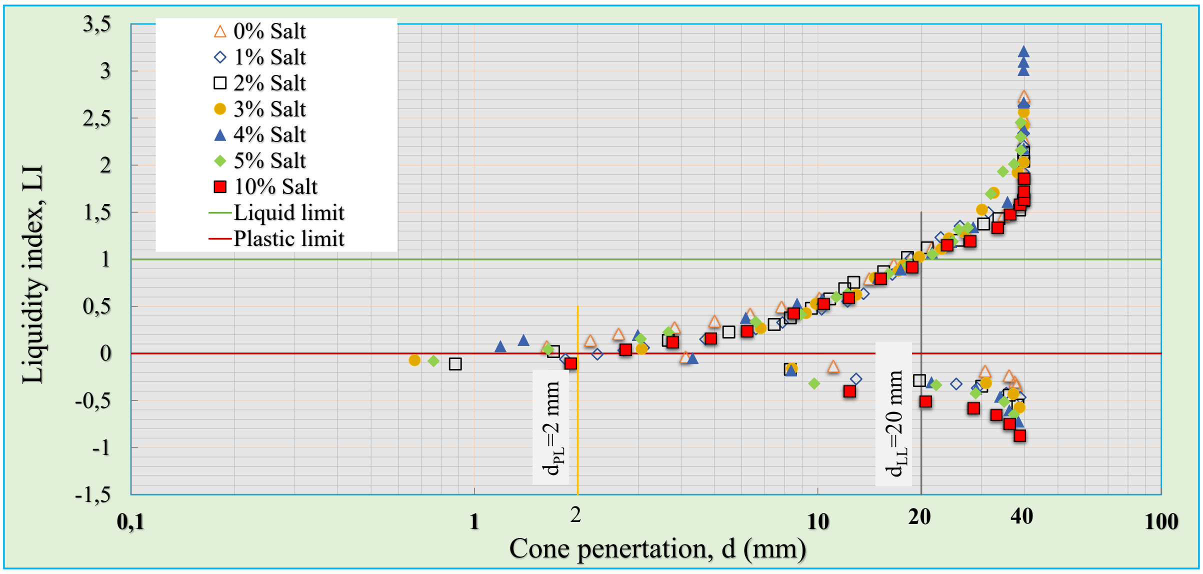

Fig. 9. Liquidity index cone penetration relationship for fallcone test

In Fig. 10, liquidity index dependent undrained shear strength values for sensitivity ratio 1, 2, and 4 are calculated and curves are plotted for liquidity index dependent undrained shear strength using the relation proposed by Shimobe and Spagnoli (2020) and shown in equation 3. The sensitivity ratio (S_t=1) line also indicates that it is for remolded specimens. It shows that most of the experimental specimens are around the S_t=1 line in the plastic and liquid cases. At very high liquidity index values, the undrained shear strength value stabilizes and has a high Sensitivity ratio (S_t=4).

$$S_u = 98 \times S_t \times exp[\ln\{0.4755/(I_L + 0.5012 \times (1 - I_L)\}/0.19] \ [16] \tag{3}$$

Shimobe and Spagnoli (2020) determined the relationship between the liquidity index and water content ratio depending on the plasticity ratio with equation 4. In Equation 4, R_p=PL/LL is expressed as plasticity ratio, I_L as liquidity index and WCR as water content ratio.

$$WCR = (1 - R_p) \times I_L + R_p \tag{4}$$

In Fig. 11, the variation of liquidity index and water content ratio is presented for all salt water mixtures. Liquidity index values increase with increasing water content ratio. In the study, 0.2, 0.4 and 0.6 lines of the plasticity ratio were drawn. It was found that the mixtures with low salt contents were closer to the Rp=0.2 line, while those with increasing salt contents were closer to the Rp=0.6 line. For example, when the results obtained from experiments with distilled water are examined, it is seen that the results closest to the Rp=0.2 line are obtained. With increasing salt concentration, the plasticity ratio first approached 0.4. Then, when the salt concentration was increased to 10%, the plasticity ratio was very close to the 0.6 line. In this case, it is concluded that the plasticity ratio increases with increasing salt concentration.

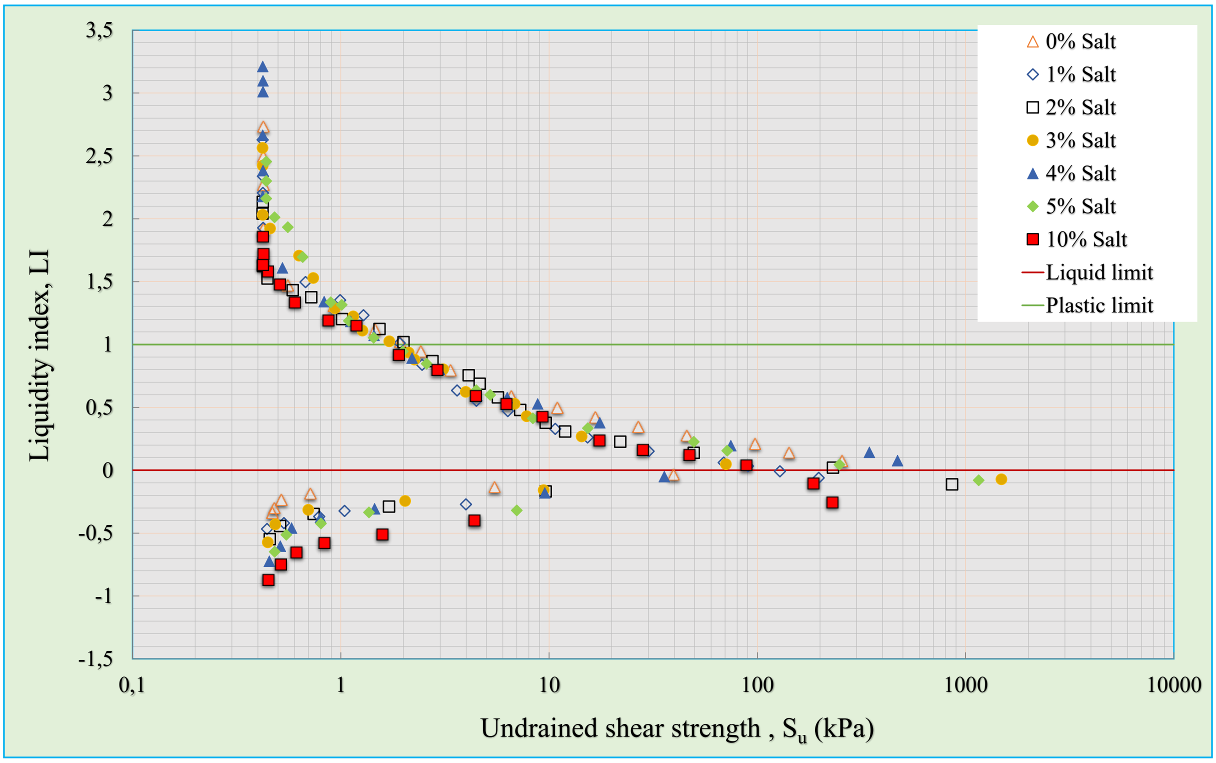

Fig. 10. Liquidity index undrained shear strength relationship for fallcone test

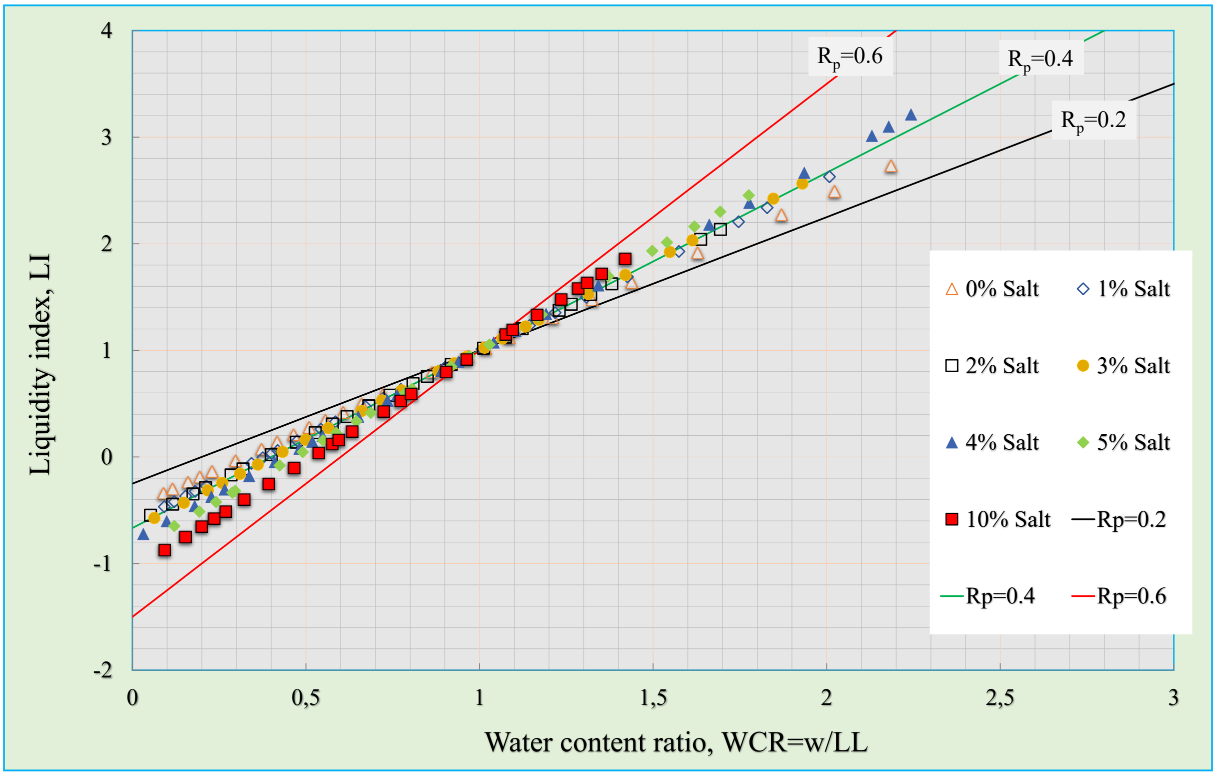

Fig. 11. Liquidity index water content ratio relationship for fallcone test

Empirical correlations of undrained shear strength with the water content ratio of various researchers are given in Table 4. With the data obtained in this study, the variation of water content ratio with undrained shear strength is shown in Fig. 12 on bentonite clay samples with different salt concentrations. Fig. 12 shows that there is an exponential corelation between water content ratio and undrained shear strength. Maximum undrained shear strength values of the samples were obtained when the water content ratio was between 0.3 and 0.5. Thereafter, the undrained shear strength of all samples decreases exponentially with increasing water content ratio. When the water content ratio is equal to one, the water content of the samples is equal to the liquid limit values. In this case, Fig. 12 shows that the undrained shear strength values vary between 1.6 kPa and 2.8 kPa. With increasing salt content, undrained shear strengths were obtained at very low water content ratios. For example, in the 10% brine mixture, the undrained shear strength value reached a minimum when the water content ratio was only 1.3, while in the 0% brine mixture, the water content ratio increased up to 1.8 and the undrained shear strength value was minimum.

Table 4. Relationships between undrained shear strength and water content ratio WCR

Equation No	Authors	Equation	Definition

4. Conclusions

In this study, a series of laboratory studies were carried out to investigate the effect of bentonite clay, which has high plasticity, on different salt concentrations. In addition to the experiments with distilled water, the salt concentration was increased by 1% from 1% to 5%. In addition, 10% salt water mixture experiments were carried out to examine the effect of high salt concentration. Casagrande liquid limit, Fallcone liquid limit and conventional method plastic limit experiments were performed at six different salt concentrations. In the experiments, in order to clearly determine the change in salt water content, starting from very low water content, the water content was increased step by step and ended at an average of 30 steps. The water content ratio in the experiments varied between 1.5 and 3 times. This means that the experiments were carried out up to water contents up to 3 times the liquid limit value of each mixture. The results obtained can be summarized as follows:

1) Liquid limit values were obtained by using Casagrande test results on bentonite clay samples with different salt concentrations. High R^2 values were obtained with the equations proposed in Table 2. According to the Casagrande test results, there was a significant decrease in the liquid limit values with increasing salt concentration. For example, in the experiment with distilled water, the liquid limit was 219.68%, while the liquid limit was 195.79% at 5% salt content and 169.15% at 10% salt content. 1) Decreases similar to the liquid limit were obtained in the plasticity index values of the same samples. While the plasticity index was 172.06% in the experiment with distilled water, it was determined as 137.17% in the 5% salt water mixture. In the experiment with 10% salt content, the plasticity index was calculated as 108.54%, the lowest value.
2) According to the experimental results of the Casagrande test, it is seen that the plasticity ratio line of all experimental data is between 0.2 and 0.4. While the plasticity ratio is much closer to the 0.2 line for the data at low salt contents, the plasticity ratio approaches 0.4 with increasing salt content. The experiments for 10% brine mixture gave the closest results to the Rp=0.4 line.
3) When the Fallcone test results are examined, it is seen that the water content values start with approximately 5% and increase up to 300%. The variation of cone penetration with water content ratio was also obtained for all brine mixtures. The proposed equations for liquid limit values are determined separately for different salt contents in Table 3. While the liquid limit for bentonite clay was obtained as 149.82% in the experiments with distilled water, it decreased to 125.63% in 5% brine mixture and to 117.92% in 10% brine mixture. The liquid limit values decreased significantly with increasing salt content.
4) When the variation of liquidity index undrained shear strength is examined, it is seen that the experimental data are around the sensitivity ratio (St=1) line. When the soil becomes liquid, the undrained shear strength takes a constant value despite the increasing liquidity index value. In Fallcone test results, between the liquidity index and water content ratio, the lines 0.2, 0.4 and 0.6 are drawn. The data from the experiment with distilled water shows that while the values are very close to the Rp=0.2 line, the plasticity ratio changes towards 0.6 with increasing salt content. At the highest salt concentration, 10% brine content, the experimental data show that the plasticity ratio approaches the 0.6 line. Increasing salt content decreased the plasticity of the soil.
5) In addition, the variation of undrained shear strength as a function of water content ratio was investigated and the equations obtained for undrained shear strength at different salt contents were presented. Higher undrained shear strength values were obtained at lower salt concentrations.

Investigation of the effects of land surface sensitivity on rockfall analyses

Habibullah Mohammadi[1], Evrim Cüre[*1], Emel Türker[1]

[1] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract Rockfall is defined as the detachment of a rock block from the main rock mass due to physical or biological weathering, followed by its downward movement through rolling, sliding, or bouncing along the slope. Today, various methods are employed to assess rockfall hazards however, two dimensional (2D) and three-dimensional (3D) statistical simulations that model rockfall behavior are commonly preferred. In these analyses, the morphology of the terrain surface plays a critical role. For this purpose, in the present study, a total of twelve 2D rockfall simulations were performed along four different cross sections extracted from three terrain models prepared at scales of 1/1, 1/1000, and 1/5000. The parameters obtained from the analyses such as bounce height, velocity, and kinetic energy were comparatively evaluated. The results demonstrate that as the resolution of the terrain model increases, significant changes occur in both the bounce height of the rock block and the trajectory it follows. In contrast, when the terrain model resolution decreases, the rock block tends to roll rather than bounce, even on very steep slopes. These findings clearly indicate that the outcomes of rockfall analyses are directly influenced by the accuracy of the terrain model, and that higher-resolution models provide more reliable and safer solutions for engineering applications. The study highlights the importance of high precision terrain modeling in accurately assessing rockfall risks and developing effective mitigation measures.

Keywords: Digital terrain model; Rockfall analysis; Bounce height; Kinetic energy

1. Introduction

Rockfalls are among the most significant natural hazards, particularly in mountainous and steep terrains, where they may occur due to natural processes or human activities, often resulting in loss of life and property. These events pose serious risks to engineering structures such as highways, railways, residential areas, and construction sites (Volkwein et al., 2011). Falling rock blocks can disrupt transportation networks, cause economic losses, damage infrastructure, and even lead to fatal outcomes. Therefore, predicting and preventing rockfalls is of critical importance from an engineering perspective (Akin, 2013).

Rockfalls occur when rock blocks detach from slopes and descend due to gravitational forces, through free fall, rolling, or bouncing motions. These movements are influenced by various natural factors such as intense rainfall, freeze thaw cycles, earthquakes, and rock weathering. Additional elements such as the expansion of water freezing within discontinuities, the growth of tree roots, and topographic irregularities can also trigger the detachment of rock blocks (Varnes, 1978; Akın, 2020). Once detached, these blocks can gain substantial kinetic energy under the influence of topography, posing a significant threat to engineering structures. In mountainous regions in particular, many residential areas have been declared disaster prone due to rockfall hazards however, with advancements in engineering techniques, various mitigation measures have been implemented in such regions to minimize risks (Varol et al., 2023).

One of the key factors influencing the accuracy and reliability of rockfall analyses is the map scale. The map scale plays a critical role in determining the accuracy of terrain models, thereby affecting the assessment of rockfall trajectories, the movement dynamics of falling blocks, and their impact forces. The outcomes of analyses conducted at different scales can lead to significant variations in the development of rockfall hazard maps and the identification of appropriate engineering mitigation measures (Öztürk et al., 2022). While large scale maps provide generalized data that may result in certain deviations in the analysis results, small scale maps offer more detailed representations of the terrain. Therefore, it is essential for engineers performing rockfall analyses to understand how the map scale they use influences the outcomes of their assessments (Fanos et al., 2016).

In this study, the impact of map scale on rockfall analyses was thoroughly examined, the most appropriate scale ranges for field applications were identified, and the reliability of the analysis results was evaluated. By using

https://doi.org/10.31462/icearc2025_ce_geo_108

digital elevation models (DEMs) produced at different scales, the relationships between the falling dynamics of rock blocks and potential hazard zones were assessed. Additionally, the effect of map scale on the modeling precision of rockfall scenarios was investigated through comparative analyses. In this context, by integrating contemporary engineering approaches with evolving computer technologies, the study aimed to enhance the understanding of rockfall related risks and to determine how map scale influences analytical outcomes, thereby contributing to the development of more effective engineering solutions.

2. Materials and methods

This study was conducted within a designated site located in the Bulak Neighborhood of the Ortahisar District in Trabzon Province, Turkey. The study area is characterized by steep slopes and a rugged terrain composed of weathered rock masses, indicating a high potential for rockfall occurrences. Topographic and geological conditions were examined in situ, and relevant field data were directly collected from the site. Given the challenges of collecting topographic data using traditional methods in this regionprimarily due to the presence of numerous fractured and hazardous rock blocks in the source zone there was a need to employ more precise and detailed data acquisition techniques. Therefore, in order to accurately identify hazardous rock masses, various mapping methods were utilized and an integrated interpretation was developed.

The accuracy of the kinematic and slope stability analyses used in the rockfall assessments heavily depends on the precision of the acquired topographic cross-sections. For this reason, photogrammetric data collection techniques were preferred to enhance the reliability of the analyses and to most accurately represent the terrain conditions. The high-resolution terrain models obtained through this method allowed for more realistic simulations of rockfall scenarios and hazard assessments. Fig. 1 presents an orthophoto view of the study area, visually illustrating the region's topographic features and its spatial relationship with nearby settlements.

Fig. 1. The view of the study area on the orthophoto

2.1. Factors leading to rockfalls

Rockfalls occur in areas influenced by various internal and external forces. In most cases, multiple factors simultaneously contribute to the initiation of rockfall events. These factors can be broadly categorized into three main groups: structural (internal), environmental (external), and anthropogenic (human induced) factors (Volkwein et al., 2011; Bilgili, 2018). Structural factors (internal) are directly related to the geological characteristics of a slope or hillside. This group includes natural features such as fractured and jointed rock masses, as well as discontinuity surfaces with instability potential. Environmental factors (external) refer to naturally occurring processes, including intense rainfall, freeze thaw cycles, wind erosion, and snowmelt, all of which are known to trigger rockfalls. Anthropogenic (human induced) factors arise from human activities such as uncontrolled blasting operations, vibrations generated by trains or heavy construction machinery, and poorly designed slope geometries. The interaction of these factors often leads to the disruption of the natural equilibrium of slopes, resulting in the detachment and downslope movement of rock masses under the influence of gravity (Grant et al., 2018).

2.2. Rockfalls and types of rock movements

Rockfalls can be defined as the vertical movement of rock blocks of various sizes descending from a sufficiently steep slope or cliff due to the force of gravity. Depending on the slope of the terrain, rock blocks can exhibit different types of movement, such as free fall, bouncing, or rolling (Fig. 2). As shown in the figure, depending on the slope angle, rocks exhibit free fall motion at a 90° slope, bounce at a 70° slope, and roll at slopes of 30° and 45° (Fanos & Pradhan, 2018). As the blocks lose energy, in addition to rolling, movements such as dragging and sliding can also be observed. Rockfalls may involve a single block, but multiple rockfall events can occur simultaneously when several blocks detach at once (Matsuoka & Sakai, 1999). Furthermore, after a large rock block falls, it may hit the terrain and shatter into numerous smaller blocks, continuing to move as individual pieces. In such cases, since each rock fragment moves independently, it is crucial to determine the dynamic structure of rockfalls in advance, as this is essential for calculating the fall paths and kinetic energies of the blocks. For instance, a single rock block may have a small mass but can fall at a high velocity. On the other hand, in large-scale rockfalls involving multiple blocks, although the total mass may be greater, the falling speed might be relatively lower. Therefore, understanding the characteristic features of rockfalls is of critical importance for risk analysis and the design of protective measures (Varol et al., 2023).

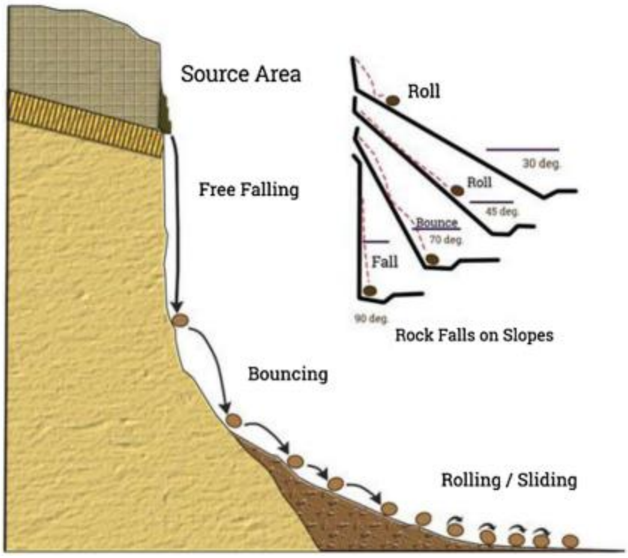

Fig. 2. Rockfall motion modes related to slope angle (Fanos & Pradhan, 2018)

2.3. Creation of the terrain surface

In this study, the rockfall risk of the region within the boundaries of the study area has been assessed, and the significance of map scale in these analyses has been highlighted. In the first phase of the study, the goal was to obtain a precise digital surface model (DSM) of the terrain. For this purpose, aerial images were captured using a Unmanned Aerial Vehicle (UAV) employing photogrammetric methods, and existing maps were produced. The DJI Mavic 3 Enterprise RTK type UAV was used to create the digital terrain model (Fig. 3). Flights were planned with an 80% overlap to obtain a more accurate model. A total of 151 high-resolution oblique and nadir images were captured. These images were processed through specialized software to generate high-resolution digital surface and terrain models. In the second phase of the study, cross-sections obtained from the photogrammetric work, including the 1/1 scale section, as well as sections from 1/1000 and 1/5000 scale maps, were used. In this context, a total of four different cross-sections were extracted, and three separate rockfall analyses were performed on each section.

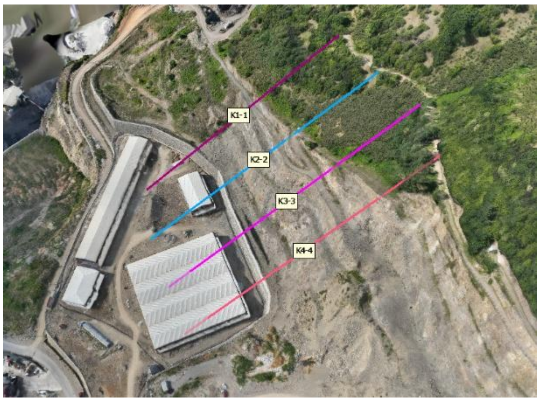
Fig. 3. DJI Mavic 3 Enterprise RTK type unmanned aerial vehicle

3. Result and discussion

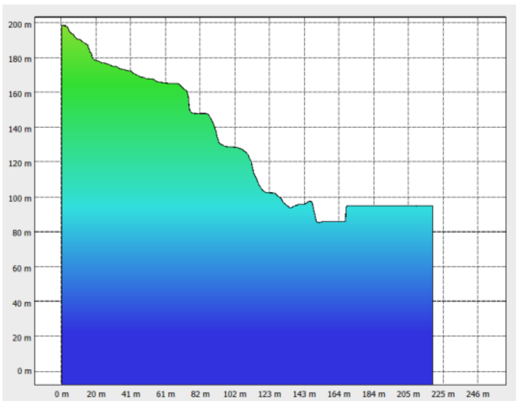
3.1. Two dimensional rockfall analysis (2D)

The two-dimensional rockfall analysis begins with the identification of the topographic and geological features of the terrain. To achieve this, field studies were conducted, maps were examined, and slope profiles were created. The terrain cross-section was modeled to accurately represent the slope's gradient and elevation, and the dimensions, weights, shapes, and sliding potential of the blocks that could cause rockfalls were determined through field observations and photogrammetric measurements. Mechanical parameters such as the normal rebound coefficient (R_n) and the tangential rebound coefficient (R_t) used in the analyses were defined based on the terrain conditions and rock characteristics. These parameters are crucial for realistically simulating the movements of the blocks, including falling, bouncing, rolling, and sliding. All collected geotechnical and geometric data were transferred to the RocFall software used for rockfall analysis. The software was input with terrain cross-sections, physical-mechanical properties of the blocks, and the defined parameters, allowing for the successful simulation of the movements and spread areas of the rock blocks. As a result of these simulations, significant outputs such as rebound height, block speeds, kinetic energy values, and maximum travel distances were obtained.

In this study, two dimensional rockfall analyses were conducted on four selected cross sections along the same route from three maps with different scales. These analyses provide significant scientific data for the technical evaluation of rock stability in the region and for managing rockfall risks. The cross sections obtained from the photogrammetric 3D model are presented in Fig. 4a, while the detailed view of the K1-1 section from these cross sections is shown in Fig. 4b.



(a)



(b)

Fig. 4. Cross sections taken from the route and the K1-1 section detail

The expressions used in the naming of the photogrammetric sections are as follows: K1-1F refers to the section obtained from the photogrammetric studies (Fig. 5), K1-1M refers to the section taken from the 1/1000 scale maps (Fig. 6), and K1-1Z refers to the section taken from the 1/5000 scale maps (Fig. 7).

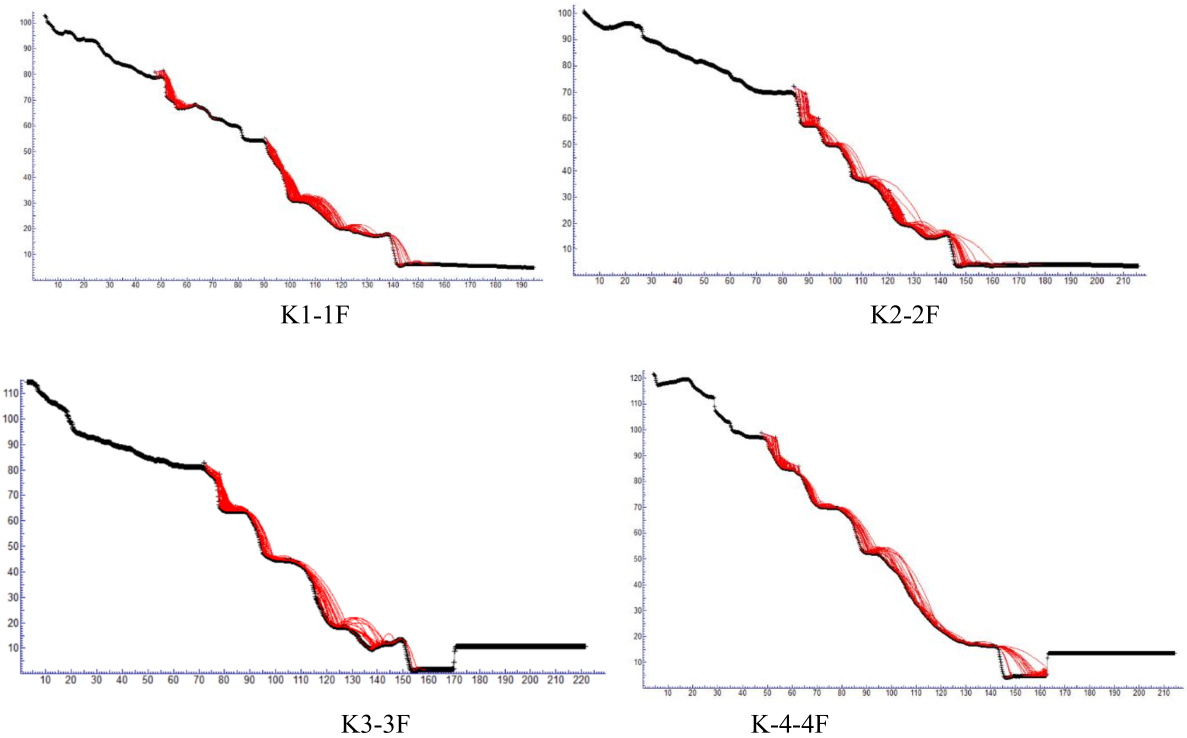


Fig. 5. Rockfall analysis and the path followed by the rock on the sections taken from the photogrammetric model

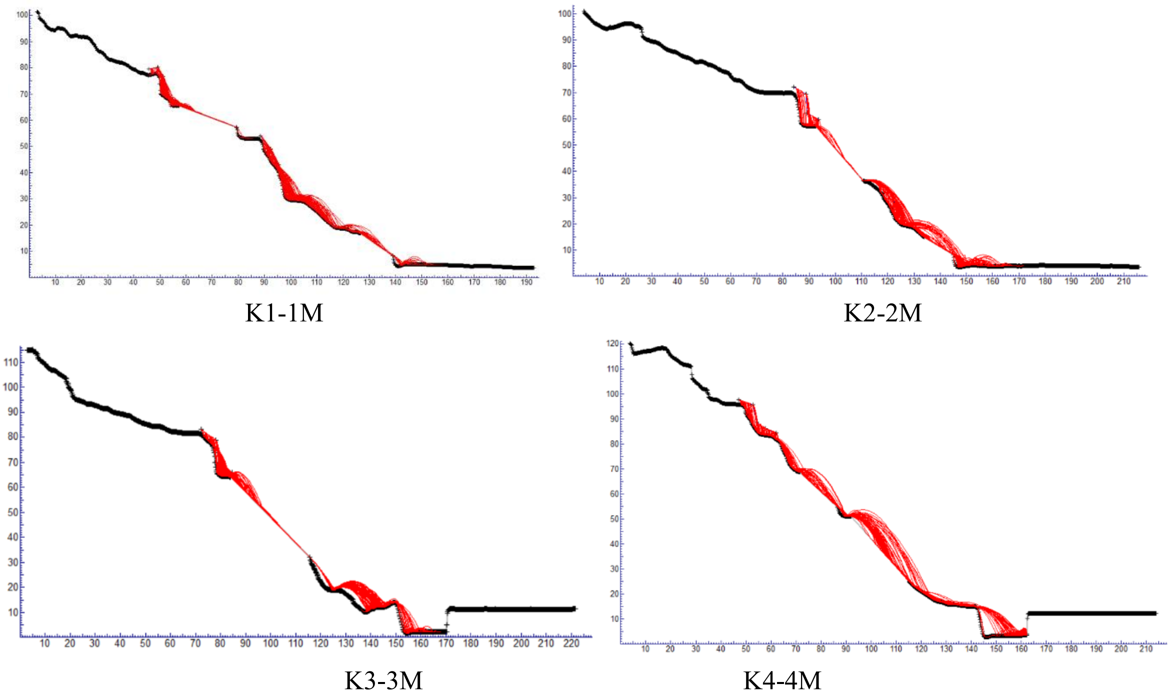

Fig. 6. Rockfall analysis and the path followed by the rock on the sections taken from the 1/1000 scale map

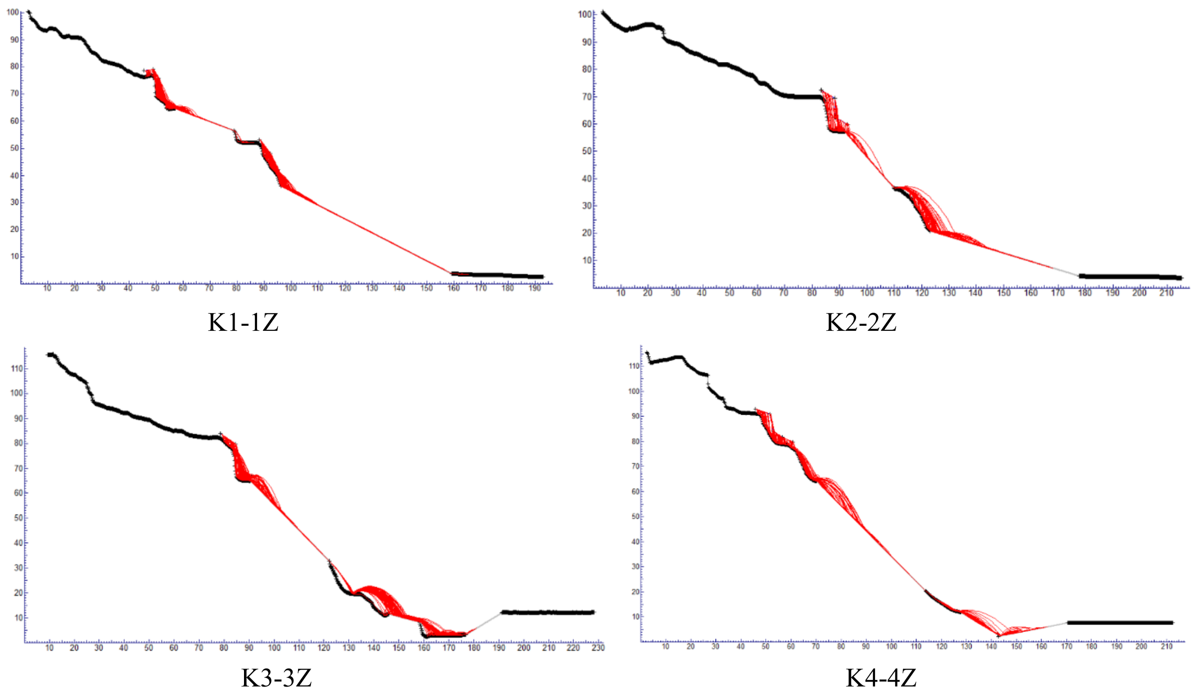

Fig. 7. Rockfall analysis and the path followed by the rock on the sections taken from the 1/5000 scale map

Rockfall analyses were performed for a total of 400 different possible scenarios across four sections, with 100 possible scenarios created for each section. Additionally, on the sections obtained from the 1/1000 scale maps shown in Fig. 6, 400 possible rockfall analyses were carried out along the same route, with 100 possible scenarios for each section. Similarly, 2D rockfall analyses were applied to the sections obtained from the 1/5000 scale maps shown in Fig. 7, where 100 possible scenarios were evaluated for each section, resulting in 400 possible analyses and scenarios in total.

To investigate the effect of terrain surface accuracy on rockfall, these two-dimensional analyses focused particularly on comparing the rebound height, linear velocity, and kinetic energy parameters. The total kinetic energy, total rebound height, and total linear velocity graphs obtained from the analyses are shown in Figs. 8-10, and detailed evaluations were made based on these graphs.

Upon examining these detailed evaluations, the total kinetic energy graphs presented in Fig. 8 compare the results obtained for each section at three different terrain accuracy levels. These graphs clearly show that kinetic energy is directly proportional to the terrain accuracy.

As shown at Table 1, when comparing the kinetic energy values, it is observed that the total kinetic energy of K1-1F is approximately 10% higher than K1-1M and 20-50% higher than K1-1Z. Similarly, K2-2F shows 10% higher energy values compared to K2-2M and 20-50% higher compared to K2-2Z. The same observation applies to K3-3F, where it exhibits 10% higher energy values than K3-3M and 20-50% higher than K3-3Z. As the terrain precision increases, it has been noted that the total kinetic energy of K4-4F changes by 10% compared to K4-4M and 20-50% compared to K4-4Z. However, it is not sufficient to only examine the maximum energy regions. In many cases, it may not be feasible to implement rehabilitation and mitigation measures solely within these maximum energy zones. Therefore, changes in total kinetic energy should also be considered beyond the maximum zone. For instance, it has been observed that the total kinetic energy between K2-2F, K2-2M, and K2-2Z shows a noticeable increase after the maximum zone.

Table 1. Comparison of kinetic energy based on cross sections

Cross Section	Comparison	Increase (%)
K1-1F	According to K1-1M	10
K1-1F	According to K1-1Z	20-50
K2-2F	According to K2-2M	10
K2-2F	According to K2-2Z	20-50
K3-3F	According to K3-3M	10
K3-3F	According to K3-3Z	20-50
K4-4F	According to K4-4M	10
K4-4F	According to K4-4Z	20-50

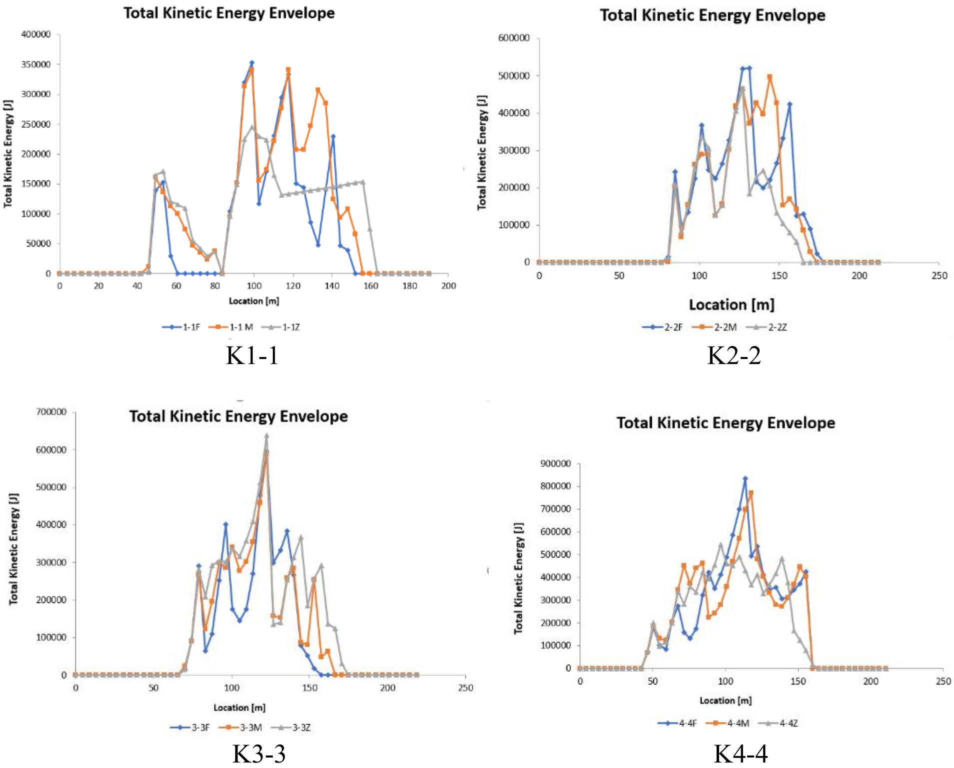

Fig. 8. Total kinetic energy graphs obtained from the rockfall analysis results

A similar behavior to the scenarios created in the comparative graph can be observed in Fig. 9. Here, although the bounce heights are relatively close in the bouncing regions, it has been observed that as the terrain accuracy increases along the slope route, the heights rise significantly. Additionally, as a result of the literature review, it has been understood that this situation has been clearly demonstrated and confirmed through video cameras in real time experiments.

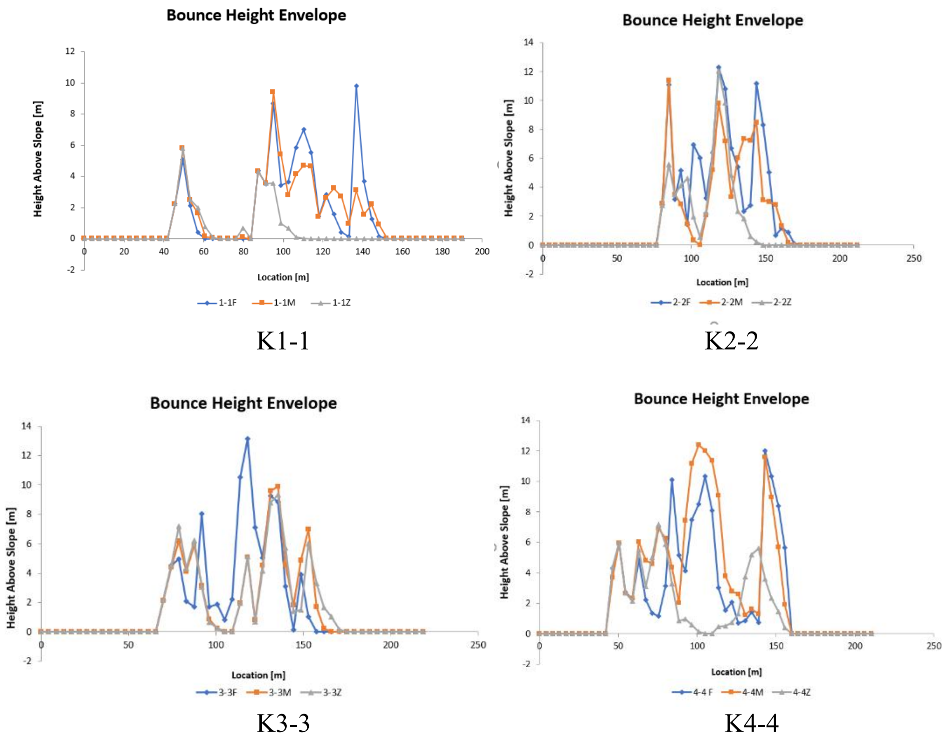

Fig. 9. The graphs of total bounce height obtained from the rockfall analysis results

The results of the rockfall analysis also reveal that as the terrain accuracy decreases, the movement of the rock blocks shifts from free fall and bouncing to rolling. This change directly affects the bounce height, and consequently, the speed and kinetic energy. In the photogrammetric analyses presented in Figure 9, it was observed that almost all the rock blocks predominantly exhibited bouncing motion. However, in the 1/1000 scale maps, the falls along the four cross-sections transitioned to rolling after a certain point, then resumed bouncing motion, and continued with rolling again.

It can be seen in Fig. 10 that the total kinetic energy exhibits a similar behavior to the total linear velocity. However, the difference between rolling and linear velocity highlights the need for a more detailed examination of linear velocity in future studies. Therefore, to further investigate the impact of terrain accuracy on rockfall analyses in future work, both the rotational velocities should be analyzed, and not only two-dimensional but also three-dimensional analyses should be conducted. This will allow for clearer and more definitive results to be obtained.

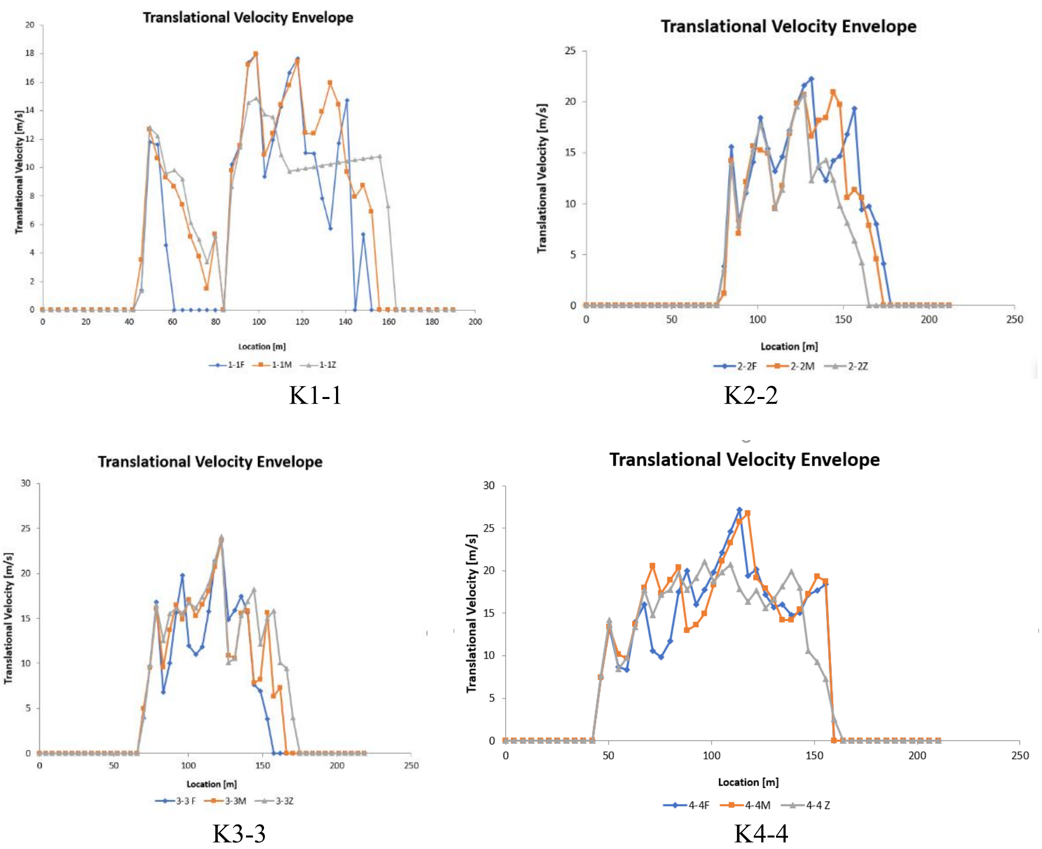

Fig. 10. Total linear velocity graphs obtained from the rockfall analysis results

4. Conclusions

In this study, various analyses were carried out to investigate the effects on rockfall behavior. Within the scope of the research, three different terrain models were used: one photogrammetric model at a 1/1 scale, one at a 1/1000 scale, and one at a 1/5000 scale. From the same region and along the same alignment, four cross-sections were selected, and for each section, 100 probabilistic scenarios were modeled, resulting in a total of 1200 numerical rockfall simulations. The results obtained from these analyses were comparatively evaluated, and the findings are presented below:

- It was observed that as terrain sensitivity increases, rockfall motion tends to occur more as bouncing and jumping rather than rolling. Additionally, the bounce height increased by approximately 10% when transitioning from the 1/1 scale to the 1/1000 scale, and by 20-50% when moving from the 1/1000 scale to the 1/5000 scale, resulting in a total increase ranging between 10% and 50%.
- It was observed that as terrain sensitivity increased, both bounce height and, consequently, velocity also increased. In the photogrammetric scale, bounce height was approximately 10% higher than that of the 1/1000 scale, and 20-50% higher than the 1/5000 scale in maximum energy zones. Overall, a significant increase in velocity was evident with the rise in terrain sensitivity.
- In the photogrammetric scale, kinetic energy was found to increase by approximately 10%, while in maximum energy zones, the variation ranged between 10% and 50%. Moreover, even greater differences

were observed locally. Therefore, considering that mitigation measures cannot always be implemented at maximum energy zones in rockfall analyses, it becomes evident that this parameter plays a highly influential and critical role.

The parameters obtained within the scope of this study clearly demonstrate how critical terrain sensitivity is, emphasizing the necessity of accurately modeling the terrain to reflect realistic rockfall scenarios. For future studies, it is recommended to include the analysis of rotational velocities to further enhance the depth of the evaluation. This recommendation stems from the observation that, as terrain sensitivity decreases, bouncing motions are increasingly replaced by rolling movements during rockfall events. Therefore, a detailed investigation of rotational behavior, along with the implementation of not only cross-sectional but also comprehensive three-dimensional (3D) analyses, would be highly beneficial.

Improvement of a collapsible soil: the sabkha

Mustafa Aytekin*[1]

[1] University of Bahrain, Department of Civil Engineering, 973, Sakhir Campus, Kingdom of Bahrain

Abstract. The sabkha is a kind of collapsible soil that is common in the Kingdom of Bahrain as well as the east part of the Kingdom of Saudi Arabia. The sabkha soils investigated in this research were taken from two locations in Bahrain. One of them is Salmabad, and the other is Zallaq. The investigation deals with the feasibility of treatment of Sabkha soil by three additive materials. The additives employed in the investigation are cement, lime, and dry palm leaves. Each agent has been added to the Sabkha in various ratios. The ratios are the dry mass of the agent to dry mass of Sabkha soil. Additive ratios for cement were 1, 3, 5, and 7%, for lime 2, 3, 4, 5, and 6%, finally for palm leaf 1, 2, and 3%. Since the Sabkha soil is a kind of collapsible soil, collapsibility tests have also been performed to find out "collapsibility index" of the Sabkha. It was found out that the average collapsibility index of the Sabkha is 0.5 that is less than 1.0. The properties of plain Sabkha and mixtures with the agents and ratios mentioned above were determined. The properties that have been determined are the optimum moisture content (OMC), maximum dry density (MDD), liquid limit (LL), plastic limit (PL), plasticity index (PI), hydraulic conductivity(k), apparent cohesion (c), internal friction angle (ϕ), unconfined compression strength (qu). It was concluded that the dry palm leaves give pretty good results in terms of gaining strength on Sabkha samples even if the maximum dry density is getting lighter when it is compared with the other agents.

Keywords: Problematic soils; Collapsible soil; Sabkha soil; Lime stabilization; Cement stabilization.

1. Introduction

The evaporation is much more than precipitation in hot and arid climates. As a result of this phenomenon, saline soils are widespread in these climates. Bahrain has a hot and arid climate. The name of "Sabkha" that is an Arabic word means coastal sediments with high salt content. Sabkha soils are defined as salt bearing formations, Mohamed, and Al-Rawas (2011). These soils are in many parts of the globe as well as in Bahrain. The active locations and potential locations of Sabkha soil on earth have been shown on a map, Mohamed, and Al-Rawas (2011). It is pointed out that Sabkha soil creates geological hazards in the Kingdom of Arabia, Youssef., Pradhan, Sabtan (2007). The Sabkha soil is a kind of collapsible soil that is called a part of problematic soil. Sabkha is a very salty and water sensitive soil, Al-Amaudi, (2008),. In general, many buildings and industrial structures are rested on Sabkha soils, a kind of collapsible soil around the globe. The Arabian Gulf region is one of the areas having many problems and suffering from the natural disasters and aggressive environment. In this region, soils are medium to fine grained sands cemented by salt. The ground water table, GWT, is vey salty and located at shallow depths in Bahrain like the other countries in the region. Sabkha soil is one of the many types of collapsible soils and in turn is one of the many types of problematic soils that are unsaturated in general (Fig. 1). Sabkha has good engineering properties when it is dry. For instance, it has moderate bearing capacity with low settlement in dry state. However, once Sabkha soil is wetted, it loses its entire structure and undergoes an exceptionally large settlement (collapse). All Sabkha soils show collapsible behavior. These types of soil deposits are often found near the mouths of rivers, along the perimeters of bays, and under swamps or lagoons. Soils that are subject to collapse occupy about thirteen million km2 of the world's surface, Abelev, & Abelev (1979), Abelev (1988), Abelev (1984).

The change in volume is associated with a change in soil structure, Jennings, and Knight (1975). Colloidal coatings which adhere to individual soil grains provide intergranular bonds and thus an apparent strength to the soil at low moisture content, but this apparent strength diminishes when the moisture content increases (Fig.2).

This phenomenon is not like the classical consolidation phenomenon, in this phenomenon no water is dissipated from the soil unlike consolidation. However, the soil will absorb water when the water is available and progressively lose its strength. The geotechnical properties of Sabkha soil have been discussed in several studies, Akili (1981), Al-Sanad, Shaqour, and Hencher (1989), Stipho, (1985).

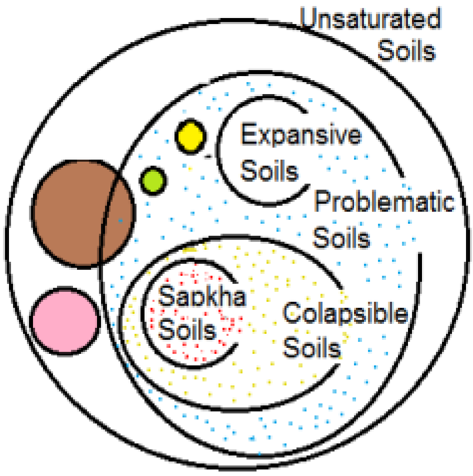

Fig. 1. Sabkha soil a kind of collapsible soil

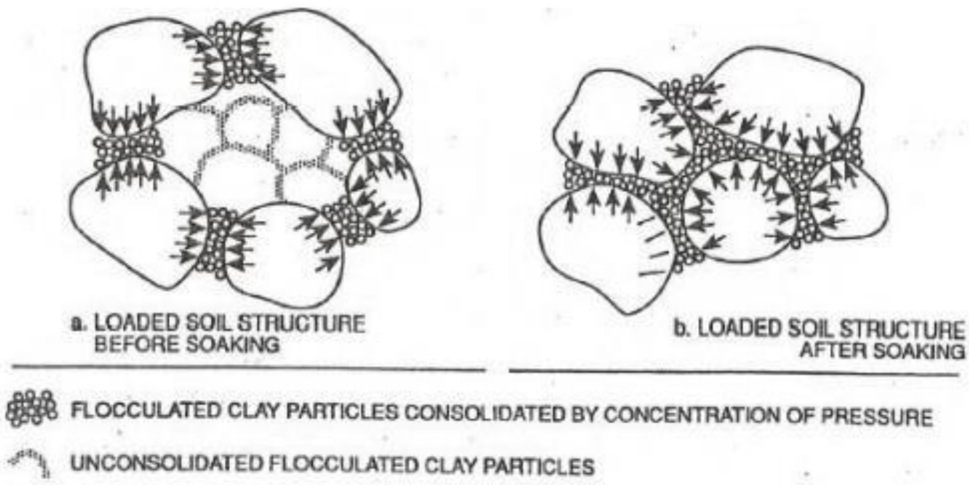

Fig 2. Structure of collapsible soil before and after soaking (Jennings, et al, 1975)

The studies have shown that most Sabkha soils possess a collapsible behavior. They have considerable strength in their dry condition but have a strong potential to lose strength after wetting. The geotechnical properties of Sabkha soils can vary widely as a function of moisture content, fines content, salt type and quantities. Due to similarities of ground conditions in the Gulf region, examples given in any Gulf state are usually applicable to Bahrain. Variation in soil moisture may result from fluctuation of brackish groundwater or a change in climatic conditions, as previously described. Akili (198l) has studied the influence of moisture content on the strength of some soils in eastern Saudi Arabia. He concluded that the maximum CBR (California Bearing Ratio) values of the soils occur just to the drier side of the optimum moisture content. The effect of leaching forces on some geotechnical properties of collapsible soils from Kuwait was investigated, Ismael, (1993). He recorded a reduction in soil shear strength and pre-consolidation pressure and an increase in soil hydraulic conductivity and void ratio because of leaching. Similar observations were noted, Lamb (1990), on examining the effect of leaching on the geotechnical properties of collapsible soils from the east central part of Iowa, USA. These two studies attribute the mechanical instability of the collapsible soils to the removal of a "cementing substance", primarily salts. The implication is that this substance acts as a binder which impacts appear cohesion to the soil, and that leaching of this material leads, in the presence of water, to the formation of a weak collapsible soil mass. The effect of soil type was examined, Doomkamp 1980, Qahwash, (1989). Doomkamp (1980), has reported that the soil in Bahrain is dominated by sand with fine contents varying from 5 to 30%, organic contents of 0.1 to 2% and traces of shells near the coastal areas. Common types of clay minerals include palygorskite and montmorillonite; such minerals are characterized by large surface areas and high ionic exchange capacities. Qahwash (1989) has discussed the influence of sand content on the performance of Sabkha soils obtained from eastern Saudi Arabia. He recorded a significant increase in soil strength (CBR values) and a dramatic reduction in swelling and plasticity potential as the sand content increased. Basma and Tuncer (1992) investigated the effect of soil type, compaction, water content, initial dry unit weight, and applied pressure on the collapse potential of Jordanian soils upon wetting. They reported that well graded soils tend to collapse more than poorly graded ones. Their study also concluded that the collapse potential decreases with an increase in: (1) the difference between the sand and clay percentages; (2) compaction water content; and (3) initial dry unit weight, while it increases with pressure on wetting.

2. Experimental work

It was found out that Sabkha soil exists in a very large portion of Bahrain then, decided to get the Sabkha samples from Salmabad and Zallaq areas from where the Sabkha soil could be collected easily. The locations where the Sabkha samples were collected are seen in Fig. 3. The materials used in this research are the Sabkha soil from the regions of Salmabad and Zallaq in Bahrain to be treated, and lime, cement, and palm (date) leaves that are the stabilizing agents. Lime and cement are used widely because they are applicable to a considerable range of soil types, readily available, low in cost, and environmentally acceptable. The palm leaf is also readily available in the gulf region and in Bahrain. The soils encountered in this investigation were taken from "Salmabad area" which is in the northern part of Bahrain. The other location was Zallaq that is located south-west of Bahrain. The lime used in soil treatment in this investigation was "high calcium" lime which contains less than 5% magnesium oxide or hydroxide. The type of cement used in this investigation is the Ordinary Portland Cement (OPC). Palms are perennial in nature and the palm leaves are a major source of natural fiber of different varieties. The most important palm leaf is It is commonly cultivated in India, Southeast Asia, Malaysia and intermittently in other warm regions including Hawaii and Southern Florida. Palm leaf fiber is used to make ropes, mats, brushes, fish nets, brooms, amongst others.

In this study, it has been used to stabilize the Sabkha soil. Properties of the Sabkha The Sabkha soils have been taken from Salmabad and Zallaq regions of Bahrain. Routine soil tests have been performed to determine the physical and plasticity properties of the Sabkha soils. However, the plastic limit test could not be conducted in soil taken from Zallaq region. The results of the routine laboratory tests are seen in Table 1.

Table 1. Physical and plasticity properties of sabkha soils

Location of sabkha sample	Salmabad	Zallaq
Average of Specific gravity	2.54	2.56
Salt concentration (g/l)	7.0	7.2
Liquid limit (LL, %)	60.1	41
Plastic limit (PL, %)	24.9	N/A
Shrinkage limit (SL, %)	16 (*)	-
Plasticity index (PI,%)	35.2	-
Optimum moisture content (%)	14	15.5
Maximum dry density (Mg/m3)	1.51	1.39
Effective diameter, (D_{10}, mm)	0.008	0.07
D_{30}, mm	0.025	0.15
D_{60}, mm	0.20	0.35

(*) SL value estimated by the plasticity chart

The particle size distribution curves (PSDCs) are seen in Fig.4, and Fig. 5. In the investigation, cement and lime stabilizations are applied the Sabkha taken from Salmabad, palm leaf stabilization is applied the Sabkha taken from Zallaq region. The Sabkha soil taken from both the Salmabad region and Zallaq region are classified as SP (Poorly graded sand) by the Unified Soil Classification System. Plasticity Properties of Sabkha Plasticity properties of plain Sabkha and several Sabkha samples stabilized by different agents namely cement and lime and their various percentages were investigated. The liquid limit of the Sabkha is increased with the addition of lime. However, it decreased with the addition of cement as seen in Fig. 6. On the other hand, plastic limit tends to increase with addition of lime or cement (see Fig 7.) but the increment is not significant. Plasticity index, which is the difference between liquid limit and plastic limit is decreased with the increment of cement up to 3%. Then, it seems to be constant. In the case of lime agent, the plasticity index has a tendency of increment as seen in Fig. 7 but the increment is not very significant.

Thus, the agent cement has a positive effect on the plasticity of Sabkha soil in terms of water sensitivity whereas lime has an extraordinarily little negative effect in this issue.

a) The sites Salmabad and Zallaq where sabkha soils were collected

b) Closer views of the sites in Salmabad and Zallaq

Fig 3. The locations where the Sabkha soils were taken (Salmabad, and Zallaq, Bahrain)

The particle size distribution curves (PSDCs) are seen in Fig.4, and Fig. 5. In the investigation, cement and lime stabilizations are applied the Sabkha taken from Salmabad, palm leaf stabilization is applied the Sabkha taken from Zallaq region. The Sabkha soil taken from both the Salmabad region and Zallaq region are classified as SP (Poorly graded sand) by the Unified Soil Classification System. Plasticity properties of plain Sabkha and several Sabkha samples stabilized by different agents namely cement and lime and their various percentages were investigated. The liquid limit of the Sabkha is increased with the addition of lime. However, it decreased with the addition of cement as seen in Fig. 6. On the other hand, plastic limit tends to increase with addition of lime or cement (see Fig 7.) but the increment is not significant. Plasticity index, which is the difference between liquid limit and plastic limit is decreased with the increment of cement up to 3%. Then, it seems to be constant. In the case of lime agent, the plasticity index has a tendency of increment as seen in Fig. 7 but the increment is not very significant.

Thus, the agent cement has a positive effect on the plasticity of Sabkha soil in terms of water sensitivity whereas lime has an extraordinarily little negative effect in this issue.

Standard Proctor Tests After the Standard Proctor Tests for samples prepared with addition of various percentages of the additive materials, the compaction curve of each case has been plotted. Stabilizers of cement and lime are used to stabilize Sabkha taken from Salmabad region. The palm leaf treatment is used for Sabkha taken from Zallaq region. Compaction curves of Sabkha soils from Salmabad and Zallaq without any additives are seen in Fig. 8.

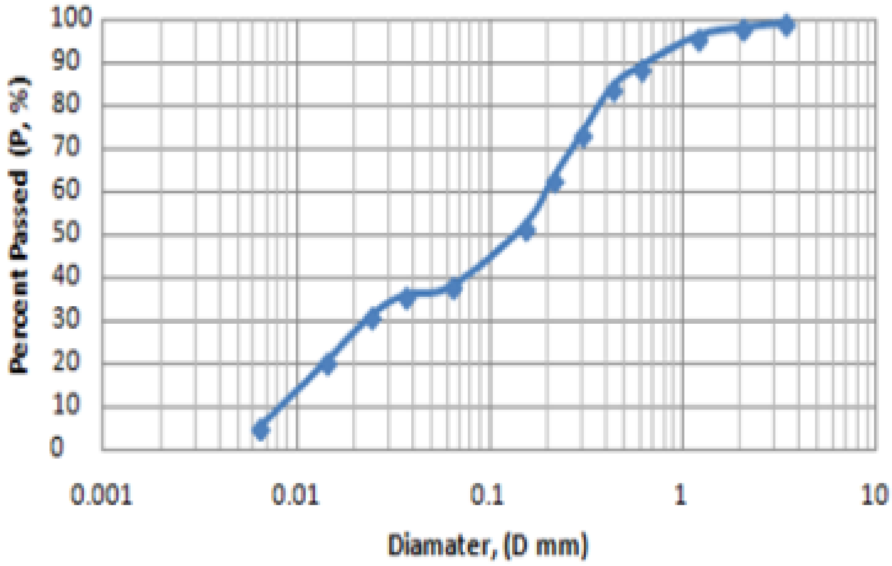

Fig 4. Particle Size Distribution Curve of the Sabkha soils taken from Salmabad

When all the compaction curves were plotted, the OMC and MDD of each mixture were determined and they are shown in Fig. 9. Among the maximum dry densities, the highest MDD was achieved when 3% of lime was used as the stabilizer as seen in Fig. 8. The highest value of the MDD is 1570kg//m^3. The same percentage of cement has an MDD of 1562kg/m^3. OMC values for this percentage (3%) of both cement and lime are 24%. In terms of MDD, 1% cement, 2 and 6% lime additives have an MDD, which is less than the MDD of plain Sabkha.

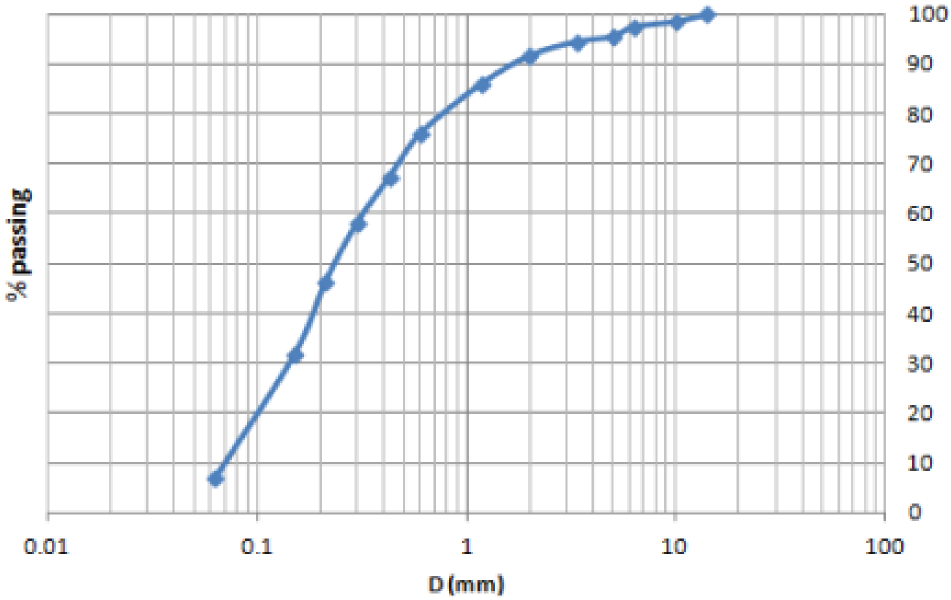

Fig 5. Particle Size Distribution Curve of the Sabkha soils taken from Zallaq

The other agent and percentage of additives give a value of MDD more than the maximum dry density of the plain Sabkha. Improvement on Sabkha by the Additives After the determination of OMC of each agent with various ratios, the samples used in the experiments were prepared by the standard compaction energy by using their OMC to have a sample at MDD.

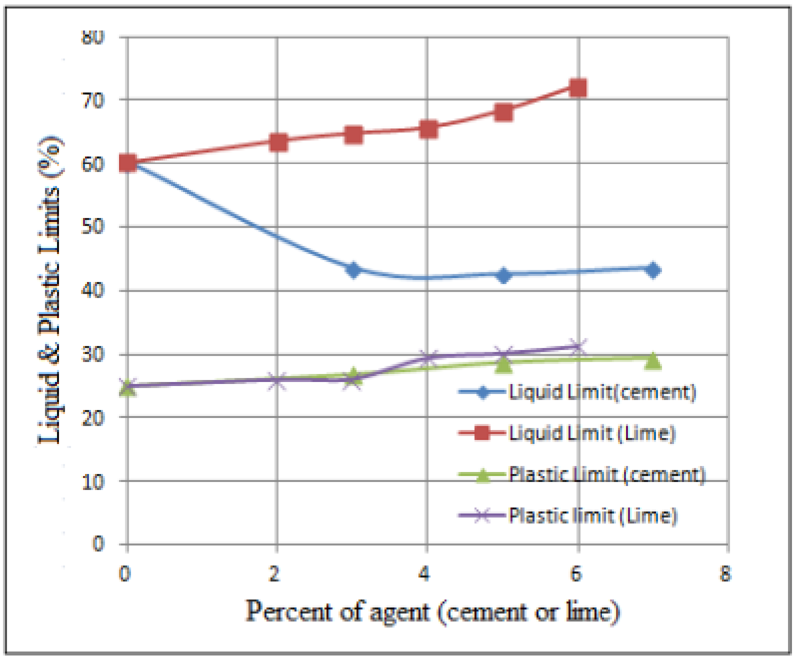

Fig 6. Variations of Liquid & Plastic Limits with ratios of cement & lime

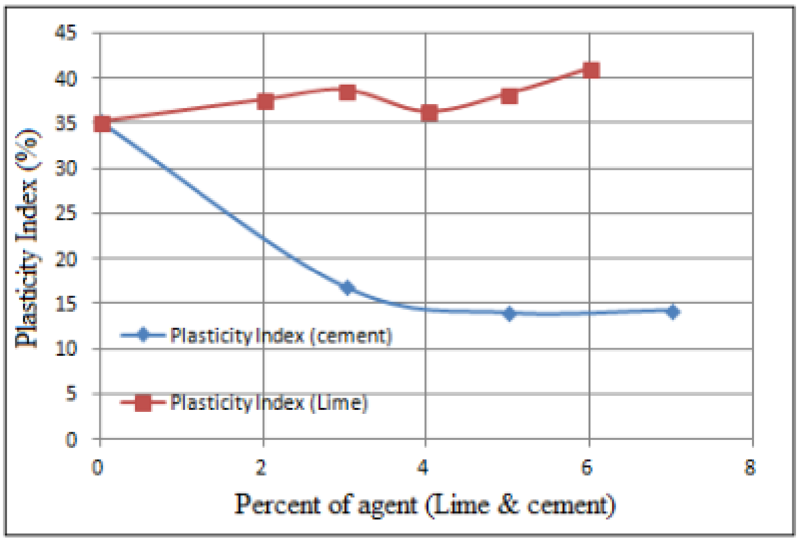

Fig 7. Variations of Plasticity Index with ratios of cement & lime

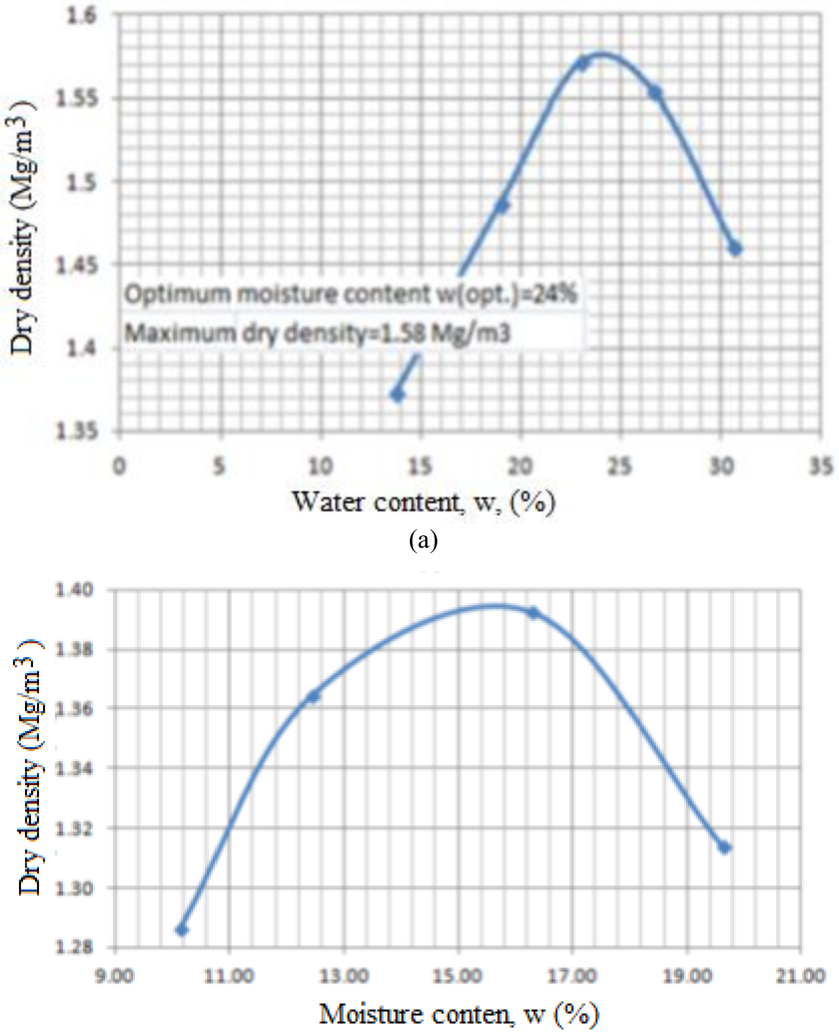
All the experiments like the unconfined compression tests (UCT), the falling head permeability tests, the direct shear test (shear box tests) were conducted by using the samples that are prepared by standard compaction energy at their OMC. Unconfined Compression Strength The unconfined compressive strength of the Sabkha is improved when it was stabilized with different additives with their various ratios and curing time. When lime is used as the stabilizer, the improvement on the compressive strength is getting higher when the ratio of lime is increased. Also curing time is very important for the lime stabilized Sabkha samples. The improvement in the compressive strength is seen in Fig. 10. The relationship between the normalized shear strength and normalized normal stress is linear as seen in Fig. 10. The shear strength of lime stabilized Sabkha is normalized by dividing it to the shear strength of the untreated Sabkha (τ/τ_o) and normal stress of treated Sabkha divided by the untreated normal stress (σ/σ_o).

If the angle between the linear line and horizontal is called as normalized friction angle by the analogy of the internal friction angle which is the angle of failure envelope in Mohr-Coulomb approach, the normalized friction angle is 45 degrees as seen in Fig. 10. The unconfined compression test results of the stabilized Sabkha are seen in Fig. 11. The compressive strength of the treated Sabkha samples with various ratios and curing times have improved strengths. The best improvement on the unconfined compressive strength was achieved when 3% of palm leaf is used as seen in Fig. 11. It may be expected to get best improvement on the cement addition, but it might happen if curing time is extended for the cement additive. The lime additive has no effect on the strength increment as much as the palm leaf does as is seen in Fig. 11.

Even the Sabkha soils used for stabilization by the palm leaf was not taken from the same region as the Sabkha used for lime stabilization, it is believed that the improvement by the palm leaf is better since tension stresses are carried by the leaf fibers. Thus, the palm leaf treated Sabkha soil gains strength for the tension stresses. The variation of the unconfined compressive strength of Sabkha sample stabilized by lime versus the curing time is seen in Fig.12.



(a)

(b)

Fig. 8. Compaction curve of the Sabkha soil with no agent (a: Salmabad, b: Zallaq)

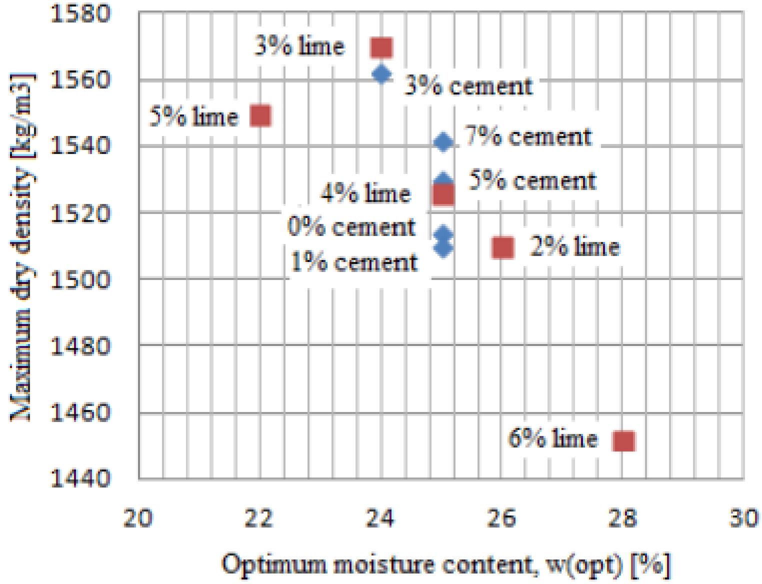


Fig. 9. Optimum moisture contents and maximum dry densities for various agents and ratios

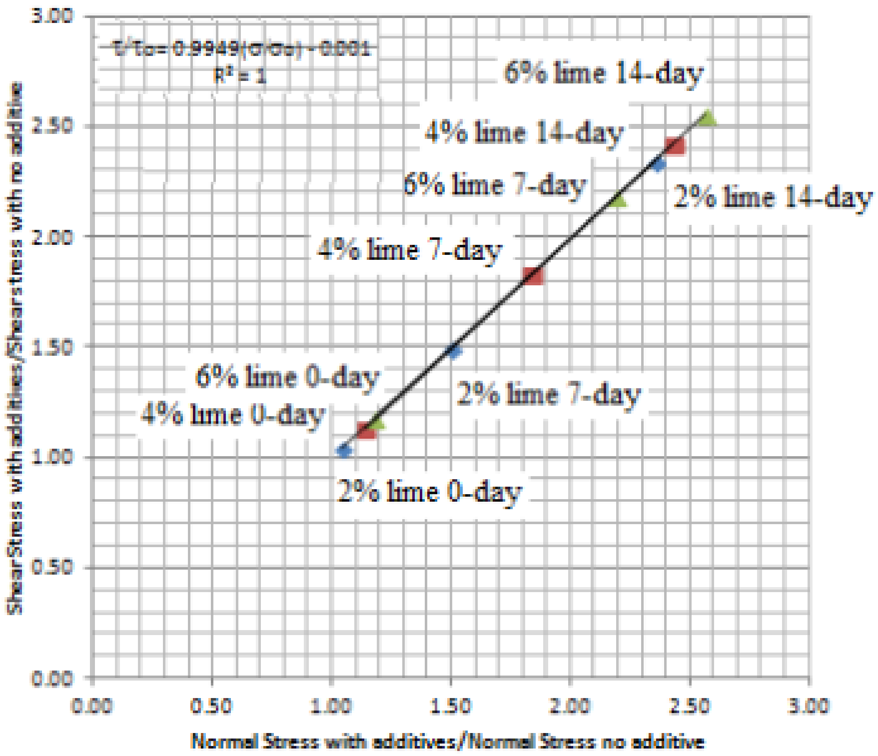

Fig. 10. Normalized values of shear and normal stresses for various percent of lime and curing

As it is seen in the figure, the improvement on the shear strength of the Sabkha soil is affected by the percentage of the agent in short term. However, improvement in shear strength for 2, 4 and 6% of the lime is almost equal in 14 days. Thus, it can be concluded that there is no need to use more percent of lime if the soil is expected to gain more shear strength in the long term. This conclusion must be verified by conducting more experiments and more curing days. Direct Shear Strength In many foundation design problems, the shear strength parameters which are cohesion (c) and internal friction angle (f) must be determined. Shear strength along the surface of the ground in contact with the base of the foundation material must be known.

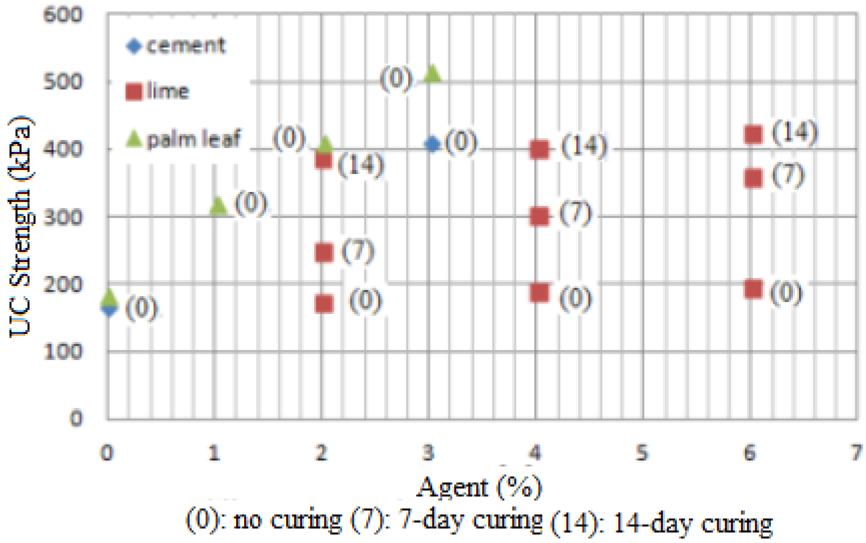

Fig. 11. Unconfined compressive strengths of the treated Sabkha

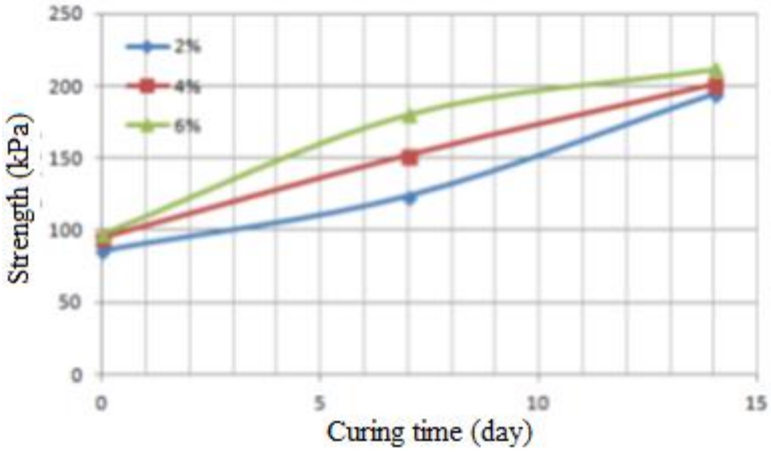

Fig. 12. Variation of shear strength of lime treated soil curing

Also, in the estimation of ultimate bearing capacity of any type of foundations, the shear strength parameters of the soil will be needed. After the estimation of these parameters, the shear strength can be estimated by Mohr-Coulomb equation:

$$\tau_f = c + \sigma \tan\phi \tag{1}$$

The shear strength parameters, c and ϕ were estimated by the direct shear tests in Sabkha soil, which was stabilized by 2% lime additive. The apparent cohesion c = 2.26kPa, and the internal friction angle ϕ = 40 degree as seen in Fig. 13. These values can be used to estimate the principal major stress under consolidated-drained condition with any lateral (confining) stress less than over-consolidation pressure. The major principal stress calculated by Eq. (2) can be assumed as the ultimate bearing capacity of the Sabkha soil at a depth under consideration. Eq. (2) can be driven using Fig. 14. If the lateral confining pressure ($\sigma 3$) is 50kPa (the minor principal stress) at the depth of soil under consideration, the major principal stress, $\sigma 1$, (or ultimate passive strength) under drained conditions can be estimates as 240kPa by using the Mohr's circle seen in Fig.14.

The ultimate passive strength of soil that is stabilized by 4% of lime has an apparent cohesion, c = 21.8kPa, and internal friction angle σ = 33 degrees as seen in Fig. 15. The ultimate passive strength of the Sabkha soil stabilized by 4% of lime can be calculated as 250kPa under the identical conditions for the Sabkha stabilized by 2% of lime. Similar calculation for the ultimate passive strength of Sabkha soil can be performed for the other stabilizers and their percentages. It easily can be seen that the ultimate passive strength of the Sabkha soil (from Fig. 16): c=5.4kPa, and σ = 36 degrees stabilized by 6% of lime is 214kPa.

As a rule of thumb, it is believed that there is a good relation between the density of a material and its strength for the same material. The strength will increase when density is increased.

This rule is also true in this case since the density of Sabkha soil stabilized by 6% lime is 1452kg/m3 that is the least density among the others (see Fig. 16) so that it gives smallest strength. When the failure envelopes of the lime stabilized Sabkha soil are plotted on one plot as seen in Fig. 17, it is clearly seen that 4% of lime addition gives the When the variation of major principal stresses versus the maximum dry density of the samples is checked, palm leaf stabilized Sabkha soil is better than the others as seen in Fig. 18. The best improvement on the major ultimate stress was achieved at 1% palm leaf stabilized Sabkha samples.

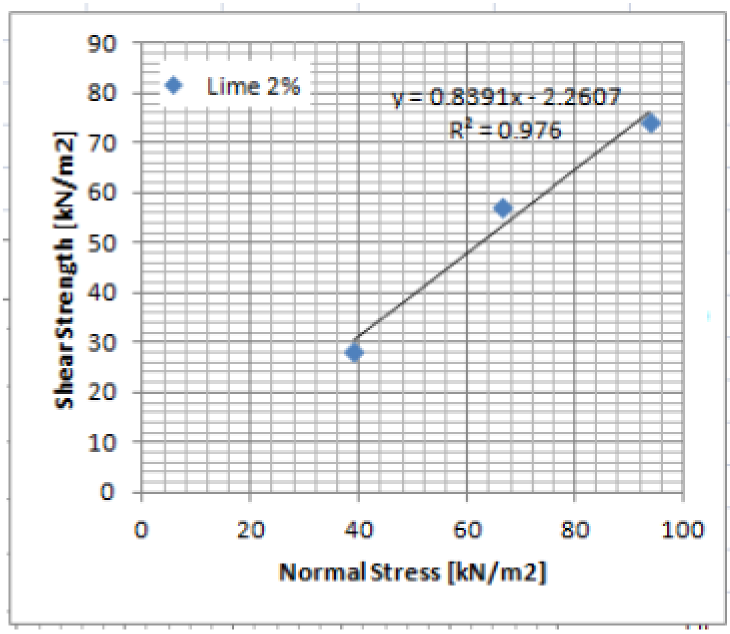

Fig. 13. Failure envelope of Sabkha soil stabilized by 2% lime

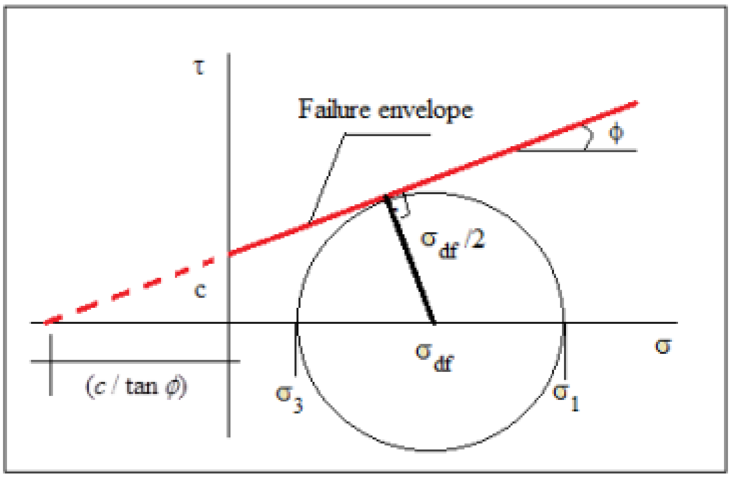

Fig. 14. Estimation of major principal that can be considered as ultimate passive strength

There might be a little effect of the natural Sabkha because palm leaf added Sabkha was taken from Zallaq and the other agents were added to the Sabkha taken from Salmabad. However, both Sabkhas were classified as poorly graded sand so that the effect of the places can be ignored in this state. All the failure envelopes were plotted for each different agent and the percentages of the additives. The failure envelopes are given for the agent of lime (2, 4, and 6%) above.

$$\sin\phi = \frac{\sigma_{df}/2}{(c/\tan\phi) + \sigma_3 + \sigma_{df}/2}$$
$$\sigma_{df} = 2\left(\frac{c * \cos\phi + \sigma_3 \sin\phi)\backslash}{1-\sin\phi}\right) \tag{2}$$
$$\sigma_1 = \sigma_3 + \sigma_{df}$$
$$\sigma_1 = \sigma_3 + 2\left(\frac{c * \cos\phi + \sigma_3 \sin\phi}{1-\sin\phi}\right)$$

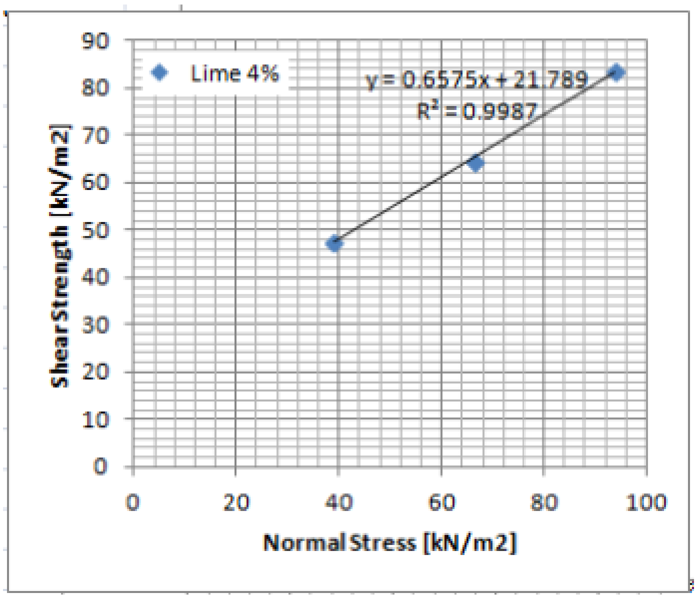

Fig. 15. Failure envelope of Sabkha soil stabilized by 4% lime

One more failure envelope is given in Fig. 19 for the agent of cement (5%) and the others are not given to prevent the large number of figures that are like each other better failure envelope compared to the other percentages of the lime. Similar calculations were performed for the other cases investigated. The ultimate passive strengths were found, and they are shown in Table 2.

Table 2. Ultimate passive strength (σ_1) of sabkha soil with additives and ratios

Type of Sample	Percent (ratio)	c (kPa)	ϕ (degree)	σ3 (kPa)	σ1 (kPa)	ρd_max (kg/m3)
Plain sabkha	No additive	10.0	30	50.00	185	1514
Lime (%)	2	2.3	40	50.00	240	1510
Lime (%)	4	21.8	33	50.00	250	1526
Lime (%)	6	5.4	36	50.00	214	1452
Cement (%)	3	20.1	37	50.00	281	1562
Cement (%)	5	20.17	38	50.00	293	1530
Cement (%)	7	50.0	65	50.00	?	1542
Palm leaf (%)	1	23.0	41	50.00	342	1370
Palm leaf (%)	2	8.0	46	50.00	346	1340
Palm leaf (%)	3	15.0	47	50.00	398	1319

3. Hydraulic conductivity

The hydraulic conductivity depends on several factors in soil such as pore size distribution of soil matrix, void ratio, grain size distribution, fluid viscosity and roughness of the soil particles. In the treatment of Sabkha soil, pore size distribution, void ratio, roughness of soil particles and somehow the grain size distribution will be changed so that the value of the hydraulic conductivity will also be affected. The hydraulic conductivity of the Sabkha is not affected much when cement or lime is used as the stabilizers. The variation on the hydraulic conductivity is not significant when either cement or lime is used as the stabilizer. However, the hydraulic conductivity is affected by the palm leaf as seen in Fig 20. The variation on the hydraulic conductivity is significant when the palm leaf is used as stabilizer. This future of the palm leaf can be considered when designing a project in which more strength and more permeable soil layer is needed. However, if the designing of a project requires more strength and less permeable soil layer, the choice of palm leaf as the stabilizer is not a proper selection.

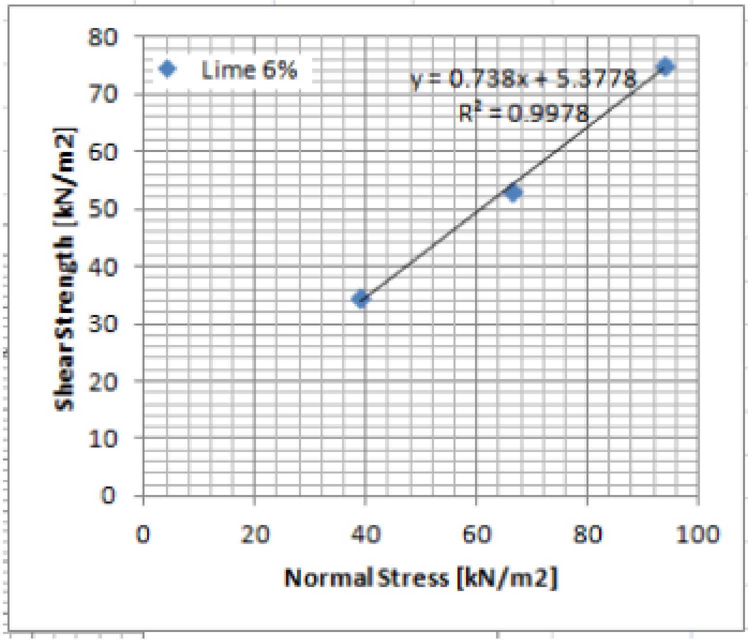

Fig. 16. Failure envelope of Sabkha soil stabilized by 6% lime

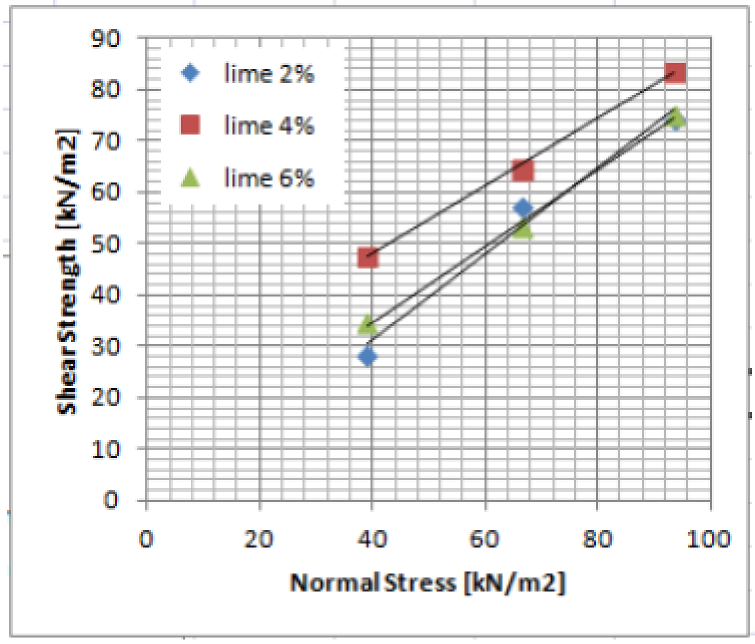

Fig. 17. Comparison of the failure envelopes of Sabkha soil stabilized for lime agent

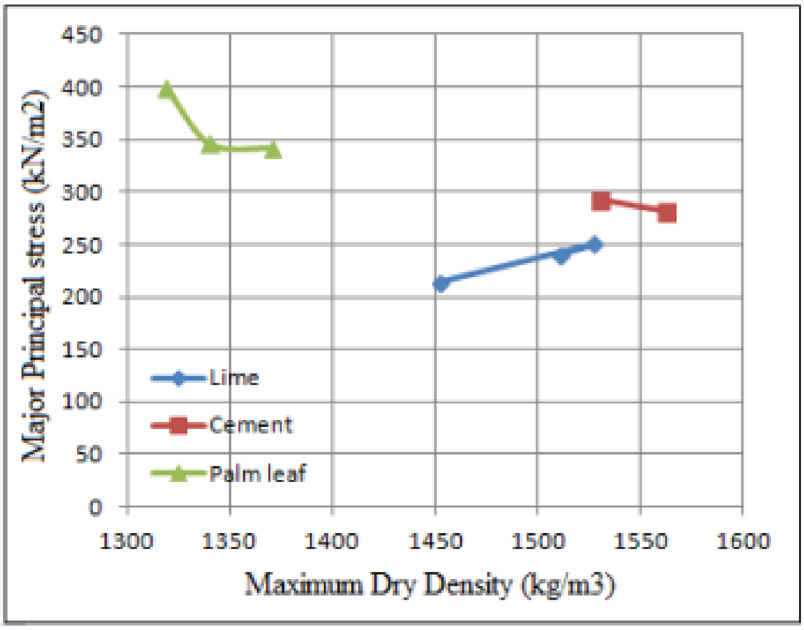

Fig. 18. Variation of Major Principal Stress with Type of Additives and Ratios

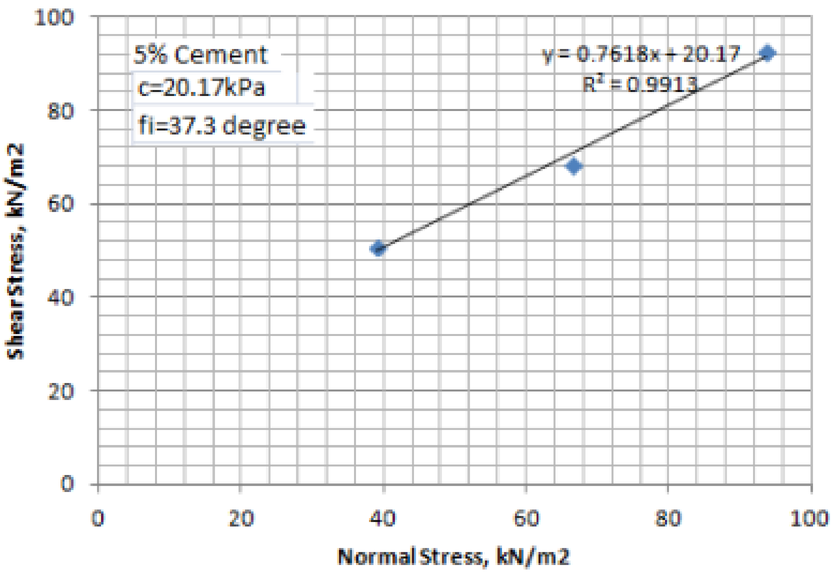

Fig. 19. Failure envelope of Sabkha soil stabilized by 5% cement

4. Collapsibility of the Sabkha

When the loaded soil is exposed to moisture, and certain critical moisture content is exceeded, the fine silt or clay bridges that are providing the cementation will soften and weaken and/or dissolve to some extent. Eventually, the binders reach a stage where they no longer resist deformation forces and the structure collapses (see Fig.22). To conduct a collapse test on Sabkha soils taken from the Salmabad, and Zallaq regions, undisturbed soil samples were taken from both regions as seen Fig.21. The consolidation ring was used while the undisturbed samples were being taken. The collapse test results on Sabkha taken from Salmabad region were used to plot void ratio versus logarithm of effective stress (applied pressure) as seen in Fig. 22. One of the collapse tests conducted on Sabkha soil taken from Salmabadan is given in Table 3.

To evaluate soil collapsibility, various criteria have been defined by many researchers. According to the criteria, the Sabkha soils studied in this research can be named as a collapsible soil with moderate trouble Feda criteria (Doomkamp, et all, 1980):

Table 3. The results of the collapse test (Salmabad)

Applied pressure (kPa)	Dial gage reading (dz, mm)	Final gage reading (df, mm)	Hi, mm	ei %
25	0	156	1.97	1.407
50	156	284	1.94	1.394
100	284	455	1.91	1.377
200	455	540	1.89	1.369
200	540	820	1.84	1.341
400	820	1134	1.77	1.309
800	1134	1593	1.68	1.263
1600	1702	2022	1.60	1.221

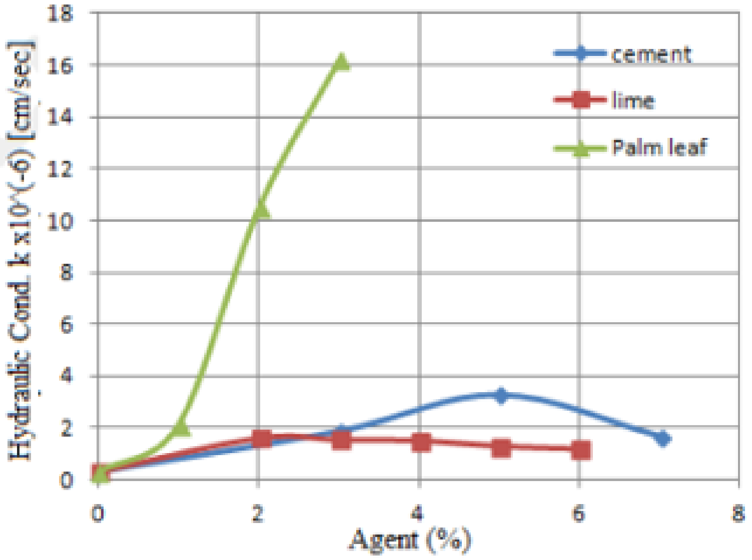

Fig. 20. Variation of the hydraulic conductivity of Sabkha by the stabilizers

Fig. 21 Undisturbed Sabkha samples taken from the field

$$i_c = \frac{\frac{m}{S_r} - PL}{PI}\% = \frac{\frac{0.35}{0.61} - 0.396}{0.3523} = 0.504 < 1 \Rightarrow Collapsible$$

Lin and Wang criteria (Lin, et all, 198812):

$$i_{cz} = \frac{h_z - h_{zS}}{h_i} = \frac{1.89 - 1.84}{2} = 0.025 = 2.5\% \Rightarrow Medium\ \ Collepsibility\ \ (seeTable2.3)$$

$$i_c = \frac{\frac{m}{S_r} - PL}{PI}\% = \frac{\frac{0.35}{0.61} - 0.396}{0.3523} = 0.504 < 1 \Rightarrow Collapsible$$

Lin and Wang criteria (Lin, et all, 198812):

$$i_{cz} = \frac{h_z - h_{zS}}{h_i} = \frac{1.89 - 1.84}{2} = 0.025 = 2.5\% \Rightarrow Medium\ \ Collepsibility\ \ (seeTable2.3)$$

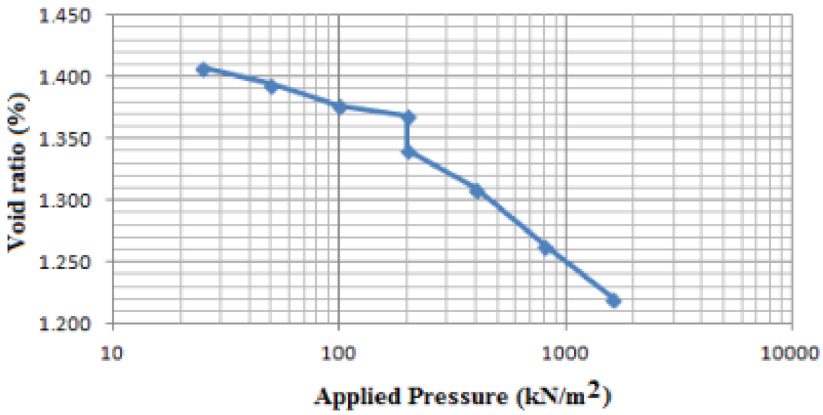

Fig. 22. Void ratio versus logarithm of applied pressure for Sabkha taken from Salmabad

Because the maximum dry density and collapse potential values are in the range of collapsible soils according to the criteria given by Feda 1960, Lin and Wang Criteria 1988.

5. Result and conclusions

First, the soil was classified according to the Unified Soil Classification System (USCS). Both Sabkhas were poorly graded sand (SP) with a small amount of gravel. A summary of the results from the conducted tests are seen in Table 4. In the investigation, sieve analysis, Atterberg limits (consistency limits) tests, the standard proctor tests, falling head permeability tests, direct shear tests, and unconfined compression tests were conducted on the plain Sabkha samples. Then, the same tests were performed on the stabilized Sabkha samples. For the stabilization cement, lime, and palm leaf agents were employed. The Sabkha soil samples taken from Salmabad were stabilized by 3, 5, and 7% of cement and 2, 3, 4, 5, and 6% of lime. However, the Sabkha samples taken from Zallaq were stabilized by 1, 2, and 3% of palm leaf. The liquid limit of the Sabkha is increased with addition of lime. However, it decreased with the addition of cement. plastic limit tends to increase with addition of lime or cement, but the increment is not significant. The plasticity index decreased with the increment of cement up to 3%. Then, it seems to be constant. In the case of lime agent, the plasticity index has a tendency of increment, but the increment is not very significant. Therefore, it can be concluded that the agent cement has a positive effect on the plasticity of Sabkha soil in terms of the water sensitivity of Sabkha whereas lime has a very little negative effect in this issue. The OMC and MDD of each mixture of samples were determined. Among the maximum dry densities, the highest MDD has been achieved when 3% of lime was used as the stabilizer. The highest value of the MDD is 1570kg/m^3. The same percentage of cement has an MDD of 1562kg/m^3. OMC values for these percentages (3%) of both cement and lime are 24%. In terms of MDD, 1% cement, 2 and 6% lime additives have an MDD, which is less than the MDD of plain Sabkha. The other agent and percentage of additives give a value of MDD more than the maximum dry density of the plain Sabkha. The unconfined compressive strength of the Sabkha is improved when it was stabilized with different additives with their various ratios and curing time. When lime is used as the stabilizer, the improvement on the compressive strength is getting higher when the ratio of lime is increased. Also curing time is very important for the lime stabilized Sabkha samples.

Table 4. Summary of laboratory tests

(0)*: No curing, (7)*: 7-day curing, (14)*: 14-day curing.

The best improvement on the unconfined compressive strength was achieved when 3% of palm leaf is used. It may be expected to get the best improvement on the cement addition. Maybe it would happen if curing time were extended for the cement additive. The lime additive has no effect on the strength increment as much as the palm leaf does. The Sabkha soils used for stabilization by the palm leaf were not taken from the same region as the Sabkha used for lime stabilization, but it is believed that the improvement by the palm leaf is better since tension stresses are carried by the palm leaf fibers. Thus, the palm leaf treated Sabkha soil gains strength for the tension stresses. Improvement on shear strength for 2, 4 and 6% of the lime is very close to each other in 14 days curing. Thus, it can be concluded that there is no need to use more percent of lime if the soil is expected to gain more shear strength in the long term. This conclusion must be verified by conducting more experiments and more curing days. The shear strength parameters, c and ϕ were estimated by the direct shear tests on Sabkha soil, which was stabilized by 2% lime additive. The apparent cohesion c = 2.26kPa, and the internal friction angle ϕ = 40 degrees. These values can be used to estimate the principal major stress under consolidated-drained condition with any lateral (confining) stress less than over consolidation pressure. The major principal stress can be calculated by Eq. (3.2). When the failure envelopes of the lime stabilized Sabkha soil are plotted on one graph, it is clearly seen that 4% of lime addition gives the better failure envelope compared to the other percentages of the lime. When the variation of major principal stresses versus the maximum dry density of the samples, palm leaf stabilized Sabkha soil is better than the others. The best improvement on the major ultimate stress was achieved at 1% palm leaf stabilized Sabkha samples. There might be a little effect of the natural Sabkha because palm leaf added Sabkha was taken from Zallaq and the other agents were added to the Sabkha taken from Salmabad. However, both Sabkhas were classified as poorly graded sand so that the effect of the places can be ignored in this state. The hydraulic conductivity of the Sabkha is not affected much when cement or lime is used as the stabilizers. The variation on the hydraulic conductivity is not significant when either cement or lime is used as the stabilizer. However, the hydraulic conductivity is affected by the palm leaf. The variation on the hydraulic conductivity is significant when the palm leaf is used as stabilizer. This future of the palm leaf can be considered when designing a project in which more strength and more permeable soil layers are needed. However, if the designing of a project requires more strength and less permeable soil layer, the choice of palm leaf as the stabilizer is not a proper selection. The Sabkha soils studied in this research can be named as a collapsible soil with moderate trouble since the maximum dry density and collapse potential values are in the range of collapsible soils according to the criteria given by Feda 1960, Lin and Wang Criteria 1988.

Abstract. Cemented paste backfill (CPB) technology is widely employed in mining operations to mitigate environmental and geotechnical risks by reducing tailings volume. The overall performance of CPB is strongly influenced by the properties of the tailings, binder, and mixing water used in the mixture. With the increasing depletion of freshwater resources, sustainable alternatives that minimize freshwater consumption in CPB production have gained growing importance. In this study, process waters with different pH levels were utilized as mixing water to investigate their impact on CPB performance and to reduce reliance on freshwater. CPB samples were prepared using a constant solid content of 76%, a fixed cement dosage of 6% by weight, and mixing waters with pH values of 4.67 (acidic), 10.95 (basic), and 7.61 (tap water). These samples were subjected to curing periods of 3, 14, 28, and 56 days. Subsequently, mechanical and microstructural analyses were conducted. The results revealed that all samples exhibited increased strength after 28 days of curing. However, a decline in strength was observed in the samples prepared with low-pH water after 56 days. The acidic environment promoted excessive ettringite formation, which adversely affected the strength development. Microstructural evaluations indicated that the low-pH samples had fewer hydration products and a higher concentration of ettringite crystals. These findings confirm that acidic mixing waters hinder cement hydration and negatively influence the mechanical properties of CPB.

1. Introduction

Cementitious composites such as paste backfill, concrete, and mortar are multifunctional structural materials extensively employed across various sectors, particularly in construction and mining industries (Sambucci et al., 2021). These heterogeneous and composite systems are composed of multiple constituents, each fulfilling distinct roles within the mixture (Li & Li, 2019). Cementitious materials primarily comprise three core components: aggregates (e.g., mine tailings, sand, gravel, or crushed stone), binders (e.g., cement, slag, fly ash), and mixing water (Li et al., 2022). Alongside these primary constituents, chemical or natural additives (e.g., accelerators) are frequently incorporated to enhance specific characteristics such as workability, freeze-thaw resistance, and mechanical strength when required (Amare et al., 2023). The function of each component, as well as the proportions and interactions among them, significantly influences the development of desired material properties (Fode et al., 2023). Overall, the proper selection and accurate proportioning of these components critically impact strength, durability, workability, and other performance attributes (Li et al., 2023).

Among these components, mixing water holds a particularly vital role in determining the quality and performance of cementitious systems (Shanmugasundaram & Praveenkumar, 2021). Both the quantity and the quality of the water used profoundly affect the mechanical strength and workability of the mixture (da Rocha Gomes et al., 2023). Water fulfills several essential functions within the cementitious matrix, making its appropriate use highly critical (Nazar et al., 2020). Generally, water initiates the hydration reaction by chemically interacting with cement particles, leading to the formation of crystalline structures that solidify the matrix (Zhang et al., 2019, Yu & Shui, 2014). An adequate amount and quality of water are essential for a proper hydration process and for achieving the intended strength development (Jain et al., 2022). Furthermore, water content critically influences the workability of the mixtures during processes such as transportation, pouring, and placement (Solak et al., 2018). Insufficient water can render mixtures difficult to handle, whereas excessive water

* Corresponding author, E-mail: erol.yilmaz@erdogan.edu.tr

https://doi.org/10.31462/icearc2025_ce_geo_177

may improve flowability at the expense of mechanical strength. Therefore, an optimal balance between workability and strength must be achieved (Liu et al., 2021).

The role of mixing water becomes even more crucial when cementitious materials are transported over long distances or to locations with limited accessibility. Workability, largely governed by water content, serves to reduce operational challenges and labor demands, making it a key design consideration for such mixtures (Deng et al., 2023). Compared to conventional cementitious systems, cemented paste backfill (CPB) is one method where workability is particularly prioritized (Wang et al., 2023). CPB represents an advanced backfilling technology where a paste, produced at surface plants, is subsequently transported and placed into underground mine voids (stopes) via gravity or pumping methods (Jiang & Fall, 2017; Guner et al., 2023). Given that many mining operations today reach depths exceeding one kilometer — with coal mines extending to about 1500 meters and metal ore mines reaching depths up to 4350 meters — transporting CPB over such distances without segregation (i.e., sedimentation) becomes a critical operational challenge (Xie et al., 2017; Jiang et al., 2020). Consequently, fresh CPB must possess sufficient fluidity to enable efficient pumping from surface facilities to underground voids without significant material separation (Behera et al., 2021). CPB with optimal fluidity can be conveyed through pipelines with minimal frictional resistance, preserving homogeneity throughout transport. Moreover, fluid CPBs exhibit better adherence to surrounding rock surfaces, fostering stable mechanical bonding and enhancing predictability in strength gain (Cheng et al., 2020; Qi et al., 2018). Inadequate workability, on the other hand, severely undermines the performance, quality, and long-term stability of CPBs, and substantially increases the risk of operational failures such as pipeline blockages (Sari et al., 2023). Thus, ensuring the appropriate quantity and quality of mixing water is fundamental for achieving the intended operational design in all cementitious mixtures, including CPBs (John et al., 2018).

The quality of available mixing water may vary significantly depending on its source, which can be influenced by factors such as seasonal fluctuations and geographic location. To minimize adverse impacts and preserve the strength and durability of cementitious materials, fresh water sources with assured purity (e.g., municipal tap water, well water, rainwater, lake or river water) are predominantly utilized (de Godoy et al., 2020). Notably, global production of concrete composites currently consumes over two billion tons of fresh water annually, accounting for approximately 9% of industrial freshwater usage worldwide. Projections suggest that by 2050, nearly 75% of the water required for concrete production will be concentrated in regions facing significant water scarcity (Younis et al., 2018, 28). Simultaneously, factors such as population growth, industrial expansion, and climate change are exacerbating the depletion of freshwater resources globally (Tortajada, 2020). Fresh water is not only essential for construction materials but is also fundamental for human survival, agriculture, industry, energy generation, and numerous other sectors. Preserving freshwater resources is, therefore, crucial for sustainable industrial practices and ensuring access to clean water for future generations (Coffetti et al., 2022; Hussain et al., 2019).

The growing concerns about global freshwater scarcity, driven by rapid population increase, climate change, unsustainable consumption patterns, and uneven geographical distribution of water resources, have intensified the search for alternative water sources. Although about 70% of Earth's surface is covered by water, only 3% constitutes freshwater, and approximately 70% of this is trapped in glaciers, leaving merely 1% accessible for use. This stark reality underscores the urgent need for sustainable water management practices. Despite significant research efforts, the global freshwater supply continues to dwindle due to increasing demands. Based on current trends and forecasts, substantial freshwater shortages are anticipated in the near future. Consequently, utilizing potable water for concrete and CPB production is increasingly viewed as unsustainable, compelling researchers and industries alike to explore alternative water sources. In response to these challenges, industries across the globe are seeking sustainable and environmentally responsible solutions, including the substitution of fresh water in cementitious mixtures (Yang et al., 2024).

Given these imperatives, exploring the viability of alternative mixing waters is essential to reduce dependency on freshwater in cementitious applications and to advance toward a more resource-conscious future. In the literature, several studies have focused on investigating alternative water sources primarily for concrete — the cementitious material with the highest freshwater demand. Harial et al. (2023), for instance, examined the reuse potential of untreated wash water from concrete truck mixers, concluding that this wastewater had negligible adverse effects on hydration kinetics and the mechanical properties of fresh and hardened mortars. Tamashiro et al. (2022) studied the use of vinasse wastewater from the sugar and alcohol industry, finding that concrete incorporating vinasse exhibited superior compressive strength after extended curing compared to conventional concrete. Meena et al. (2019) evaluated primary, secondary, and tertiary treated wastewater for concrete production, observing strength reductions of 6–15% with tertiary treated water, but compliance with ASTM C-94 standards. Ismail et al. (2011) investigated the feasibility of employing industrial wastewater from polyvinyl acetate resin production, reporting modest to moderate improvements in compressive strength and dry density relative to fresh water controls. Gupta et al. (2021) compared tap water, grey water, pond water, and treated sewage water, finding that grey and treated sewage waters enhanced strength by 2.1% and 6.9%, respectively, whereas pond water resulted in a 5.1% strength reduction. Pan et al. (2021) studied seawater and sand mixtures, revealing initial strength enhancements but slight strength reductions by 28 days of curing, alongside increased dynamic modulus of elasticity at early stages.

While numerous studies address the use of sustainable and environmentally friendly water sources (e.g., seawater, sewage, domestic wastewater, treated spring water) as alternatives to fresh water for concrete production, research on alternative waters for CPB applications remains notably limited. To address this gap, the present study investigates the influence of process water with varying pH levels on CPB performance as an alternative to freshwater. By doing so, the aim is to minimize freshwater consumption during CPB production, contributing beneficially to both operational efficiency and ecological sustainability. For this purpose, CPB samples were prepared with a constant solids content (76%), a fixed cement dosage (6% by weight), CEM I 42.5 R cement type, and mixing waters with different pH values (4.67, 7.61, 10.95). The samples were subjected to different curing periods (3, 14, 28, and 56 days). Subsequent mechanical and microstructural tests were performed to evaluate the effects of mixing water pH on the strength and durability characteristics of the CPB samples.

2. Materials and methods

2.1. Components of CPB

2.1.1. Mixing waters

The chemical characteristics of the process waters utilized as mixing waters play a vital role in determining the filling strength and structural stability. Additionally, the chemical makeup of the mixing water exerts a considerable impact on the cement hydration mechanism. In this research, process waters with distinct pH values and tap water, were employed. The geochemical analysis data pertaining to these waters are provided in Table 1. A prominent observation from the table is that the sulphate concentration in both acidic and basic waters is markedly higher compared to that in tap water.

Table 1. Chemical and geochemical data of mixing waters.

	LPW (%)	**HPW (%)**	**TW (%)**
		Geo-chemical parameters	
pH	4.67	10.95	7.61
EC (µS/cm)	5117	4165	0.08

Fe (mg/L)	3.46	2.94	0.05

2.1.2. Physical and chemical characterization of mine tailings

The mine tailings utilized in this research were sourced from a copper mining operation located in Turkey. The physical characteristics of the tailings are presented in Table 2, while their chemical composition is detailed in Table 3. The particle size distribution curve of the tailings, which were used as binder material in this study, is illustrated in Fig 1. According to the proportion of particles smaller than 20 µm, the tailings are classified as fine-grained material.

Table 2. Physical parameters of mine tailing and cement

Characteristics	Mine tailing	Cement
Specific gravity Gs	3.73	2.95
Specific surface area Ss (m^2/g)	2.71	0.37
Maximum dry density MDD (kg/ m^3)	2.45	-
Optimum moisture content OMC (%)	12.6	-
D_{10} (μm)	6.77	4.67
D_{30} (μm)	24.8	23.9
D_{50} (μm)	55.4	37.1
D_{60} (μm)	76.4	56.3
Coefficient of uniformity C_u	11.26	12.17
Coefficient of curvature C_c	1.23	2.14

Table 3. Chemical parameters of mine tailing and cement

Chemical parameters	Mine tailing	Cement

2.1.3. Binder

Portland cement of type CEM I 42.5 R was employed as the binder in this study. The physical and chemical properties of the cement are presented in Tables 2 and 3. The specific gravity (G_s) and specific surface area (S_s) of the cement were determined to be 2.95 and 0.37 m²/g, respectively.

2.2. Manufacturing of CPB samples

The fabrication of cemented paste backfill (CPB) samples was carried out through a systematic sequence of operations to ensure consistency and reproducibility. In the mixture design, the proportions of cement, tailings, and water were optimized based on a fixed water-to-cement ratio to attain the intended mechanical characteristics. Throughout the study, all mixtures were prepared with a constant solid concentration of 76% and a fixed cement content of 6% by weight. The components—namely, the tailings, binder, and selected mixing water—were blended using a UTEST-brand laboratory mixer for approximately 10 minutes, ensuring a homogeneous and uniform mixture in line with the proportions outlined in Table 4. The resulting slurry was cast into cylindrical molds with dimensions of 5 cm in diameter and 10 cm in height, equipped with perforated bases to allow drainage. To improve packing density and minimize entrained air, each sample was tamped 20–25 times using a metal rod. The molded specimens were then transferred into a curing chamber set at 21±2 °C and 90±5% relative humidity, where they were kept for predetermined curing durations. Upon completion of the curing process, the CPB samples were considered ready for experimental evaluation (Fig 2).

Fig. 2. Preparation of backfill samples

2.3. Experimental methodology

2.3.1. Slump test
According to the ASTM C143 standard, this test is applied to determine the vertical deformation (in centimeters) that occurs in a sample due to its own weight. Compared to the conventional slump test, the mini slump test offers significant advantages in terms of material efficiency and time savings. The mini slump procedure requires only approximately 16% of the material used in the standard slump cone method. Experimental findings have shown that the correlation factor between the results of the mini and standard slump tests is approximately 2. The dimensions of the mini slump cone are 100 mm at the base, 50 mm at the top, and 150 mm in height. In this study, the mini slump test revealed that CPB samples with a solid content of 76% exhibited an average slump value of 25 cm.

2.3.2. UCS test
Following the completion of the designated curing periods (3 to 56 days), the CPB samples were demolded, and their edges and surfaces were smoothed to ensure uniform contact during testing. Subsequently, unconfined compressive strength (UCS) tests were conducted. For this purpose, the specimens were positioned between the compression plates of a UTEST brand servo-controlled universal testing machine, with a maximum load capacity of 50 kN, operating at a constant loading rate of 1 mm/min. Throughout the testing process, the compressive strength and stress–strain responses of the CPB samples were continuously monitored and recorded by the system. To ensure the reliability and reproducibility of the results, each test was conducted in triplicate, and the average UCS value was calculated from the obtained data.

2.3.3. SEM analysis
The CPB samples extracted from the central region were oven-dried at 50 °C for 24 hours to eliminate moisture. Following the drying process, the samples were coated with a thin layer of gold to ensure electrical conductivity. Scanning Electron Microscopy (SEM) analyses were then conducted. During the imaging process, a maximum magnification of 2000× was utilized, with the highest resolution set at 10 μm to capture detailed microstructural characteristics.

3. Results and discussion

3.1. Analysis of UCS test data
Figure 3 presents the unconfined compressive strength (UCS) data for CPB samples subjected to curing durations of 3, 14, 28, and 56 days. A progressive increase in UCS values was observed for all mixtures up to day 28, which is attributed to the high-alkaline conditions induced by the cement, facilitating early-stage strength development. This period coincides with intensified portlandite formation.

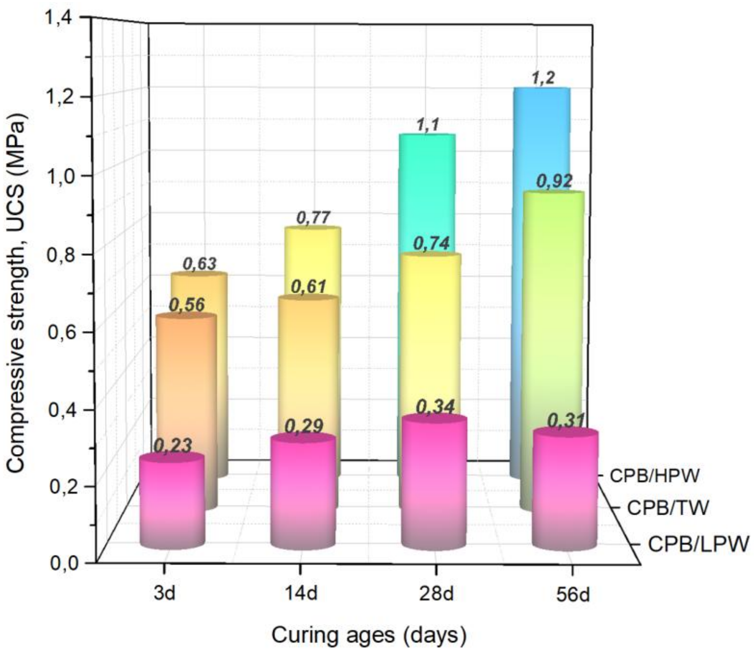

Fig. 3. Curing time-dependent ucs performance of CPB samples

On the 28th day, UCS for CPB/HPW increased by 68.25% relative to its 3-day strength, while the CPB/LPW and CPB/TW mixtures exhibited gains of 47.83% and 32.14%, respectively. Among these, CPB/HPW reached the highest UCS value at 1.06 MPa, whereas CPB/LPW demonstrated the lowest at 0.34 MPa. From day 28 to day 56, the UCS of CPB/HPW and CPB/TW samples continued to rise, whereas a reduction was recorded for CPB/LPW. The UCS of CPB/LPW decreased by 9.68% after 56 days compared to its 28-day strength, a phenomenon likely driven by the acidic nature and elevated sulfate concentration of the mixing water, which hinder cement hydration and compromise internal structural integrity. Consequently, the long-term alkalinity and mechanical performance of CPB/LPW diminish. On the other hand, the UCS values of CPB/TW and CPB/HPW increased by 24.32% and 14.15%, respectively, between days 28 and 56. At the end of the 56-day curing period, CPB/LPW exhibited the lowest compressive strength at 0.23 MPa, while CPB/HPW displayed the highest at 1.21 MPa.

3.2. SEM analysis

SEM images are highly effective for analyzing the microstructures of materials. Figure 4 shows SEM images of CPB/LPW, CPB/HPW, and CPB/TW samples cured for 56 days. Upon examining the images of the CPB/LPW samples, it is observed that the ettringite ratio is higher and the hydration products are lower compared to the CPB/HPW and CPB/TW samples. The pH value of the mixing water has influenced the environment and negatively affected the hydration products of the cement. In acidic conditions, sulfate absorption increases, leading to a greater accumulation of ettringite crystals in the filling matrix. This process causes the pores in the filling material to be filled. The excessive accumulation of these crystals at low pH negatively impacts the durability of the material.

In the image of the CPB/HPW sample, C-S-H gels formed as a result of the chemical reactions between calcium silicate and water are observed densely. These gels are critical structures that enhance the durability and hardness of concrete, and the density of these gels is directly related to the higher strength value of the CPB/HPW samples. Furthermore, the high pH value of the mixing water increased the alkalinity of the samples, positively contributing to the hydration process.

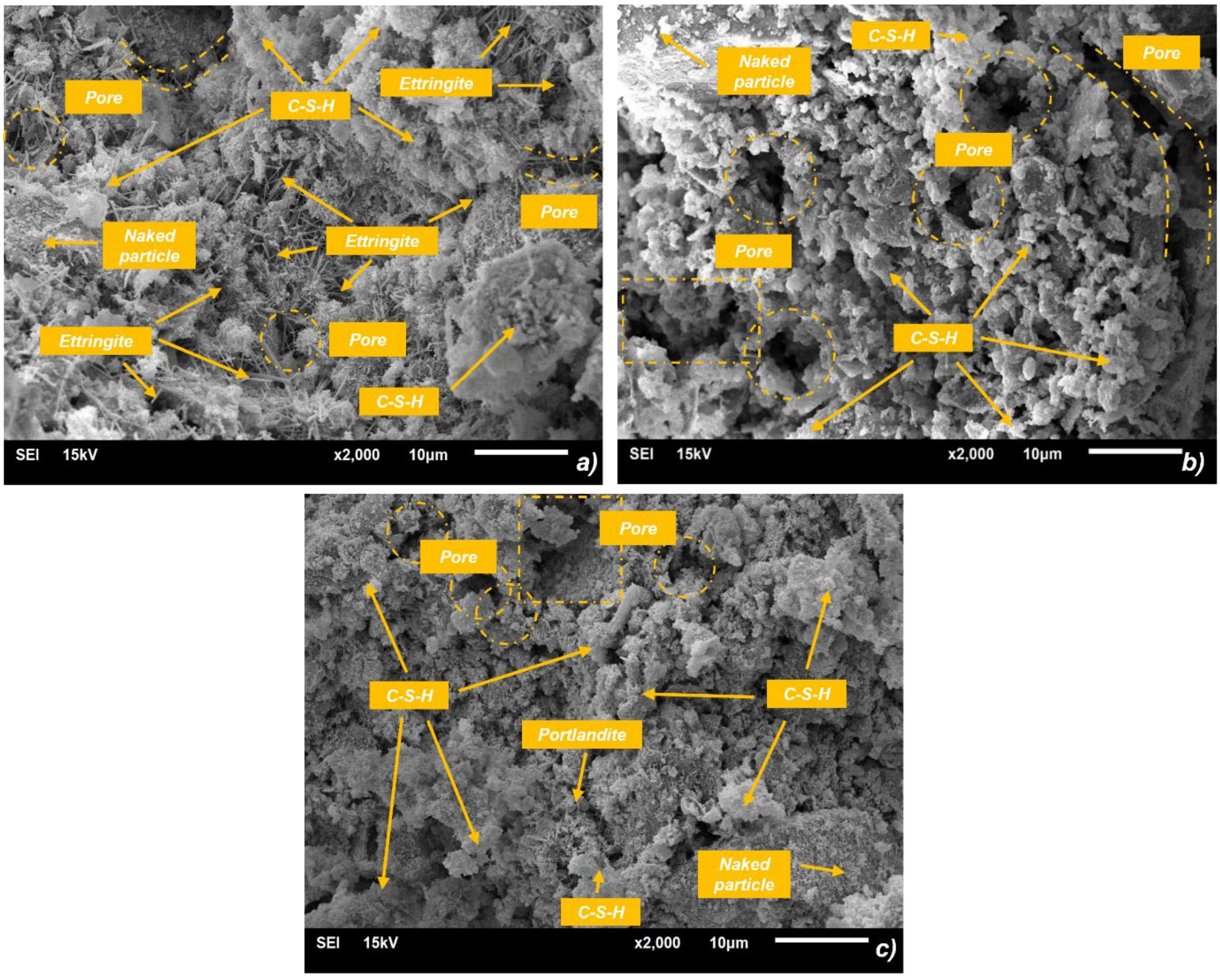

Fig. 4. SEM images of CPB samples (a;CPB/LPW, b;CPB/TW, c;CPB/HPW)

4. Conclusions

In this study, the mechanical and microstructural properties of cemented paste backfill (CPB) prepared with mixing waters of different pH levels (acidic process water, basic process water, and tap water) were investigated. CPB mixtures identified as CPB/LPW, CPB/HPW, and CPB/TW were produced with a fixed solid content of 76% and a cement content of 6% by weight. These mixtures were cured for 3, 14, 28, and 56 days. After each curing period, mechanical strength and microstructural analyses were conducted. The findings are summarized below:

- The strengths of all CPB/LPW, CPB/HPW and CPB/TW samples cured for 28 days increased. The strength values of CPB/TW and CPB/HPW samples cured for 56 days increased by 24.32% and 14.15%, respectively, compared to the samples cured for 28 days, while the strength value of CPB/LPW samples decreased by 9.68%.
- It was determined that low pH levels led to the formation of ettringite and other chemical compounds in cement-based materials due to acidic conditions. These chemical alterations negatively impacted the pore structure of the material, thereby reducing its strength. Structural degradation and uncontrolled crystal growth under acidic environments weakened the mechanical properties and overall durability of the material.
- Microstructural analyses revealed that CPB/LPW samples contained significantly fewer hydration products than CPB/HPW and CPB/TW samples. Additionally, the formation of ettringite was found to be more pronounced in CPB/LPW samples compared to the others.
- The use of low-pH mixing water created an unfavorable environment for cement hydration, and the acidic nature of the water was shown to have a detrimental effect on both the mechanical and microstructural characteristics of CPB.

In conclusion, this study demonstrated that process waters with varying pH values can be utilized in the production of cemented paste backfill. The findings provide insights that may support future research on alternative water sources in backfill applications. Moreover, the potential use of such waters as substitutes for freshwater or potable water in industrial processes may contribute to alleviating future water scarcity to some extent.

Abstract. This study aimed to investigate the lateral behavior of steel pipe piles embedded in saturated sand by considering the nonlinear behavior of both steel and soil materials. Nonlinear soil behavior was modeled using the Pressure-Dependent Multi-Yield Surface Plasticity constitutive model, while the nonlinear response of piles was represented with moment-curvature relationships. In this context, numerical simulations of 30 meter long steel pipe piles with varying section and steel grades were performed considering specified pile head displacement criteria. In addition to the nonlinear approach, simulations with linear elastic pile material were also conducted. In this way, the pile responses under both material assumptions were comparatively evaluated. Results indicated that as the pile flexural stiffness increased, the differences between linear elastic and nonlinear responses became more significant. Findings highlighted the importance and influence of incorporating nonlinear material behavior in the analysis of laterally loaded piles.

Keywords: Finite element method; Nonlinear behavior; Numerical analysis; Open Sees; Soil-pile interaction

1. Introduction

When soil conditions are inadequate in terms of bearing capacity or foundation settlements, pile foundations are the most common solution to transfer the superstructural loads to deeper soil layers, where soil properties are more generally favorable. In addition to carrying vertical loads, pile foundations also are expected to withstand the lateral forces induced by temporary or permanent events. Therefore, it is important to understand the lateral behavior of piles in terms of both pile response and soil response. In literature, numerous studies have investigated the behavior of laterally loaded piles using experimental, analytical and numerical approaches. Experimental studies are helpful observing the behavior, as they realistically capture the soil and pile conditions, especially in the full scale tests. Many researchers have investigated the lateral response of single piles in sands (Coleman, 1968; Gill, 1969; Alizadeh & Davisson, 1970; Coleman & Hancock, 1972; Bergstrom, 1974; Davis, 1977).

In addition to experimental research, significant contributions have also been made through computational studies. Reese et al. (1974) conducted a series of monotonic and cyclic lateral load tests on steel pipe piles embedded in dense sand and developed analytical relationships, known as p-y curves, between pile displacement and lateral soil reaction. Similar relationships have been widely used in analytical and numerical methods including elastic solutions, finite element method or finite difference method. Broms (1964) proposed a method to obtain the pile lateral load capacity considering the flexibility of pile. For single piles in sand, it was indicated that the ultimate lateral load which the pile can withstand was related to yielding of pile material. This approach is significant in estimation of lateral load capacity considering the nonlinear behavior of pile up to yield point of pile material. For extreme loading conditions where nonlinearity exceeds the yield point, assessment of lateral soil-pile response becomes important considering lateral load capacity and pile deformations.

In this study, emphasis was given to investigating the effects of nonlinear steel behavior on the lateral soil-pile response of steel pipe piles embedded in loose to medium-dense sand. All analyses were conducted using OpenSeesPL software. Calibration and validation procedures carried out for model and material model are elaborately presented in the following sections. Numerical simulations were performed considering both linear elastic and nonlinear pile behavior. In the scope of this study, analysis results were comparatively evaluated considering lateral response and applicability of linear elastic material was questioned.

2. Geotechnical and structural properties for numerical modeling

In this section, both geotechnical and structural parameters used in the numerical models are briefly introduced. First, the geotechnical properties of the soil profile and the parameters of the constitutive model are presented.

* Corresponding author, E-mail: fahrettinerener@gmail.com

https://doi.org/10.31462/icearc2025_ce_geo_223

Subsequently, the selection criteria for pile pipe sections and the properties of selected sections are described. Finally, the characteristics of the steel grades considered in this study are explained, along with the corresponding moment-curvature relationships of the steel sections.

2.1. Soil profile and constitutive soil model

In scope of this study, the depth of the soil profile was defined as 60 meters, corresponding to twice the pile length of 30 meters. The soil profile was hypothetically assumed to be comprised of loose to medium dense saturated sand. For this purpose, the relative density of the sand was considered as D_r = 40%. Determination of both elastic and nonlinear soil properties was derived from correlations based on relative density, overburden corrected SPT-N blow count $(N_1)_{60}$, and shear wave velocity at 1 atm, V_{S1}. The correlations used in determining the soil properties at the reference vertical effective stress level of 100 kPa; $(N_1)_{60}$ (Idriss & Boulanger, 2008), V_{S1} (Andrus & Stokoe, 2000), friction angle (ϕ) (Bowles & Guo 1996), lateral earth pressure coefficient at rest (K_0), Poisson's ratio (ν), secant deformation moduli (shear and bulk) at low shear strain level ($G_{1,max}$, $K_{1,max}$) are presented in Equation 1 to Equation 7. Parameters of both saturated mass density (ρ) and permeability (k) which were used for the constitutive model parameters were obtained from Lu et al. (2011) and Arulmoli et al. (1992).

$$D_r(\%) = 100\sqrt{\frac{(N_1)_{60}}{46}} \tag{1}$$

$$V_{S1} = 93.2\left[(N_1)_{60}\right]^{0.231} \tag{2}$$

$$\phi = 28^{\circ}(\pm 2^{\circ}) + 0.15^{\circ} D_r(\%) \tag{3}$$

$$K_0 = 1 - \sin(\phi) \tag{4}$$

$$\nu = \frac{K_0}{1+K_0} \tag{5}$$

$$G_{1,\max} = \rho V_{S1}^{\ 2} \tag{6}$$

$$K_{1,\max} = G_{1,\max}\left(\frac{2+2\nu}{3-6\nu}\right) \tag{7}$$

Pressure Dependent Multi-Yield Surface Plasticity constitutive model (Fig. 1a), which is capable of simulating the undrained behavior of saturated sand, was employed in this study. Notably, the model effectively captures the shear behavior of soils, which depends on variations in effective stress. To achieve this, a stress-dependent formulation is incorporated into the model to adjust the shear modulus with respect to the level of confinement. An important feature of the constitutive model is the inclusion of rules for both dilative and contractive behavior, allowing for a realistic simulation of the undrained response of saturated sand. These behaviors are governed by scalar functions of volumetric strain, which evolve based on the stress ratio and accumulated shear strain, as described by Yang et al. (2003). The model incorporates specific parameters, namely c_1 and d_1, that control the rates of contraction and dilation. In this way, the model enables accurate representation of volumetric tendencies under both cyclic and monotonic loading conditions. Effects of parameters on soil response are shown in Fig. 1b. Both the dilation parameter and the contraction parameter for constitutive model used in this study were adopted from Lu et al. (2011). It should be noted that the selection of soil properties was primarily based on empirical correlations and findings from previous studies.

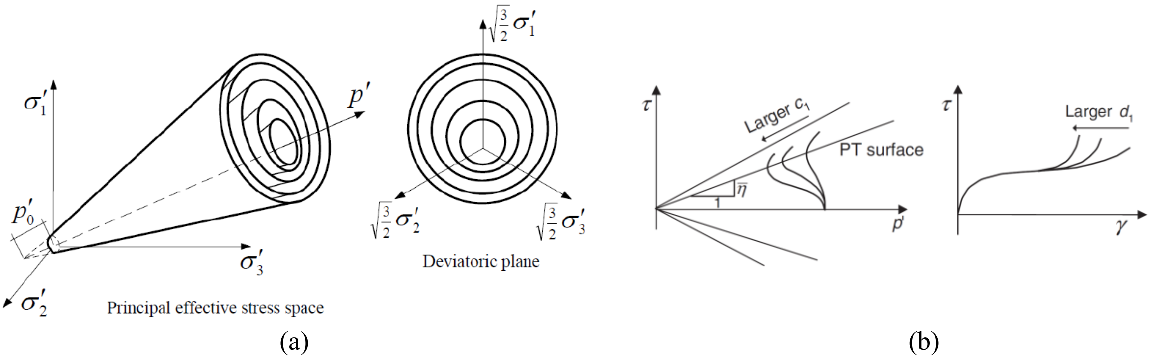

Fig. 1. Pressure Dependent Multi-Yield Surface Plasticity model: (a) multi-yield surfaces in principal stress space and corresponding deviatoric plane (Lu et al., 2011); (b) effect of dilation and contraction parameters on model response (Yang and Elgamal, 2003).

Table 1. Preliminary soil properties prior to calibration.

Soil property	Symbol	Value	Unit
Cohesion	c	0	kPa
Friction angle (triaxial conditions, $K_0 \neq 1$)	ϕ	32	Degrees
Low-strain bulk modulus at 1 atm effective stress	$K_{1,max}$	100	MPa
Low-strain shear modulus at 1 atm effective stress	$G_{1,max}$	41.5	MPa
Lateral earth pressure coefficient at rest	K_0	0.47	Unitless
Permeability	k	6.6E-5	m/s
Poisson's ratio	ν	0.32	Unitless
Reference vertical effective stress	$(\sigma'_V)_{ref}$	80	kPa
Relative density	D_r	40	Unitless
Saturated mass density	ρ	1.9	gr/cm^3
Shear wave velocity at 1 atm effective stress	V_{S1}	148	m/s
Stress dependency coefficient	m	0.5	Unitless
Contraction coefficient	c_1	0.07	Unitless
Dilation coefficient	d_1	0.40	Unitless

To ensure that the constitutive model incorporating these properties reasonably reflected the expected stress-strain behavior of the soil, a calibration process was conducted on a single soil element. This calibration was performed under the specified loading and drainage conditions as part of this study.

Geotechnical properties presented in this section are considered preliminary values prior to model calibration. The results of the calibration and the calibrated parameters are presented in the following sections. Preliminary soil properties are presented in Table 1.

2.2. Pile sections

The dimensions of the pile sections used in this study were determined in accordance with API (2000) recommendations. In order to investigate the effects of pile flexural stiffness on nonlinear behavior, three different outer diameters (D_o) were specified: 24 in (610 mm), 36 in (914 mm), and 48 in (1219 mm). The wall thickness of the tubular sections (t) was selected based on the minimum thickness criteria for driven pile installation, as specified in API (2000) (Equation 8). The D_o/t ratios calculated using Equation 8 ranged from D_o/t = 49 to D_o/t = 66 for the three different outside diameters. To maintain consistency, a constant D_o/t ratio of 50.8 was adopted. Selected dimensions of sections and corresponding section properties of piles are given in Table 2.

$$t = 6.35 + \frac{D_o}{100} \tag{8}$$

Table 2. Section properties of pile sections.

Section property	Symbol	Unit	Section: 610/12	Section: 914/18	Section: 1219/24
Outer diameter	D_o	mm	610	914	1219
Inner diameter	D_i	mm	586	878	1171
Wall thickness	t	mm	12	18	24
Area	A	m^2	0.0262	0.0507	0.0901
Moment of inertia	I	m^4	0.0012	0.0051	0.0161
Plastic section modulus	Z	m^3	0.0043	0.0145	0.0343

2.3. Characteristics of steel grades and moment-curvature relationships of sections

Steel grades used in this study were selected as S235 and S355 (EN 10025-2, 2019). The stress-strain behavior of the steel materials was defined using the governing equations (Equations 9 to 11), which account for the elastoplastic response including yield strength and strain hardening (Fig. 2). The relevant material properties for each steel grade are summarized in Table 3.

$$f_s = E_s \varepsilon_s \quad \text{for } \varepsilon_s \le \varepsilon_{sy} \tag{9}$$

$$f_s = f_{sy} \quad \text{for } \varepsilon_{sy} < \varepsilon_s \le \varepsilon_{sh} \tag{10}$$

$$f_s = f_{sy}\left[1+\left(\frac{\varepsilon_s-\varepsilon_{sh}}{\varepsilon_{su}-\varepsilon_{sh}}\right)\left(\frac{f_{su}}{f_{sy}}-1\right)\exp\left(1-\frac{\varepsilon_s-\varepsilon_{sh}}{\varepsilon_{su}-\varepsilon_{sh}}\right)\right] \quad \text{for } \varepsilon_{sh} < \varepsilon_s \le \varepsilon_{sb} \tag{11}$$

Table 3. Material properties of steel grades.

Material property	Symbol	Unit	S235	S355
Mass density	ρ_s	gr/cm^3	7.85	7.85
Elastic modulus	E_s	GPa	210	210
Shear modulus	G_s	GPa	80.8	80.8
Poisson's ratio	ν_s	Unitless	0.3	0.3
Yield strain	ε_{sy}	mm/mm	0.11%	0.17%
Yield stress	f_{sy}	MPa	235	355
Strain at onset of strain hardening	ε_{sh}	mm/mm	1.50%	1.50%
Ultimate strain capacity	ε_{su}	mm/mm	11.00%	11.00%
Ultimate stress capacity	f_{su}	MPa	360	510
Rupture strain	ε_{sb}	mm/mm	17.00%	17.00%

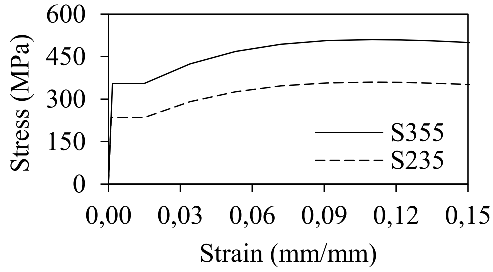

Fig. 2. Stress-strain relationships of different steel grades.

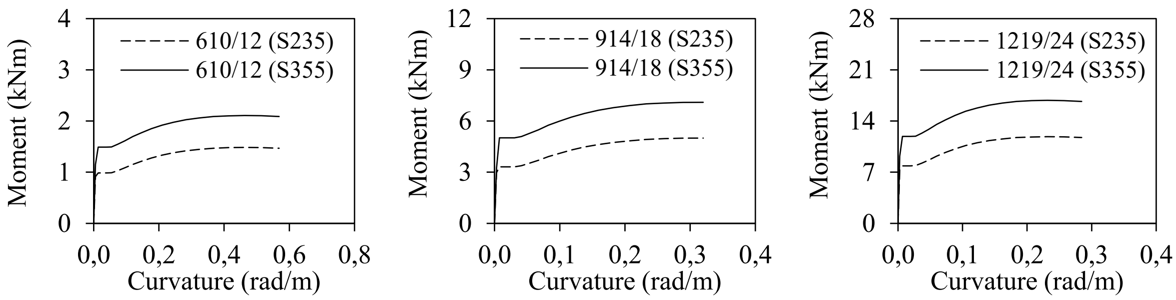

Fig. 3. Moment-curvature relationships for different sections with each steel grades.

The nonlinear behavior of piles is governed by both material and section properties. Considering this, moment-curvature relationships were utilized in this study to represent the nonlinear response of the piles. These relationships were constructed for each section based on the steel material properties and the geometric properties of sections, using both S235 and S355 steel grades (Fig. 3). It should be noted that all moment-curvature relationships were valid for piles without axial load. The effect of axial load (tension or compression) on moment-curvature and nonlinear behavior of steel was beyond the scope of this study.

3. Calibration and validation of finite element model

In this section, the calibration of a single soil element and the validation of the finite element model are presented to provide credibility to the numerical simulations. First, a soil element calibration was conducted to interpret and refine the initial soil properties in a manner that ensured consistency with the experimental results. In this context, monotonic direct simple shear (MDSS) tests performed on Nevada Sand by Arulmoli et al. (1992) under undrained loading conditions and different effective stress levels were simulated using a single soil element, and the model parameters were adjusted to reflect both the experimental stress-strain response and the corresponding stress path. Following the calibration, a full-scale lateral pile load test conducted on a steel pipe pile driven into a loose to medium-dense sand profile was simulated in the numerical model using the calibrated soil parameters. The validation of the pile load test not only confirmed the adequacy of the calibrated parameters but also allowed for the selection of both proper mesh sizes and interface element characteristics.

3.1. Single element response of soil element

The VELACS (Verification of Liquefaction Analyses by Centrifuge Studies) Project was carried out to evaluate and validate numerical and analytical methods for predicting soil behavior under earthquake-induced liquefaction (Arulmoli et al., 1992). The experimental study aimed at producing high-quality experimental data through centrifuge and laboratory testing to be used for calibration and comparison of models. In the scope of this project, MDSS tests were performed under undrained conditions on Nevada Sand with a relative density of D_r = 40%, under varying vertical effective stress levels.

Constant vertical stress was applied to the sample as it was sheared horizontally, allowing observation of pore water pressure development and stress-strain behavior. The maximum shear strain level reached in the tests was γ = 20%, reflecting large soil deformations similar to those that may be observed around laterally loaded piles under extreme displacement demands. By employing the test results under different levels of vertical effective stress, both the validity and reliability of model parameters were evaluated. In this context, the experimental results of MDSS tests conducted under vertical effective stresses of σ_v' = 80 kPa and σ_v' = 160 kPa were considered in the calibration of the soil element. Single element responses for MDSS test are illustrated in Fig. 4 and the calibrated soil properties are given in Table 4.

With the use of the preliminary soil parameters given in Table 1, it was observed that the suggested value of contraction coefficient (c_1 = 0.07) led to a stiffer shear response with respect to the soil behavior from experimental results. By adjusting the contraction coefficient (c_1 = 4.00), shear stress-shear strain responses, stress paths and porewater pressures with respect to shear strain were observed to be consistent with test results for effective stress levels which were considered in this calibration. Dilation coefficient, which was priorly suggested as d_1 = 0.40, was adjusted as d_1 = 0.38 in the calibration process. It is worth mentioning that lateral earth pressure coefficient is equal K_0 = 1 in direct simple shear conditions. Considering the stress conditions, the relationship between triaxial friction angle and direct simple shear friction angle is given in Equation 12 (Khosravifar, 2012).

$$\phi_{TXC} = \sin^{-1}\left[\frac{3\tan(\phi_{DSS})}{2\sqrt{3}+\tan(\phi_{DSS})}\right] \tag{12}$$

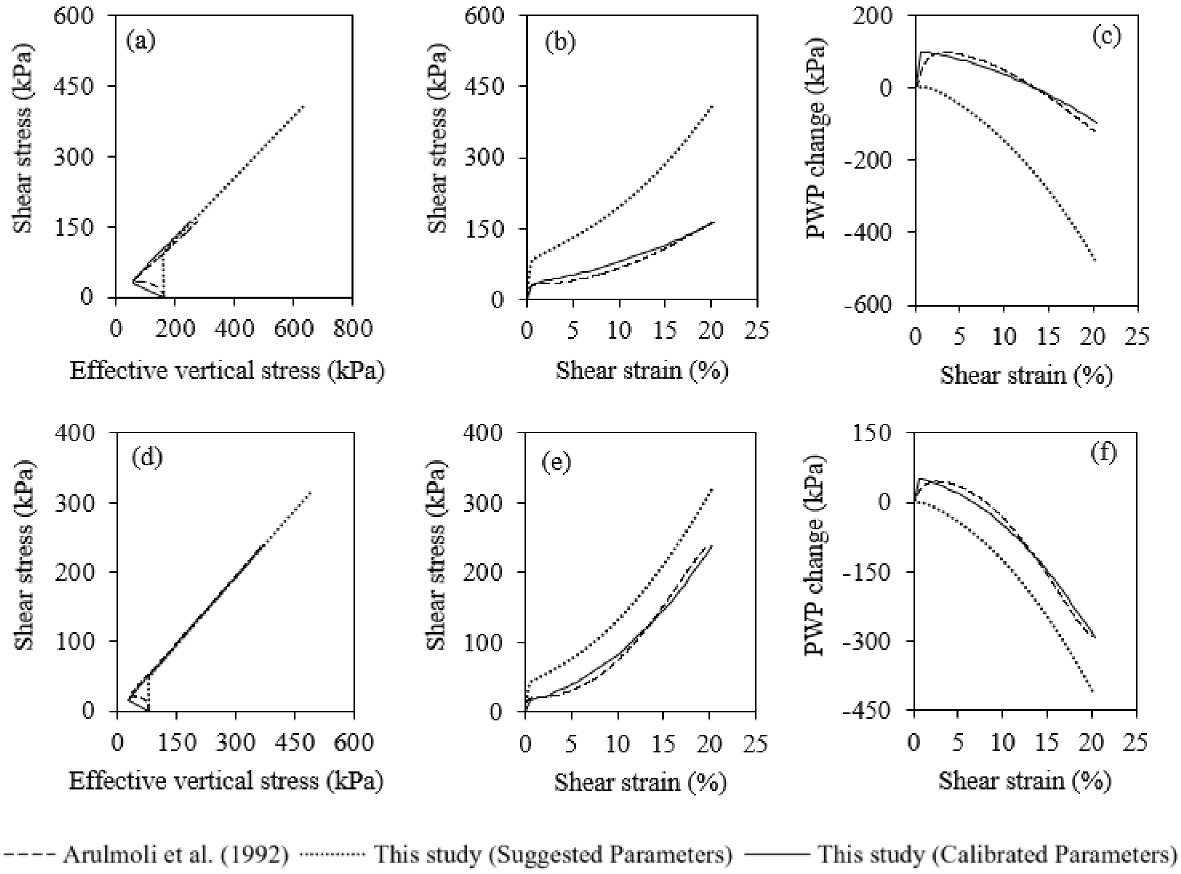

Fig. 4. Single element simulation of undrained MDSS test conducted on Nevada Sand (D_r= 40%) with suggested and calibrated model parameters: (a) Effective stress path, (b) shear stress-shear strain response and (c) porewater pressure (PWP) change for σ_v' = 160kPa; (d) Effective stress path, (e) shear stress-shear strain response and (f) porewater pressure (PWP) change for σ_v' = 80kPa (Arulmoli et al., 1992).

Table 4. Soil properties after calibration.

Soil property	Symbol	Value	Unit
Cohesion	c	0	kPa
Friction angle (triaxial conditions, $K_0 \neq 1$)	ϕ_{TXC}	32	Degrees
Friction angle (direct simple shear conditions, $K_0 = 1$)	ϕ_{DSS}	28	Degrees
Low-strain bulk modulus at 1 atm effective stress	$K_{1,max}$	100	MPa
Low-strain shear modulus at 1 atm effective stress	$G_{1,max}$	41.5	MPa
Lateral earth pressure coefficient at rest (TXC)	$K_{0,TXC}$	0.47	Unitless
Lateral earth pressure coefficient at rest (DSS)	$K_{0,DSS}$	1.00	Unitless
Permeability	k	6.6E-5	m/s

Stress dependency coefficient	m	0.5	Unitless
Contraction coefficient	c_1	4.00	Unitless
Dilation coefficient	d_1	0.38	Unitless

3.2. Validation of finite element model

Validation of the finite element model was carried out using the results of a full-scale lateral pile load test conducted by Rollins et al. (2005) on a steel pipe pile embedded in a soil profile predominantly composed of loose to medium dense fine sand. The objective of the original experimental study was to compare the lateral responses of a full-scale pile group and a single pile, and to evaluate the accuracy of various analytical methods. In the present study, the single pile test results were utilized to validate the finite element model developed using calibrated soil parameters derived from single element simulations. In the experimental study, the single pile which is an open-ended steel pipe with an outer diameter of D_o = 324 mm and a wall thickness of t = 9.5 mm, driven to a depth of approximately 11.5 meters. The yield strength of the test pile was f_{sy} = 404.6 MPa. The displacement-controlled lateral load was applied 0.69 meters above the ground surface. Groundwater level was observed to be at 0.5 meter depth.

The numerical model was created using OpenSees PL software. As the finite element and loading conditions were symmetrical, only half of the system was modeled (Fig. 5). An interface layer was defined to simulate the relative displacement that may occur between the pile surface and the surrounding soil. This interface layer was modeled using solid elements of infinitesimally small thickness, taken as 1% of the outer diameter of the pile. The pile was modeled using beam elements over the central axis of the pile. Rigid link elements were connected to connect the centerline of the pile to adjacent nodes at a radial distance equal to the outer radius of the pile to obtain appropriate interaction with the adjacent mesh. This configuration was implemented along the depth to establish kinematic compatibility between the beam elements representing the pile and the corresponding nodes of the interface layer. The pile material was modeled with linear elastic material, while both the surrounding soil and the interface layer were modeled using the Pressure-Dependent Multi-Yield (PDMY) model. The interface angle was defined using Equation (13), and the deformation modulus of the interface layer was calibrated based on the results of the single pile load test. To reflect the influence of interface behavior, the finite element model was constructed in two configurations: one including the interface layer and one without it, and two separate simulations were carried out accordingly.

$$\phi_{\text{interface}} = 0.67\phi_{\text{soil}} \tag{13}$$

Results of numerical simulations indicated that both the model with and without the interface layer produced consistent outcomes in terms of maximum bending moment and the relationship between lateral load and pile head displacement (Fig. 6). A similar agreement was observed in the bending moment distributions along pile length corresponding to lateral load levels of P = 24 kN and P = 89 kN (Fig. 7). In terms of pile head displacements, under a lateral load of P = 89 kN, the model without the interface layer predicted a lateral displacement of y = 35 mm, whereas the experimental result indicated a displacement of y = 46 mm. This meant that the model produced a stiffer response without interface layer. When the deformation modulus of the interface layer was set equal to 5% of deformation modulus of the soil, as adjusted during the validation, the predicted pile head displacement increased to y = 42 mm under the same level of loading. Since the pile outer diameter was given as D_o = 324 mm, the observed lateral displacement corresponded to approximately $y = 0.14D_o$, which validated that the numerical simulation delivered reasonable results in modelling of observed pile behavior.

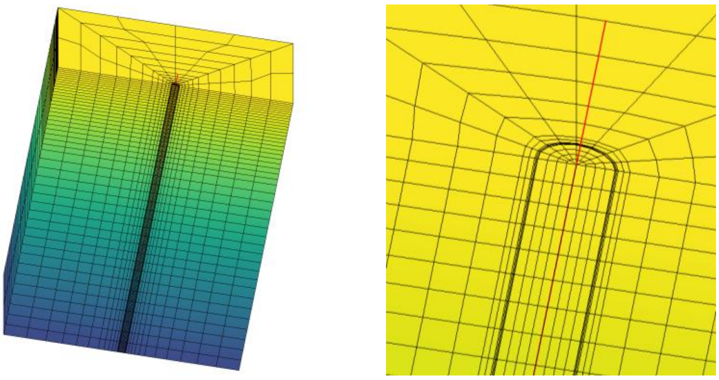

Fig. 5. Finite element model created for pile load test simulation, showing the half-model configuration (left) and finite element mesh around the pile head zone (right).

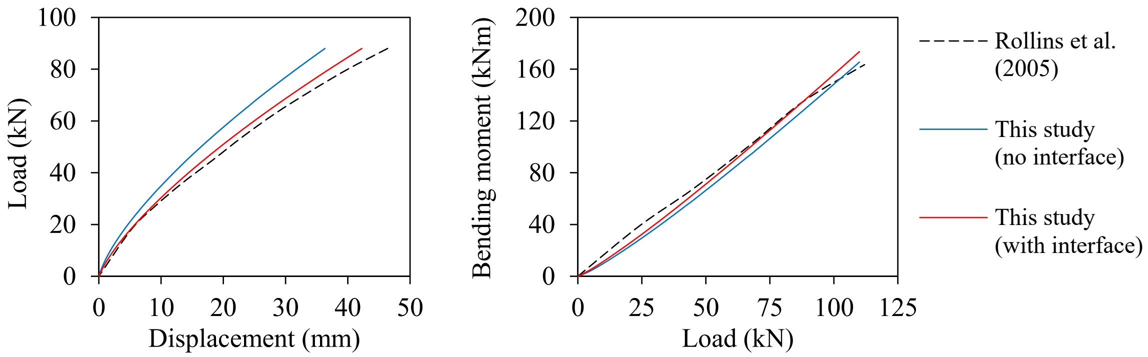

Fig. 6. Comparison of results from numerical simulations and experimental data: lateral load-displacement and lateral load-maximum bending moment relationships.

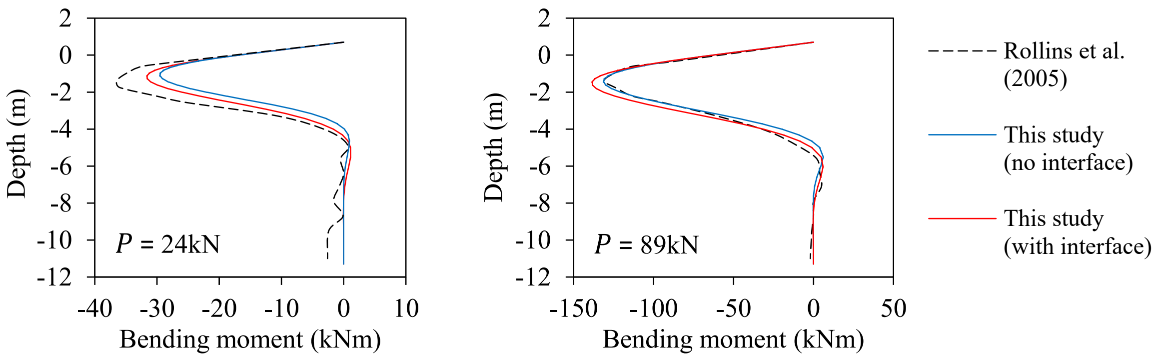

Fig. 7. Comparison of results from numerical simulations and experimental data: bending moment distribution along the pile length for lateral load levels of P = 24 kN and P = 89 kN.

4. Numerical simulations

Numerical simulations were carried out using calibrated soil parameters and interface properties derived during the validation. To assess the pile response under significant lateral deformation demands, displacement-controlled loading was applied at the pile head, with the maximum lateral displacement set to 20% of the pile outer diameter ($0.20D_0$). Three different steel pipe sections were analyzed, and the nonlinear behavior of steel was modeled using moment-curvature relationships specific to each section to capture the nonlinear flexural response under increasing lateral load. Moreover, a linear elastic material model was also assigned to the pile elements to examine the extent to which linear elastic assumption remained valid. By comparing the outcomes from both material models, the displacement range beyond which linear elastic assumption became inadequate was identified. All finite element models considered in this study are illustrated in Fig. 8. In the simulations, the results were normalized by both the pile diameter and length to eliminate the influence of pile size and to enable cross-section-independent comparisons. Normalized values for bending moment, lateral pile head load, head displacement and pile length were calculated using Equations 14 to 17.

$$M_{normalized} = \frac{M}{E_s D_o^{\,3}} \tag{14}$$

$$P_{normalized} = \frac{P}{E_s D_o^{\,2}} \tag{15}$$

$$y_{normalized} = \frac{y}{D_o} \tag{16}$$

$$L_{normalized} = \frac{z}{L} \tag{17}$$

Incremental displacement loadings were applied from the pile head level for each pile. The corresponding normalized lateral load values at the pile head, the relationship between normalized lateral load and maximum normalized bending moment, and the normalized bending moment-depth distribution obtained under a lateral displacement equal to $0.20D_0$are presented in Fig. 9. The results clearly indicated that, as the pile diameter and flexural stiffness increased, the depth at which the maximum normalized bending moment occurred at $0.20D_0$ pile head displacement shifted from approximately 8% to 18% of the total pile length, measured from the ground surface. Furthermore, the ratio of maximum normalized bending moments obtained from simulations with linear elastic assumption to those from nonlinear assumption ranged between 1.66 and 1.91 for S235-grade steel, and between 1.13 and 1.37 for S355-grade steel. It was further observed that the aforementioned ratio tended to increase as the pile flexural stiffness increased. In terms of maximum normalized pile head loads corresponding to a pile head displacement equal to 20% of the outer diameter, ratio between linear elastic behavior to nonlinear behavior was obtained as approximately 1.27 for all piles with S235 grade and 1.13 for all piles with S355 grade.

Lastly, it is worth mentioning that differences between linear elastic and nonlinear responses became evident beyond a normalized lateral pile head load of approximately $P_{normalized}$ = 11 for S235-grade steel and $P_{normalized}$ = 13 for S355-grade steel, for all pile sections. These findings emphasize the importance of incorporating nonlinear steel behavior in the analysis of laterally loaded piles. It is also highlighted that identifying the displacement and lateral load thresholds at which the linear elastic material assumption remains valid is essential for ensuring accurate and reliable estimations.

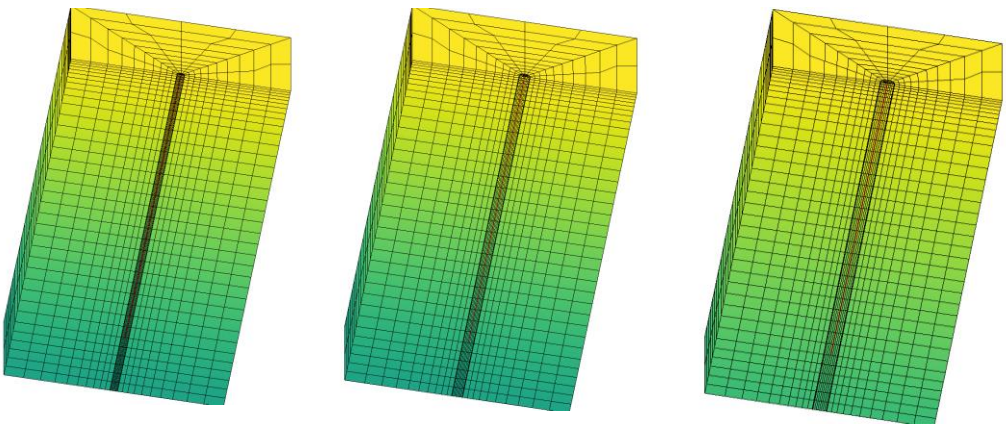

Fig. 8. Finite element models for numerical simulation of lateral pile load test: model for 610/12 pile (left), model for 914/18 pile (middle) and model for 1219/24 pile (right).

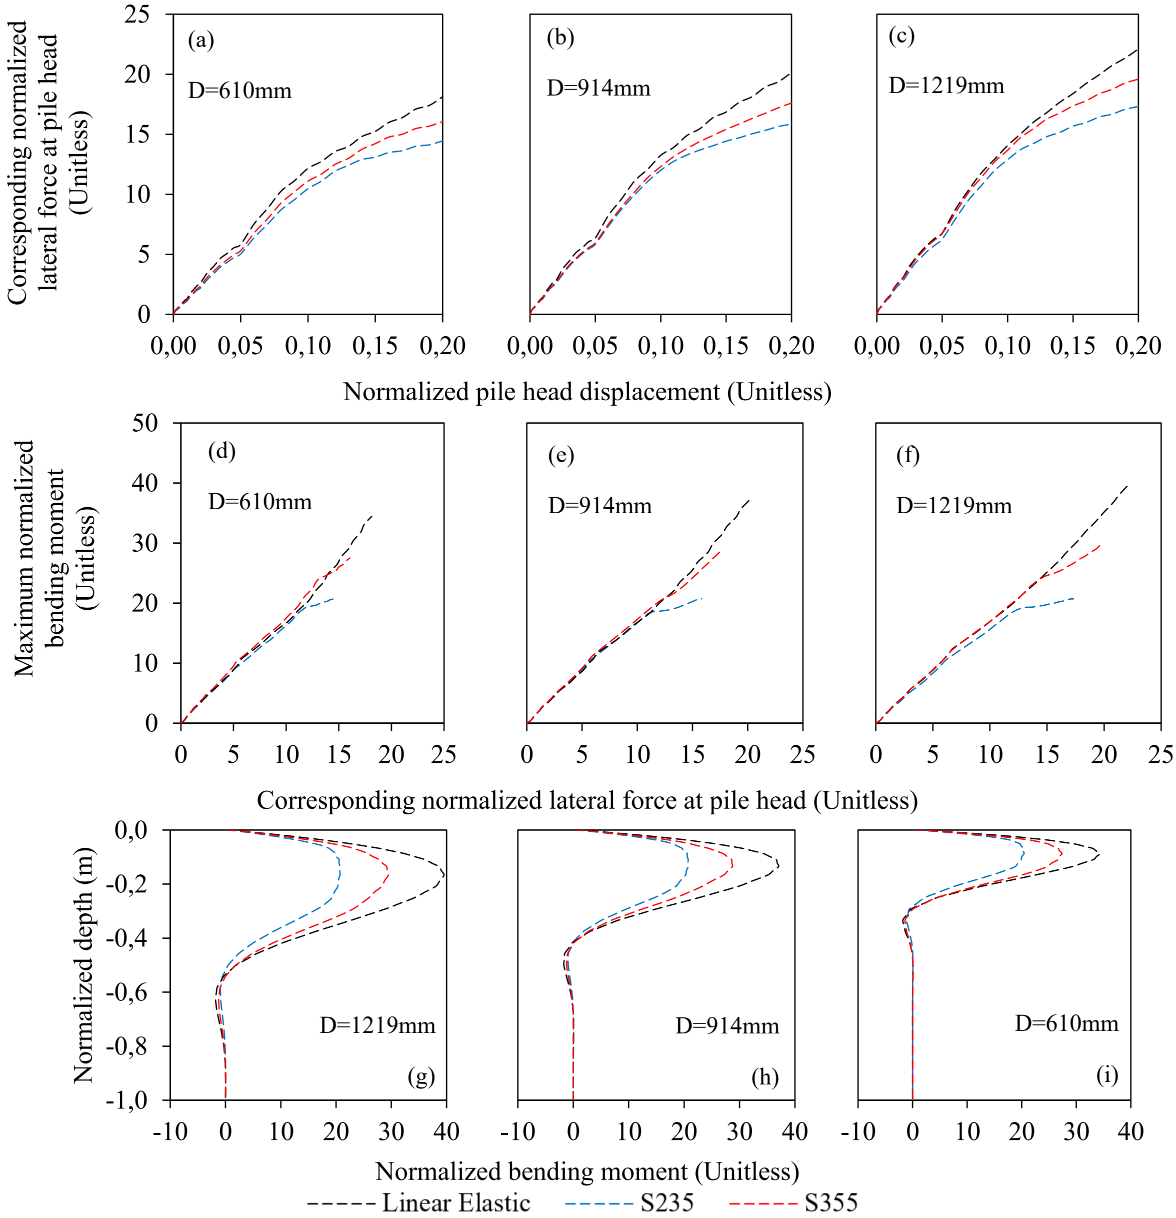

Fig. 9. Normalized displacement-lateral load relationships (a, b, c), lateral load-bending moment responses (d, e, f) and bending moment distribution along depth for the lateral pile head displacement equal to $0.20D_0$ (g, h, i) for different pile sections and materials.

5. Conclusions

This study presented a comprehensive numerical investigation of lateral behavior of steel pipe piles installed in loose to medium-dense sand with focus on the imposed lateral load at the pile head level. Numerical simulations based on PDMY soil model and moment-curvature relationships were implemented using OpenSeesPL software to simulate the nonlinear behavior of the steel piles. The study included extensive soil model calibration and validation of the finite element model with experimental data from the available literature.

The results revealed that the use of linear elastic material for piles led to a significantly stiffer pile response compared to nonlinear pile behavior, considering the steel grades used in this study. The maximum normalized bending moment ratios between linear elastic and nonlinear behavior ranged from 1.66 to 1.97 for S235-grade steel piles, and from 1.13 to 1.37 for S355-grade steel piles. These ratios were found to decrease with increasing yield strength. Moreover, as the flexural stiffness of pile increased, the ratio tended to increase as a result of stiff response of linear elastic behavior. Finally, it was found that the difference between linear elastic and nonlinear responses became particularly evident beyond normalized pile head load thresholds of $P_{normalized}$ = 11 for S235 and $P_{normalized}$ = 13 for S355 steel grades, regardless of flexural stiffness. The findings highlighted both the necessity to account for nonlinear steel behavior in the analysis of laterally loaded piles and the necessity to find the limits for pile head displacement and lateral pile head load up to which the linear elastic assumption was valid.

It should be mentioned that the conclusions drawn from this study are valid only within the limits of the pile lengths, cross-sectional characteristics, steel grades, and soil conditions employed. The conclusions are valid only under the assumed conditions, and it is not recommended to extrapolate the same beyond these specified parameters. For enhancing the validity and reliability of the conclusions, field tests and physical model tests are recommended for future studies. Additionally, to confirm the consistency of the observed trends, additional studies involving various soil profiles and pile geometries are recommended.

Abstract: In Civil Engineering, it is very important that structures are built on geotechnically suitable soils. However, it is not always possible to find a soil with suitable properties due to the increasing population and decreasing usage areas. Therefore, it is an important need to carry out improvement works on problematic soils with low bearing capacity, low swelling-settling resistance, high permeability and insufficient engineering properties. If stabilisation is not provided in such problematic soils, great material and moral losses may occur. Although commonly used remediation methods increase safety, due to their high cost and negative effects on the environment, alternative methods that are economical and leave a low carbon footprint have started to be sought. It is known that carbon footprint has significant environmental impacts such as climate change and resource depletion. Therefore, it has become a very important issue to reduce the carbon footprint in the construction sector and to turn to natural resources with lower environmental impacts. Hemp fibre can be an alternative in this regard. Thanks to the fact that hemp is a natural and sustainable additive material with low carbon emissions, both an environmentally friendly and economical solution can be obtained. The use of hemp fibre can not only improve soil stabilisation, but also contribute to sustainable construction practices. . Furthermore, hemp's carbon sequestration capabilities, rapid growth process, low water demand and insulating properties minimise environmental negative impacts. In the future, natural materials such as hemp fibre are expected to be more widely used in ground improvement processes. In this way, both engineering and environmentally efficient, cost-effective and sustainable construction may become possible.

Keywords: Natural fibers; Geotechnics; Hemp; Ground improvement

1. Introduction

In civil engineering, it is very important that the structures can serve safely. In order to avoid loss of life and property, especially when a natural event such as an earthquake occurs, buildings should be built on the right ground, with materials in accordance with quality standards, designed in accordance with engineering calculations and regularly inspected.

It is very important to find the appropriate ground for the structure to be built (Zardari et al.,2021). When the building is built on a wrong ground, negativities such as collapse, swelling, liquefaction, slipping may occur on the ground. This may cause the structure to topple, collapse, collapse, damage the carrier system or completely collapse in a disaster such as an earthquake, causing great loss of life and property. In order to avoid losses, the ground must be selected correctly. However, it is not always possible to find the right and suitable ground. Especially in today's conditions, it has become very difficult to find ground with suitable engineering properties due to the increase in population, increase in construction and decrease in the areas allocated for construction (Kebe, 2023). For this reason, it has gained importance in civil engineering applications to make use of the existing areas, to improve and stabilise the soil properties with some studies and to make them suitable for construction. However, there are some disadvantages in these applications. Examples can be given as follows;

- High cost of implementation,
- Additives can enter the groundwater and impair water quality,
- Toxic gases may be released,
- May cause air pollution,
- Vibrations can disrupt the underground ecosystem.

These kinds of negativities cause great damage to the environment. Preventing environmental damage and reducing costs economically has made it necessary to search for alternative improvement methods. In order for these alternative methods to be low carbon footprint applications, it is necessary to use natural materials or to recycle and utilise existing wastes that harm the environment (Zardari et al.,2021)

This research was completed by reviewing theses and articles on ground improvement studies with hemp fibres. The main objective of the studies is to provide an environmentally friendly alternative to traditional stabilisation methods. In this context, clay soils with poor bearing capacity were evaluated by reinforcing with hemp fibres.

The effect of factors such as type, mechanical properties, roughness, amount and length of hemp fibres on the data were investigated.

In addition, these studies address the history, benefits and applications of natural and synthetic fibres in soil reinforcement. Literature reviews indicate that fibre reinforced soils are a low cost and environmentally advantageous stabilisation technique. It has been found that the addition of natural and synthetic fibres increases the California bearing ratio (CBR) and free compressive strength values, and decreases the plasticity index and volume change (Vitoşoğlu & Şengül,2023)

In short, this study aims to guide geotechnical and transportation engineers in stabilising soils with low bearing capacity with natural and synthetic fibres.

2. What is ground improvement?

All structures are built on or in the ground. Loads are transferred to the ground by the constructed structures and the ground is expected to be able to safely carry these loads. However, not all soils have the same bearing capacity. In such a case, ground improvement is used.

As a result of the increase in population and rapid urbanisation, it has become necessary to use soils that do not have suitable engineering properties for the construction of buildings. The soils encountered may have problems such as insufficient bearing capacity, settlement, swelling and liquefaction. In such soils, ground improvement methods are used to ensure that the structures are safe, durable and serviceable in the long term (Kebe, 2023)

Soil improvement methods are generally in the form of techniques to improve the mechanical, physical, hydraulic and chemical properties of the soil.

3. Ground improvement methods

3.1. Chemical improvement methods

These are the techniques of changing soil properties by chemical reactions.

- Chemical Stabilisation: It is the process of increasing the strength by mixing binding materials such as lime, cement, fly ash, silica fume into the soil.
- Injection Techniques: It is the process of strengthening the ground by using mortar, chemical solutions or polyurethane injections in low strength soils.
- Ion Exchange: Plasticity and swelling potential of clay soils are reduced by ion exchange.

3.2. Mechanical improvement methods

Methods that improve the organisation, compaction and strength of soil particles.

- Laying (Additional Layers): It is the process of spreading the load over a large area by laying fill, geosynthetic materials or concrete on weak soils.
- Compaction: It is the process of increasing the density of the soil by compacting it with machines such as cylinders, vibratory compactors and rammers.
- Consolidation: It is the process of accelerating the settlement process that will occur over time by removing water from the ground with preloading or drainage systems.
- Deep Mixing: It is the application of mechanical and chemical improvement techniques together by injecting cement or binder materials into the ground.

3.3. Thermal improvement methods

These are the methods based on changing the physical and mechanical properties of the soil by using heating or cooling processes.

- Geothermal Heating: In frozen ground, pipes are placed in the ground. Hot water or steam is passed through the pipes. The heated ground softens, thus facilitating the excavation or compaction of the ground.
- Freezing-Thawing: This method is based on controlled freezing or thawing of the ground. In water-saturated soils, the ground freezes and works like a barrier, which creates an impermeable barrier and provides support in the excavation area. Multiple freezing and thawing of the ground is used to make hard soils brittle and loose to facilitate excavation.
- Thermal Shock: It is stabilised by changing the soil structure with sudden temperature changes. The ground is first heated by flame or hot steam and then cooled rapidly. As a result of this sudden temperature change, the ground cracks or becomes more brittle. It is used to facilitate excavation operations on soils such as high strength, rock and hard soil.

3.4. Physical improvement methods

- Shock Loading: Compacting soil using dynamic compaction techniques.
- Vibratory Compaction: Applying vibrations to enhance soil particle arrengement.
- Blasting: Using controlled explosions to densify loose soils.
- Electrokinetic Methods: Using electric currents to facilitate drainage and compaction (Çukurova Üniversitesi, 2015).

3. Materials used in soil improvement

Various materials are used in soil improvement, especially in soil improvement using additives. Soil improvement usually includes additives that are categorized as synthetic or natural materials (Hannura, 2024)

4.1. Synthetic additivies

These substances are usually chemical or polymer based and can change the properties of the soil (Gül, 2024)

- Polymers: They can be in the form of Polypropylene (PP), Polyurethane (PU), Polyethylene (PE), Epoxy resins. They have structures that provide elasticity to the soil. They provide elasticity and durability to the soil.
- Geosynthetic Materials: Geotextiles, geogrids, geonets and geomembranes, which are frequently used in improvement, provide soil stabilization, resistance, waterproofing and filtration.
- Chemical Stabilizers: Cationic Polymers, Sodium Silicates, Asphalt Emulsions are examples of chemical stabilizers. These substances are used to harden the soil and reduce water permeability.
- Inorganic Binders: They are inorganic materials such as fly ash, silica fume, slag. These materials chemically react with cement and other binders in the soil and increase the strength and durability of the soil.
- Nano Materials: Special additives developed to strengthen the bonds between soil particles. Requires advanced technology.

4.2. Natural additives:

- Lime: Increases plasticity and durability, especially in soils with high clay content.
- Cement: Increases soil strength, combines with water and becomes rigid.
- Clay Minerals: Used to increase the stability and durability of Bentonite and Kaolin minerals, even if only for a short time.
- Sand and gravel: Used to store compactness and stability in loose soils.
- Volcanic Ashes: Pozzolans, which are volcanic substances, are used to react with lime or cement and cause deterioration.
- Organic Fibers: Used in organic fiber methods such as straw and coconut fiber. It is used for general purposes such as swelling, shrinkage, cracking reduction, increasing the strength of the soil, and preventing fragments.

4. Hemp fibres

Hemp fibres are another example of organic fibres with a natural and durable structure. Like other fibres, studies have shown that it prevents swelling and cracking of floors, reduces strength and prevents erosion.

Hemp fibres are attracting attention as a natural and environmentally friendly reinforcement material for floor improvement. Various academic studies show how hemp fibres improve the technical properties of floors. In most of the studies, hemp fibres have been added to the soil in certain proportions and some experiments have been carried out on doped soil samples. These experiments are designed to test the strength, basic parameters and bearing capacity of the soil, such as the free compression test, the triaxial compression test and the California Bearing Ratio (CBR). As a result of all these experiments, it has been observed that there is an improvement in the parameters of the ground (Akyol, 2022). In some of the studies, hemp geotextiles were made and the soil was covered with geotextiles, which increased the strength of the soil and improved the angle of internal friction.

Hemp fibres can also be used in civil engineering applications other than soil improvement. For example, these fibres can be used as additives in building materials. In the studies carried out, hemp fibres were used as an additive and insulating material in concrete.

The use of hemp mixed with lime and water as a concrete additive has been called hemp concrete. Hemp concrete is lighter and more insulating than other doped concretes. In addition, it stores CO_2 thanks to its CO_2-absorbing property and is emerging as a sustainable and environmentally friendly option with a low carbon footprint. This environmentally friendly application can be used not only in buildings, but also in concrete roads and infrastructure.

6. Conclusion

The results of all the studies conducted and described above show that hemp fibres are an effective additive material in soil improvement projects. Hemp fibres will increase the strength of the soil, reduce deformations and improve the weak soil. As these applications become more widespread, buildings will be constructed on reinforced soils that are both safer and more environmentally friendly, reducing the carbon footprint and improving the soil economically using sustainable methods.

Abstract. Increasing global demand for natural construction materials has highlighted the urgent need for sustainable solutions that prioritize the reuse of waste materials, reduce environmental impact, and conserve natural resources. In line with these objectives, this study investigates the long-term filtration performance of Recycled Concrete Aggregate (RCA) obtained from a concrete road as part of a road renewal project at Karadeniz Technical University for its potential use as a filtration material in under-road drainage systems. RCA, derived from the renovation works, was tested in an improved and remanufactured ASTM D5101 standard test system. This system has features enhancements such as increased sample dimensions (diameter and height from 10 cm to 15 cm) and additional manometer ports (from 6 to 8). Notably, experiments conducted under low hydraulic gradient, results closer to real field conditions and pioneering innovation in filtration performance research. The study evaluated the clogging behavior of the RCA-geotextile system caused by water flow using key parameters such as gradient ratio (GR) and permeability ratio (KR). The results demonstrated that RCA exhibited filtration performance comparable to natural filter materials at an acceptable level. The innovative reuse of RCA not only provides a functional filtration material but also contributes significantly to the principles of sustainability by reducing construction waste and minimizing reliance on natural resources.

Keywords: Recycled aggregate; Geotextile; Long-term filtration; Sustainability.

1. Introduction

Advancements in construction technology and rapid urbanization have significantly increased the volume of construction and demolition waste (C&DW), posing a major challenge to environmental sustainability (Hassan et al., 2022). Annually, the construction sector generates 333 million tons of waste in Europe, 534 million tons in the United States, and 1.13 billion tons in China (Menegaki & Damigos, 2018). This large-scale waste production, especially in developing countries, exacerbates environmental risks such as toxic effects on freshwater ecosystems, soil acidification, and eutrophication due to nutrient accumulation, ultimately threatening ecosystem health and human well-being (Ferronato et al., 2023).

In this context, the recycling of construction waste is considered a key strategy in achieving environmental sustainability goals.Government policies promoting the recycling of construction waste are crucial in mitigating environmental issues (Menegaki & Damigos, 2018). Recycled concrete aggregate (RCA) offers significant advantages over natural aggregates (NA) due to its widespread availability and cost-effectiveness. Notably, RCA demonstrates performance characteristics closest to natural aggregates among recycled aggregates (C&D Waste), making it a promising material for sub-surface drainage systems in road construction.

Sub-surface drainage systems play a vital role in efficiently discharging water infiltrating the pavement structure and subgrade. Various types of surface water drainage systems are utilized, with pipe drains being among the most commonly preferred solutions. In these systems, geotextiles and aggregates are used together, where the geotextile prevents the passage of foreign particles while allowing water to pass through, effectively mitigating the risk of piping in the soil. However, drainage system clogging can lead to water accumulation within pavement layers, reducing the soil's load-bearing capacity and causing premature fatigue cracking (Haider & Chatti, 2009). This not only shortens the service life of roadways but also increases maintenance costs, resulting in economic losses. The hydraulic efficiency of the system largely depends on the particle size distribution and permeability coefficient of the aggregate. The tendency of fine particles to clog geotextile pores during filtration is a critical

*Corresponding author, E-mail: ahmetbenli61@gmail.com

https://doi.org/10.31462/icearc2025_ce_geo_275

factor in determining the long-term performance of drainage systems (Palmeira & Gardoni, 2000; Bayın Sarıahmetoğlu et al., 2021).

Despite numerous studies on RCA in drainage applications, limited research has focused on its long-term clogging behavior under low hydraulic gradients, which is more representative of real-world conditions. This study addresses a gap in the literature by examining the long-term clogging behavior of RCA obtained from a concrete roadway rather than general RCA applications. Unlike previous studies, the RCA used in this research was obtained from a road pavement as part of a road renewal project, offering a novel contribution to the evaluation of its filtration performance in subsurface drainage systems.

This study evaluates the filtration performance of recycled pavement concrete aggregate (RRCA) sourced from concrete waste arising from Karadeniz Technical University's road renewal works. A modified test setup based on the ASTM D5101 standard was used to analyze the clogging performance of a drainage system incorporating RCA and nonwoven polypropylene geotextile, a commonly used material in drainage applications. The enhanced ASTM D5101 test system features increased specimen diameter and height, along with an increased number of manometer ports, allowing for more precise and reliable measurements (ASTM International, 2021). Consequently, the long-term filtration performance of the RRCA-geotextile system under low hydraulic gradient was assessed with greater accuracy and detail. The study examines whether the clogging parameters remain below the upper limits defined in the standards. Additionally, a distinguishing aspect of this study is that the concrete source used for RRCA is from a local institution's road waste, emphasizing its relevance to regional waste management and sustainability efforts.The experiments focused on analyzing the clogging tendencies and filtration performance of RRCA and geotextile combinations over time. Instead of high hydraulic gradients, which are known to accelerate geotextile clogging in perforated pipe drains (French drains), this study concentrated on low hydraulic gradient conditions that align more closely with real-world highway drainage designs (Bayın Sarıahmetoğlu et al., 2021). Previous research indicates that high hydraulic gradients in subsurface drainage can worsen geotextile clogging (Pak & Zahmatkesh, n.d.), whereas the low-gradient drainage designs commonly adopted in highway engineering provide more practical and reliable performance.

In this context, the recycling of construction and demolition waste (C&DW) for engineering applications is considered an effective approach to promoting environmental sustainability. This study examines the performance of recycled road concrete aggregate (RRCA) in drainage systems, specifically evaluating key parameters such as permeability, clogging potential, and filtration efficiency of RRCA-geotextile systems under varying hydraulic conditions. By ensuring that clogging parameters remain within standard limits, this research offers valuable insights into the long-term viability of RRCA in practical engineering applications.

2. Meterials and methods

In the modified ASTM D5101 test system, Recycled Concrete Aggregate (RCA), obtained from a concrete pavement that had reached the end of its service life within the Karadeniz Technical University campus, was utilized together with a nonwoven geotextile. These materials were selected for their potential application in the design and implementation of sustainable drainage systems. The use of RCA contributes to the reutilization of construction and demolition waste, promoting environmental sustainability and resource efficiency.

2.1. Recycled concrete aggregate (RCA)

The RCA used in this study was subjected to a series of tests within the framework of the modified ASTM D5101 test in order to characterize its geotechnical properties, which are critical for drainage applications. the material was processed and analyzed through a set of standardized geotechnical laboratory tests, including pycnometer test, standard proctor compaction test (in accordance with ASTM D698-12). These tests provided data on the particle size distribution, specific gravity, compaction of the RCA.

The mix design of the sample was designed to represent the most unfavorable condition (within the Turkish standard), with the objective of inducing maximum clogging.To achieve the targeted particle size distribution for the study, the materials obtained were processed using a jaw crusher. The resulting aggregate was then prepared to match the gradation outlined in the experimental design. The images of the obtained recycled concrete aggregate are presented in Fig 1.

Fig. 1. The RCA sample was prepared in accordance with the specified gradation.

The pycnometer test was conducted to determine the specific gravity of soil or aggregate particles. The specific gravity of the material plays a crucial role in evaluating its volumetric properties and in calculating other geotechnical parameters. In addition, the Proctor test was employed to determine the mechanical properties of the RRCA specifically to identify its maximum dry density and optimum moisture content. These parameters are essential for understanding the compaction behavior of the RCA and assessing its suitability for use in drainage systems. The specific gravity values obtained from the pycnometer test and the optimum moisture contents and maximum dry density obtained from the Proctor test are presented in Table 1, Equation 1. and Table 2 accordingly.

$$\rho_s = \rho_w \frac{M_2 - M_1}{(M_4 - M_{1)} - (M_3 - M_2)} 2.645 g/cm^3 \quad (1)$$

Table 1. Pycnometer Test Results

37.9 g	81.8	166.9	139.6

Table 2. Properties of RRCA

Gs	w_{opt} (%)	MDD (kN/m^3)
2.645	16.1	16.66

*Gs: Specific gravity, w_{opt}: Optimum moisture content, MDD: Maximum dry density

2.2. Geotextile

Geotextile materials used together with aggregates are widely preferred engineering solutions for building efficient and sustainable drainage systems. In these systems, the geotextile's filtration capacity is the main factor that affects the overall filtration performance. Therefore, selecting a suitable geotextile material is very important for the effective operation of the drainage system. Choosing the right type of geotextile helps achieve satisfactory filtration by preventing the movement of fine soil particles while allowing water to pass through, thus maintaining the stability of the system. Nonwoven geotextiles are generally preferred in filtration applications, as they offer both technically and economically efficient solutions. The geotextile used in the study is presented in Fig 2.

Fig. 2. Geotextile

Table 3. Properties of geotextile

Properties	Unit	Test Standard	GT 1
Mass per Unit Area	g/m^2	ASTM D 5261 (2018)	123
Thickness (at 2kPa)	mm	ASTM D 5199	1.3
Tensile Strength (MD- CMD)	kN/m	ASTM D 4632	-
Elongation at Break (MD-CMD)	%	ASTM D 4632 (2023)	min. 50
Static Puncture Resistance	N	ASTM D 6241 (2022)	1800
Permittivity (1/s)	mm	ASTM D 4491 (2022)	110
Characteristic Opening Size	l/(s·m^2)	ASTM D 4751 (2021)	0.3

2.3. Methods

In order to evaluate the long-term filtration performance of the recycled concrete aggregate (RRCA) obtained from a concrete pavement located within the university campus, a three-stage particle size reduction process was applied. In the first stage, concrete debris was broken down into approximately 8–10 cm pieces using a demolition hammer. In the second stage, the material was further reduced to particle sizes ranging from 1 to 3 cm using a jaw crusher. Finally, in the third stage, the aggregates were processed into suitable sizes for sieve analysis (Fig 3-4). The samples were then prepared following the mix ratios provided in the Table 4.

Table 4. Material percentages to be used according sieve numbers

Sieve No.	10	18	30	40	50	70	100	Pan
% Quantity	10	15	9	14	13	19	10	10

Fig. 3. Three-stage particle size reduction

Fig. 4. Jaw crusher and grinding machine

The test apparatus was redesigned in accordance with the ASTM D5101 standard and includes various innovative features that distinguish it from those used in previous studies. Modifications such as increasing the sample diameter and height, as well as adding additional manometer ports, allowed for more comprehensive and precise measurements under conditions more representative of the field (Fig. 5).

The developed system enabled the measurement of both the permeability coefficient of the RCA material alone and the overall permeability coefficient of the system composed of RCA and geotextile under different hydraulic gradients. Furthermore, it allowed for the determination of key hydraulic parameters such as the gradient ratio (GR) and the permeability ratio (KR).

Unlike the standard ASTM D5101 procedure, the experiments in this study were designed to evaluate the long-term clogging performance of the material. The specimens were kept in the test system for approximately six months, during which clogging-related parameters were monitored. The experiments were continued until an ideal hydraulic gradient and permeability ratio were achieved. At the end of the testing period, to determine the amount of fine particles that had been displaced, the sample was carefully removed and reanalyzed using sieve analysis.

Measurements obtained from manometers installed at different heights were utilized in Equations (2) through (5) to determine the GR values.

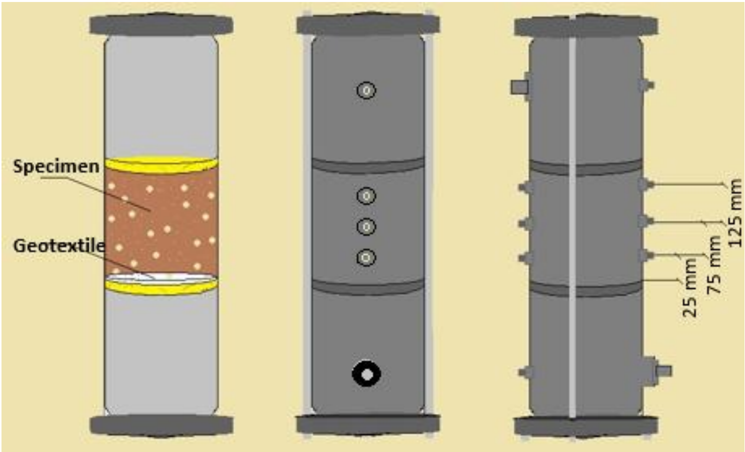

Fig. 5. Developed ASTM D5101 test system

$$GR_1 = \frac{i_{0-25}}{i_{25-75}} = 2 \times \frac{h_{25} - h_0}{h_{75} - h_{25}} \tag{2}$$

$$GR_2 = \frac{i_{25-75}}{i_{75-125}} = \frac{h_{75} - h_{25}}{h_{125} - h_{75}} \tag{3}$$

$$GR_3 = \frac{i_{0-25}}{i_{25-125}} = 4 \times \frac{h_{25} - h_0}{h_{125} - h_{25}} \tag{4}$$

$$GR_4 = \frac{GR_1 + GR_2}{2} \tag{5}$$

h0, h25, h75, h125 : Manometer readings at different heights

i: Hydraulic gradient.

The KR parameter defined in the ASTM D 5101 Standard (Equation 6) is expressed as the ratio of the aggregate permeability coefficient (as described in Equation 6) to the system permeability coefficient (as described in Equation 7) (Sariahmetoglu, 2021).

$$KR = \frac{k_{aggregate}}{k_{system}} \tag{6}$$

$$k_{system} = \frac{Q}{A \times t} \times \frac{1}{i_{system}} \times \frac{\mu_T}{\mu_{20}} = \frac{Q}{A \times t} \times \frac{l}{h_{150} - h_0} \times \frac{\mu_T}{\mu_{20}} \tag{7}$$

$$k_{aggregate} = \frac{Q}{A \times t} \times \frac{1}{(U_{avg} - A_{avg})} \times \frac{\mu_T}{\mu_{20}} \tag{8}$$

k_{system} : The permeability value of the system at 20°C is, (cm/s),
Q : The accumulated flow volume at time t, (cm^3),
i : Hydraulic gradient,
A : Cross-sectional area of the sample, (cm^2),
t : The time required to collect the amount of drained water, Q (s),
μ_T : The viscosity of water at temperature T.
μ_{20} : The viscosity of water at 20°C,

l : The length of the sample,
U_{avg} : The average of the upper manometer readings,
A_{avg} : The average of the lower manometer readings.

4. Results and discussion

Long-term filtration test results, conducted under i = 0.33 hydraulic gradient using an improved ASTM D5101 standard-based experimental setup with a recycled concrete aggregate–nonwoven geotextile system, were analyzed in terms of the GR and KR values defined in the referenced standard. GR values greater than 1 is indicative of the onset of clogging within the system, suggesting that fine particles migrate downward due to water flow and gravity, ultimately obstructing the system. Conversely, a GR value less than 1 implies that piping occurs where migrating fines pass through the geotextile, thereby enhancing the filtration performance.

In deviation from the standard ASTM D5101 test configuration, the filtration system utilized in this study was designed with specimens measuring 150 mm in diameter and 150 mm in height. To achieve higher precision in hydraulic gradient measurements, manometer ports were positioned at vertical distances of 25 mm, 75 mm, and 125 mm from the geotextile layer. The GR and KR values were subsequently determined based on pressure data recorded from these manometer points.

The time-dependent variations of GR and KR values for RCA are presented in Fig.s 6 and 7, respectively. As illustrated in the graphs, the onset of partial clogging in the RCA system can be identified.

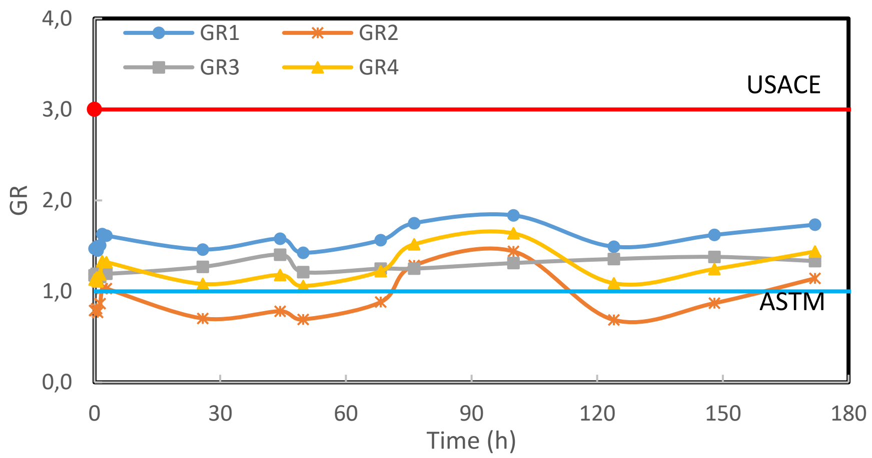

Fig. 6. Time-dependent GR values for RRCA

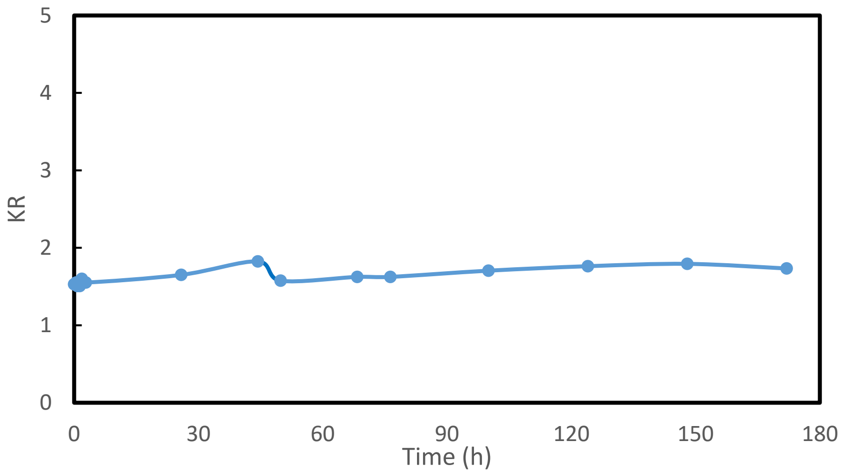

Fig. 7. Time-dependent KR values for RRCA

5. Conclusions

Enhanced long term filtration test was conducted to evaluate the filtration performance of drainage systems composed of recycled concrete aggregate -obtained from road renovation work- and geotextile. Based on the data obtained from the experiments, the following conclusions can be drawn:

- GR values exceed 1 and exhibit an increasing trend, indicating downward migration of fine-grained particles through the system.
- Although the system has initiated signs of clogging, it is still capable of maintaining its functionality, as the GR value has not exceeded the critical clogging threshold of 3
- To accurately evaluate the clogging performance of the system, the GR and KR values should be evaluated collectively.
- The utilization of recycled waste materials in place of natural aggregates in drainage systems contributes to energy conservation and the advancement of circular economy, while proposing a solution to the burden on waste management problem.

Abstract. Cement-based backfill (CBF) remains a widely adopted solution for the sustainable and effective management of mine tailings. Nonetheless, the environmental challenges linked to tailings disposal and the high financial and ecological cost of cement production have prompted the exploration of alternative materials and techniques. This research explores the influence of sand incorporation on CBF formulations, aiming to enhance the particle size distribution of fine-grained, poorly graded tailings, improve mechanical strength, and lower overall expenses. CBF samples were produced with a constant binder ratio of 4 wt% and solid content of 80 wt%, then subjected to both unconfined compressive strength (UCS) and ultrasonic pulse velocity (UPV) assessments across various curing durations (3 to 180 days). Sand replaced tailings at incremental proportions of 5%, 15%, 25%, 35%, and 45% by weight. The findings indicate that adding sand up to 35% and allowing curing up to 90 days noticeably boosts CBF performance. Conversely, exceeding 35% sand content or extending curing beyond 90 days resulted in reduced quality and mechanical behavior. Strong correlations were established between UCS and UPV based on varying sand contents and curing durations. Furthermore, the predicted UCS values closely aligned with experimental data (R^2 = 97.9%). These results highlight the potential of incorporating alternative aggregates in CBF systems, paving the way for cost-efficient, practical, and scalable backfill strategies in underground metal mining operations.

Keywords: Cement-based backfills; Strength; Ultrasonic; Sand; Microstructure

1. Introduction

Cement-based backfill (CBF) has gained increasing attention as a key component of sustainable and modern mining operations, owing to its wide range of advantages (Zhang et al., 2023). Beyond enhancing underground safety by reinforcing surrounding rock structures, CBF also mitigates technical and environmental challenges associated with tailings management (Yin et al., 2023; Haiqiang et al., 2016). Typically, CBF is produced by mixing mine tailings with cement, water, and various additives—either natural or chemical—at a surface backfill plant, then delivered to underground voids via gravity flow or pumping systems (Qu et al., 2023). In recent years, the growing demand for industrial ore production has led to the processing of lower-grade ores, which in turn has significantly decreased the particle size of tailings generated during mineral processing (Kasap et al., 2022a). This shift in tailings characteristics has adversely affected the performance of CBF mixtures and increased cement consumption (Ban et al., 2022). Elevated cement usage not only imposes additional financial burdens on mining operations but also intensifies environmental concerns due to the associated rise in CO_2 emissions (Kasap et al., 2023). Consequently, in addition to the use of cement-replacing additives, there is a growing need to explore alternative materials—particularly aggregates derived from waste—as substitutes for tailings to alleviate these environmental and technical issues (Sari et al., 2023).

Sand, a fundamental component in construction materials like cement and concrete, is an inorganic material exhibiting diverse mineralogical characteristics (Li et al., 2021). Its physical and chemical properties play a key role in influencing the gradation profile of cementitious mixtures, along with factors such as maximum particle size and surface texture (Behera et al., 2020). In particular, the angular shape and particle size of sand contribute to enhancing the mechanical performance of these mixtures by increasing internal friction among particles (Yan et al., 2023). Improved particle packing, especially in fine-grained matrices, leads to a denser and more stable structure (Jiang et al., 2020). Additionally, the mineralogical composition of sand can aid hydration reactions

[*] Corresponding author, E-mail: erol.yilmaz@erdogan.edu.tr

https://doi.org/10.31462/icearc2025_ce_geo_324

within cement-based systems, positively influencing the microstructure of the hardened matrix (Li et al., 2023). However, due to its chemically inert nature, sand cannot independently trigger hydration processes and does not alter the composition or nature of hydration products (Alp et al., 2009). Despite its many advantages, the coarse and angular geometry of sand particles tends to raise the water demand of mixtures, which can negatively affect their workability. As such, careful control over both sand content and particle size distribution is essential during mix design (Kasap et al., 2022b). Recently, sand has gained popularity as a partial binder or aggregate replacement in cement-based backfill (CBF) systems, due to its favorable properties (Zaibo et al., 2022). Its affordability and potential to correct poor gradation in fine tailings make it a valuable additive in CBF applications (Guner et al., 2023).

Numerous studies have examined various characteristics of cement-based backfills (CBFs) incorporating sand (Ouyang et al., 2022; Yan et al., 2022; Xin et al., 2022). Yi et al. (2015) analyzed the impact of integrating sand-silt tailings and polypropylene fibers into CBF mixtures. Their findings revealed that the inclusion of these components enhanced the ductility of the CBFs by up to three times and effectively prevented strength degradation compared to conventional samples. In another study, Sun et al. (2018) explored the strength evolution of CBFs prepared with Aeolian sand, assessing variables such as cement dosage and water content. They observed that incorporating 5% sand into the mixture negatively affected the microstructure, resulting in a marked reduction in 28-day compressive strength. Yang et al. (2020) focused on stress behavior in CBFs composed of gobi sand and mine tailings subjected to varying flow cycles. Their results indicated that an increase in particle size and density led to strength losses, underscoring the importance of optimizing the sand-to-tailings ratio. Zhou et al. (2021) investigated CBF mixtures enhanced with sand and glass fibers of varying lengths (3–15 mm), and reported substantial improvements in mechanical performance—specifically compressive, tensile, and shear strength—when glass fibers were added to sand-based CBFs.

While sand has been widely utilized in the literature to enhance the quality and mechanical performance of cement-based backfills (CBFs), studies focusing on the long-term mechanical and microstructural evaluation of sand-containing mixtures—particularly using non-destructive testing methods—remain limited. The present work investigates how sand influences the behavior and performance of CBFs by employing both destructive (unconfined compressive strength, UCS) and non-destructive (ultrasonic pulse velocity, UPV) techniques, with the aim of mitigating strength losses associated with fine tailings and reducing cement consumption. CBF specimens were prepared with a constant binder content of 4 wt% and solid content of 80 wt%, and were subjected to curing periods ranging from 3 to 180 days. Sand was incorporated into the mixtures by partially replacing tailings at proportions of 5%, 15%, 25%, 35%, and 45% by weight. In addition to mechanical testing, microstructural changes were characterized using scanning electron microscopy (SEM). UCS values were also predicted through regression analysis using UPV data, and the reliability of the developed models was validated through statistical methods, including F-tests and t-tests. A comprehensive interpretation of the test results and analytical findings is provided in the subsequent sections of the study..

2. Materials and methods

2.1. CBF components

2.1.1. Tailings and sand

Mine tailings, as a primary constituent of cement-based backfill (CBF), play a significant role in determining the overall performance of the mixture. Consequently, accurate characterization of these tailings is essential for effective backfill design. In this study, the tailings were sourced from the filtration system of an underground copper mining operation situated in northwestern Turkey. Additionally, sand samples were obtained from a nearby quarry in close proximity to the mining site. The particle size distributions of both materials were analyzed using a Malvern Mastersizer 3000 laser diffraction device (Fig. 1). According to the results, the copper tailings exhibited a relatively coarse texture, with 27.9% of the particles having a diameter smaller than 20 µm.

Table 1 presents the physical properties of the copper tailings and sand samples used in this study. The specific gravity values, measured using a Quantachrome Ultrapyc 1200e helium gas pycnometer, were 3.61 for the tailings and 2.59 for the sand. Furthermore, specific surface areas determined via a single-point BET analysis (Quantachrome Quadrosorb SI) were 2.63 m²/g for the tailings and 0.72 m²/g for the sand. To assess the chemical composition of both materials, X-ray fluorescence (XRF) analysis was performed using a PANalytical Zetium spectrometer (Table 2). The results revealed that Fe_2O_3 (42.2%) and SiO_2 (24.1%) were the dominant constituents in the copper tailings, while CaO (56.3%) was the primary component identified in the sand samples.

2.1.2. OPC and blend water

Ordinary Portland Cement (OPC, CEM I 42.5 R) was selected as the primary binder material in this research. The physical properties of the cement are summarized in Fig. 1 and Table 1. The median particle size (D50), specific gravity (Gs), and specific surface area (Ss) of OPC were determined to be 24.8 µm, 3.15, and 0.39 m²/g,

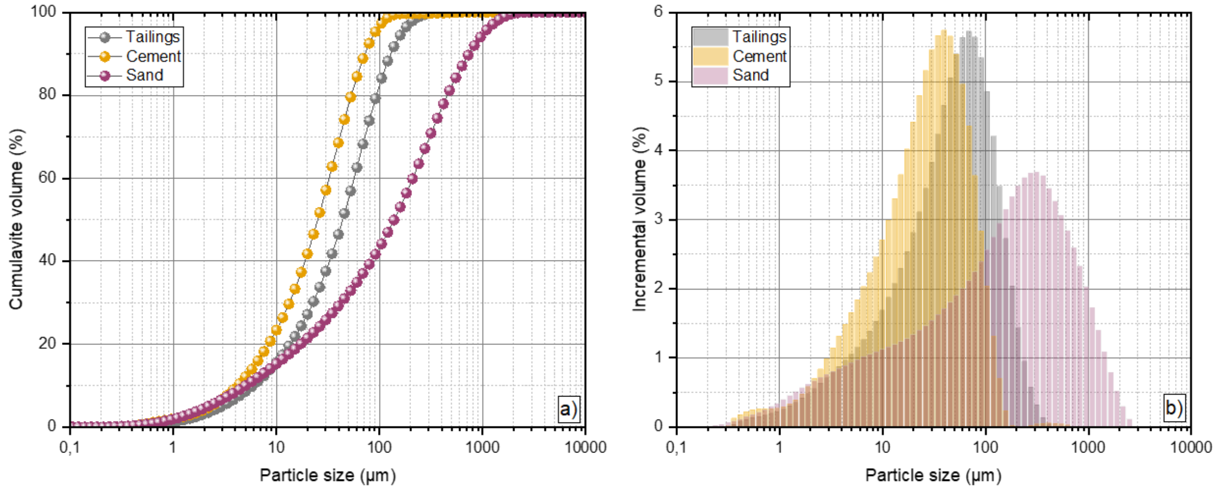

Fig. 1. Variation in cumulative (a) and incremental (b) particle sizes of components in cement-based fills

Table 1. Main physical features of ingredients

Property	OPC (CEM I 42.5 R)	Tailings	Sand
Specific gravity, G_s (unitless)	3.18	3.65	2.62
Specific surface, S_S (m^2/g)	0.39	2.66	0.73
Void ratio	0.49	0.78	0.71
Uniformity coefficient*	7.43	9.53	41.01
Curvature coefficient**	1.40	1.31	2.03
D_{10}, μm (effective diameter)	4.47	6.04	51.61
D_{30}, μm	14.14	22.52	467.63
D_{50}, μm (average diameter)	25.05	44.34	1415.01
D_{60}, μm	32.42	57.37	2041.21
D_{80}, μm	54.44	93.63	2569.44

respectively. According to the XRF analysis results presented in Table. 2, CaO (62.7%) was the predominant oxide, followed by SiO_2 (16.9%) and Al_2O_3 (6.11%). Water used in cement-based backfill (CBF) systems plays a crucial role in both achieving adequate workability and initiating the hydration processes necessary for strength development and material transport within underground voids. Although CBF systems can utilize water from various sources—such as municipal supply, surface water bodies, or process water—this study exclusively employed tap water. The key chemical parameters of the mixing water were sulfate (SO_4^{2-}), calcium (Ca^{2+}), and pH, which were measured at 5.22 mg/L, 36.1 mg/L, and 7.86, respectively.

2.2. Blend conception and preparation of CBFs

In the laboratory production of cement-based backfill (CBF) specimens, a fixed binder content of 4 wt% and a total solids content of 80 wt% were employed. Curing durations extended up to 180 days. To assess the effect of sand as a partial substitute for copper tailings, six different mixtures were prepared with sand replacement levels of 0% (control), 5%, 15%, 25%, 35%, and 45% by weight. The complete mix proportions used for CBF production are provided in Table 3. Each mixture was homogenized in a 10-liter capacity mechanical mixer for approximately 10–12 minutes. Upon completion of mixing, the solids content of the mixtures was verified using a mini-slump cone test to ensure compliance with the 80 wt% target.

For each mixture, the fresh paste was cast into three cylindrical plastic molds with a diameter-to-height ratio of 5×10 cm, in accordance with the designated curing intervals. The molded samples were then stored in a curing chamber maintained at a constant temperature of 21°C and relative humidity of 91% to ensure consistent hydration conditions. Fig. 3 illustrates the step-by-step procedure followed during the preparation and curing of the CBF specimens.

Table 2. Main chemical features of ingredients

Property	OPC (CEM I 42.5 R)	Copper tailings	Sand
CaO	63.78	4.25	56.78
Fe_2O_3	3.04	41.47	1.07
SiO_2	17.28	23.83	2.65

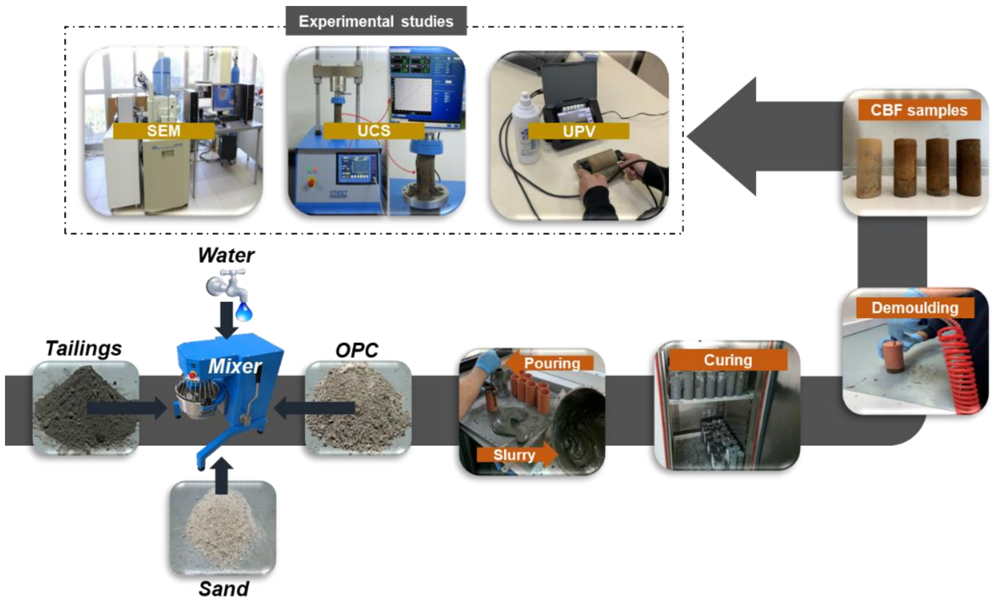

Fig. 3 Stages of readiness and trials for CBFs

2.3. Methods

2.3.1. Strength testing procedures

The uniaxial compressive strength (UCS) of the cement-based backfill (CBF) specimens was evaluated using a UTEST Multiplex electromechanical testing system, which has a maximum load capacity of 50 kN and operates at a constant displacement rate of 1 mm/min, in accordance with the ASTM C39 standard. Prior to testing, the top and bottom surfaces of the cylindrical specimens (with a diameter-to-height ratio of 5×10 cm) were carefully leveled using a sharp razor blade to ensure even load application. Following surface preparation, the samples were positioned between the compression platens of the UCS device, and strength tests were conducted. For each mixture type, three replicate specimens were tested, and the average of the measured values was reported as the representative UCS.

2.3.2. SEM observations
Scanning electron microscopy (SEM) is commonly employed to investigate the surface morphology and hydration products of cement-based backfills (CBFs). In this study, the microstructural properties of polished cross-sectional samples (from the hardened surfaces) of CBFs were analyzed using a JEOL JSM-6510 scanning electron microscope. This instrument provides a resolution of 3 nm and magnification capabilities ranging from 5x to 1,000,000x, with a current emission of 0.9 nA and an acceleration voltage of 20 kV. To examine the surface morphology in detail, small pieces were cut from 90-day-old hardened CBF samples, dried at 50°C for 75 hours, and then coated with a thin gold film. The microstructural features were then observed at magnifications between 50x and 9,000x using SEM

2.3.3. Ultrasonic pulse velocity testing
Ultrasonic Pulse Velocity (UPV) is one of the most widely used non-destructive techniques for assessing the strength properties of cement-based mixtures. This method not only provides valuable information regarding the strength of the material but also offers insights into the homogeneity of the mixture. UPV measurements were conducted using the Proceq Pundit Lab 200 instrument on samples prepared according to the CBF mix designs, which had completed their designated curing periods. All testing parameters and procedures were carried out in accordance with ASTM C 597-16 standards. The transmission of ultrasonic pulses (ranging from 24-500 kHz) between the data collector and the transducers is quantified by the equation UPV(X, T) = X/T, where UPV(X, T) represents the propagation velocity (m/s) of the ultrasonic wave, X is the distance between the transmitter and receiver, and T is the time it takes for the pulses to travel this distance. Prior to testing, the surfaces of the samples were smoothed with a razor blade to ensure optimal contact between the transmitter and receiver. An ultrasonic gel was then applied to the surfaces to improve the interface, followed by UPV testing. Each test was repeated three times, and the average values were recorded.

3. Results and discussions

3.1. Sand content and age-related variations in CBF strength
Fig. 4 illustrates the uniaxial compressive strength (UCS) results for all cement-based fill (CBF) mixtures, based on the compositions outlined in Table 3 (waste/sand ratio: 100/0, 85/15, 75/25, 65/35, 55/45, and 45/55), with curing times extending up to 180 days. It is evident that the UCS values of all CBF samples increased over time with prolonged curing. Additionally, the substitution of tailings with sand significantly enhanced the mixture's gradation, leading to a notable improvement in strength. However, after 90 days of curing, a considerable decrease in UCS values was observed in the control sample and in mixtures with lower sand substitution rates (e.g., 15% and 25%). The highest strength, recorded at 90 days, was 2.91 MPa for the T65/S35 mixture. This indicates that incorporating up to 35% sand as a tailings substitute significantly boosts the UCS values. For instance, at 28 days of curing, the UCS value for the T65/S35 mixture reached 1.05 MPa, while the control mixture (T100) exhibited a strength of only 0.46 MPa under similar curing conditions. On the other hand, higher sand substitution levels (e.g., 45%) led to a sharp decline in strength, as exemplified by the 28-day UCS value of 0.73 MPa for the T55/S45 mixture. The observed improvements in UCS for sand-substituted CBFs are primarily attributed to enhanced gradation, which fills the voids in the matrix and supports the ongoing hydration reactions [15].

The coarser grain size of sand (coarse aggregate) in comparison to tailings increases the contact area and friction between the particles in the CBF matrix. This enhanced interaction provides significant resistance to external forces, resulting in higher mechanical properties for CBFs that incorporate sand compared to those without. However, as shown in Fig. 4, when the sand content exceeds 35%, a decline in strength is observed. The addition of more than 35% sand disrupts the homogeneity of the CBF mixtures, hindering proper adhesion of hydration products. Excessive sand content also impedes particle cohesion, leading to segregation within the mixture. Moreover, for pipeline-transported materials such as CBF, higher sand content increases the water demand, which negatively impacts the workability of the mixture (Cao et al., 2021; Zheng & Li, 2020). Therefore, careful control of both the sand quantity and grain size is essential to optimize the performance of CBFs.

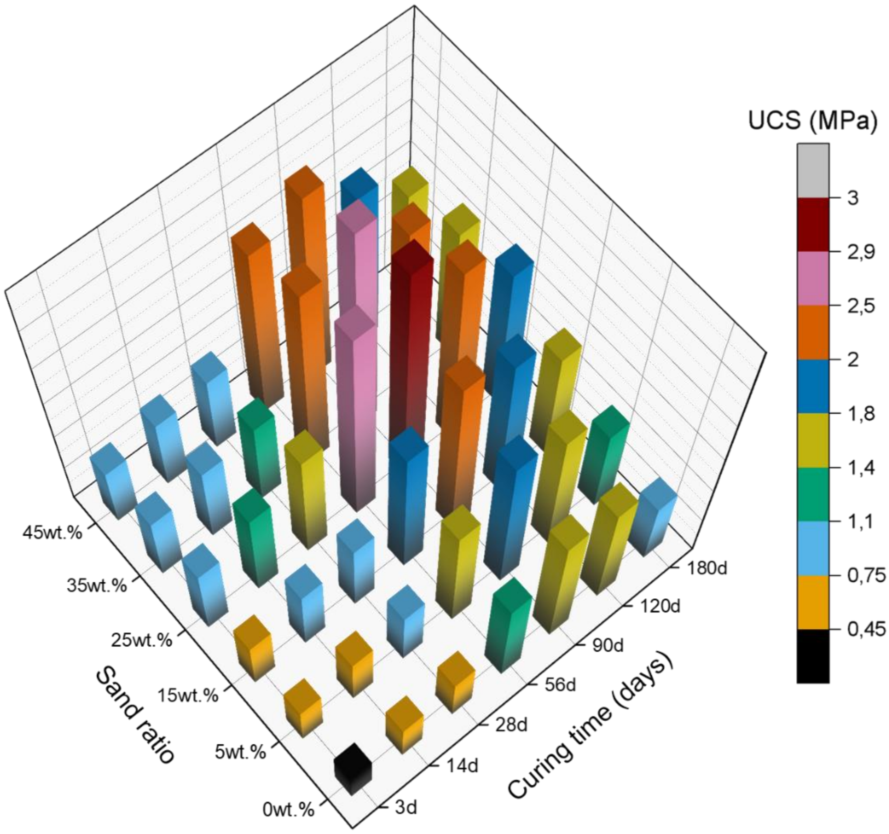

Fig. 4. The strength evolution of entire CBF samples

3.2. Morphological features of CBF surfaces

Examining the surface morphology of cement-based mixtures like CBF provides valuable insights into various parameters, including strength development and the distribution of hydration products (Solaymani et al., 2018). Scanning electron microscopy (SEM) enables high-resolution imaging of the surface structure of CBFs, allowing for detailed observation. Numerous studies have demonstrated a strong correlation between SEM images and the surface morphology of cement-based mixtures (Elenkova et al., 2015). In this study, SEM micrographs were used to investigate the surface morphology of CBF samples and the structural changes resulting from hydration reactions. During the hydration process in CBFs, minerals such as calcium silicate hydrate (C-S-H) gels, portlandite, and etrengite are typically formed. Etrengite manifests as fine, needle-like crystals that often intertwine. C-S-H gels appear in various forms but are typically spherical or network-like, and in some cases, they may exhibit branched or fibrous structures, which can sometimes be mistaken for etrengite. Portlandite typically forms regular, layered hexagonal plate structures that fill the spaces between the grains in cementitious mixtures (Kasap et al., 2022c).

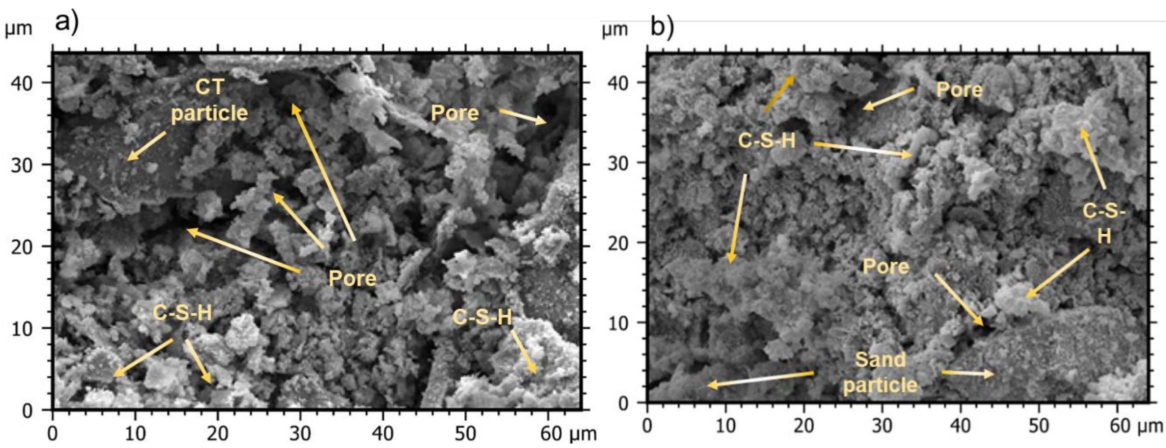

Fig. 5. Surface morphology of T100 (a) and T65/35 (b) based on SEM micrographs cured for 90 days

Fig. 5 presents SEM micrographs of 90-day-old CBFs (T100-control and T65/35) at ×2000 magnification. The surface morphology of the samples reveals that C-S-H gel forms a dense network surrounding the CBF particles, effectively filling the voids. In comparison, the presence of portlandite is minimal. This observation suggests that the portlandite formed during the early stages of hydration in CBFs is gradually consumed over time, thereby promoting the continued formation of C-S-H gels (Wang et al., 2021). Additionally, etrengite was observed in certain areas of the surface morphology. The SEM results clearly indicate that the control sample (T100) exhibits a more porous and weaker structure in terms of hydration products when compared to the sand-substituted CBF (T65/35). The incorporation of sand in CBFs mitigates gradation issues caused by the fine nature of the waste material and enhances the formation of hydration products, largely due to the high CaO content in the sand. Consequently, this leads to improved packing density in CBFs, significantly reducing porosity and permeability (Jiang et al., 2019). Furthermore, the more porous structure of the control sample allows for greater air and moisture penetration between grains, which can lead to the oxidation of pyrite in the tailings (Jiang et al., 2017). Therefore, using sand (particularly up to 35 wt%) as a partial replacement for fine-grained waste material substantially improves the microstructure of CBFs, thereby enhancing both the quality and performance of the fills

3.3. UPV measurements and their impact on ucs in cement-based fills

Fig. 6 illustrates the UPV (ultrasonic pulse velocity) results for all cement-based fills (CBFs) with varying sand replacement ratios for tailings, cured up to 180 days. The data clearly indicate that substituting sand significantly enhances the UPV values of the CBFs. In line with the UCS results, the highest UPV values were observed at 90 days curing time and at the optimal sand replacement rate of 35% by weight. However, when the sand replacement rate exceeded 35%, an uneven increase in grain gradation led to structural degradation caused by segregation. This segregation resulted in a more porous CBF structure, increasing oxidation rates and consequently lowering UPV values (Wang et al., 2021). Despite this, sand-substituted CBFs still achieved higher UPV values compared to the control samples. The highest UPV value (3890 m/s) was recorded for the T65/35 sample, while the lowest value (394.1 m/s) was found in the 180-day T100 sample.

The incorporation of sand helps form a denser CBF structure by alleviating gradation issues associated with mine tailings. Additionally, its high CaO content, similar to cement, enhances the formation of hydration products. These hydration products fill the voids in the CBF, leading to an increase in the solid phase density. As a result, the porosity of CBFs decreases with sand substitution, thereby improving the UPV values significantly. In agreement with the SEM findings (Fig. 5), it is evident that sand-substituted CBFs exhibit more advanced hydration and lower void ratios compared to the control samples. Previous studies have demonstrated that cementitious mixtures with better gradation and density tend to have higher UPV values due to their enhanced resistance to environmental factors (Prasad & Lakshmi, 2020).

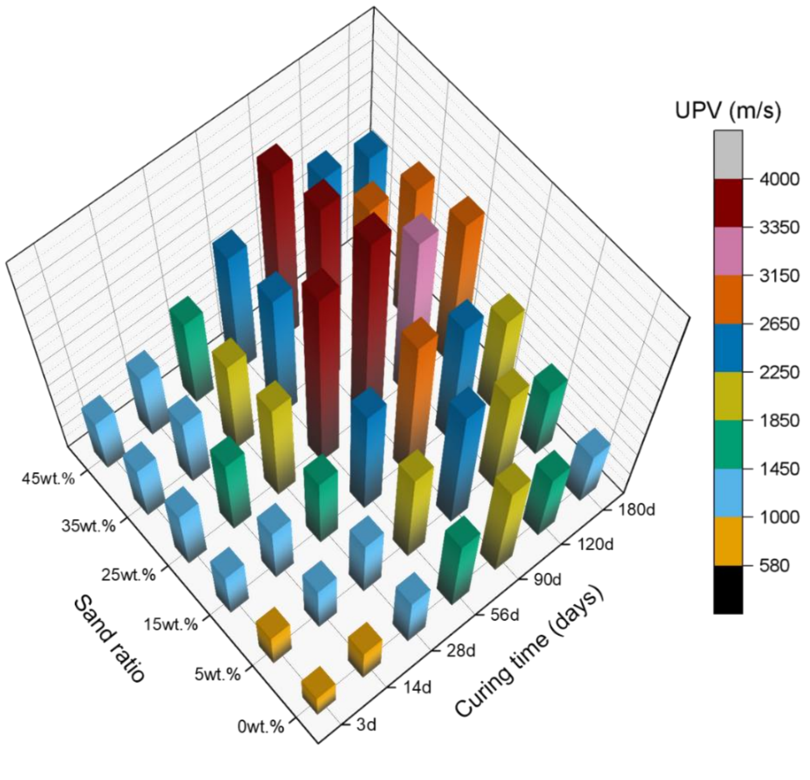

Fig. 6. UPV outcomes of CBF samples

Table 4. Statistical test findings for CBF Samples

Regression type	Equation	R^2
Linear	UCS = 0.00031UPV-0.0009	0.948
Polynomial	UCS = 6E-3UPV^2+0.00156UPV+0.404	0.957
Exponential	UCS = 0.3018e$^{0.00264UPV}$	0.963
Power	***UCS = 4.2566E-4UPV$^{0.899}$***	***0.979***

The relationship between UCS and UPV values of cementitious mixtures is significantly influenced by various factors such as solids content, cement type and proportion, and the presence of additives. Regression models that account for these factors can offer highly accurate predictions for the strength of cementitious mixtures. Existing literature underscores the importance of the UCS-UPV relationship in materials like CBFs and proposes various methods to optimize this correlation (Yingliang et al., 2020). In this study, the UCS-UPV relationship in CBFs was thoroughly analyzed using multiple curve fitting techniques, including linear, polynomial, exponential, and power models, as shown in Table 4).

The results indicate that the power models provided the most robust equations, with a correlation coefficient (R^2) of 0.985 across all CBF samples (Fig. 7). Furthermore, to evaluate the accuracy of the most effective equation and compare the standard deviations, both F-tests (Fisher's test) and t-tests were conducted (Fig. 7). Specifically, the F- and t-tests were utilized to verify the suitability of the relationship between the variables in the proposed equations. While the t-test typically compares two groups with homogeneous variables, alternative t-test methods are available for non-homogeneous groups. Therefore, prior to the t-test, the F-test is recommended to assess the homogeneity of the variances (Cui et al., 2020; Ashrafian et al., 2018). In this study, a 5% significance level was applied for both the F- and t-tests.

The F value of the power model for all CBF samples (1811.2) exceeds the critical F value (F_{cr} = 1.401), confirming that the variables in the CBFs are homogeneous. Additionally, the P value (2.12E-19, at a 95% confidence level) is lower than 5%, indicating statistical significance. When analyzing the t-test results, it is evident that the calculated t value (t_s = 16.119) is greater than the critical t value (t_{cr} = 2.003). Similar to the F-test, the P values from the t-test (4.06E-22) are also less than 5%, further confirming the reliability of the regression analysis. These findings demonstrate a strong correlation between UCS and UPV, indicating that UCS data can be accurately predicted from UPV measurements.

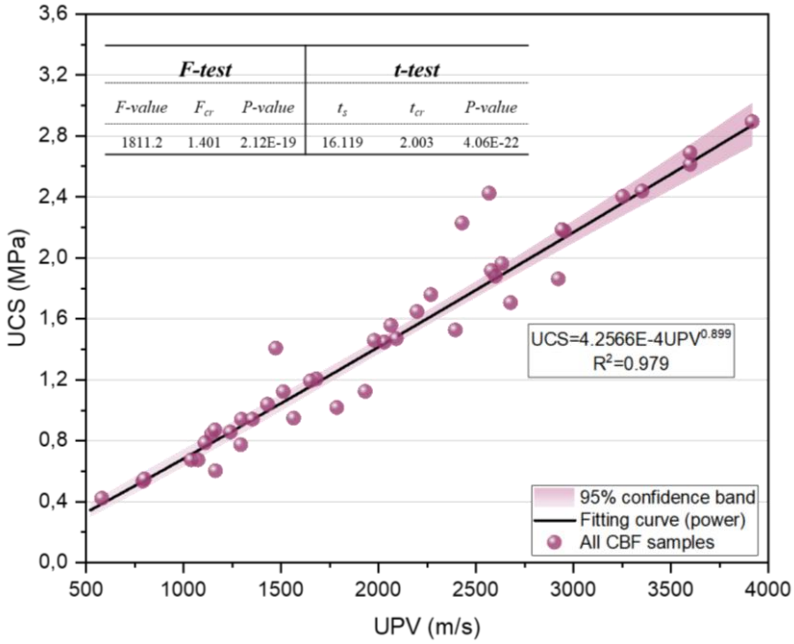

Fig. 7. Correlations among UCS and UPV variables of CBF samples

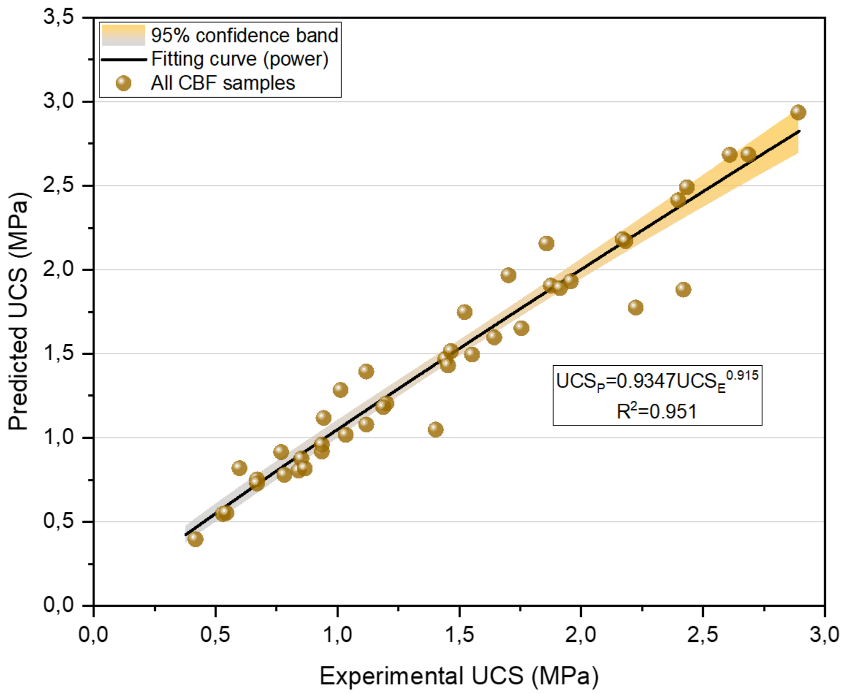

Fig. 8. Correlations among experimental and predicted strength results of CBF

Fig. 8 illustrates the correlation between the experimental and predicted UCS values for all CBFs. As in the previous analyses, the power equation was applied to assess the regression analysis. The R^2 value obtained from the power equation was 0.951. Moreover, the majority of the measured and predicted UCS values fall within the 95% confidence interval, indicating the effectiveness of the methods used to predict UCS. The applicability and accuracy of the power equation were further validated through UPV tests. The regression analysis confirms that the non-destructive UPV test can be utilized to develop a cost-effective, practical, and efficient backfill design for underground metal mining.

4. Conclusions

In this study, cement-based fill (CBF) mixtures were prepared in the laboratory with constant binder content (4 wt%) and solid content (80 wt%), and cured for up to 180 days. The quality and performance of CBFs with varying sand replacement proportions (15%, 25%, 35%, and 45%) were evaluated using both destructive (UCS) and non-destructive (UPV) methods. Additionally, the microstructural characteristics of the CBF samples were analyzed using the SEM technique. Various curve fitting and statistical methods were applied to evaluate the relationship between UCS and UPV. The key findings from the tests and analyses are summarized as follows:

- UCS values of CBFs increased with curing time up to 90 days, after which the strength of all samples began to decrease towards 180 days.
- Increasing sand as a tailings substitute (up to 35 wt.%) significantly improved the performance of the CBFs. However, segregation was observed in all mixtures beyond the 35% substitution rate.
- SEM analysis showed a greater formation of hydration products in sand-substituted CBFs compared to the control sample. Additionally, the increased basicity of the mixing medium due to sand (high CaO content) improved the CBFs' resistance to acid attack and degradation.
- The relationship between UCS and UPV values was evaluated using different curve fitting methods (e.g., linear, polynomial, exponential). The results indicated that the most suitable regression curve is the power model.
- The relationship between experimental and predicted UCS was determined as UCSPredicted = 0.9347 × UCSExperimental0.915 for all CBF samples.

Overall, the tests and analyses demonstrated a strong correlation between UCS and UPV values. While the relationship can vary depending on the proportions, types, and number of constituents, this study highlights the impact of the physical (e.g., grain size and surface area) and chemical (e.g., CaO content) properties of sand used as a tailings substitute on early and long-term UCS, UPV, and microstructure. Future studies will focus on evaluating the impact of various additives (e.g., chemical or natural) on the quality and performance of CBFs through other non-destructive methods.

Effects of fire-caused disasters on natural building stones used ın historical buildings

M. Enes Kılıç*[1], S. Banu İkizler[1], Hakan Ersoy[2]

[1] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye
[2] Karadeniz Technical University, Department of Geological Engineering, 61080 Trabzon, Türkiye

Abstract. Fire-induced disasters can cause not only physical damage to historical structures but also irreversible losses in cultural heritage. In this study, the effects of fire on historical building stones were investigated under laboratory conditions to gather data for selecting appropriate restoration materials for fire-damaged structures. According to Eurocode 1 (2011) standards, four different types of natural building stones were heated up to 680 °C, and changes in their physical and mechanical properties such as dry density, specific gravity, uniaxial compressive strength, and indirect tensile strength were examined in detail. Experimental results revealed no significant change in dry density, with the greatest reduction recorded in Rize Andesite at 6.5%. Specific gravity increased by up to 5.5% in Erzurum Andesite, attributed to the formation of new minerals due to fire exposure. Trabzon Basalt exhibited substantial decreases of 62% in longitudinal wave velocity, 56% in uniaxial compressive strength, and 64% in indirect tensile strength. Microstructural analyses using SEM (scanning electron microscope) confirmed that fractures and clumping within the stones contributed to these losses. While minor voids closed after thermal treatment, slightly increasing density, major cracks and larger voids had a reducing effect, leading to minimal overall changes in density. The findings of this study provide critical insights for developing effective restoration strategies aimed at preserving historic structures following fire damage.

Keywords: Fire; Building stone; Disaster; Historical structures

---

1. Introduction

The devastation caused by fire-related disasters at both national and international levels is too significant to be overlooked. It is well-established that such disasters impact not only the physical environment but also profoundly affect the psychological and social well-being of individuals living in the affected areas. Historical structures constructed from natural stone materials are among the most vulnerable building groups to the adverse effects of fires. Damage to these structures entails not only the loss of architectural heritage but also the erosion of cultural identity and historical continuity. Disasters occurring in various parts of the world significantly threaten efforts to preserve cultural heritage. In the face of fires, historical buildings jeopardize not only their physical existence but also the artistic and cultural values they embody, as well as human life itself. Such catastrophes often result in irreversible losses. Throughout history, destruction caused by fires in historic structures has been widespread across different regions of the world, and this issue persists to the present day.

Studies investigating building stones exposed to high temperatures have reported significant findings. Zhang et al. (2016) observed changes in P-wave velocity and microstructural transformations in limestone samples subjected to temperatures ranging from 25°C to 900°C. Their results indicated decreases in both rock strength and P-wave velocity between 200°C and 600°C, with a notable increase in crack network density starting from 600°C. Similarly, Özgüven & Özçelik (2013) examined building stones under high temperatures ranging from 200°C to 1000°C. They observed a white color change on the stone surface at 800°C, and after 900°C, an exothermic heat increase was noted as the limestone reacted with water. Kılıç (2006) investigated the relationship between P-wave velocity, mass loss, and mechanical properties during the calcination process of limestone samples, identifying 900°C as the temperature at which calcination was completed and the maximum mass loss occurred. A common conclusion across these studies is the significant deterioration and alteration of the physical, mechanical, and microstructural properties of natural stones when exposed to high temperatures (Chakrabarti et al., 1996; Chaki et al., 2008; Chen et al., 2012).

Table 1 presents a comparison of the experimental parameters used in this study with other methods reported in the international literature. In this research, experiments were conducted to determine the behavior of natural

building stones, characteristic of historical structures, under the influence of fire. An oven was employed as the heat source, and cooling was carried out naturally at room temperature. The heating rate was set exponentially, with the samples being heated for two hours, reaching a maximum temperature of 680 °C. This temperature was selected to represent real external fire conditions. To evaluate the mechanical properties of the samples, uniaxial compressive strength and indirect tensile strength tests were conducted. The natural stones used in the study were carefully selected from stone types commonly found in historical buildings.

Table 1. Comparison of Experimental Parameters with Methods in the Literature

Experimental parameters	Widely applied	Seldom applied	In this study
Heat source	Furnace	Open fire	Furnace
Cooling technique	In a heating furnace or at room temperature	With liquid nitrogen	At room temperature
Heating rate (°C/min)	1-10	Exponential logarithmic	Exponential logarithmic
Thermal treatment duration(h)	2-6	Different periods	2
Maximum applied temperature	600-1000	Fire temperature	Fire temperature
Mechanical Tests	Uniaxial Compression or Indirect Tensile	Schmidt hammer	Uniaxial Compression or Indirect Tensile
Rock Types	All Common Types	Used in Historical Structures	Used in Historical Structures

2. Studies conducted and findings

2.1. Procurement and locations of natural building stones

This study aims to conduct a detailed investigation of the natural stone materials used in the construction and restoration of historical structures located in the Eastern Black Sea Region. To this end, the characteristics and sourcing processes of the stones preferred in the region's historical monuments have been comprehensively addressed. The natural building stones utilized in the study were selected from locations historically used in the construction of heritage structures (Table 2), and the physico-mechanical alterations of the rocks employed in the construction of the historical structures depicted in Figure 1 were examined in detail.

Table 2. Rock types used in the study, their locations, and the historical structures where they were used for construction/restoration

Historical Structures Used	Rock Type	Source Location
Fatih Mosque (Trabzon) Ayasofya Mosque (Trabzon)	Andesite	Erzurum (City Center)
Tabakhane Mosque (Trabzon) Kapu Mosque (Giresun)	Andesite	Ankara (Gölbaşı)
Musapaşa Mosque (Trabzon) Taşören Mosque (Çaykara, Trabzon)	Basalt	Trabzon (City Center)
Gümüşhane Emirler Mosque	Andesite	Rize (İyidere)

2.2. Determination of the Physical and Mechanical Properties of the Specimens

The sample preparation process was carried out in accordance with ASTM (1994) standards. As the initial step, a total of 40 core samples were extracted from rock blocks obtained from the provinces of Rize, Trabzon, Ankara, and Erzurum, with 10 samples taken from each region (Figure 2). Special attention was given to ensure that the cores prepared for experimental analyses were free from voids, weathering, or any form of damage. For each location, the core samples were classified into two groups: the first five cores were designated as unexposed (UNCUT) rocks, while the latter five were categorized as fire-exposed (FIRE) rocks. Experimental studies were then conducted on the samples classified in this manner. The cores shown in Figure 2 were labeled during the experimental process. In this context, the andesite samples obtained from Rize were marked with the letter "R," the basalt samples from Trabzon with "T," the andesite samples from Ankara with "A," and the andesite samples from Erzurum with "E."

Within the scope of this study, eight blocks with regular geometric shapes (15 × 20 × 10 cm), sourced from quarries, were utilized. In order to determine the effects of high-temperature exposure on the physical and mechanical properties of the samples, as well as the rate of change in these properties, the initial physical and mechanical characteristics of the specimens at room temperature were first measured. The uniaxial compressive strength was determined with a length-to-diameter ratio of 2.5, while the indirect tensile strength was assessed with a length-to-diameter ratio of 1. The relevant samples were cut and prepared in accordance with the dimensions and geometric specifications required for the Brazilian test setup. For each location, five specimens were prepared for thermal treatment and five as initial (untreated) specimens, resulting in a total of ten specimens per location and forty specimens overall. As illustrated in Figure 3, the load must be applied symmetrically with respect to the center axis of the specimen to generate a characteristic tensile stress within the sample.

This approach enabled the comparison of initial values with those obtained from samples subjected to fire temperatures and facilitated the identification of changes induced by temperature increases. For both pre- and post-exposure conditions, the specific gravity, dry density, longitudinal wave velocity, tensile strength, and uniaxial compressive strength of the samples were determined. Detailed information regarding the number and dimensions of the specimens is presented in Table 3.

Table 3. Dimensions and Numerical Distribution of the Specimens

Structural Properties	Number of Samples in Experimental Studies				Dimensions of the Specimens
	Erzurum Andesite	Ankara Andesite	Trabzon Basalt	Rize Andesite	
SEM	2	2	2	2	$1cm^3$
Uniaxial Compressive Strength	10	10	10	10	length/diameter rate 2.5/1
Indirect Tensile Strength	10	10	10	10	50-60mm length/diameter rate 1/1
Dry Density	10	10	10	10	
Longitudinal Wave Velocity	10	10	10	10	
Specific Gravity	3	3	3	3	

2.3. Specimens exposed to external fire temperatures

With the onset of a fire, temperature values increase rapidly. The temperature can reach approximately 600 °C within the first 10 minutes, 700 °C by the 15th minute, 800 °C by the 30th minute, and up to 1000 °C by the 90th minute. It is known that, after three hours, temperatures can reach approximately 1100 °C, and in some cases, even higher values between 1500 °C and 1700 °C (Kılıç, 2010a). In this study, a Protherm brand muffle furnace was utilized to apply thermal treatment to the samples. The maximum temperature was set at 680 °C, representing an external fire scenario, in accordance with Eurocode 1 (2011) standards. The heating process of the furnace was conducted following the temperature-time curve outlined in Eurocode 1 (2011) (Figure 4). To minimize the risk of cracks and damage that may arise from rapid heating and cooling processes, the temperature increase rate was carefully controlled. Upon reaching the target temperature, the samples were maintained at this level for two hours to ensure homogeneous heat distribution within the rock. At the end of the experiment, the samples were allowed to cool gradually at room temperature in a controlled manner.

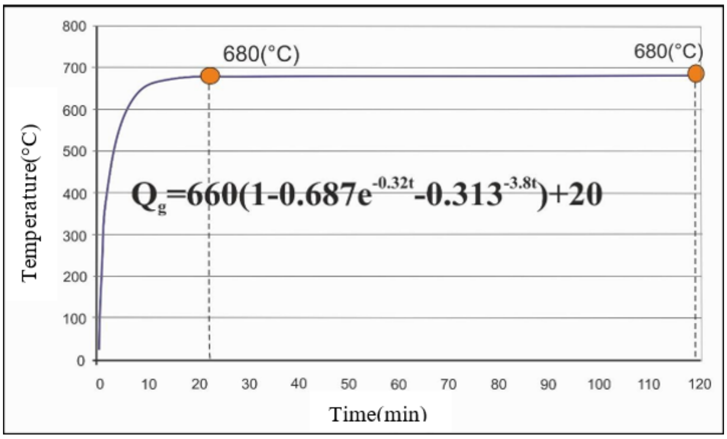

Figure 4. External Fire Temperature-Time Curve (Eurocode, 2011)

2.4. Changes in Physical and Mechanical Properties

In order to investigate the changes in the physical and mechanical properties of natural building stones exposed to external fire temperatures, the initial properties of these rocks were first determined (Table 4). A review of the literature indicates that exposure to high temperatures leads to significant decreases particularly in the uniaxial compressive strength and tensile strength of rocks (Becattini et al., 2017; Ersoy et al., 2019). In many of these studies, the selected high-temperature range typically falls between 200 °C and 1000 °C (Atalar et al., 2021; Sun et al., 2016). In the present study, a real external fire temperature of 680 °C was selected, and experiments were conducted on rocks commonly used in contemporary historical structures (Table 5). A marked decrease in uniaxial compressive strength, tensile strength, and longitudinal wave velocity was observed across all four sample types. Conversely, a noticeable increase in specific gravity was recorded for all samples. Figure 5 presents the graphs illustrating the changes observed in the physical and mechanical properties of the rocks used in this study, comparing the results obtained under initial conditions and after exposure to external fire temperatures.

Table 6 presents the percentage change rates in the physical and mechanical properties of the samples exposed to fire. These rates reflect the increases (+) and decreases (–) in the material properties due to thermal effects, thereby providing a comprehensive assessment of the impact of fire on the material characteristics.

The evaluation of the SEM images presented in Figures 6 and 7 revealed that, overall, small voids closed and agglomeration increased due to melting in all thermally treated samples, while the fractured structure was largely preserved. In the samples obtained from Ankara, it was observed that although small voids were closed due to agglomeration after thermal treatment, this process led to the formation of isolated microcracks. Similarly, in the samples sourced from Erzurum, partial melting resulted in the closure of small voids, but also transformed the samples into a more fractured structure. In the samples from Rize, despite the closure of voids, a noticeable increase in crack continuity was detected. In contrast, the samples from Trabzon exhibited a different behavior compared to the others, with an increase in small voids and the development of new voids following agglomeration after thermal treatment.

3. Conclusions

In this thesis study, the changes in the physical, mechanical, and microstructural properties of historical building stones exposed to an external fire temperature of 680 °C under laboratory conditions were investigated. A test group was established by considering the dimensions and numerical distribution of the samples. The specimens were heated in a controlled manner up to 680 °C, representing external fire conditions, and underwent various physical and chemical transformations during the process. The closure of small voids exerted an increasing effect on dry density, whereas larger voids and fractures resulting from agglomeration had a decreasing effect. The balancing of these opposing effects resulted in no significant change in dry density values. Additionally, partial melting and agglomeration, occurring without mass loss, led to structural changes within the solid grains independently of porosity, indicating the possible formation of high-specific-gravity minerals at elevated temperatures.

In the samples dried at 105 °C, it was determined that free water in the rock pores was completely evaporated, while the water bound within the crystal structures of minerals remained unaffected. However, in the samples heated up to 680 °C, it was observed that crystalline water was also released from the mineral structures. Besides water loss, micro-cracks formed due to agglomeration caused a sudden decrease in longitudinal wave velocity, leading to a reduction in the mechanical strength of the rocks. Significant reductions in both uniaxial compressive strength and indirect tensile strength were identified in the thermally treated samples, with this strength loss being more pronounced in specimens exhibiting substantial decreases in longitudinal wave velocity.

The findings were presented with supporting graphical data, and microstructural changes were examined in detail through SEM imaging. These results provide crucial insights into understanding the alterations in the physical and mechanical properties of historical building stones after fire exposure and contribute to the selection of appropriate restoration materials.

Liquefaction analysis of various soil profiles based on TBEC 2018: Case studies from Elazığ Province

Kübra Sertkaya*[1], Mesut Gör[1], Rahim Khan Nasery[1], Ahmet Altunbey[1]

[1] Fırat University, Engineering Faculty, Department of Civil Engineering, 23119 Elazığ, Türkiye

Abstract. Earthquakes, being natural disasters resulting from the abrupt release of energy within the Earth's crust, cause significant environmental and economic hazards. The damages inflicted by recent seismic events in Turkey has necessitated a detailed investigation of soil properties. Under seismic loading, soils experience a sudden increase in pore water pressure, resulting in a loss of rigidity whereby the soil exhibits a fluid-like behavior. This liquefaction is commonly observed in saturated and loose soils, can lead to the weakening, settlement, lateral spreading, or failure of structural foundations. The increasing use of areas prone to liquefaction, such as agricultural lands and alluvial plains, as construction sites has further amplified the significance of this issue. Therefore, understanding the liquefaction behavior of saturated fine-grained soils is crucial for mitigating seismic hazards and ensuring structural safety. To achieve this, structures should be founded on stable soil strata. This study aims to evaluate the liquefaction potential of different locations within the Elazığ city center. For this purpose, data reports from borehole investigations conducted at three distinct sites in the Elazığ city center, along with field and laboratory test results, were utilized. The liquefaction potential of soil layers between depths of 1.50-20.00 m was assessed based on soil classifications, test results, and Standard Penetration Test (SPT) results, in accordance with the criteria specified in the Turkish Building Earthquake Code (TBEC-2018) for an earthquake magnitude of Mw=7.5. Through comprehensive analyses and evaluations, this study presents a detailed assessment of liquefaction risk and identifies potential liquefaction zones.

Keywords: Elazığ province; TBEC 2018; SPT; Soil liquefaction; Earthquake

1. Introduction

Located in an active seismic region, Turkey has historically experienced a significant number of natural disasters, with earthquakes standing out as the most devastating. Research indicates that approximately 58% of individuals impacted by natural disasters in the country have been affected by earthquakes (Kundak & Kadıoğlu, 2011). Earthquakes inflict both direct structural damage and indirect effects by altering the geotechnical properties of the soil. Saturated and loose soils are especially susceptible during seismic activity, where strong ground motions can weaken inter-particle bonds and trigger soil liquefaction. This phenomenon presents significant threats to the stability of structures. Liquefaction—frequently observed in loose, water-saturated soils (Aytaş, 2019)—can weaken building foundations, leading to settlement, lateral spreading, or structural damage. A superstructure may remain statically sound; however, without appropriate precautions to address potential soil-related issues, its integrity can still be jeopardized. Consequently, a thorough understanding of the liquefaction behavior in saturated, fine-grained soils is crucial for minimizing earthquake-induced hazards and maintaining structural integrity under dynamic loading conditions (Altındiş, 2020). The Mw 6.8 earthquake that struck in 2020 along the East Anatolian Fault—impacting the Elazığ region (see Figure 3.1)—along with the Mw 7.7 Kahramanmaraş-Pazarcık and Mw 7.6 Elbistan earthquakes on February 6, 2023, have once again underscored the critical importance of liquefaction phenomena (Altındiş, 2020). Figures 1 and 2 illustrate the effects of liquefaction and lateral spreading triggered by the 2023 Kahramanmaraş-Pazarcık and Elbistan earthquakes. Liquefaction continues to be a major geotechnical concern, driving ongoing research within the field of geotechnical earthquake engineering. This phenomenon poses substantial risks to structural foundations during seismic events, emphasizing the need for designing and constructing structures that are resilient to its impacts (Alpaslan, 2013). Liquefiable and non-liquefiable soils exhibit distinct differences in terms of their profiles and geotechnical characteristics (Cubrinovski et al., 2019). To evaluate the potential for liquefaction, geotechnical investigations typically utilize a range of in-situ testing methods, such as the Standard Penetration Test (SPT), Cone Penetration Test (CPT), and shear wave velocity measurements. These testing methods provide critical information for assessing soil response under seismic loads (Emiroğlu & Arsoy, 2019). In the case of gravelly soils, the Dynamic Penetration Test (DPT) may

*Corresponding author , E-mail: kubrasrtky@gmail.com

https://doi.org/10.31462/icearc2025_ce_geo_335

be more advantageous than other in-situ techniques (Roy et al., 2022). Among these, the Standard Penetration Test (SPT) is widely favored due to its practicality in obtaining samples from boreholes and its suitability for a broad range of soil types (Li et al., 2022). Analyses based on SPT data categorize regions according to their liquefaction potential as "high," "low," and "very low" (Orhan & Ateş, 2010). The Turkish Building Earthquake Regulation (TBEC-2018), published on March 18, 2018, and effective from January 1, 2019, provides guidelines for assessing soil liquefaction potential using Standard Penetration Test (SPT) data. Liquefaction analyses are performed for design earthquakes with magnitudes of 6.5, 7.0, and 7.5 resulting in the identification of areas susceptible to liquefaction. These analyses contribute to the development of liquefaction potential maps and seismic settlement potential maps, which are crucial for informed engineering design and effective risk mitigation strategies. Furthermore, Geographic Information System (GIS) applications are increasingly employed in liquefaction studies (Özdin, 2023; Şekho, 2023). In parallel, design charts are being developed to support both liquefaction assessments and ground improvement efforts aimed at mitigating liquefaction-induced hazards (Dağdeviren, 2019). In areas identified as susceptible to liquefaction, suitable ground improvement techniques—specifically tailored to the local soil conditions—should be selected and applied prior to construction (Sertkaya, 2024).

2. Material and method

In this study, data reports from drilling surveys conducted in various neighborhoods of Elazığ city center, along with field and laboratory test results, were utilized. The liquefaction potential of soil layers within the depth range of 1.50 m to 20.00 m, soil classifications, and Standard Penetration Test (SPT) results were evaluated using Excel, in accordance with the criteria specified in the Turkish Building Earthquake Regulation (TBEC-2018).

2.1. Experimental studies

In the Elazığ city center, specific areas within the Aksaray, Kesrik, and Sürsürü neighborhoods (N) were selected as study sites. During the field investigations, Standard Penetration Tests (SPT) were conducted to delineate the soil profiles and evaluate the engineering characteristics of the soils in these areas, while both disturbed and undisturbed samples were collected for laboratory analysis (Figure 3). The study utilized data from 8 boreholes (BH), each extending to a depth of 20.00 meters, within these regions (Table 1). During the drilling operations, groundwater levels within the soil profiles were recorded, and varying soil profiles were observed across all study sites.

Groundwater level measurements taken from the boreholes at the investigation sites indicated groundwater presence at depths of 3.50 meters in Aksaray Neighborhood, 0.50 meters in Kesrik Neighborhood, and 5.50 meters in Sürsürü Neighborhood.

2.2. Laboratory studies

To assess the liquefaction susceptibility of soils under seismic loading, both in-situ testing and laboratory analyses are performed on disturbed and undisturbed samples collected from boreholes. Laboratory tests include water content determination, sieve analysis, Atterberg limits, consolidation, hydrometer analysis, triaxial compression, and natural unit weight determination to evaluate the soil properties (Table 2-7).

2.3. Liquefaction analysis according to TBEC 2018

The regulation, published on March 18, 2018, and effective from January 1, 2019, provides the standards to be used for structures to be built in earthquake-prone areas.

To calculate the liquefaction resistance using SPT test results, the raw SPT field data obtained from the site must be recalculated with specific correction factors. This recalculation process is outlined in Equations (1-6) and Table 8.

$$N_{1.60} = NC_NC_RC_SC_BC_E \quad (1)$$

In this context, C_N represents the geological stress (depth) correction factor applied to cohesionless soils, C_R denotes the rod length correction factor, C_S indicates the sampler type correction factor, C_B represents the borehole diameter correction factor, and C_E signifies the energy ratio correction factor.

The depth correction factor, C_N, is calculated using the relation given in equation (2).

$$C_N = 9.78 \times (1 \div \sigma_{VO}')^{0.5} \leq 1.70 \quad (2)$$

In the expression presented in equation (2), the effective vertical stress at the testing depth, σ_{vo}' (kN/m²), is determined based on the field conditions under which the Standard Penetration Test (SPT) is conducted. Additionally, the SPT results must be adjusted according to the proportion of fine-grained particles in the soil.

$$N_{1.60f} = \alpha + \beta N_{1.60} \quad (3)$$

$$\alpha=0 ; \beta=1 \text{ (IDI} \leq \%5) \quad (4)$$

$$\alpha = exp[1.76 \times (190 \div IDI^2)] ; \ \beta = 0.99 + IDI^{1.5} \div 1000 \ (\%5< \text{IDI} \leq \%35 \quad (5)$$

$$\alpha = 5.0 ; \ \beta = 1.2 \ \text{(IDI} \geq \%35) \quad (6)$$

The correction factors in the liquefaction analysis of this study are as follows:

The values of C_R=1.00, C_S=1.20, C_B=1.10, and C_E=0.75 have been applied. Based on the laboratory test results, the fine-grain ratio exceeds 35% in all the studied areas.

The liquefaction resistance (τ_R) was calculated by multiplying the cyclic resistance ratio corresponding to a moment magnitude 7.5 earthquake ($CRR_{M7.5}$) by the magnitude scaling factor for the design earthquake (C_M) and the effective vertical stress (σ') (Equation 7-9).

$$\tau_R = CRR_{M7.5} \times C_m \times \sigma' \quad (7)$$

The cyclic resistance ratio was calculated using the equation provided in Equation (8).

$$CRR_{M7.5} = (1 \div 34 - N_{1.60f}) + (N_{1.60f} \div 135) + (50 \div (10N_{1.60f} + 45)^2 - 1 \div 200 \quad (8)$$

The earthquake magnitude correction factor, C_M, is calculated based on the moment magnitude (M_W) of the design earthquake.

$$C_M = (10^{2.24} \div {M_W}^{2.56}) \quad (9)$$

The earthquake magnitude correction factor (C_M) was calculated based on the design earthquake magnitude (M_W = 7.5). The shear stress developed in the soil was calculated as shown in Equation (10).

$$\tau_{deprem} = 0.65 \times \ \sigma_{vo} \times (0.4 \times s_{DS}) * r_d \quad (10)$$

Here, σ_{vo} represents the total vertical stress at the depth where liquefaction evaluation is performed, and r_d denotes the stress reduction factor at the corresponding depth. These values are calculated using the relationships provided in Equations (11-14).

$$rd = 1.0 - 0.00765 \times z \qquad z \leq 9.15m \quad (11)$$

$$rd = 1.174 - 0.0267 \times z \qquad 9.15m < z \leq 23m \quad (12)$$

$$rd = 0.744 - 0.008 \times z \qquad 23m < z \leq 30m \quad (13)$$

$$rd = 0.50 \qquad z > 30m \quad (14)$$

S_{DS} values represent the short-period design spectral acceleration coefficient. Ground motion values for three different locations were obtained using the Turkey Earthquake Hazard Map (Table 8).

Table 8. Ground motion values

Neighborhood	Ss	S_1	S_{DS}	S_{D1}	PGA (g)	PGV (cm/sn)

According to the criteria specified in the Turkish Building Earthquake Code (TBEC-2018), the potential for soil liquefaction has been assessed (Figure 4). Liquefaction is not expected under the following conditions:

- If the ratio of cyclic shear stress to the cyclic resistance ratio (τ_R / $\tau_{Dep.}$) is greater than 1.1, (FS >1.1),
- If the Plasticity Index (PI) is greater than 12%,
- If the corrected Standard Penetration Test (SPT) blow count ($N_{1.60}$) is greater than 30,
- If there is no groundwater present at the site.

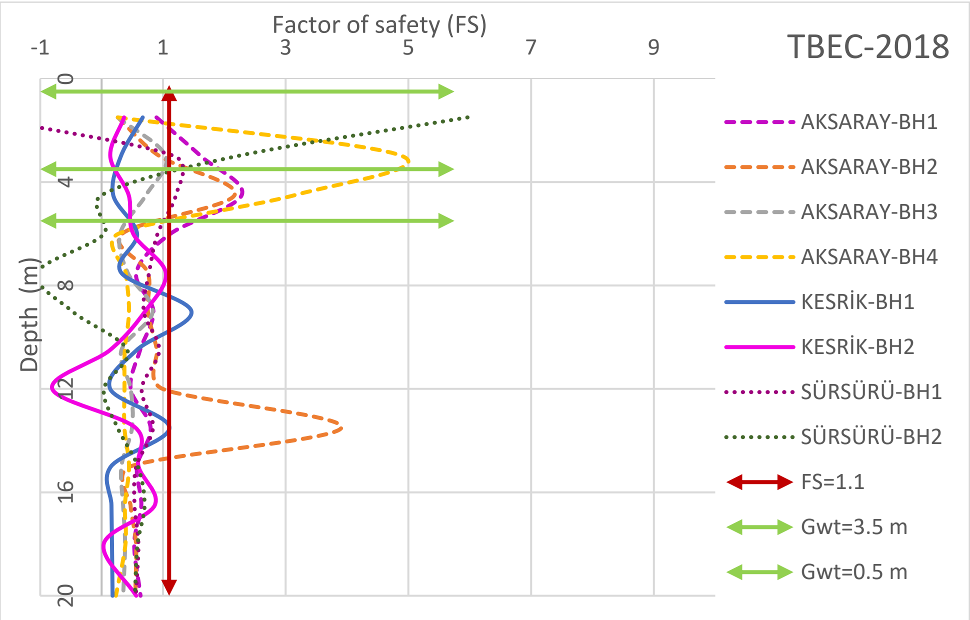

Fig. 4. Soil liquefaction

3. Conclusions

The analysis results indicate variability in the subsurface conditions across the region in terms of depth and topography, with some areas exhibiting a greater susceptibility to liquefaction. Based on the criteria specified in TBEC-2018, the assessment of liquefaction potential was carried out by taking the following factors into account:

- Presence of groundwater is required for liquefaction risk: Therefore, liquefaction risk is not expected in locations and depths where groundwater is absent.
- Plasticity index (PI) greater than 12: When the plasticity index (PI) value is greater than 12, liquefaction risk is considered to be low or unlikely.

- Corrected SPT values ($N_{1.60}$) greater than 30: In cases where the corrected SPT values ($N_{1.60}$) are greater than 30, the liquefaction risk is very low or not expected. Additionally, it has been observed that liquefaction risks increase at lower SPT values.
- Based on the analyses conducted in Aksaray Neighborhood according to TBEC-2018, liquefaction is not anticipated at depths of 4.50 m and 6.00 m in borehole BH1, at depths of 4.50 m and 13.50 m in borehole BH2, and at a depth of 4.50 m in borehole BH4, as the factor of safety is greater than 1.10 at these points. Furthermore, liquefaction is expected at all depths below the groundwater table in borehole BH3.
- Based on the analyses conducted in Kesrik Neighborhood according to TBEC-2018, liquefaction is not anticipated at depths of 9.00 m and 13.50 m in borehole BH1, as the factor of safety is greater than 1.10 at these points. In borehole BH2, liquefaction is expected at all depths below the groundwater table (excluding the zone at a depth of 12.0 meters).
- Based on the analyses conducted in Sürsürü Neighborhood according to TBEC-2018, liquefaction is expected at all depths below the groundwater table in borehole BH1. In borehole BH2, liquefaction is expected at all depths below the groundwater table, with the exception of the zones at depths of 7.50 and 9.00 meters.

Determining the subsurface liquefaction potential in Elazığ Province is critically important for ensuring the safety of construction and infrastructure developments in the area. In this context, increasing the number of field investigations, laboratory experiments, and geophysical surveys at different locations will enhance the detailed assessment of soil profiles. Analyzing the collected data in accordance with TBEC-2018 standards and advanced tools like DEEPSOIL will allow for a more accurate estimation of liquefaction risk. In regions with potential for liquefaction, the most suitable and cost-effective ground improvement methods should be identified based on the soil conditions. Comprehensive engineering analyses carried out within this framework will play a key role in planning safe construction practices and mitigating regional disaster risks.

Determination of soil amplification factors by seismic soil response analysis in Altınşehir region

Bahadır Atlılar*[1], Ahmet T. Gezgin[1], Mustafa Şenkaya[1]

[1] *Bursa Uludag University, Department of Civil Engineering, 16059 Bursa, Türkiye*

Abstract: In most of the engineering studies in our country, ground magnification is performed with empirical formulas based on S-wave velocity. However, it is well-known that ground growth varies depending on the local ground conditions. This change has a different significance for the areas where units of different geological ages coexist, such as the Bursa plain. Dec. The Quaternary-aged Alluvial Formation (Qal) and the Neogene-aged Mudanya Formation (Tmm) are being studied in the region within the borders of Nilüfer district, which spreads over a wide area in the Bursa Plain. In these formations, soil profiles have been idealized using geotechnical parameters obtained from mechanical drilling and geophysical parameters obtained from field studies. Seismic records that will describe the earthquake effects on the fault segments close to the region were selected from these ground profiles and examined by seismic ground response analysis performed by the DeepSoil program.

Keywords: Soil profile; Soil response analysis; Earthquake; Geotechnics; Geophysics; Earthquake engineering

1.Introduction

Turkey's location on an active plate boundary necessitates a detailed assessment of local soil conditions, particularly in densely populated areas near active faults. Bursa, a major city in the Marmara Region, is a key focus due to its demographic and tectonic characteristics. Within Bursa, Altınşehir in Nilüfer district is characterized by Quaternary alluvial deposits and a shallow groundwater table, resulting in widespread water-saturated soils. These conditions critically affect seismic wave propagation and ground response. The area's mixed building stock further underscores the need to evaluate local site effects for earthquake resilience carefully.

Another critical dimension of the study is identifying the region's earthquake hazard. The location of Altınşehir has the potential to be affected by earthquakes of different magnitudes due to its proximity to the active fault lines of the Marmara Region. In this study, the earthquakes that may affect Altınşehir were analyzed in detail, and possible scenarios were determined in light of historical and current earthquake data. Ground motions seismic sources may generate may be interpreted by considering fault types, fault orientation, depths, and distances to the region. The potential impacts of the active fault segments around Bursa on Altinsehir have been considered. The fault segments used in this study were selected from the North Anatolian Province in the active fault database of Turkey (Emre et al. 2018). Earthquakes with higher earthquake magnitude values and more probable expected earthquakes were selected.

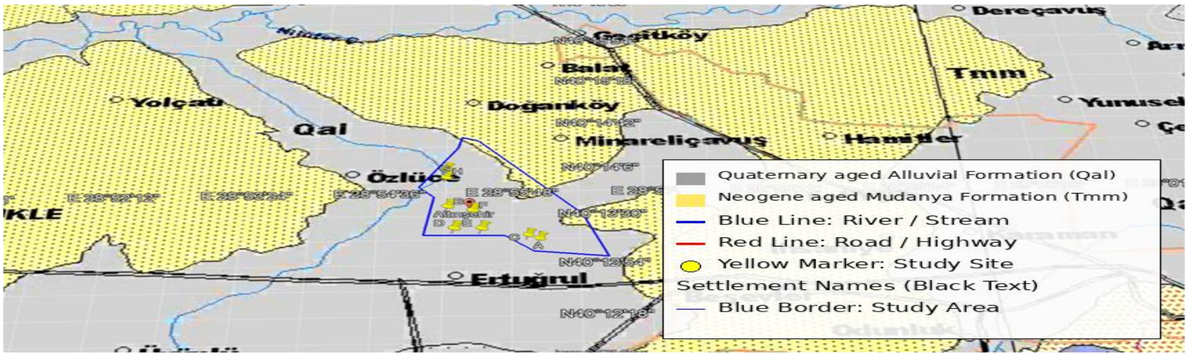

Fig.1. Investigation areas in Altinsehir on the geological map

This study selected earthquake input records based on seismic scenarios using the PEER (Pacific Earthquake Engineering Research Center) database. One key focus in analyzing local soil effects in areas like Altınşehir is the evaluation of soil amplification ratios. While previous studies often estimated amplification using empirical formulas based on Vs30 values, such methods can be inadequate in regions with complex soil structures due to limited consideration of local conditions. In this study, site-specific geophysical measurements and field and laboratory tests enabled the development of soil profiles that more accurately reflect real soil behavior, allowing for more reliable modeling of local effects and a more accurate prediction of seismic loads on structures.

2. Methodology

2.1. Identification of earthquake input motion

In this study, to determine the seismic hazard and local soil behavior of Altınşehir (Nilüfer/Bursa) region, active fault segments and earthquakes similar to these faults were modeled. Both local fault segments and earthquake records selected from the PEER (Pacific Earthquake Engineering Research Center) database were used in the modeling. For the seismic hazard analysis of the study area, first of all, the direct fault lines that may have an impact on Altınşehir Neighborhood were identified. In this context, six fault segments were included in the scope of the analysis, considering the direct fault map of Turkey and literature sources. These segments have a strike-slip fault type and exhibit a right-lateral movement characteristic. The characteristics of the selected segments are presented in Table 1. In addition to fault type, size (Mw), focal depth, and shortest distance to the study area (Rrup) were considered during segment selection.

Table 1. Fault segments affecting the study area

No	Fault Segment	Fault Type	Faulting Direction	Mw	Rrup (km)	Depth(km)
1	1999 İzmit Segment (I 35-34*)	Strike-slip	RL	7.4	100–150	17–18
2	1999 İzmit Segment (I 28*)	Strike-slip	RL	6.94	100–150	17–18
3	Edincik Fault	Strike-slip	RL	7.01	50–100	16–18
4	Gediz Segment	Strike-slip	N-LL	7.1	100–150	16–18
5	Gemlik Fault	Strike-slip	RL	6.73	0–50	17–18
6	Kayapa-Yenişehir Fault	Strike-slip	RL	7.01	-	-

*I34-35: Numbering On The Active Fault Map (Emre vd. 2018) *I28: Numbering On The Active Fault Map (Emre vd. 2018)

Following the characteristics of the selected fault segments, eight earthquake records were obtained from the PEER NGA database. The earthquakes were chosen to have similar fault typology (mostly strike-slip), similar magnitudes (Mw 6.2-7.4), and source-sink characteristics comparable to the study area. This approach aims to model the possible ground motions that may occur in the study area effectively.

Table 2. Earthquakes selected from PEER database

No	Fault Segment	Fault Type	Fault Type	Faulting Direction	Mw	Rrup (km)	Depth (km)
1	1990 - Manjil (İran)	Abbar	Strike-slip	RL	7.37	12.55	15
2	1995 - Kobe (Japonya)	Kobe University	Strike-slip	RL	6.90	9.2	18
3	2004 - Parkfield (ABD)	Diablo Canyon	Strike-slip	RL	6.20	78.32	5–8

2.2. Identification of soil profiles

The Altınşehir Neighborhood and its surroundings are located in the western part of the Bursa Plain and are characterized mainly by Quaternary-aged alluvial deposits. The general geology of the area consists of clay layers with poor engineering properties, classified as soft soils. Drilling and geophysical studies have revealed soil layers with low wave propagation velocities and low bearing capacity from the surface. Hydrogeologically, the groundwater level is very close to the surface, with measurements indicating a depth of approximately 3–6 meters. The alluvial fill formed by the Nilüfer Stream and its tributaries is the primary reason for the high groundwater level. Under saturated soil conditions, this significantly affects soil behavior under seismic loads, necessitating effective stress parameters and consideration of pore water pressure effects in the analyses.

Determination of geotechnical parameters appropriate to the lithology was the primary step in constructing soil profiles. The engineering parameters used to evaluate the soil layers' bearing capacity, settlement properties, and dynamic behavior were obtained from field tests (SPT, MASW) and laboratory tests. Based on the information obtained from drilling logs and geophysical measurements, stratification boundaries and soil types were defined, and detailed profiles were modeled. The sample soil profile A (Fig.2) below covers a depth range of 0-20 m. In the upper layer of the profile, there is a three-meter-thick sandy silty clay with low consistency and wave velocity values. The average Vs value measured in this layer is 151 m/s, which was obtained from seismic surface wave analysis (MASW). Groundwater level was observed at a depth of approximately 3 m. The second layer is a clay with the same lithologic characteristics, but located at deeper depths and representing more solid ground conditions. In this layer, the average Vs value was determined as 297 m/s. The unit volume weight (γ) of both layers was determined as 18.5 kN/m³ due to laboratory analysis of the samples taken. According to the results of the Standard Penetration Test (SPT), N60 values were 11 for the upper layer and 16 for the lower layer. These values were used in undrained shear strength (Su) calculations for cohesive soils based on the Stroud (1974) correlation. The obtained Cu values are 52.14 kPa and 84.48 kPa, respectively. Plastic limit (PI) values were also included in the profile to define cohesive soils' plasticity properties and apply reference curves to analytical models.

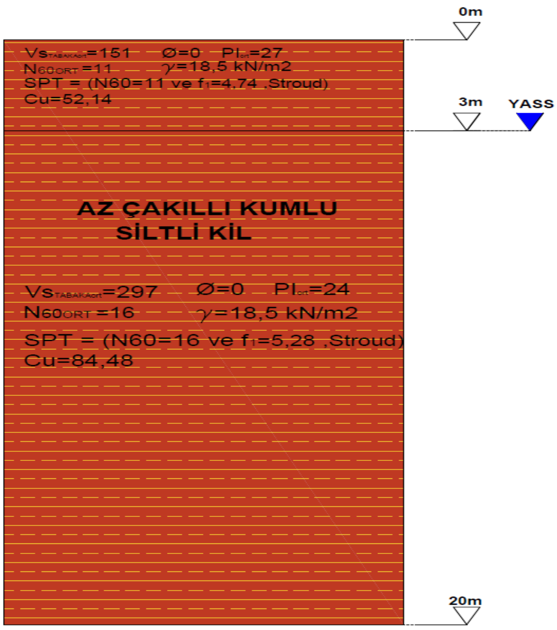

Fig.2. Soil profile A

2.3. Seismic soil response analysis

In this study, 1-D ground seismic response analyses were performed using DEEPSOIL v7.0 software to evaluate the dynamic behavior of the soils in Altınşehir region. In the analyses, the nonlinear analysis method was preferred. In these analyses under time-domain solution type, the hyperbolic (GQ/h) model and the non-Masing hysteretic reloading/unloading formulation were used to model the soil behavior more realistically. With this method, especially the development of Pore Water Pressure (PWP) in the soil was considered, and the plastic deformation potential of the soil under dynamic loading was evaluated in detail.

The analysis method was also compared with the equivalent linear (frequency domain) analysis method, and the effect of nonlinearities in soil behavior was more clearly demonstrated. The automatic profiling tool provided by DEEPSOIL was used to define and model each layer based on field and laboratory data. The soil profile used in the analysis was obtained from the geotechnical and geophysical data shown in Fig.2. Vs30 values of the layers forming the profile were defined by averaging the results of seismic MASW tests for each layer. Unit volume weight values were obtained from laboratory tests, and when more than one data point was available, the average value was taken and integrated into the model. SPT-N values were used for shear strength values; Stroud (1974) correlations were used for clay soils, and Kulhawy and Mayne (1990) correlations were preferred for coarse-grained soils (sand and gravel). In addition, the plasticity index (PI) values of the clay units were taken as a basis for the reference curve generation. They were recorded on the profile to be used in the analyses. Reference shear modulus (G/Gmax) and damping ratio curves were defined following Vucetic & Dobry (1991) for clay soils, Seed & Idriss (1970) for sand soils, and Menq (2003) for gravel soils. The Matasovic (1993) model for clay soils and the Vucetic/Dobry (1988) model for sand and gravel units were used as the PWP model. These literatures were selected for the most appropriate modeling of the soil lithology, considering the compatibility of the available drilling and laboratory data. According to TBDY 2018, the horizontal elastic spectrum curve was drawn in the seismic detail report taken according to DD-2 (standard earthquake design ground motion) and soil class by the parcel coordinates of the soil profile on the AFAD seismic hazard map.

2.4. Spectral behavior of soil profiles in Altınşehir Region

The spectra obtained by using selected earthquake records (Manjil, Kobe, Parkfield, Tottori, Landers, Kocaeli, Duzce, Morgan Hill) for eight different soil profiles from A to H (Fig.3) were compared with the design spectra in TBDY-2018 regulation. (Fig.3.) It was observed that the spectra of soil profiles gave values above the design spectra in high frequency (short periods) and low frequency (long periods) regions with some earthquake records. In particular, soil profiles C and D caused significant magnifications against strong ground motions such as Landers and Kobe.

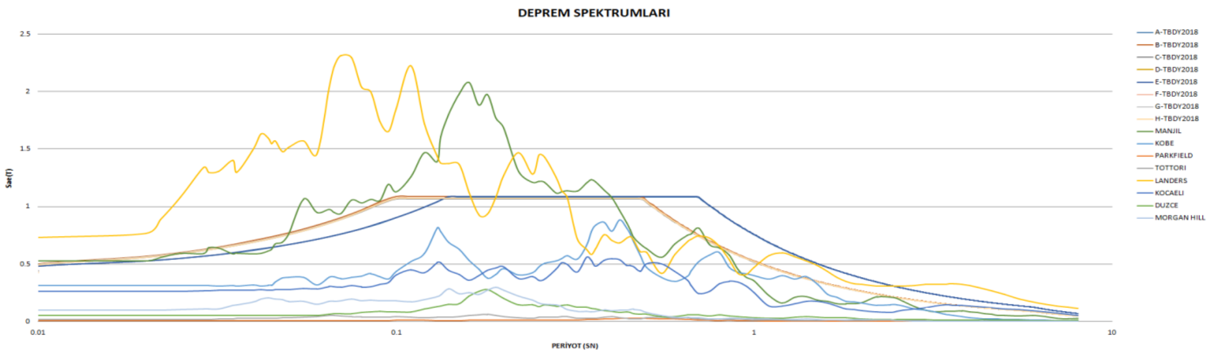

Fig.3. Spectrum curves

Real earthquake records, selected from the appropriate fault segments presented above in Table 2, are imposed on the model, and the response of the ground under different spectral characteristics is analyzed. When determining the amplification factor, the top layer's ground motion is compared with the earthquake waves entering the bedrock record to reveal how the ground motion is amplified in the ground profile. In this approach, the ratio of the acceleration values at the surface to the acceleration values at the bedrock is taken to determine the extent to which the ground layers amplify the earthquake waves. Therefore, the calculations are based on the bedrock input and surface records [Fig.5]. Amplification values for different period intervals are found, and the intervals where the ground amplification of the structure is effective are determined.

3. Results and discussion

3.1. Relationship between spectral magnifications and building types

According to the analyzed earthquake response spectra, spectral acceleration varies significantly depending on the structure's natural period. In the short-period range (T < 0.3 s), spectral acceleration typically ranges between 0.3g and 0.7g, affecting low-rise, stiff structures through rapid, high-frequency motions. In the medium-period range (0.3 s – 1.0 s), the spectra reach their peak values, often between 0.8g and 2.3g, making this interval the most critical for structural design, particularly for mid-rise reinforced concrete buildings. In the long-period range (T > 1.0 s), spectral acceleration tends to decrease, typically between 0.1g and 0.6g, indicating that displacement demands become more dominant than acceleration in tall, flexible structures. In comparisons made with the design spectrum obtained following the 2018 Turkish Building Earthquake Code (TBDY 2018), it has been observed that the spectra derived from actual earthquake records can exceed the local design spectrum, particularly in the medium-period range. This highlights the critical importance of site-specific spectral analyses for accurate structural design and performance evaluation.

3.2. Evaluation of amplification factors

Earthquake-specific nonlinear and equivalent linear soil seismic response analyses were performed for 8 soil profiles (A, B, C, D, E, F, G, H) according to selected earthquake records in the study area, and amplification factors were obtained (Fig.4).

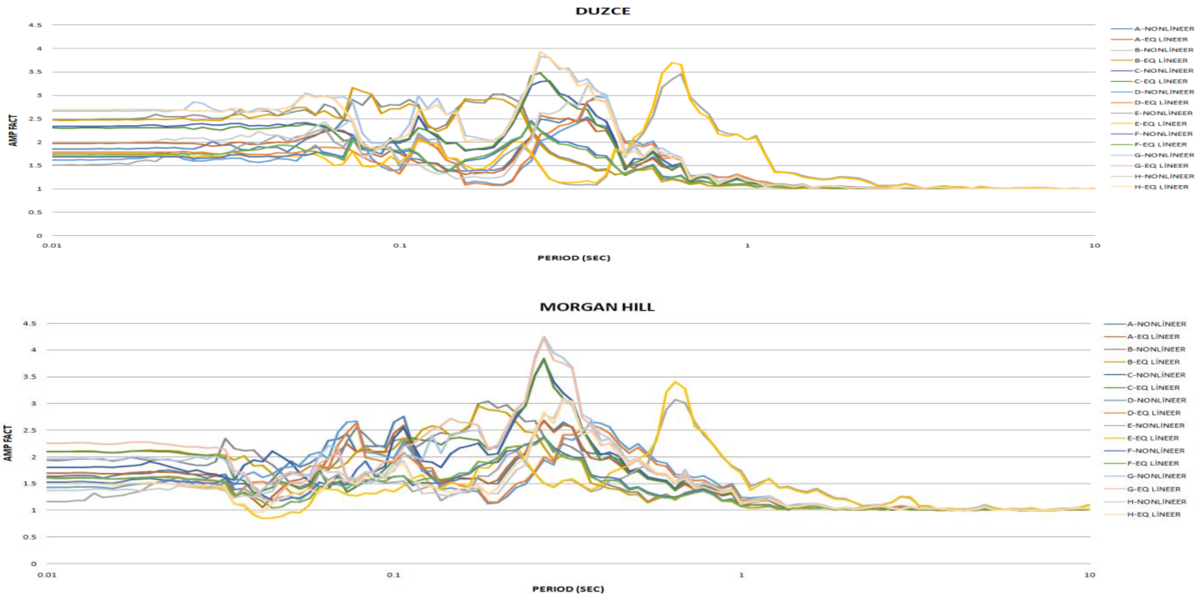

Fig.4. Amplification factors of earthquakes

This study analyzed different earthquakes based on graphs comparing linear and nonlinear results. For the Manjil earthquake, the differences between linear and nonlinear analyses became especially evident at longer periods (beyond 0.5 seconds). At short periods (0.01-0.3 s), low-rise buildings showed low amplification, while at medium periods (0.3-1 s), significant amplifications were observed for soil profiles D, E, and H, particularly affecting 4-8 story buildings. At long periods (above 1 s), profiles E, F, and G showed amplifications above 2, indicating increased risk for 10-story buildings and taller structures. Nonlinear analyses generally exhibited higher amplifications, especially for E and G profiles with weak layers.

The Kobe earthquake, characterized by very high accelerations, showed dominant nonlinear behavior. Short-period ground motions were not over-amplified, but at medium periods (0.3-1 s), magnifications reached 2.5-3.5 for some soils, posing a risk for mid-rise buildings. No striking resonance was observed at longer periods. Linear and nonlinear results were similar for soil profiles A, B, and C, but differed significantly for E, G, and H profiles.

In the short-period range (0.01-0.3 s) for the Parkfield earthquake, amplification factors were stable (1.2-2.3) with minor differences between linear and nonlinear analyses, suggesting linear assumptions are acceptable for low-rise structures. However, amplification increased at medium periods (0.3-1 s), critical for mid-rise buildings. Long-period responses showed a general decrease.

In the Tottori earthquake, short-period amplification remained between 1.5 and 2.5. At the same time, at medium periods (0.3-1 s), nonlinear analyses showed magnifications exceeding 3.0 in B, D, and E profiles, making nonlinear behavior significant for mid-rise structures. At long periods, some profiles, especially E, indicated possible resonance risks.

The Landers earthquake showed significant amplification in the long-period range (1-3 s), with C-Eq Linear profiles exceeding 10 in amplification, highlighting serious resonance risks for high-rise buildings. Short and medium periods showed moderate magnification.

In the Kocaeli earthquake, short-period magnification was low, but at medium periods (0.3-1 s), magnifications reached 2-3.5 for some soils, indicating risk for 4-8 story buildings. No significant resonance was observed at long periods.

The Düzce earthquake showed similar trends: low short-period amplification, increased magnifications (2-4) at medium periods, and notable risks at long periods (around 3-3.5 magnification in E-Nonlinear-Equivalent analyses) for multi-story structures.

The Morgan Hill earthquake generally showed low amplifications at short periods but increased to 2-2.5 in some cases. All soil profiles experienced higher amplifications in the medium period range, with G and C profiles reaching 3.5-4, which is critical for 4-8 story buildings. At long periods, only E-Nonlinear-Equivalent profiles showed significant amplification.

Overall, the medium period range (0.3-1 s) across all earthquakes presents critical risks for mid-rise buildings. In some cases, long-period amplifications indicate potential resonance risks for high-rise structures. Nonlinear analyses consistently revealed more pronounced amplification effects than linear models, especially for soils with weak layers.

4. Conclusions

This study evaluated various earthquake ground motions on eight different soil profiles through linear and nonlinear site response analyses. The resulting amplification factors and spectral acceleration values were interpreted in relation to period-dependent soil-structure interaction. The results were also compared with the Turkish Building Earthquake Code (TBDY-2018) design spectra. The main conclusions are summarized below:

- The relationship between soil type and period was evident; soft soil profiles (such as C, E, and G) produced higher amplification values, particularly in short-to-mid period ranges, with this behavior being more pronounced under the Morgan Hill and Tottori earthquakes.
- The characteristics of different earthquakes had significant effects on amplification factors. The Landers and Tottori earthquakes generated high spectral accelerations in short and intermediate periods, strongly influencing the site response.
- The Kobe earthquake exhibited relatively lower spectral acceleration and a flatter response curve compared to others, indicating a lower level of localized amplification.
- Nonlinear analyses provided more realistic amplification predictions, especially in the resonance-sensitive period ranges (approximately 0.2–0.6 seconds), by accounting for effects such as energy dissipation and stiffness degradation.
- The spectral comparisons revealed that some real earthquake records (notably Landers and Manjil) exceeded the TBDY-2018 design spectra, especially in the short-period range. This suggests that real earthquake demands may pose higher risks than code-based expectations.
- TBDY-2018 design spectra generally remain conservative, but in some cases ($T < 0.3$ s), the code spectra underestimate the actual demands, highlighting the need for detailed dynamic analysis in critical structures.
- In the long-period range ($T > 1$ s), spectral acceleration and amplification factors decreased significantly, indicating that tall structures on such soils may experience reduced seismic demand.
- In some critical middle and high-period regions, significant differences between nonlinear and equivalent linear analyses began to occur. This increased the use of nonlinear analysis, suggesting that linear analysis alone would be sufficient.
- The analyses also revealed critical period ranges where soil-structure resonance effects are likely to occur, particularly between 0.3–0.7 seconds for mid-rise buildings (4–8 stories) and above 1 second for high-rise structures. In these ranges, nonlinear amplification became significantly pronounced, indicating a higher seismic risk due to potential resonance between soil and structure.

Deformation analysis of anchored retaining systems: a case study with PLAXIS modeling and field data comparison

Saeid Zardari*[1], Aslı D. Sağlam[1]

[1]*Istanbul Okan University, Department of Civil Engineering, 34959 Istanbul, Türkiye*

Abstract. Deep excavations have become a crucial aspect of civil engineering due to increasing urbanization and construction activities. Excavations carried out for the foundation systems and underground structures of high-rise buildings can affect surrounding soil conditions, leading to deformations. To ensure the safety of excavation sites, the use of effective support systems is essential. In this study, the performance of anchored bored pile retaining systems was analyzed using the finite element method (FEM), and the results were compared with inclinometer measurements taken on-site. Initially, the roles and functions of anchors and bored piles in retaining structures were discussed. This was followed by an investigation of the system's behavior through analyses conducted under different conditions. The modeling was performed using PLAXIS software, and the computed deformations were compared with field measurements to identify discrepancies. Back-analysis was conducted to examine the key factors influencing the performance of the retaining system, and significant insights were drawn regarding the engineering design of deep excavation support systems.

Keywords: Anchored bored pile; Retaining systems; Finite element method; PLAXIS; Inclinometer measurements

1. Introduction

Deep excavations in urban areas pose significant engineering challenges due to unfavorable risks affecting the stability of surrounding structures and soils. As the complexity and scale of construction projects continue to increase, the demand for safe and durable excavation support systems has also grown. Among these systems, anchored and bored pile retaining structures are widely preferred due to their high load-bearing capacities and adaptability to varying ground conditions. These systems are commonly employed to provide lateral support during excavation, especially in constrained spaces and for deep foundations required by high-rise buildings. Bored piles and anchors offer effective resistance against lateral forces during excavation and help to control ground movements. The performance of these systems is influenced by several factors, including anchor spacing, pile arrangement, and soil properties. Numerous studies have emphasized the critical role of these factors in ensuring the stability and safety of excavation sites. Numerical modeling tools such as PLAXIS are widely used to predict deformation behavior; however, the accuracy of these predictions needsa validation through field measurements.

1.1. Literature review

Several studies on the deformation behavior of deep excavation support systems highlight the necessity of reliable analysis methods to accurately predict system performance. In this context, the Finite Element Method (FEM) has become a standard tool for modeling soil-structure interaction. Meanwhile, observational data, such as inclinometer measurements obtained from the field, play a crucial role in enhancing the accuracy of numerical models and ensuring the reliability of geotechnical designs. Studies focusing particularly on the lateral deformation behavior of pile-supported systems have been recognized as critically important for the safe design and performance assessment of deep excavation support structures.

In a study conducted by Ou et al. (1993), it was observed that ground settlements occurred at approximately 50% to 70% of the maximum lateral deformation, and that the maximum lateral deformation corresponded to about 0.2% to 0.5% of the excavation depth. Similarly, Fernie and Suckling (1996), based on their research in the United Kingdom, stated that maximum lateral movements in retaining structures within stiff soils should range between 0.15% and 0.30% of the excavation depth. In another study, Carder (1995) found that lateral deformations in retaining systems installed in stiff soil conditions are directly related to the rigidity of the system. In this context, it was emphasized that in high-rigidity systems, the maximum deformation corresponds to approximately 0.125%

* Corresponding author, E-mail: saeid.zardari@okan.edu.tr

https://doi.org/10.31462/icearc2025_ce_geo_369

of the excavation depth, while in medium-rigidity systems, it is around 0.2%, and in low-rigidity systems, about 0.4%. It was also concluded that deformations increase as the system rigidity decreases.

Ma'ruf and Darjanto (2017), in their study on the cut-and-cover tunnel construction of the Nicoll Highway project in Singapore, identified that the main cause of excessive displacements was the misinterpretation of soil properties. Through back-analyses, they demonstrated that improvements such as the addition of struts to the support system and assuming a zero internal friction angle for coarse-grained clay soils significantly reduced excessive deformations and substantially increased the safety factor.

In a study conducted within the scope of a hotel construction project, Aktan (2014) investigated the effects of variations in soil elasticity modulus and internal friction angle on the performance of retaining systems. He observed that increasing the elasticity modulus significantly reduced lateral displacements, and that decreasing anchor spacing also contributed to minimizing deformations.

Rahmani and Laman (2016) analyzed three different projects to investigate the impact of groundwater levels on retaining systems. Finite element analyses revealed that as the groundwater table approaches the surface, lateral displacements in retaining structures increase, highlighting the necessity of considering groundwater effects in design calculations.

Steiner (2001) found that significant surcharge loads caused by truck-mounted cranes at deep excavation sites led to an increase in anchor forces. Cengiz (2008), in a project located in Moscow, compared field-measured displacements of a diaphragm wall retaining system supported by anchors and struts with results from finite element analyses performed using PLAXIS software. It was determined that the lateral displacements obtained from the numerical model were higher than the field measurements. Subsequent parametric studies, in which cohesion, internal friction angle, and elasticity modulus were increased by 10%, 20%, and 30%, respectively which indicated that the closest agreement with field measurements was achieved when the parameters were increased by 30%. In a more recent study by Ma and Cao (2024), it was reported that three-dimensional modeling more accurately represents deformation behavior in supported excavations in clay compared to two-dimensional analyses. Their findings emphasized the importance of considering three-dimensional effects in numerical simulations.

The primary objective of this study is to analyze anchored bored pile retaining systems using the finite element method and to evaluate the accuracy of the numerical results by comparing them with inclinometer measurements obtained from the field. Although many studies in the literature focus predominantly on theoretical approaches regarding similar systems, verification through field data remains limited. In this regard, the present study aims to combine theoretical analyses with on-site measurements to provide more reliable and practical insights into the real behavior of retaining structures.

2. Materials and methods

2.1. Project site and subsurface conditions

In the project addressed in this study, the construction of a building comprising six basement levels, one ground floor, and five above-ground floors is planned. The project site covers an area of 5,919.46 m², with the building footprint occupying approximately 4,200 m². The site layout plan and the side elevation of the project are presented in Fig. 1.

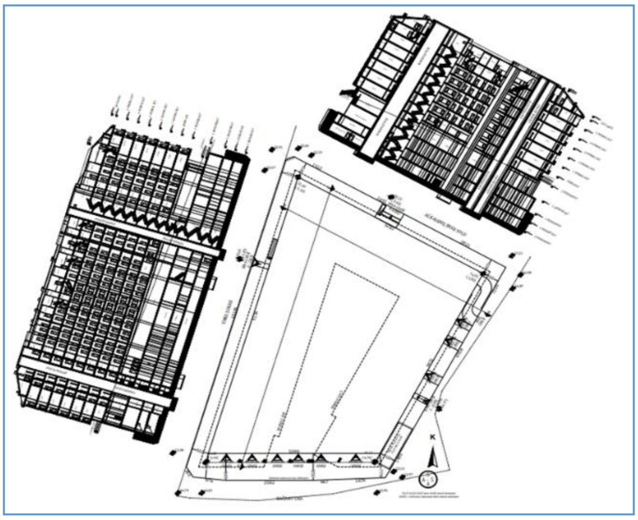

Fig. 1. General plan of the project (Source: the authors)

Due to the multi-basement design of the building, the use of deep excavation support systems has become essential. Accordingly, an anchored bored pile retaining system has been designed for the project. The excavation depth varies across the site, ranging from 11.30 meters to 18.20 meters depending on the location.

A total of 13 boreholes were drilled within the study area to determine the geological and geotechnical characteristics of the site. Laboratory tests, including direct shear, Atterberg limits, moisture content, sieve analysis, and hydrometer tests, were conducted on the samples obtained from the boreholes.

Within the scope of the project, Section-7, identified as the critical section due to a greater-than-expected increase in deformations, was examined in detail. The laboratory test results for the SK1 and SK5 borehole samples taken from this section are presented in Table 1.

Table 1. Soil laboratory test results for the project area (Source: the authors)

Borehole No	Depth	Atterberg Limits			Water Content	Natural Density	Sieve Analysis Result [%]				Direct Shear Test Result	
		LL [%]	PL [%]	PI [%]	ω [%]	[g/cm^3]	Gravel	Sand	Silt	Clay	c [kPa]	ϕ[º]
SK-1	5.50-6.00	44.4	21.9	22.5	26.0	1.88	0.00	11.06	30.35	58.59	71.17	7.26
SK-1	8.50-9.00	42.3	20.3	22.0		1.89	0.00	9.19	90.81		73.24	7.41
SK-1	19.50-20.00					1.95	0.00	10.53	89.47		79.43	8.20
SK-5	3.00-3.50	36.4	185	17.9	22.26	1.91	30.78	23.12	18.97	27.13	51.17	14.05
SK-5	8.50-9.00					1.94	14.95	16.42	68.63		84.52	10.72
SK-5	17.50-18.00	40.9	21.3	19.9		1.95	0.00	18.40	81.60		95.70	8.62

2.2. Numerical modeling

Within the scope of the project, Section-7, identified as critical due to deformation increases exceeding predictions, was analyzed in detail using the Finite Element Method (FEM). These analyses were conducted to evaluate the deformations that occurred in the retaining system during the excavation process. The detailed results of the analyses are presented in the subsequent sections of the study.

In selecting the soil models, the Mohr-Coulomb model was adopted for the artificial fill and the sandstone (arkose) layers, while the Hardening Soil (HS) model was chosen for the stiff clay layer. In the reviewed design report, it was observed that the soil parameters used in the modeling of the shoring system were not based on site-specific laboratory or field tests, but they were rather based on typical values reported in the literature.

In this study, the same soil parameters from the design report were adopted in the initial modeling phase. The soil parameters used in the finite element analyses are summarized in Table 2.

Tablo 2. Analysis parameters based on the values in the calculation report (Source: the authors)

	Natural unit weight	Elastic modulus	Cohesion	Internal friction angle	Poisson's ratio
Symbol	γ_n	E	c	ϕ	υ
Unit	[kN/m^3]	[kN/m^2]	[kPa]	[º]	-
Upper layer clay	18.5	21000	19	28	0.28
Lower layer clay	19	30000	22	28	0.28
Very Weak Sandstone-Arkose	22	150000	50	32	0.28

In selecting the excavation support method, it was essential to design the retaining systems to minimize deformations in order to prevent adverse impacts on adjacent existing structures and roads. Accordingly, a retaining system consisting of bored piles combined with prestressed ground anchors was selected as the most suitable excavation support solution for the site. This selection and its details were thoroughly documented in the corresponding design report. A photograph of the site implementation is presented in Fig. 2.

Fig. 2. Field visual of the relevant project (Source: the authors)

In the design report, considering the excavation depth, the pile diameter was specified as 65 cm. The center-to-center spacing between the piles was determined to be 90 cm. For the bored piles, concrete class BS30 was selected, with an assumed modulus of elasticity of 30,000,000 kN/m².

The equivalent thickness (d) parameter represents the cross-sectional area of a unit width (1 meter) of material along the principal axis of the wall. While for flat plates with a rectangular cross-section the equivalent thickness is directly equal to the section thickness. For systems such as pile walls, where a distinct continuous section does not exist, a lower equivalent thickness is defined. This value is determined based on equivalent stiffness parameters to model the piles as a continuous diaphragm (Kalpakcı et al., 2015). Accordingly, for the bored piles with a diameter of 65 cm and a center-to-center spacing of 90 cm, the cross-sectional properties were calculated using "Eq. 1," and the equivalent thickness was found to be 0.563 meters.

$$d = \sqrt{12\frac{EI}{EA}} \tag{1}$$

In prestressed anchorage applications, 0.6" low relaxation super tendons were used. Anchor drill diameter was designed as 120 mm. The modulus of elasticity for the injected anchor root was assumed to be 10,000,000 kN/m² and the modulus of elasticity for the super tendon ropes was 195 MPa as shown in Table 3. Anchors with a root length of 9 m were installed at 1.80 m horizontal spacing between the 4th and 7th levels. This layout implies the placement of one anchor for every two bored piles.

Table 3. Properties of cables with 13 mm and 15 mm diameter (ASTM A416, 1997)

Nominal Diameter	13 mm (0.5 inch)		15 mm (0.6 inch)	
Halat Tipi Cable Type	Normal	Super	Normal	Super
Average Diameter [mm]	12.5	12.8	15.2	15.5
Average Cross-Section Area [mm²]	93	99	139	140
Unit Weight (kg/m)	0.74	0.78	1.10	1.10
Minimum Breaking Load [kN]	165	184	244	261
Elastic Modulus [MPa]		195		

For each of the prestressed anchor ropes used, the working load was calculated as 182.3 kN, considering a factor of safety of 0.70 (140 mm² × 1860 N/mm² × 0.70). Accordingly, the maximum working load of a three-strand anchor was determined to be approximately 546 kN. Anchor root lengths were designed as 9 m. Considering the interaction of the injected anchor root with the very stiff to hard, medium plasticity clay unit, the average safe unit wall friction value according to the PTI (1996) standard was assumed to be approximately 120 kPa. According to these data, the safe bearing capacity for a 120 mm diameter anchor root was found to be approximately 405 kN. As a result, the anchor loads were determined as 300-350 kN at the upper levels and 400 kN at the lower levels where the depth of excavation increases.

Monitoring of excavation support systems is of great importance during deep excavations as deformations may occur that may threaten the safety of surrounding structures. In this study, inclinometer measurements were used to determine the horizontal displacements. Inclinometers monitor the lateral movements of the support systems during excavation by tracking the deformations of the pipes placed through inclination sensors. The data obtained is critical for early detection of potential risks and timely engineering measures.

3. Results and discussion

3.1. Numerical analysis results

In this section, the critical section, Section-7, is analyzed using the parameters specified in the soil and the calculation report of the existing project. Section-7 modeling based on these parameters was created with Plaxis 3D program and numerical analyses were performed. The model of Section-7 is presented in Fig. 3.

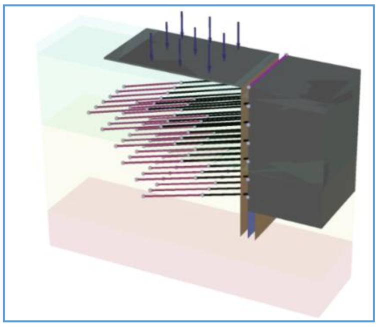

Fig. 3. Modeling of section-7 in the Plaxis 3D program (Source: the authors)

As presented in Table 4, the deformation values obtained from the finite element analyses and the ratio of the horizontal displacement in the X-axis direction to the excavation depth at the top of the pile in the relevant section. In addition, the displacements of the third stage were also evaluated in the modeling in order to examine the sudden displacements in the third stage occurring at the site.

Table 4. Relationship between maximum lateral displacement and excavation depth calculated for section-7 (Source: the authors)

Section-7 (Initial Analysis)	Lateral Displacement at the Top Elevation	Excavation Depth	Displacement Ratio
Unit	[mm]	[m]	[%]
Third stage	0.87	8.75	0.01
Final stage	10.81	16.95	0.06

The acceptable deformation rate for prestressed anchored shoring systems is determined as 0.2%, and the alarm level (maximum allowable limit) is accepted as 0.5% (Ministry of Environment and Urbanization, 2018). In the European Union standard "EN 1997-1 Geotechnical Design-Part 1: General Rules", it is stated that horizontal wall movements should be between 0.1% and 0.2% of the excavation depth in tight soils and between 0.4% and 0.5% in loose soils. In accordance with these regulations, the deformation rate obtained for the prestressed anchored shoring system section is within the specified limits.

3.2. Inclinometer measurement results

After the excavation of the third stage of the shoring depth in Section-7, sudden displacements were observed in the inclinometer number 6. Deformation measurements were performed and the data obtained are shown in Fig. 4 and presented in Table 5.

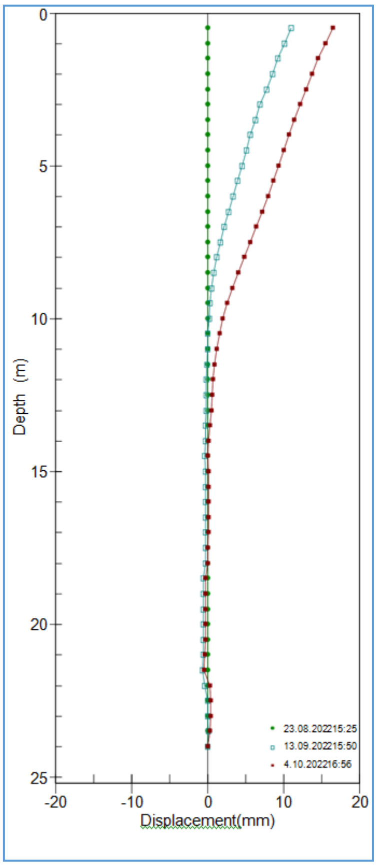

Fig. 4. Lateral deformation graph of inclinometer no. 6 in section-7 (Source: the authors)

As seen in Fig. 4, the maximum horizontal displacement value obtained from the inclinometer measurement at the site was realized at the top of the shoring system. The maximum horizontal deformation depending on the depth of excavation is given in Table 5.

Table 5. Maximum Horizontal Deformation Measured Depending on Excavation Depth (Source: the authors)

Reading Sequence	Measured Maximum Horizontal Displacement [mm]	Excavation Depth [m]	Deformation Rate [%]
1. Reading	0.00	0.00	0.00
2. Reading	11.02	6.25	0.17
3. Reading	16.48	8.75	0.19

Despite the tensioning of the first stage and second stage anchors, a sudden increase in displacement was observed in the X axis of the shoring system when the excavation depth reached 8.75 m. This necessitated some modifications to the project. The causes of this sudden displacement were investigated by back analysis.

3.3. Back analysis

Some situations encountered in the field during the implementation phase may differ from the predictions made during the model phase. Although a general profile can be estimated in the soil data report, data collected from specific areas in the field having different soil conditions may be encountered during the implementation phase due to the inability to obtain data from all areas. When such conditions are encountered, some modifications may need to be made in the fabrications within the scope of the project. In this study, various back analyses were performed to investigate the causes of sudden displacements and evaluated by comparing with the inclinometer measurements in the field. Since the deformation values obtained from the results of the inclinometer measurements in the field occur at the top elevation of the shoring system, the deformations at the top elevation of the system were also analyzed and the results obtained were cross-compared.

3.3.1. Influence of surcharge load on horizontal deformations

Surcharge loads play an important role in soil mechanics. Usually, surrounding structures, vehicles or materials create additional loads on the ground and are defined as surcharge loads. These loads have many important effects on the soil. The surcharge loads can affect factors such as horizontal earth pressure, total soil stress, consolidation, shear strength and groundwater status. They can also create additional lateral forces on ground walls or other structural elements by generating additional horizontal pressure on the ground. These forces can have a direct impact on the stability and design of structures. In this section, the effect of surcharge loads on lateral deformations is investigated and the visualization of the modeling is presented in Fig. 6.

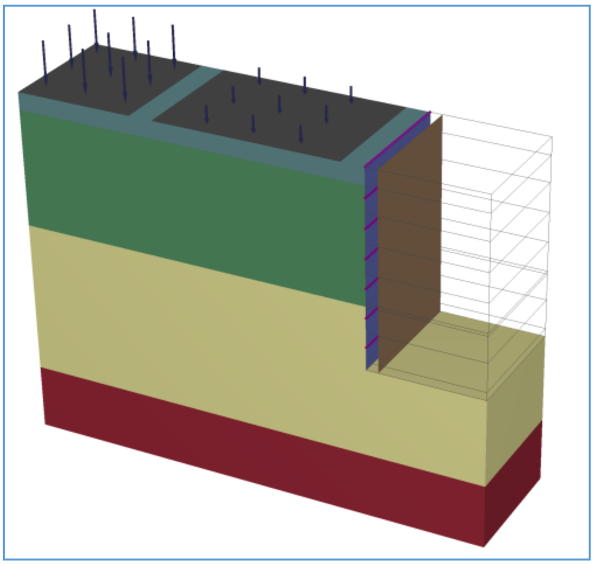

Fig. 6. Plaxis 3D program section-7 model with surcharge loading (Source: the authors)

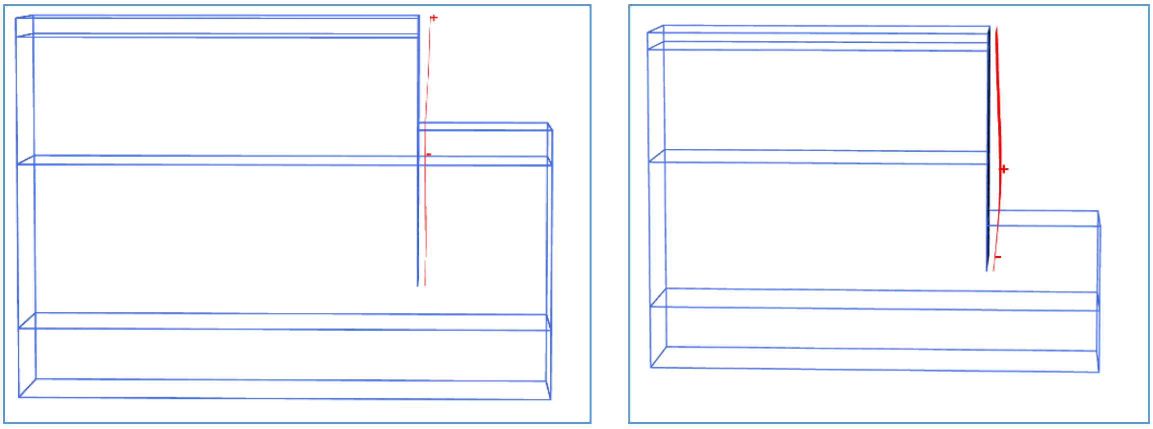
In the presented model, the road load is increased from 10 kPa to 35 kPa as surcharge loads. In addition, a building load of 90 kPa was added behind the roadway. Fig. 7, presents the horizontal deformation graph in the third and final stage. In the third stage, the horizontal deformation value at the top elevation increased from 0.87 mm to 1.78 mm. This result shows that an increase in the amount of deformation is observed with the increase in the surcharge load. In the last calculated stage, the horizontal deformation value at the top elevation increased from 10.81 mm to 22.45 mm. The calculated results are presented in Table 6.



(a) (b)

Fig. 7. (a) 3rd stage horizontal deformations graph, (b) final stage horizontal deformations graph (Source: the authors)

Table 6. Comparison of initial analysis and back analysis horizontal deformations in PLAXIS (Source: the authors)

	Calculated Shoring Top Level Horizontal Deformation Value (mm) (Initial Analysis)	Calculated Shoring Top Level Horizontal Deformation Value (mm) (Back Analysis)
3rd Stage Condition	0.87	1.78
Final Stage Condition	10.81	22.45

3.3.2. Influence of inadequate anchor prestressing on lateral displacements

Even if the analysis are correctly made, some problems may be encountered in the field. One of these problems is that the prestressed anchors cannot take sufficient load. When prestressed anchors fail to take sufficient load, sudden lateral displacements may occur in the area where the inclinometers are located during excavation of a lower stage. If no action is taken to correct the fabrication after these sudden displacements, larger displacements may occur later in the construction which can cause irreversible problems. In order to investigate the deformations, the anchor loads of the first two stages in the model were reduced from 330 kN to 100 kN and the horizontal deformations graph is presented in Fig. 8.

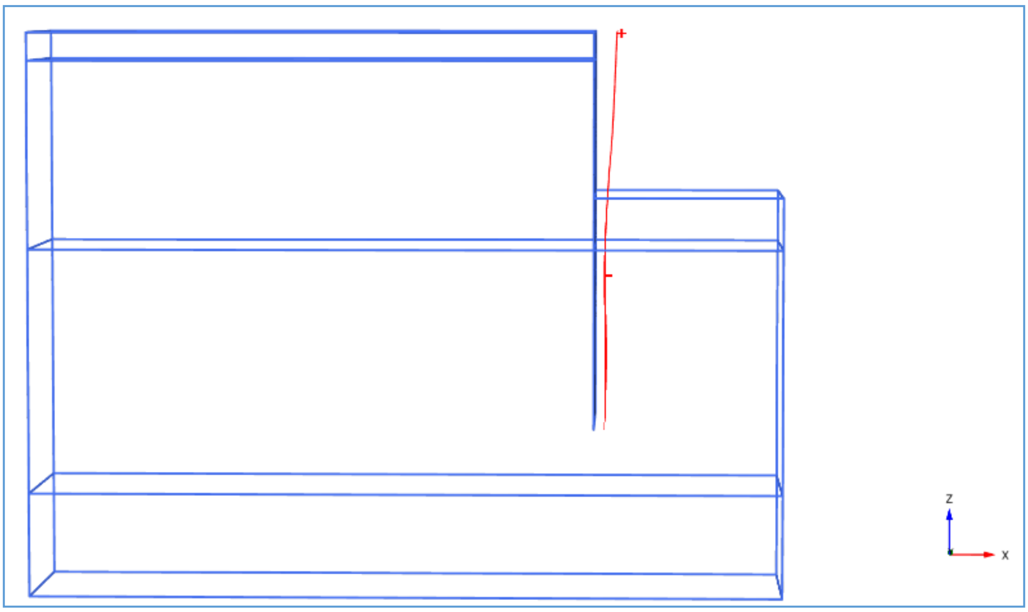


Fig. 8. Horizontal deformation graph in the third stage (Source: the authors)

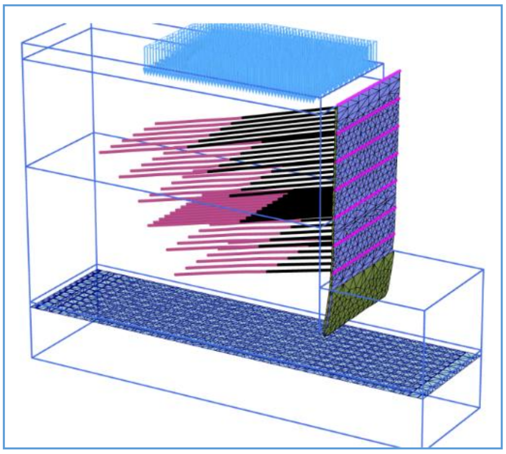
According to the results, the maximum horizontal deformation value was obtained as 2.19 mm in the calculation made in the third stage. This indicates that the inadequate anchorage load increased the deformations. The comparison between the initial analysis and the back analysis is given in Table 7.

Table 7. Horizontal Deformation Comparison of Initial Analysis and Back Analysis (Source: the authors)

	Calculated Shoring Top Level Horizontal Deformation Value (mm) (Initial Analysis)	Calculated Shoring Top Level Horizontal Deformation Value (mm)(Back Analysis)
3rd Stage	0.87	2.19

In order to prevent sudden displacement increases, a 4th stage excavation was made in the relevant section and additional anchors were added at 0.9 m intervals. The visualization of this arrangement in the field and the 3D model in Plaxis program are presented in Fig. 9. After the anchors were subjected to the stressing process, the inclinometer measurements were performed again. The graph of the deformation values obtained is shown in Fig. 10.



(a) (b)

Fig. 9. (a) Field visualization with anchors added to the 4th stage, (b) model with additional anchors in the 4th stage in Plaxis 3D program analysis (Source: the authors)

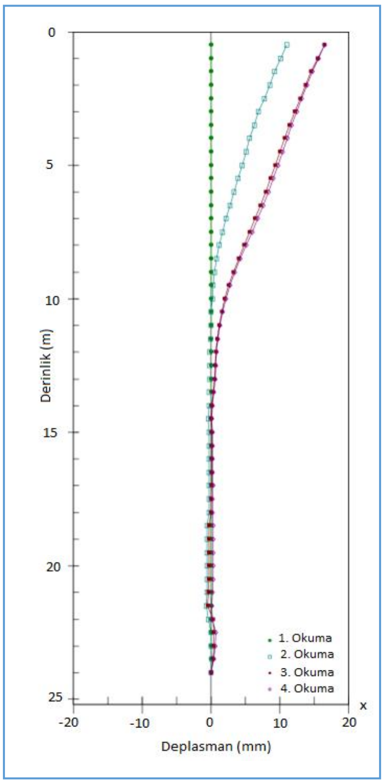


Fig. 10. Horizontal deformation graph depending on excavation depth obtained from inclinometer measurement (Source: the authors)

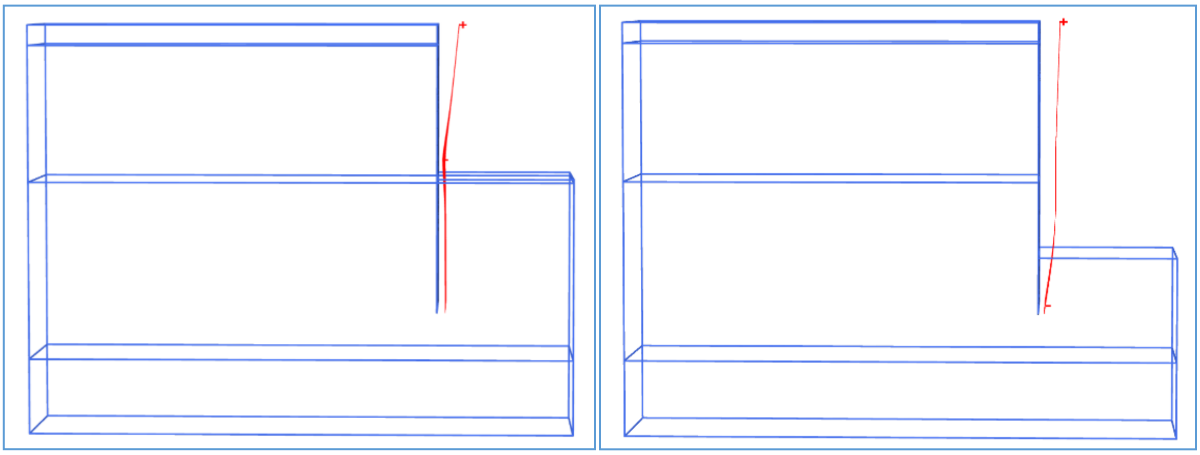
According to the graph in Fig. 10, it is observed that the maximum horizontal displacement value obtained from the inclinometer measurement in the field after the tensioning of the 4th stage anchors remained at the same value as the previous reading. The depth-dependent deformations are presented in Table 8 below.

Table 8. Maximum Horizontal deformations depending on excavation depth obtained from inclinometer measurement (Source: the authors)

Reading Order	Measured Maximum Horizontal Deformation [mm]	Excavation Depth [m]	Deformation Rate [%]
1st Reading	0.00	0.00	0.00
2nd Reading	11.02	6.25	0.17
3rd Reading	16.48	8.75	0.19
4th Reading	16.48	11.25	0.15

In addition, the horizontal deformation value of the top point of the 4th stage shoring system calculated by the finite element method was 3.02 mm and the horizontal deformation of the last stage was 27.78 mm (Fig 11).



(a) (b)

Fig. 11. (a) Horizontal deformations graph in the fourth stage, (b) horizontal deformations graph in the final stage (Source: the authors)

The horizontal deformation values obtained from the back analysis and the inclinometer measurements made in the field gave very similar results. This similarity played an effective role in stopping sudden displacements. Fig. 12 shows the graph of total horizontal deformations obtained from inclinometer measurements. Table 9 presents the calculated deformation value and the measured deformation value and their corresponding deformation ratios.

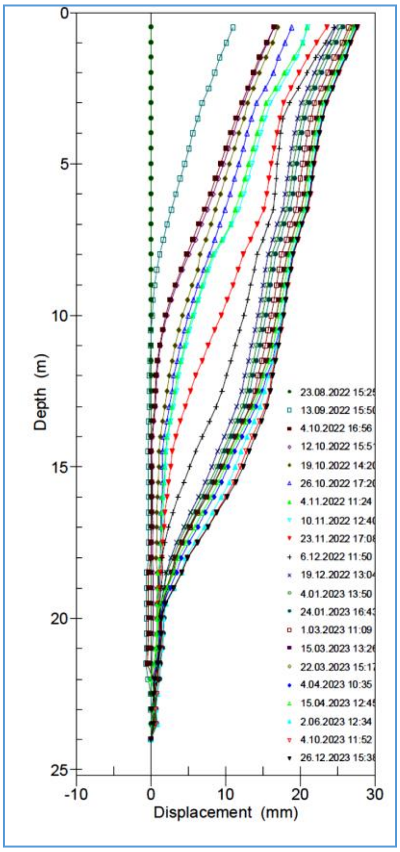


Fig. 12. Horizontal deformations graph of inclinometer final measurement (Source: the authors)

Table 9. Comparison of horizontal displacements calculated with finite elements and measured with inclinometer (Source: the authors)

Section No	Top Level Horizontal Deformation [mm]	Excavation Depth [m]	Deformation Rate [%]
First Analysis Calculated	10.81	16.95	0.06
Back Analysis Calculated	27.78	16.95	0.16
Measured with Inclinometer	27.60	16.95	0.16

The deformations remained at normal values thanks to the additional anchors made in the field. It was understood that increasing the number of anchors was effective in stopping the displacements. This was proved by back analysis.

4. Conclusions

The foregoing study, comprehensively investigated the effectiveness of anchored bored pile shoring systems in deep excavation support projects by comparing numerical modeling and field inclinometer measurements. To do so, the sudden deformations occurring after the third stage excavation were particulariy analyzed and the causes of the deformation increase were investigated in detail through back analysis. In the evaluations made in section-7, which is relatively critical, the performance of the system was compared with both finite element analysis using Plaxis 3D software and field observations.

Results of the analysis are as follows:

- In the initial analysis, the surcharge load was taken as 10 kPa and the horizontal deformation at the last stage of the shoring system was calculated as 10.81 mm. In the back analysis, the surcharge load was increased to 35 kPa and a building load of 90 kPa was added and the deformations increased to 22.45 mm. This result showed that as the surcharge loads increase, the deformation also increases.
- Anchor prestressing loads were taken as 330 kN in the initial model. In the back analysis, when the prestressing load was reduced to 100 kN in the first two stages, the horizontal deformation in the 3rd stage increased to 2.19 mm. Inadequate anchorage loads increased the deformations about three times and showed that the stability of the shoring is directly dependent on these loads.

- After the excavation of the 3rd stage, additional anchors were placed in the 4th stage in order to prevent sudden deformations. After this intervention, the horizontal deformation at the top of the shoring measured with an inclinometer was 27.60 mm and the deformation calculated by the finite element method was 27.78 mm. Since the measured values were close to each other, it has proven that the intervention is effective.
- In order to ensure safe and economical design of shoring systems, it is critical to include the correct surcharge loads in the model during the design phase. It is also recommended to place the anchors correctly while carefully monitoring their stresses during the implementation process.
- Regular deformation monitoring by instrumental observations (especially inclinometer measurements) throughout the construction process is critical for early detection of potential risks and timely interventions in the field.

Evaluated numerical modeling and field measurements presented this study, combinedly with the defined main criteria that should be considered in the safe design and implementation of deep excavation support systems helped provide important guildlines to the design and implementation phases of similar future projects.

Abstract. The rapid depletion of natural resources and the increase in waste materials have highlighted the importance of research on recycling and sustainability. The use of demolition waste instead of natural aggregate in civil engineering fields, might contribute to sustainability. In this study, the reusability of demolition waste in under-road drainage systems was investigated. In the laboratory experiments, long-term filtration performance and clogging behavior of drainage systems using natural aggregate (NA), recycled concrete aggregate (RCA), recycled asphalt aggregate (RAP) and non-woven geotextile materials were observed. For this purpose, long-term filtration tests (LFT) of aggregate-geotextile systems were performed in the long-term filtration test apparatus developed in accordance with ASTM D5101 standard. The enhanced LFT tests were performed at hydraulic gradient of i =0.33, simulating practical conditions. Throughout the experiment, the hydraulic gradient ratio (GR) and permeability ratio (KR) values of the system were determined at different hydraulic gradients. Depending on these parameters, the filtration performance and clogging behavior of the system were analyzed. The migration of fine particles from in the upper layers to lower layers was evaluated based on gravity, the structural condition of the sample and the direction of water flow. The experimental results indicates that the performance of demolition wastes met the standard criteria. Reusing recycled materials will help address the issue of waste material storage while also contributing to the preservation of national resources and environmental protection.

Keywords: Recycled aggregate; Geotextile; Long-term filtration; Sustainability

1. Introduction

Technological advancements and the rapid growth of population have led to an increase in both the quantity and diversity of needs, significantly raising consumption levels. Although a linear relationship existed between resource use and the level of development in the past century, recent studies have shown that the presence of natural resources in countries can pose environmental threats if not managed with an adequate level of awareness (Kernera et al., 2023; Onifade et al., 2023). The level of consumption reached has prompted governments to develop policies aimed at reducing the use of natural resources, and studies have shown that these policies have been effective in mitigating environmental threats (Lv & Guo, 2025; Zhao et al., 2024).

The construction sector also plays a significant role in the increase in natural resource consumption (Schiller & Roscher, 2023; Evci et al., 2024). It is projected that 2.2 billion tons of construction and demolition waste will be generated globally within the next nine years, necessitating a reevaluation of traditional methods. To reduce construction waste—which poses a significant environmental problem especially in developing countries—it is essential to limit the use of natural resources, integrate technological innovations into the sector, and ensure that sustainable practices developed under the circular economy approach are implemented in practice, not just in theory (Saroosh & Khan, 2024; Hasselsteen et al., 2024; Wu et al., 2025).

To promote sustainability in the construction sector and minimize the use of natural resources, a variety of strategies have been adopted to reutilize construction and demolition wastes, including recycled concrete aggregate (RCA), reclaimed asphalt pavement (RAP), steel slag, glass, wood, brick, tire ash, and plastic waste (Simões dos Reis et al., 2021; Akponovo & Onyebuchukwu, 2023).

In subgrade drainage applications, the selection of appropriate materials for the fill layer and ensuring proper gradation particularly determining the amount of fine particles are critically important for achieving sufficient hydraulic conductivity, enabling effective drainage, and extending the service life of the road (Kavitha et al., 2024).

* Corresponding author, E-mail: ustarume@gmail.com

https://doi.org/10.31462/icearc2025_ce_geo_395

Recycled concrete aggregate (RCA) is considered a viable alternative to natural aggregate for use as subgrade drainage fill material (Meddah et al., 2020; Neupane et al., 2025). RCA exhibits characteristics similar to those of conventional crushed aggregates in terms of water absorption, California Bearing Ratio (CBR), cohesion, and elastic modulus (Arulrajah et al., 2012), as well as permeability, compressibility, and mechanical properties (Shrinidhi et al., 2025). Moreover, its performance in long-term filtration tests involving geotextile materials has also been shown to be comparable (Bilgen et al., 2020).

Another material investigated as an alternative to natural aggregate in subgrade drainage systems is reclaimed asphalt pavement (RAP). Li et al. (2023) stated that issues related to agglomeration and gradation variability in RAP can be mitigated by subjecting the material to a fine crushing and screening process. Furthermore, long-term filtration tests conducted by Sarıahmetoğlu et al. (2020) demonstrated that, when the bitumen content in RAP is properly controlled, it can exhibit performance comparable to natural aggregate, thereby serving as a viable alternative material.

In this study, long-term filtration tests (LFT) were conducted using a test system designed and developed in accordance with the ASTM D5101 standard, under a hydraulic gradient of $i = 0.33$, to investigate the clogging and filtration performance of construction and demolition waste materials. Within the scope of the research, the filtration and clogging behavior of recycled concrete aggregate–geotextile and recycled asphalt aggregate–geotextile systems were compared with the performance of natural aggregate–geotextile systems. This comparison aimed to support existing literature and promote the use of construction waste materials as an alternative to natural resources.

2. Materials

2.1. Aggregates

In this study, long-term filtration tests were conducted in accordance with ASTM D5101, using natural aggregate as well as recycled concrete aggregate (RCA) and recycled asphalt pavement (RAP) derived from construction and demolition waste for drainage applications (Fig 1). The materials were oven-dried for 24 hours and then tested using a pycnometer and Standard Proctor test in accordance with ASTM D698-12 (Table 1). The remaining materials were then stored under appropriate conditions until the preparation stage of the filtration specimens.

Table 1. Results of the above mentioned experiments

Aggregate Type	p_s (g/cm^3)	MDD (kN/m^3)	W_{opt} (%)
NA1	2.79	22.5	8.45
RCA1	2.44	13.8	22.10
RAP1	2.13	17.5	10.5

Fig 1. Aggregates; (a) Natural Aggregate, (b) Recycled Concrete Aggregate, (c) Reclaimed Asphalt Pavement

2.2. Geotextile

The selection of an appropriate nonwoven geotextile for filtration applications is crucial for the performance of the drainage system. The apparent opening size (AOS) and vertical permeability values ensure that the geotextile functions effectively as a filtration material. While maintaining the stability of the system, the geotextile should allow the passage of water but prevent clogging and blocking. An incorrect geotextile selection can lead to a decrease in system permeability and a reduction in the particle size of the material. In this study, a polypropylene nonwoven geotextile with an opening size of 0.095 mm (Fig 2.) was used, and the properties of the material are presented in the table 2.

Table 2. Properties of the geotextile

Properties	Unit	Test Standard	GT
Mass per Unit Area	g/m²	EN ISO 9864	200 (±40)

Fig 2. Geotextile

3. Methods

In this study, the specimens were prepared and subjected to a long-term filtration test under a hydraulic gradient of i = 0.33. Based on the data obtained, the gradient ratio (GR) and the permeability ratio (KR) parameters were determined, and the physical clogging mechanisms were identified and analyzed.

For the execution of the experiments, natural aggregate (NA), recycled concrete aggregate (RCA), and recycled asphalt pavement (RAP) were initially procured. Each material was separately subjected to sieving and stored based on the resulting particle size. Following the sieve analysis, the aggregates were sorted by type and particle size and stored under appropriate conditions. For each aggregate type, a Standard Proctor test was conducted in accordance with ASTM D698-12 to determine the optimum moisture content of the sample. Specimen's recipe given at table 3.

Table 3. Specimen recipe

Sieve No	10	18	30	40	50	70	100	Pan
% Retained	10	15	9	14	13	19	10	10

Long-term filtration tests were conducted on the experimental system, as specified in the ASTM D5101 standard, which has been further developed and redesigned. The system was used to examine the permeability performance of the drainage layer formed by non-plastic aggregates (PI<5%) and geotextile. In this system, the size of the sample chamber and the number of manometers in the middle chamber of the standard long-term filtration test system have been increased to ensure more accurate determination of the GR and KR values. This adjustment was made to ensure that the data obtained from the experiment is more consistent with field application data. Based on the maximum particle size of the aggregate used in the experiment, cylindrical samples with a diameter of 150 mm and a height of 150 mm were employed.

Additionally, in the improved system utilized in this project, a manometer port was added at a height of 125 mm, supplementing the existing manometers positioned at 25 mm and 75 mm above the geotextile layer, as in the standard system (Fig 3).

After the sample was placed into the system, the lower, middle, and upper assembly processes were completed using silicone, and the system was left for one day to ensure its impermeability. After performing the necessary checks, the connections of the water inlet and outlet reservoirs were established. To achieve the system's water saturation, water was introduced through the lower port and the system was left for approximately 3–4 days. By introducing water from the bottom, potential particle movement from the upper part of the sample towards the geotextile was prevented before the experiment began. Once the system reached saturation, the water was introduced from the top, and the LFT was initiated (Fig 4).

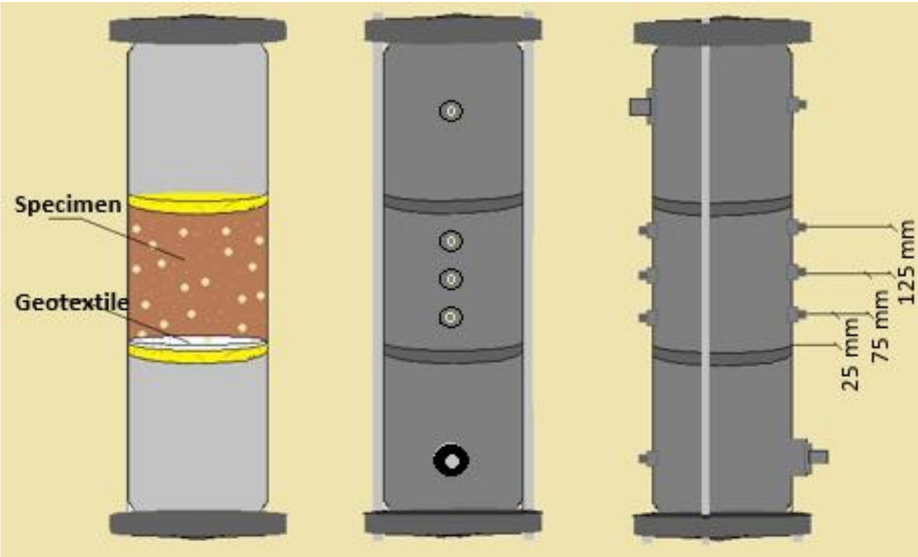

Fig 3. Demonstration of enhanced lft

Fig 4. Experimental system

The system was adjusted to a hydraulic gradient (i) of 0.33, and readings were taken from the manometers. Following the readings, the flow of water was measured and recorded in the prepared tables. Based on these values, the hydraulic gradient ratio (GR) and permeability ratio (KR) were calculated, and their relationship was determined.

The data obtained from the readings of manometers placed at different heights were used in the formulas provided in Equations 1-4 to calculate the GR values.

$$GR_1 = \frac{i_{0-25}}{i_{25-75}} = 2 \times \frac{h_{25} - h_0}{h_{75} - h_{25}} \tag{1}$$

$$GR_2 = \frac{i_{25-75}}{i_{75-125}} = \frac{h_{75} - h_{25}}{h_{125} - h_{75}} \tag{2}$$

$$GR_3 = \frac{i_{0-25}}{i_{25-125}} = 4 \times \frac{h_{25} - h_0}{h_{125} - h_{25}} \tag{3}$$

$$GR_4 = \frac{GR_1 + GR_2}{2} \tag{4}$$

h_0, h_{25}, h_{75}, h_{125} : Manometer readings at different heights,
i : hydraulic gradient.

The KR parameter provided in the ASTM D 5101 Standard (Equation 5) is defined as the ratio of the aggregate permeability coefficient (Equation 6) to the system permeability coefficient (Equation 7) (Sarıahmetoğlu, 2021).

$$KR = \frac{k_{aggregate}}{k_{system}} \tag{5}$$

$$k_{system} = \frac{Q}{A \times t} \times \frac{1}{i_{system}} \times \frac{\mu_T}{\mu_{20}} = \frac{Q}{A \times t} \times \frac{l}{h_{150} - h_0} \times \frac{\mu_T}{\mu_{20}} \tag{6}$$

$$k_{aggregate} = \frac{Q}{A \times t} \times \frac{1}{(U_{avg} - A_{avg})} \times \frac{\mu_T}{\mu_{20}} \tag{7}$$

k_{system} : The permeability value of the system at 20°C is, (cm/s),
Q : The accumulated flow volume at time t, (cm^3),
i : Hydraulic gradient,
A : Cross-sectional area of the sample, (cm^2),
t : The time required to collect the amount of drained water, Q (s),
μ_T : The viscosity of water at temperature T.
μ_{20} : The viscosity of water at 20°C,
l : The length of the sample,
U_{avg} : The average of the upper manometer readings,
A_{avg} : The average of the lower manometer readings.

4. Results and discussion

In the experimental setup established based on the ASTM D5101 standard, a geotextile–aggregate system was formed using three different material types: natural aggregate, recycled concrete aggregate, and reclaimed asphalt pavement. Long-term filtration tests were conducted under a hydraulic gradient of i = 0.33. The experimental data obtained were evaluated in accordance with the GR (Gradient Ratio) and KR (Permeability Ratio) criteria defined in the aforementioned standard. A precise analysis of the filtration performance of the materials was carried out by comparing the GR values calculated from manometer readings taken at different levels.

According to the ASTM D5101 standard, a GR value equal to 1 in a geotextile–aggregate system indicates that there is no flow restriction or clogging within the system. A GR value greater than 1 implies that particle migration has started in the direction of water flow, indicating increased clogging and a reduction in flow rate. Conversely, a GR value less than 1 suggests that fine particles have passed through the geotextile, potentially leading to piping, which subsequently increases the water flow through the system.

The time-dependent GR (Fig 5) and KR (Fig 6) values of the natural aggregates are provided. From the graphs, it can be observed that the GR values fall within the range of $1 < GR < 3$. These values indicate the occurrence of clogging in the system. Furthermore, the KR values also support this observation.

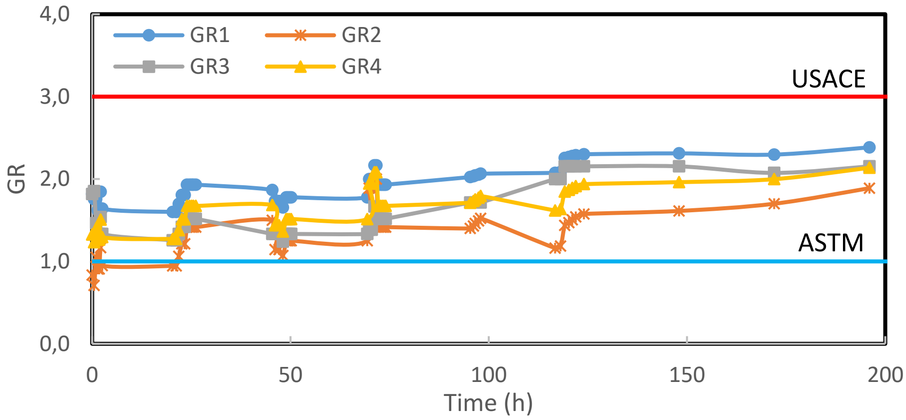

Fig 5. Time-dependent GR values of NA

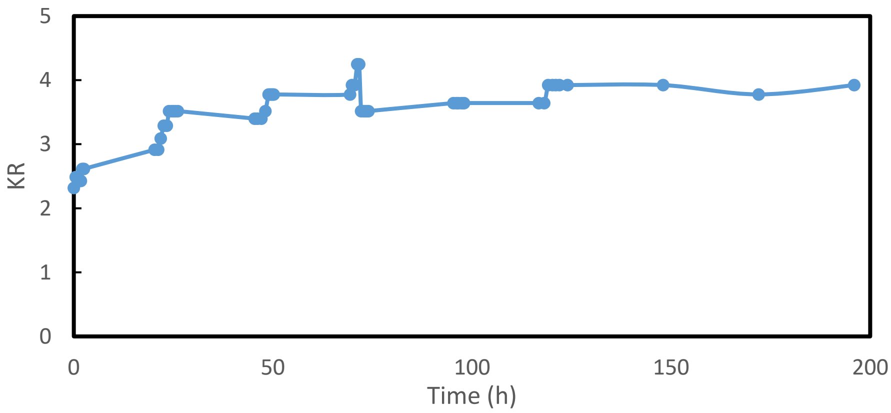

Fig 6. Time-dependent KR values of NA

Below are the time-dependent GR (Fig 7) and KR (Fig 8) graphs for RCA. As seen in the graph, it can be stated that partial clogging has started for RCA. However, it can be observed that RCA yields better results compared to NA.

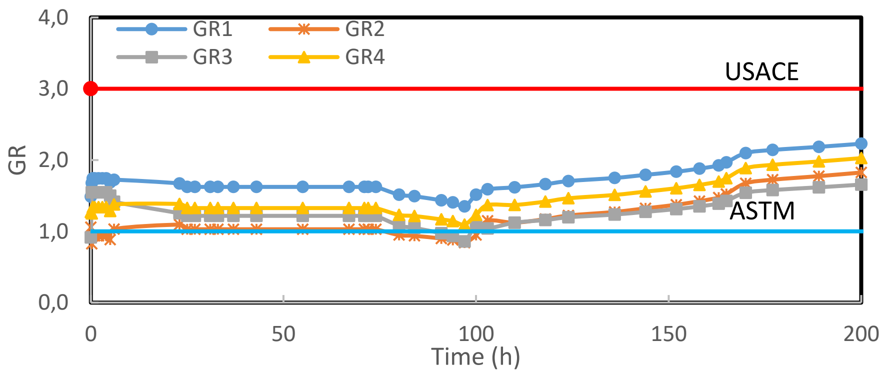

Fig 7. Time-dependent variation of GR values for RCA

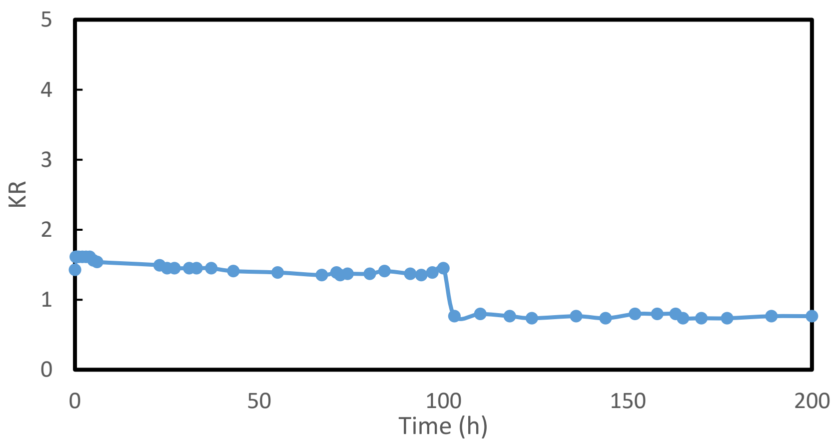

Fig 8. Time-dependent variation of the KR value for RCA

The GR and KR values of RAP are presented in Fig. 9 and Fig. 10. The obtained values show that the GR and KR parameters support each other. G1, GR3, and G4 values remain above the 1 threshold, indicating clogging, while the GR2 value signifies the possibility of piping.

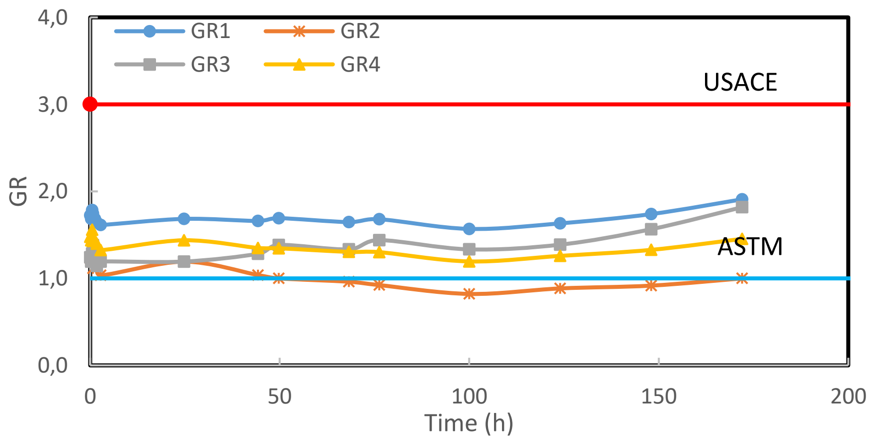

Fig 9. Time-dependent variation of GR values for RAP

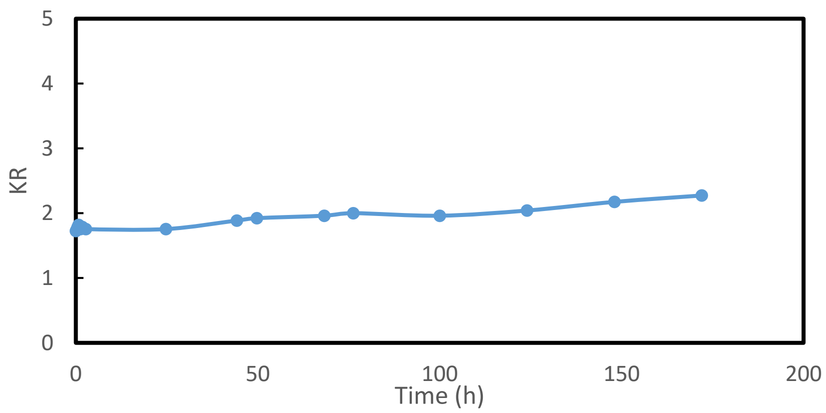

Fig 10. Time-dependent variation of the KR value for RAP

5. Conclusion

To evaluate and compare filtration performance of different aggregates (natural or recycled) an enhanced long term filtration test system was redesigned and custom-manufactured in accordance with ASTM D5101 standard. Based on the data obtained from the experiment, the following conclusions can be derived:

- Under low hydraulic gradient conditions, systems exhibited GR values below the critical clogging threshold of 3, confirming their suitability for use as drainage materials in systems with low hydraulic gradients.
- GR values exceed 1, indicating a tendency toward time-dependent clogging.
- Although the GR value of the system with natural aggregates remained within acceptable limits, the KR values exceeded the critical threshold. In terms of filtration performance, the system with natural aggregates demonstrated the lowest capacity.
- The use of suitable recycled materials instead of natural material is considered to contribute to sustainability and circular economy.

Abstract. Cemented paste backfill (CPB) are widely used for safe disposal and stability drives of environmentally hazardous mine tailings. However, the economic and environmental concerns associated with cement consumption have highlighted the need for alternative materials. This study explores the potential of tea waste, a type of agricultural byproduct, as a substitute in CPB. The research focused on evaluating the performance of CPB mixtures with a fixed solid-to-cement ratio (70/5 by weight), using metal mine wastes and varying curing times. Various tea wastes, including tea production powder waste, brewed tea waste and tea fiber were incorporated into the filling mixtures, replacing 10% by weight of the cement content. Uniaxial compressive strength (UCS) and three point flexural tests were conducted to assess the mechanical properties, while scanning electron microscopy (SEM) were employed to analyze the microstructural changes. The results highlighted significant differences between each types of tea waste, with each having distinct effects on backfill performance. The study provides a comparative analysis of their impact on the strength and overall filling performance. In conclusion, the findings demonstrate that tea waste can be effectively utilized as a partial replacement for cement in CPB mixtures, offering a sustainable solution to reduce environmental damage by recycling agricultural waste while improving mine tailings management..

Keywords: Cementitious fills; Tailings-tea waste; Strength behaviour; Microstructure

1. Introduction

Mine tailings constitute an inevitable byproduct of mineral extraction processes, with their volume varying considerably depending on the scale of resource recovery (Adewuyi et al., 2024). Large-scale mining operations, in particular, generate substantial quantities of tailings, the management of which presents significant environmental challenges. Due to the presence of heavy metals and toxic substances, mine tailings have the potential to contaminate soil and water resources, thereby disrupting ecosystems, threatening biodiversity, and posing long-term risks to human health (Kasap et al., 2022). Accordingly, the development and implementation of comprehensive and strategic tailings management practices are imperative to mitigate these adverse environmental impacts. Globally, the annual generation of mine tailings is estimated to be in the billions of tons (Araya et al., 2021). The extraction of valuable metals such as coal, gold, and copper is especially associated with the production of extensive volumes of tailings. For instance, copper mining alone results in the generation of hundreds of millions of tons of tailings each year, a portion of which contains hazardous chemical components that contribute to environmental degradation (Hassan et al., 2024). Consequently, the formulation of effective tailings management and recycling strategies is of paramount importance. In this context, the Cemented paste backfill (CPB) method has emerged as a widely adopted and innovative approach for the sustainable disposal and utilization of mine tailings.

CPB method is primarily employed to fill voids and fractures within underground mining operations. This technique involves the preparation of a backfill mixture composed of mine tailings (70–85 wt.%), cement (3–7 wt.%), water, and various chemical additives, ensuring adequate flowability for effective placement (Guner et al., 2023). By occupying the spaces created during mining, this backfill enhances the structural integrity of underground workings and significantly mitigates the risk of ground subsidence or collapse. Moreover, CPB contributes to improved mining efficiency, restricts the ingress of water into subterranean systems, and minimizes environmental impacts associated with tailings disposal (Sari et al., 2023). Upon hardening, the CPB mixture exhibits high mechanical strength and durability, offering long-term geotechnical support and fostering the sustainability of mining operations. Despite its advantages, the relatively high cement content required for CPB

* Corresponding author, E-mail: erol.yilmaz@erdogan.edu.tr

https://doi.org/10.31462/icearc2025_ce_geo_607

poses economic challenges for mining companies, prompting ongoing research into cost-effective alternative binders or additives (Saedi et al., 2021). In this regard, tea waste—an agricultural byproduct—has emerged as a potential sustainable additive for use in CPB formulations.

Tea, a widely consumed herbal beverage, is derived from the processed and dried leaves of Camellia sinensis L. Originally cultivated in China and India, tea is currently grown in geographically limited regions due to the specific climatic conditions required for the plant's growth. The majority of global tea cultivation and consumption is concentrated in Asia (Yazici & Goksu, 2017). Additionally, several tropical African countries—including Kenya, Malawi, Rwanda, Tanzania, and Uganda—also contribute significantly to global tea production. Nations such as China, India, Sri Lanka, and Kenya are among the leading producers, with China alone accounting for approximately 64% of the total global tea cultivation area and 49% of overall tea production (FAO, 2023). Türkiye ranks eighth globally in terms of tea cultivation area, with approximately 82,000 hectares, and fourth in production, yielding about 1.45 million tons annually. In Türkiye, tea is cultivated in the humid, rainy, and high-altitude foothills of the Eastern Black Sea region, characterized by rugged topography. Tea is one of the most significant agricultural commodities in Türkiye and plays a critical role in the regional economy. The principal tea-producing provinces include Rize, Trabzon, Artvin, and Giresun. The tea harvest typically begins in the spring, and the freshly picked leaves are processed without delay. Although tea processing methods vary depending on the desired product, in Türkiye, tea is predominantly processed into black tea through a series of stages, including withering, CTC (crush, tear, curl), fermentation (oxidation), drying (baking), and sorting (as illustrated in Figure 1).

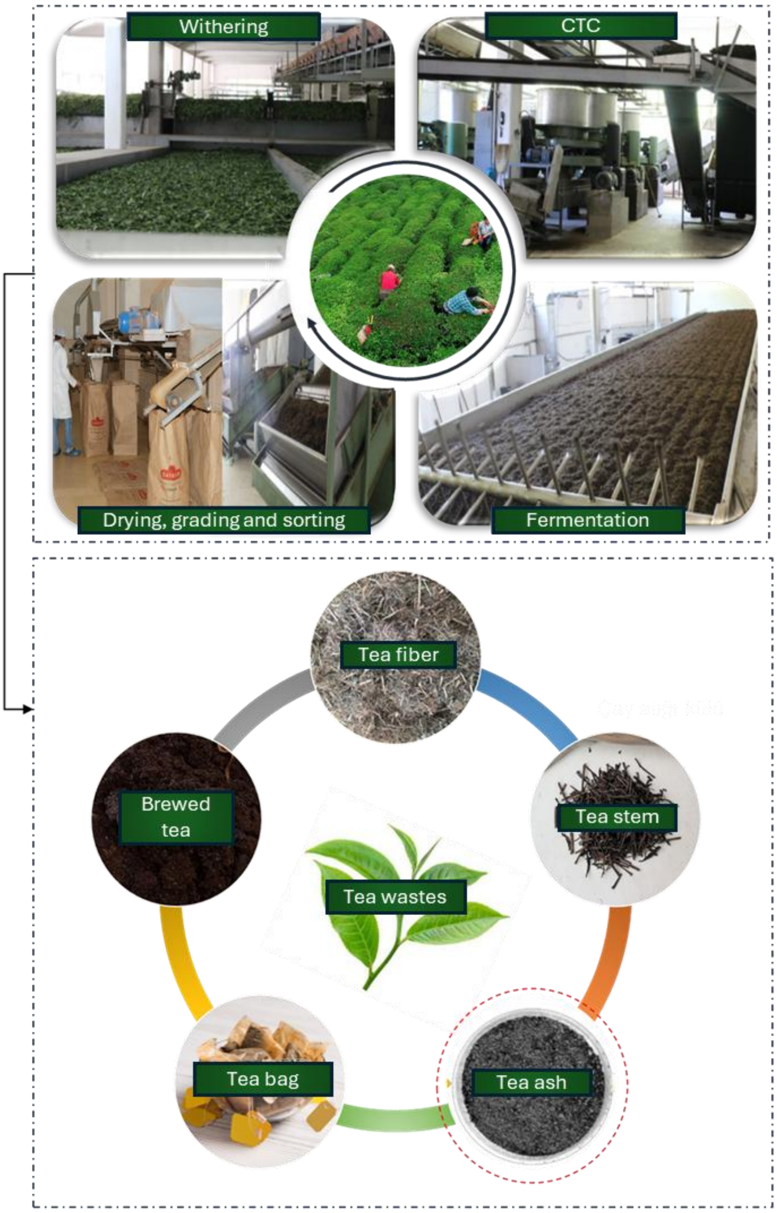

Fig. 1. Production process of tea waste

The growing global demand for tea has led to a significant increase in tea consumption, which in turn contributes to the generation of considerable amounts of tea waste—primarily consisting of leaves, stems, and buds. Annually, the volume of tea waste produced worldwide is estimated to reach approximately 5 million tons (Debnath et al., 2021). In Türkiye's Eastern Black Sea region, where tea cultivation is a major agricultural activity, the waste generated during the production process predominantly originates from the by-products of tea leaf processing. These wastes are primarily composed of organic matter, fibers, and fine particulate material. The substantial quantities of tea waste produced by the active tea industry present challenges in terms of both storage and environmental management, potentially contributing to issues such as erosion, and soil and water pollution (Wang et al., 2024). As a result, there is a pressing need for sustainable and effective disposal methods. In this context, the utilization of tea waste within the backfill process presents a promising solution, offering potential environmental and operational benefits.

Various studies in the literature have explored the utilization of agricultural and organic wastes—primarily in the form of ash or fiber—as alternative materials in cemented paste backfill applications. For instance, Qi et al. (2022) investigated the use of corn straw ash, derived from biomass combustion, as a partial replacement for cement and fly ash in CPB mixtures intended for coal mine applications. Their findings indicated that the incorporation of corn straw ash, at substitution rates ranging from 0 to 40 wt.%, enhanced the setting time, water retention, and flowability of the backfill. Similarly, Jin et al. (2024) evaluated ashes obtained from agricultural residues such as corn straw, peanut shells, and wood chips in self-compacting backfill mixtures. Their research focused on the durability of these materials under freeze-thaw conditions and prolonged sulfate exposure, concluding that optimal performance was achieved at a water-to-binder ratio of 0.6. Liu et al. (2023) examined the replacement of cement with rice straw ash in various binder proportions and observed that its inclusion improved the shear strength and refined the microstructure of the backfill through the generation of supplementary hydration products. Additionally, Wang et al. (2023) incorporated corn straw fibers (1–3% by mass of coarse aggregates) into cemented coal gangue backfills to enhance mechanical properties. Their results demonstrated that fiber additions of 1–2% notably improved the mechanical performance during early curing stages. Pan et al. (2024) employed alkali-treated rice straw fibers in lithium mica tailings backfills and reported that the highest unconfined compressive strength (UCS) and Brazilian tensile strength values were achieved at optimal fiber contents of 0.15% and 0.60%, respectively.

A review of the existing literature reveals that organic additives have been incorporated into cement-based mixtures for a variety of purposes, and numerous studies have been conducted in this field. Notably, a significant portion of these researches focuses on reducing cement-related costs while producing high-quality materials through the use of more economical and sustainable alternatives. However, despite the growing interest in organic waste utilization, no studies have been identified that examine the application of tea waste in cemented paste backfill systems. This research aims to address this gap by investigating the potential use of tea waste in CPB mixtures. Specifically, the study evaluates the effects of tea production waste from factories—both in powder and fiber form—as well as brewed tea waste on the performance of CPB mixtures. The effectiveness of these additives was assessed through mechanical testing, including uniaxial compressive strength (UCS) and flexural strength (via three-point bending tests), as well as microstructural analysis using scanning electron microscopy (SEM). The results obtained provide new insights into the viability of tea waste as a sustainable additive in CPB applications.

2. Materials and methods

2.1. Ingredients

The metal mine tailings used in the preparation of the backfill mixtures were obtained from a mining operation located in the northern region of Türkiye, which engages in both underground and open-pit mining activities. The primary binder material, CEM I 42.5R Portland cement, was sourced from production facilities situated near the Black Sea, in proximity to the mining site. Tap water was also used as mixing water in CPB mixture. To characterize the physical properties of the mine tailings, several analytical instruments were employed: particle size distribution was determined using a Malvern Mastersizer, specific gravity was measured with a Quantachrome Ultrapyc 1200e helium gas pycnometer, and specific surface area was assessed via BET analysis using Quantachrome's Quadrosorb SI device. The detailed results of these measurements are presented in Table 1.

Furthermore, the chemical composition of the tailings was analyzed using X-ray fluorescence (XRF) spectrometry with the PANalytical Zetium instrument, revealing that the predominant oxidized component was ferric oxide (Fe_2O_3), comprising 38.52% of the total composition.,

Tea wastes utilized in this study comprised tea powder waste (TP) and tea fiber waste (TF), both obtained from the final production stages of black tea processing facilities operated under the General Directorate of Tea Enterprises (ÇAYKUR), as well as dried brewed tea waste (TB). These materials were incorporated into the CPB mixtures as illustrated in Figure 2. Prior to use, TP and TB were sieved to ensure particle sizes below 250 µm, whereas TF was incorporated into the mixtures in fiber form with a uniform length of 10 mm.

Table 1 Physical and chemical properties of tailings

Physical characteristics of mine tailings						
Specific surface (S_s), m^2/g	Specific gravity (G_s)	D_{10} (μm)	D_{30} (μm)	D_{60} (μm)	Uniformity coefficient, (C_u)	Curvature coefficient, (C_c)
2.78	3.63	7.30	26.40	57.30	7.85	1.67
Main chemical components of mine tailings (%)						
SiO_2	Fe_2O_3	CaO	MgO	Al_2O_3	K_2O	SO_3
28.65	38.52	4.85	2.08	8.32	0.37	0.81

2.2. CPB preparation and mix design

Cemented paste backfill samples were prepared under controlled laboratory conditions with a constant solid content of 70% by weight and a cement content of 5% by weight. To evaluate the influence of tea waste on the performance of the backfill, 10% of the cement mass was replaced with tea waste in the CPB mixtures. The mixture designs are detailed in Table 2. For each curing period, three replicate samples were produced for subsequent slump and mechanical strength testing. The constituent materials were accurately weighed using a precision scale and thoroughly blended in a 10-liter laboratory mixer to ensure homogeneity. The resulting mixtures were cast into cylindrical molds (diameter × height: 5 × 10 cm) for uniaxial compressive strength testing and prismatic molds (40 × 40 × 160 mm) for three-point bending tests. All specimens were cured in a controlled chamber maintained at 22 ± 3 °C temperature and 90 ± 5% relative humidity for durations ranging from 3 to 28 days. It is important to note that tea fiber waste was utilized exclusively in the prismatic samples designated for bending tests. The materials employed in the study and the preparation process of the CPB mixtures are illustrated in Figure 2.

Table 2 CPB recipe design

Samples	Solid content (wt. %)	Binder dosage (wt. %)	Slump (cm)	Mixture ratio (%)		Curin tme (days)
				CEM I 42.5R	Tea waste	
CPB@C1	70	5	21	100	-	3, 7, 14, 28
CPB@TB	70	5	21	90	10	3, 7, 14, 28
CPB@TP	70	5	21	90	10	3, 7, 14, 28
CPB@C2	70	5	21	90	10	7, 14, 28
CPB@TF	70	5	21	90	10	7, 14, 28

C: control; TB: brewed tea waste; TP: tea production waste; TF: tea fiber

2.3. Methods

The fluidity of the CPB mixtures was assessed using a mini slump test, employing a cone with a height of 15 cm, in accordance with the ASTM C143 standard. The use of the mini slump cone, as opposed to the conventional Abram's slump cone (30 cm in height), offered significant advantages in terms of both material efficiency and time savings during testing. Furthermore, a correlation was established between the results obtained using the mini slump cone and those from the standard cone. Based on this correlation coefficient, the mini slump cone was adopted for subsequent tests to enable rapid and reliable estimation of the target slump values throughout the study.

The uniaxial compressive strength (UCS) and corresponding stress–strain relationships of the CPB samples were determined in accordance with the ASTM C39 standard. Testing was conducted using a servo motor-controlled UTEST Multiplex testing machine, which has a load capacity of 50 kN and operates at a constant displacement rate of 1 mm/min. Additionally, three-point bending tests were performed to evaluate the flexural strength of the backfill specimens. Prismatic samples prepared for bending tests were positioned on the testing apparatus with a span length of 100 mm between the supports, and the measurements were subsequently carried out under controlled conditions.

To gain a clearer understanding of the pore structure and hydration products formed within the CPB samples following mechanical testing, Scanning Electron Microscopy (SEM) analyses were conducted using a JEOL JSM-6510 device. Polished sections were prepared from regions near the center of the specimens to ensure representative microstructural characterization. The SEM instrument operated with a resolution of 3 nm, a magnification range of 5× to 1,000,000×, an electron emission current of 0.9 nA, and an acceleration voltage of 20 kV.

Fig. 2. CPB preparation phases: a) main ingredients, b) mixing, casting and curing, c) testing

3. Results and Discussions

3.1. Impact of tea wastes (TP and TB) on the ucs performance of CPB

The influence of tea production waste (sieved tea powder waste, TP) and brewed tea waste (dried and sieved, TB) on the uniaxial compressive strength (UCS) of the CPB mixtures is illustrated in Figure 3. As shown, the highest UCS values at all curing intervals were observed in the control samples (CPB@C1). Specifically, CPB@C1 exhibited a compressive strength of 0.36 MPa at 3 days and increased to 0.83 MPa at 28 days. Similar to the control, mixtures containing TP and TB (CPB@TP and CPB@TB) demonstrated progressive strength development with extended curing time.

However, the replacement of 10% cement by mass with tea waste resulted in a noticeable reduction in strength compared to the control. For instance, at 14 days of curing, CPB@C1 achieved a strength of 0.72 MPa, whereas CPB@TB and CPB@TP reached 0.62 MPa and 0.44 MPa, respectively. The variation in UCS performance between the two tea waste types may be attributed to the surface properties of the materials. In particular, the washing of brewed tea waste likely removes impurities and surface-bound particles that could interfere with particle bonding, thus enhancing the contact surface and contributing to improved strength relative to TP.

3.2. Evaluation of tea fiber waste (TF) influence on the flexural strength of CPB

The results obtained from the three-point bending tests conducted on CPB mixtures incorporating tea fiber waste (1 cm length) are presented in Figure 4. It was clearly observed that the flexural strength of all mixtures increased with extended curing time. After 7 days of curing, the control samples (CPB@C2) exhibited a flexural strength of 0.32 MPa, whereas the CPB@TF samples reached 0.28 MPa. This trend continued over time, with flexural strength values increasing notably after 14 days of curing. At 28 days, the flexural strengths of CPB@C2 and CPB@TF were recorded as 0.48 MPa and 0.51 MPa, respectively.

These results indicate that the inclusion of tea fiber waste contributes to enhanced flexural performance over time. This improvement can be attributed to the interaction between the hydration products and the fiber surfaces, which likely promotes better bonding and modifies the internal pore structure of the matrix, thereby improving crack resistance and overall bending performance.

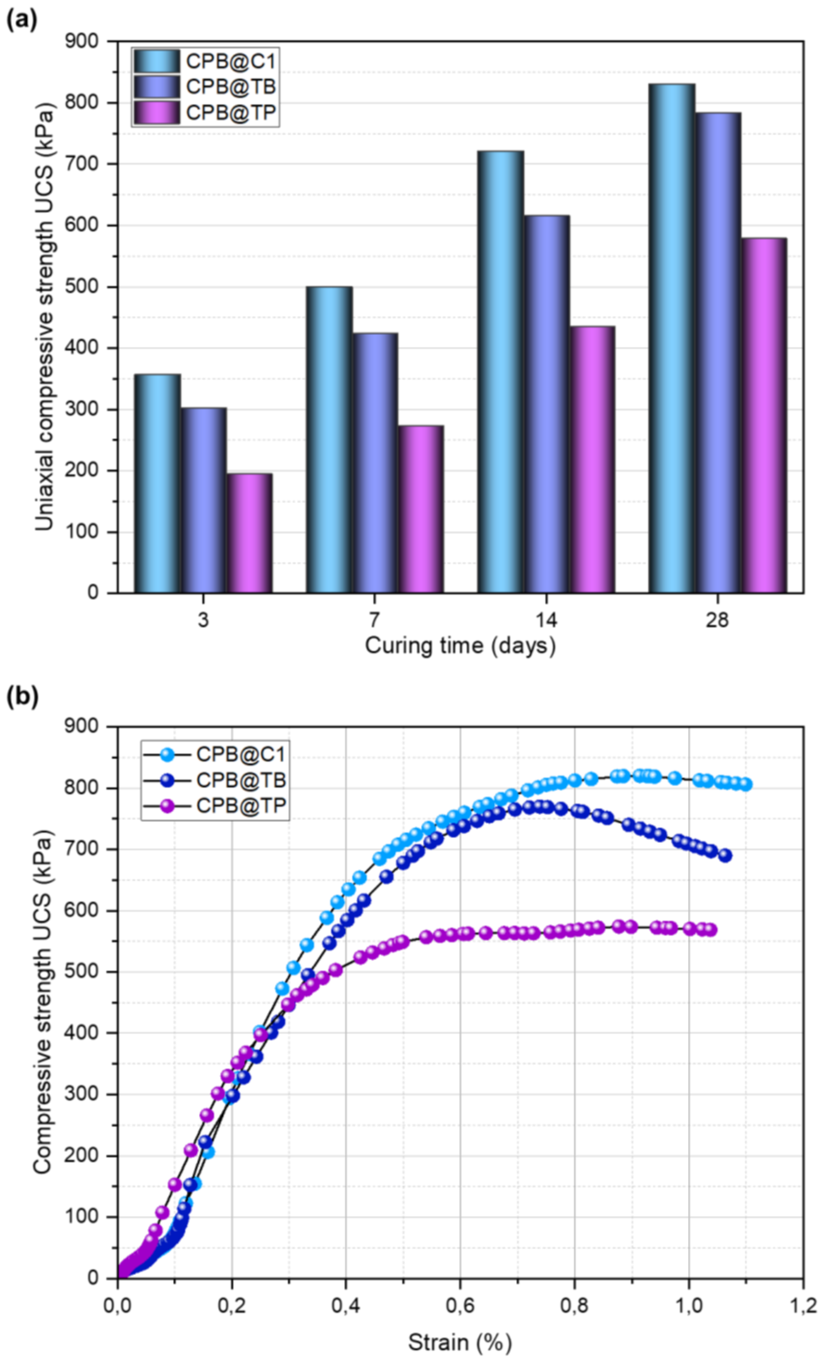

Fig. 3. UCS-curing time plots of CPBs and (b)stress–strain curves of 28-day cured samples

3.3. Results of scanning electron microscopy (SEM)

Scanning electron microscopy (SEM) analyses were conducted to evaluate the influence of tea waste on the hydration process and pore structure of the CPB mixtures. SEM micrographs of the samples cured for 28 days are presented in Figure 5. Figures 5a, 5b, and 5c correspond to the control sample (CPB@C1), the mixture incorporating brewed tea waste (CPB@TB), and the one containing factory tea production waste (CPB@TP), respectively. Figure 5d shows the microstructure of the sample containing tea fiber waste (CPB@TF), which was subjected to flexural testing. As observed, the quantity and density of hydration products—primarily calcium silicate hydrate (C-S-H gel) and calcium hydroxide (CH or portlandite)—in the CPB@TP and CPB@TB samples appear to be lower than those in the control sample. This difference is also reflected in the variation of pore sizes and their distribution throughout the matrix. In the case of CPB@TF, SEM images reveal that tea fibers introduce voids within the matrix but also serve as bridges between other constituents, enhancing internal bonding. These observations suggest that tea fiber waste contributes positively to the structural integrity and mechanical performance of the backfill through physical reinforcement and interaction with hydration products.

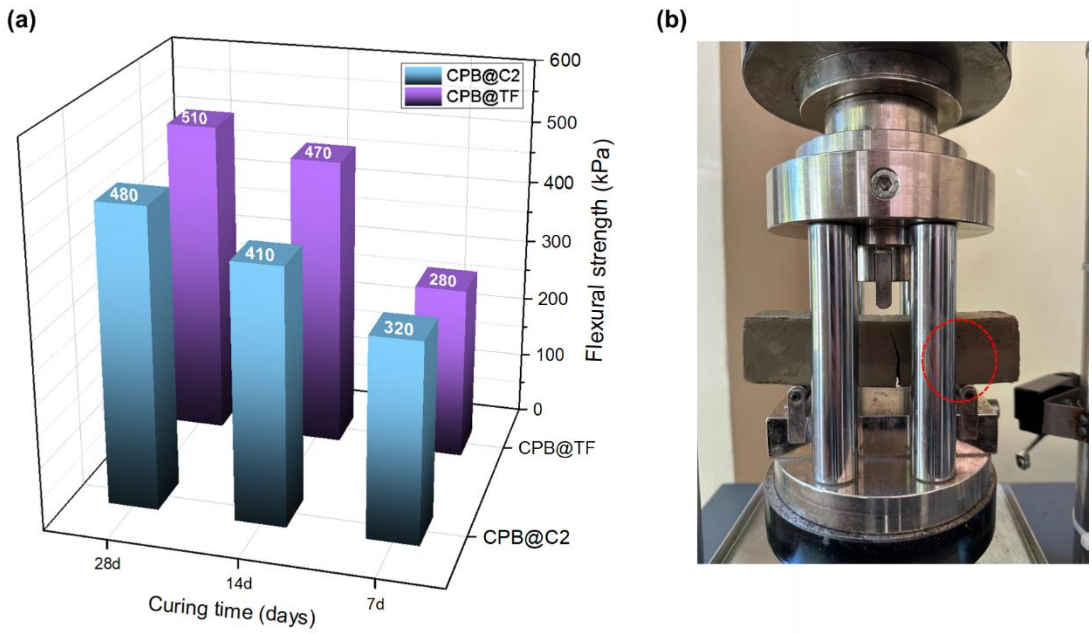

Fig. 4. (a) Flexural strength-curing time of CPBs and (b) crack formation

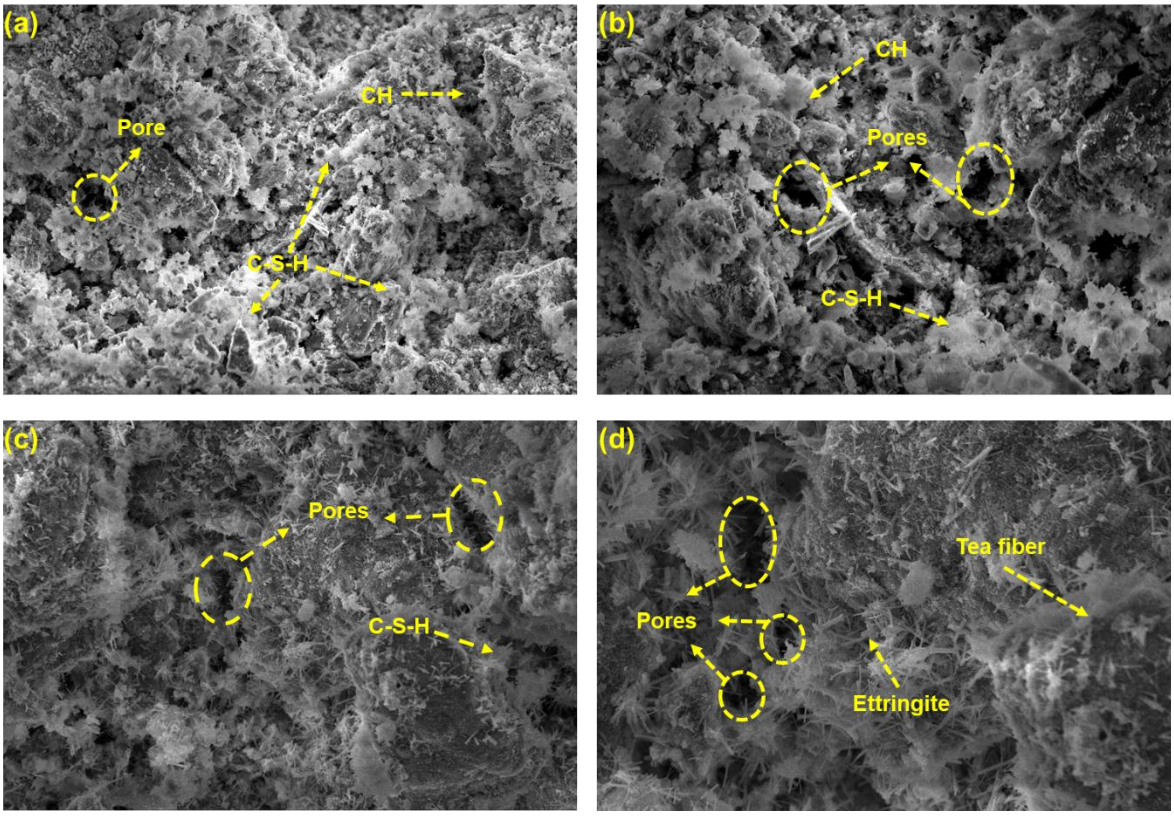

Fig. 5. SEM results of 28-day cured (a) CPB@C1, (b) CPB@TB, (c) CPB@TP and (d) CPB@TF

4. Conclusions

In this study, the influence of various tea wastes—namely tea powder waste (TP), brewed tea waste (TB), and tea fiber waste (TF)—on the performance of cemented paste backfill (CPB) mixtures was systematically investigated. After undergoing preprocessing steps such as drying and sieving, TP and TB were incorporated into CPB mixtures with a constant solid content of 70% and a cement dosage of 5% by weight. Tea wastes were substituted for 10% of the cement content, and their effects on the mechanical and microstructural properties of the backfill were evaluated through uniaxial compressive strength (UCS) tests, three-point bending tests, and scanning electron microscopy (SEM) analysis across different curing durations (up to 28 days). The outcomes of these experimental evaluations are summarized as follows:

- The uniaxial compressive strength (UCS) of all filling mixtures increased with extended curing time. The highest UCS value, 0.83 MPa, was recorded in the control sample (CPB@C1) at 28 days.
- In general, mixtures incorporating brewed tea waste (TB) exhibited superior UCS performance compared to those containing factory tea production waste (TP).
- Results from the three-point bending tests indicated that mixtures with tea fiber waste (CPB@TF) demonstrated higher flexural strength than the control samples (CPB@C2) after 14 days of curing. Specifically, while the flexural strength of CPB@C2 reached 0.41 MPa and 0.48 MPa at 14 and 28 days, respectively, CPB@TF achieved higher values of 0.47 MPa and 0.51 MPa at the same curing periods.
- SEM analyses revealed that hydration products were less abundant in the CPB@TB and CPB@TP samples compared to the control, likely due to the increased water absorption capacity of tea wastes. In CPB@TF mixtures, tea fibers appeared to act as physical bridges within the matrix, contributing to improved flexural strength by enhancing structural connectivity and reducing voids.

In conclusion, this study investigated the potential use of various tea wastes—originating primarily from tea agriculture, a key economic activity in the studied region—as alternative cement substution in the CPB method. The findings indicate that tea wastes possess distinct characteristics that necessitate specific pre-treatment processes (e.g., sieving and drying) to optimize their performance in CPB applications. Based on the results, it is evident that tea wastes hold promise as partial cement substitutes. Future research will aim to enhance the applicability and effectiveness of tea wastes in CPB through advanced treatment techniques, broader substitution ratios, and extended curing periods.

Examining the dynamic performance of loose sands reinforced by recycled concrete aggregate (RCA)

Olguhan Ş. Karahasan*[1], Burak Akçay[1]

[1] *Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye*

Abstract. The enhancement of seismic performance in fully saturated sand through the inclusion of Recycled Concrete Aggregate (RCA) was investigated using two-dimensional finite element analyses conducted in PLAXIS 2D. The dynamic response of an RCA-reinforced soil system supporting a six-story structure was evaluated under seismic excitation. The incorporation of RCA significantly mitigated the maximum settlement beneath the raft foundation, reducing it from 13.6 cm to 2.5 cm, and effectively confined the deformation to a shallow subsurface zone. This localized deformation pattern substantially minimized differential settlement and preserved the foundation's load-bearing capacity. Stress distribution analyses revealed a more homogeneous principal stress field beneath the foundation. Compressive and tensile stresses were reduced by approximately 28 kN/m² and 8 kN/m², respectively. Additionally, uplift-induced tensile stress concentrations at the raft edges were significantly diminished. At the superstructure level, RCA inclusion resulted in a modest increase in top slab bending moments by approximately 4–6%, while shear force demands remained constant or decreased marginally (up to 3%), indicating that structural implications are limited to minor flexural design considerations. These results substantiate the efficacy of RCA as a sustainable and mechanically competent soil improvement material that enhances the stiffness and strength of saturated sands without imposing adverse effects on superstructural performance. To advance practical applications, future research should focus on full-scale experimental validation, long-term seismic performance monitoring, and comprehensive parametric studies examining the influence of RCA gradation and volumetric content on dynamic soil behavior, aiming to inform and refine performance-based seismic design frameworks.

Keywords: RCA; Soil improvement; Seismic performance; Loose sand; Plaxis 2D

1. Introduction

Sandy soils susceptible to liquefaction pose a critical risk to infrastructure and structural safety, particularly due to the sudden loss of shear strength under seismic loading. The literature highlights that settlements and shear deformations in such problematic soils can lead to damage or even collapse of supporting systems; accordingly, soil improvement techniques have been extensively investigated to safeguard both lives and assets.

Conventional stabilization methods typically employ binders such as cement, lime, or microsilica; however, these approaches are limited by high energy consumption and significant carbon emissions, raising concerns about environmental sustainability. In this context, the principles of circular economy—which emphasize the recovery and reuse of construction-sector waste—promote the use of recycled concrete aggregate (RCA) as an economical and eco-friendly alternative. RCA, derived from the crushing and screening of waste concrete, offers suitable physical and mechanical properties for soil stabilization while contributing to waste management and the reduction of carbon footprint.

Recent efforts have demonstrated the multifaceted potential of recycled concrete aggregates (RCA) across both structural and geotechnical applications. Momotaz et al. (2024) investigated concrete kerb sections incorporating RCA, tyre-derived aggregates, and polypropylene fibers, revealing that fiber-reinforced mixes can endure nearly 2 000 cyclic loads while significantly enhancing post-cracking behavior. Huan He et al. (2023) characterized 1.18–2.36 mm RCA fractions from China and Australia, showing markedly lower particle strength and distinctive interparticle contact stiffness, yet uncovering ductile failure modes under compression. Shriful Islam et al. (2023) applied 5–35 % RCA in slope stabilization—both mixed and as vertical drains—achieving reduced consolidation settlement, increased shear strength, and up to seven-fold permeability gains that mitigate excess pore-water pressure. Weiwei Xiong et al. (2023) combined excavated soil and fine RCA to produce unfired clay bricks

*Corresponding author, E-mail: olguhan@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_geo_627

(UCBs), identifying optimal mix proportions (w/c = 0.65, a/s = 0.5, c/s = 0.3, AC = 5 %) that deliver favorable density and strength via enhanced hydration. Ahmad et al. (2023) demonstrated that load-bearing bricks made with 100 % RCA through compression casting satisfy ASTM criteria and outperform both burnt-clay and natural-aggregate units in strength and acid/brine resistance. Lin et al. (2023) systematically assessed steel, polyvinyl alcohol, carbon, and polypropylene fibers in RCA concrete, finding steel fiber to yield the greatest improvements in energy dissipation (+81.8 %) and toughness (+22.9 %) and proposing a validated segment-based stress–strain model. Singh et al. (2022) examined fine RCA compatibility with natural and coarse RCA, showing that 30 % FRCA best suits natural coarse aggregates, while 60–100 % FRCA pairs optimally with coarse RCA to meet M30 strength targets. Adomako et al. (2023) introduced a dry-washing (RCZ) process for concrete sludge, reporting that increasing RCZ content enhances aggregate quality (Los Angeles and micro-Deval tests) and yields acceptable environmental performance despite residual paste minerals. Collectively, these studies underscore RCA's promise yet reveal that an integrated, data-driven assessment of its effects on seismic-induced settlement and liquefaction remains absent—an omission this work seeks to address.

In this study, no laboratory tests were conducted; instead, the required shear strength and pore-water pressure parameters for a uniformly graded, liquefaction-prone sandy soil were obtained from selected literature sources. The effects of varying RCA content on soil strength, settlement, and liquefaction potential were examined using established empirical correlations and numerical evaluation methods. The primary objective is to present an academic framework—free from laboratory-induced uncertainties—demonstrating how RCA addition can minimize settlement and liquefaction risks in problematic sandy soils. The analytical findings are expected to inform the use of alternative materials in infrastructure projects within seismic regions and to guide policies on waste concrete management.

2. Methodology

In the designed Plaxis 2D analyses, a fully saturated, loose sand deposit was considered. A six-storey structure on a 10m wide raft foundation, with a foundation depth of 2m, is planned on this sand. Also, the groundwater level (GWL) is at a depth of 2 meters. Hardening Soil with small (HS small) constitutive model was adopted for the soil, and an Undrained-A drainage condition was applied to simulate the critical seismic scenario. The structural elements were modeled as "plate" elements and interconnected via node-to-node anchors to ensure monolithic behavior under earthquake loading. Seismic parameters corresponding to earthquake ground motion level DD-2 and local soil class ZD were selected for the center of Erzincan. From the AFAD-TDTH (Turkish Seismic Hazard Map) portal, the short-period spectral acceleration (S_{DS} = 1.445 g), 1-second spectral acceleration (S_{D1} = 0.782 g), peak ground acceleration (PGA = 0.602 g), and peak ground velocity (PGV = 39.534 cm/s) were obtained. The 1992 Erzincan earthquake record was scaled to the 2018 Turkish Seismic Design Code (TBDY) spectrum using SeismoMatch and input into Plaxis 2D as an acceleration-time history. To accurately capture dynamic soil–boundary interaction, prescribed displacement boundary conditions were assigned in the X direction, and fixed displacements in the Y direction. Mesh refinement followed best practices from the Plaxis 2D manuals and relevant literature to ensure reliable dynamic response. In the Dynamics module, free-field boundary conditions were applied at the lateral boundaries (Boundary Xmin and Xmax) to allow seismic waves to enter and exit without artificial reflections, while a compliant base condition (Boundary Ymin) was used at the model base to replicate realistic wave transmission through the deformable soil. Given the high risk of seismic-induced settlement and loss of bearing capacity in the ZD-class, saturated loose sand, soil improvement was deemed necessary prior to construction. The soil was thus stabilized by mixing in recycled concrete aggregate (RCA) to enhance internal friction angle and cohesion. Seismic analyses were performed using the finite element method in Plaxis 2D for both the current condition and the RCA-improved soil and the resulting displacement and stress responses were compared and interpreted.

3. Finite element modelling and seismic analysis

The Hardening Soil Small (HS small) constitutive model was employed to simulate soil behavior, and an Undrained-A drainage condition was applied to represent the critical seismic scenario. For the centre of Erzincan, seismic parameters were selected corresponding to the ground motion level DD-2 and the local soil class ZD. From the AFAD-TDTH (Turkish Seismic Hazard Map) portal, the short-period spectral acceleration (S_{DS} = 1.445 g), 1-second spectral acceleration (S_{D1} = 0.782 g), peak ground acceleration (PGA = 0.602 g), and peak ground velocity (PGV = 39.534 cm/s) were obtained. The ground motion record of the 1992 Erzincan earthquake was scaled to the 2018 Turkish Seismic Design Code (TBDY) spectrum using the SeismoMatch software and subsequently implemented in Plaxis 2D as an acceleration–time history input. Under seismic loading, finite element analyses were performed in Plaxis 2D for both unimproved (current condition) and RCA-improved soil profiles and the obtained displacement and stress responses were evaluated and compared. Fig. 1 and Fig. 2 presents the displacement results of the seismic analysis for the NRCA and RCA models.

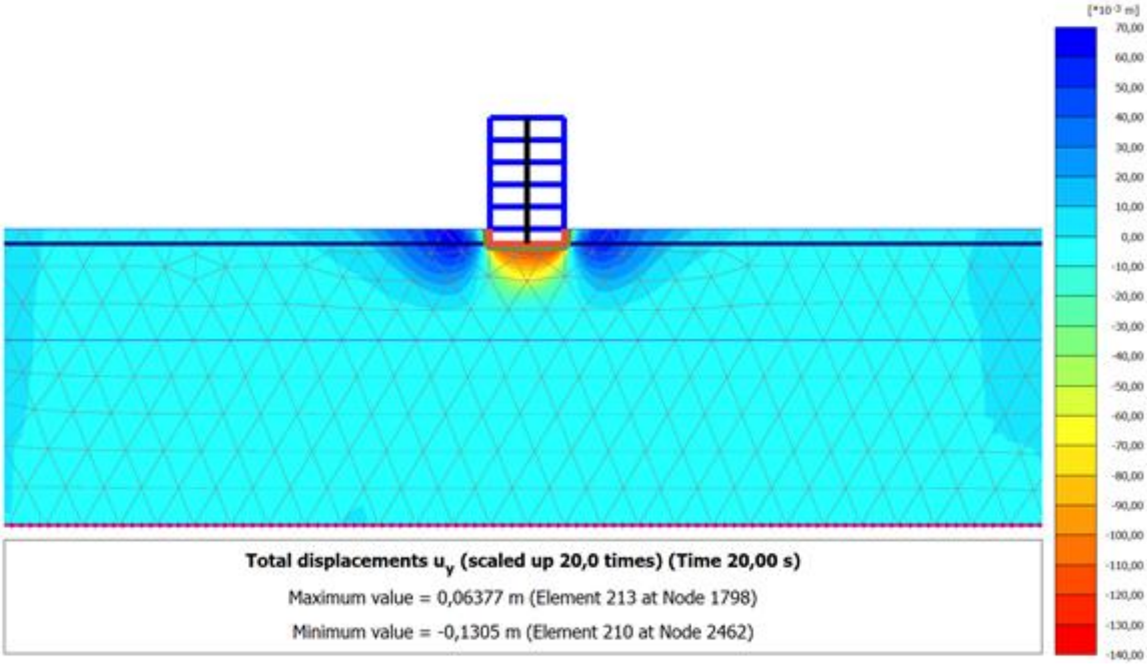

Fig. 1. The displacement results of the seismic analysis for the model NRCA

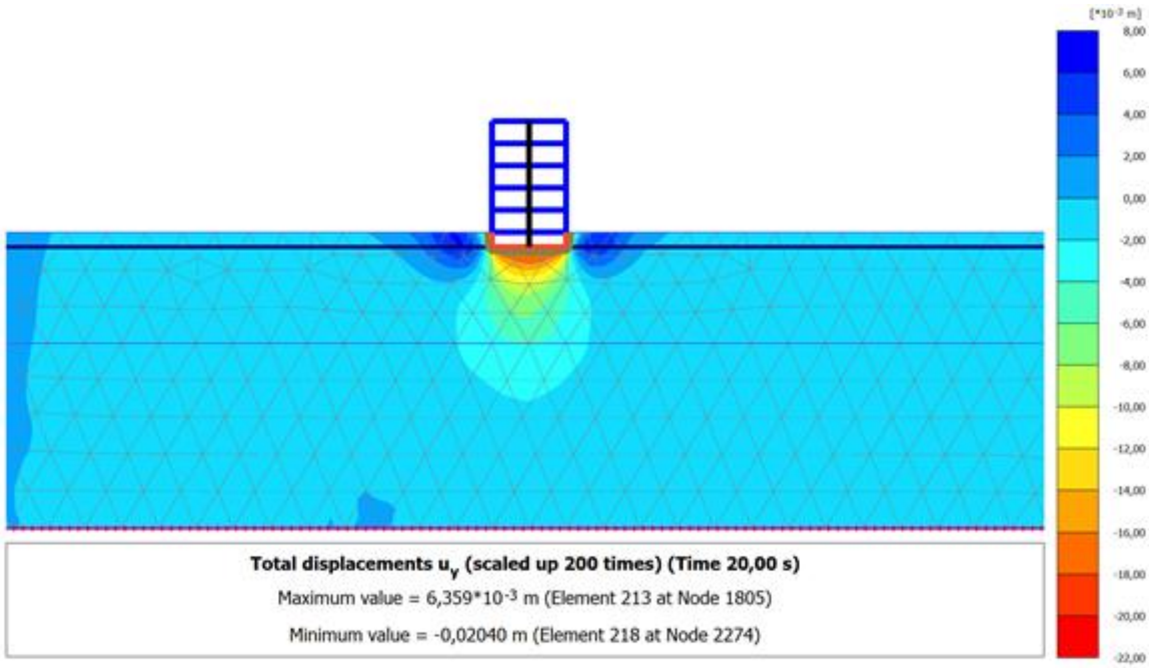

Fig. 2. The displacement results of the seismic analysis for the model RCA

The reinforced case limits maximum settlement to ≈20 mm, whereas the unreinforced soil experiences up to 130 mm of settlement. The reinforcement confines deformation to a narrow, shallow band that decays quickly with depth. In contrast, the unreinforced soil exhibits a wide, deep-penetrating settlement pattern. A concentrated, shallow deformation zone minimizes isolated settlement under the structure. A widespread, deep-seated zone can lead to uncontrolled differential movements beneath the foundation. Reinforcement with recycled concrete aggregate substantially reduces both the magnitude and lateral/depth extent of vertical displacements, thereby mitigating differential settlement and enhancing seismic performance. Fig. 3 and Fig. 4 presents the stress results of the seismic analysis for the NRCA and RCA models.

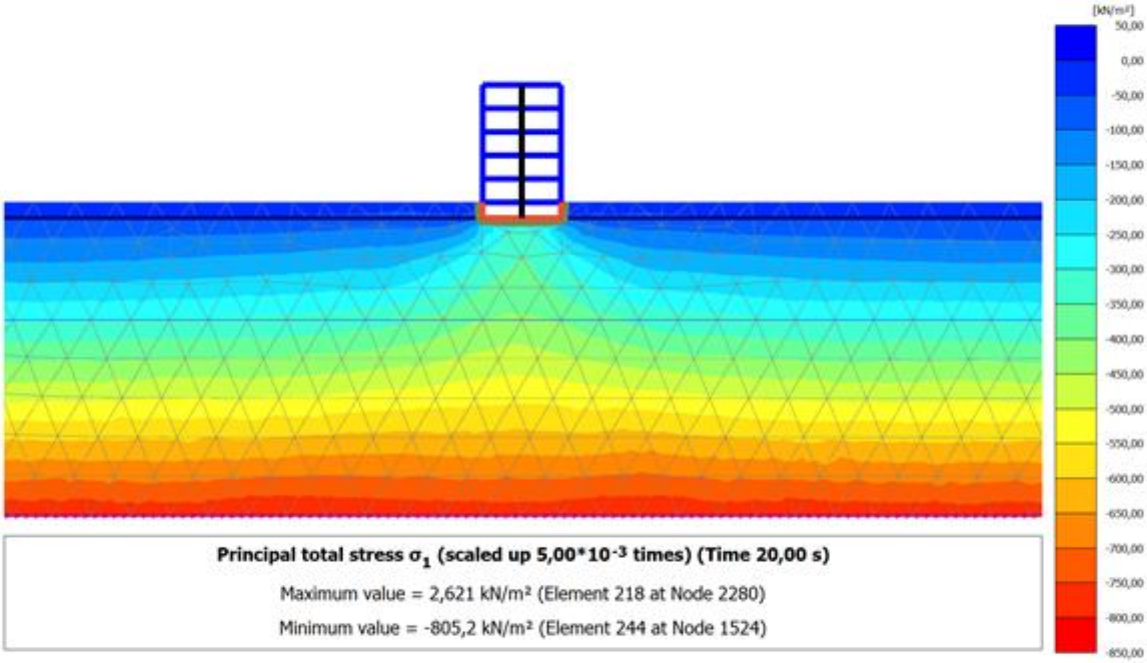

Fig. 3. The stress results (σ_1) of the seismic analysis for the model NRCA

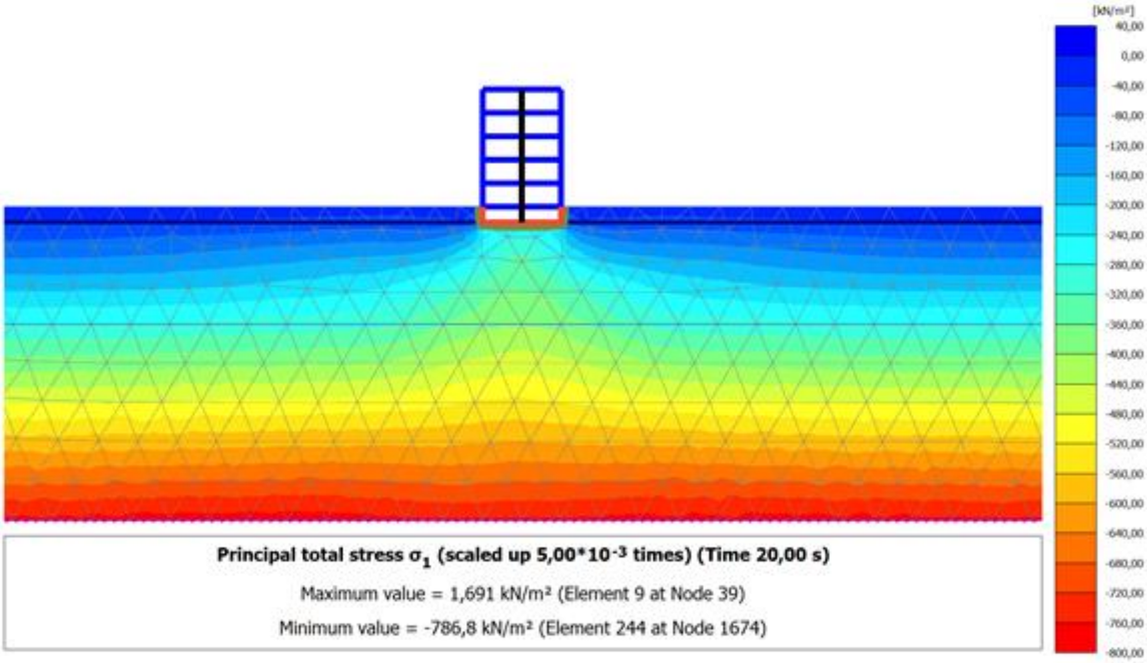

Fig. 4. The stress results (σ_1) of the seismic analysis for the model RCA

The reinforced case exhibits about 2 kN/m² lower peak tension and ~18 kN/m² lower peak compression, indicating the RCA inclusion has smoothed stress concentrations beneath the footing. In RCA model, the transition from high compression (red) to intermediate (greens/yellows) is more gradual, whereas NRCA model shows a sharper gradient immediately under the foundation. This suggests the reinforced zone distributes loads more evenly into the soil. Unreinforced soil develops pronounced tensile lobes beside the footing (blue "horns"), a sign of uplift stresses that can drive cracking or hydraulic fracturing in the pore-pressure regime. These lobes are noticeably reduced in RCA model. Both models show a downward-spreading compression bulb, but in the reinforced soil it is marginally broader and less intense—consistent with a stiffer near-surface layer that carries more load. Incorporating recycled concrete aggregate creates a stiffer, more load-bearing cap that mitigates stress peaks under dynamic loading, reduces uplifting tensile stresses at the footing edges, and generates a smoother stress diffusion into the subsoil. Together, these effects improve the seismic performance by lowering the risk of localized yielding or fracturing. Fig. 5 and Fig. 6 presents the stress results (σ_3) of the seismic analysis for the NRCA and RCA models.

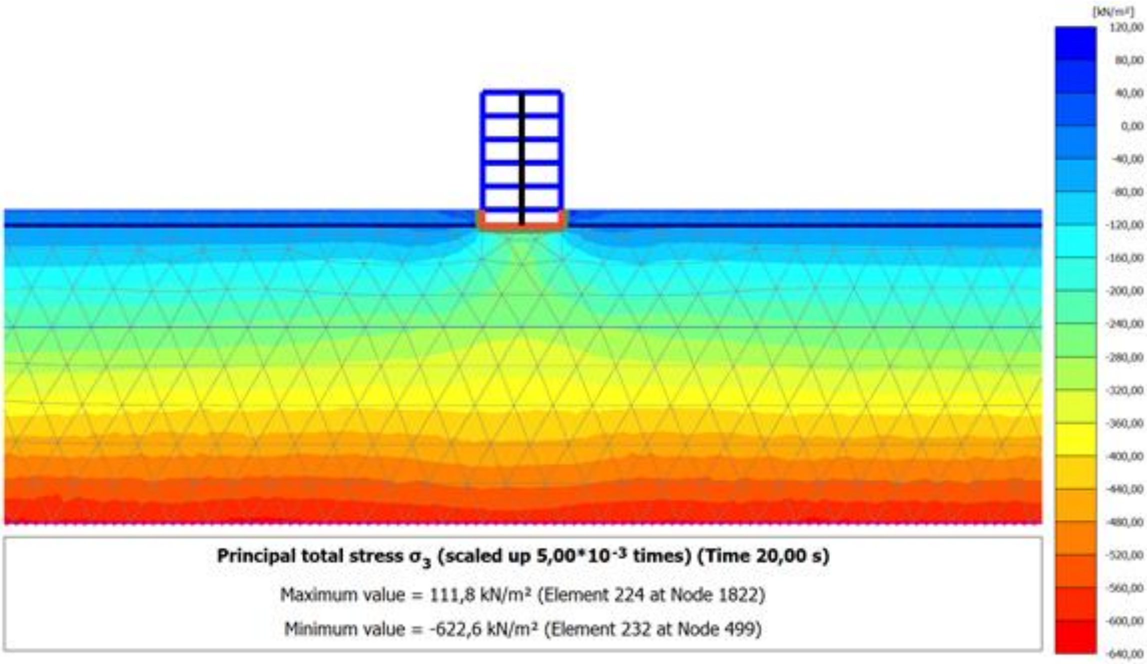

Fig. 5. The stress results (σ_3) of the seismic analysis for the model NRCA

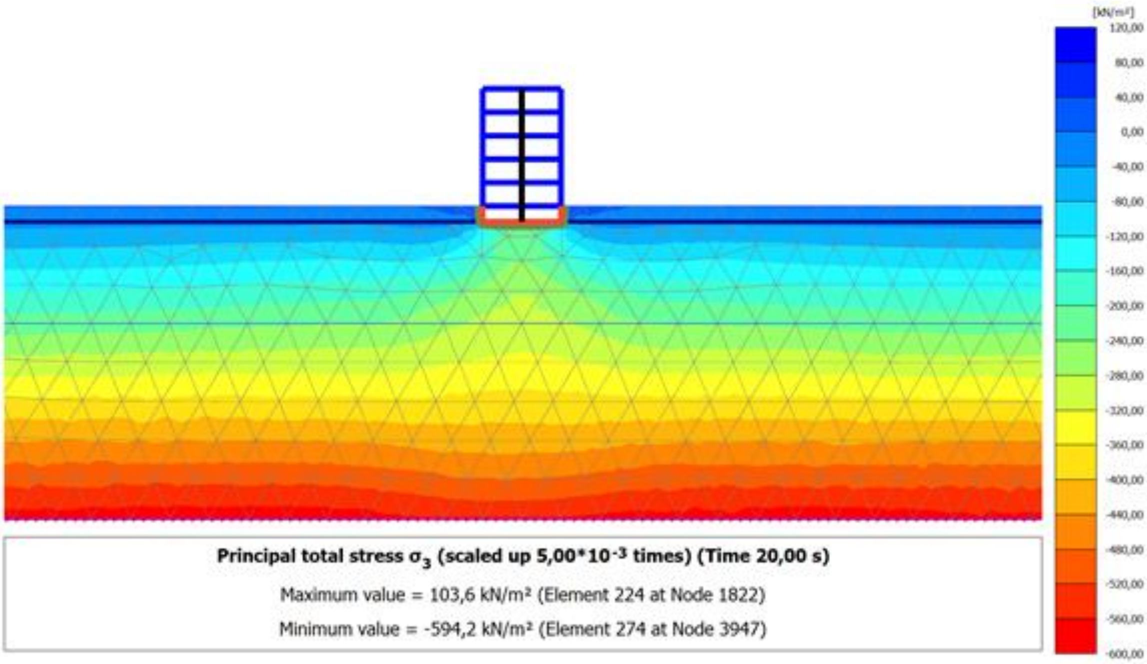

Fig. 6. The stress results (σ_3) of the seismic analysis for the model RCA

Reinforced soil shows both lower maximum tension (≈8 kN/m² reduction) and lower peak compression (≈28 kN/m² reduction), indicating milder stress concentrations. In the unreinforced model, the compressive stress bulb extends slightly deeper, whereas in the reinforced model it is more confined to a shallower, wider area near the surface. The tensile lobes at the footing edges are smaller and less intense in RCA model compared to NRCA model, reflecting reduced uplift stresses around the foundation. Fig. 7 and Fig. 8 presents the effective stress results (σ_1') of the seismic analysis for the NRCA and RCA models.

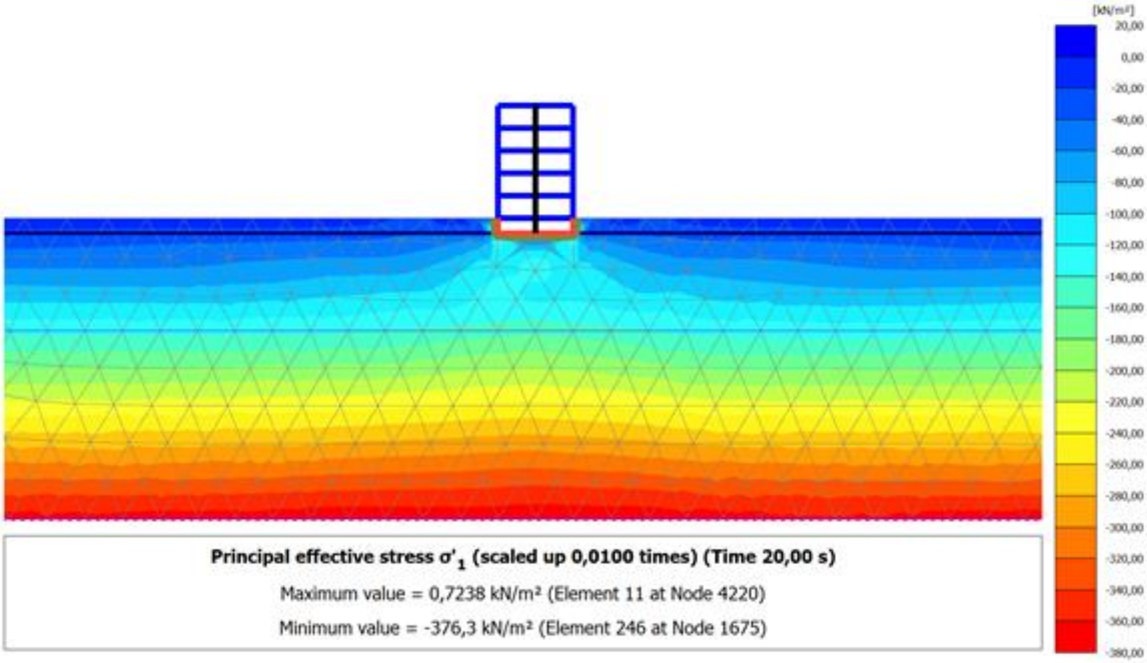

Fig. 7. The stress results (σ_1') of the seismic analysis for the model NRCA

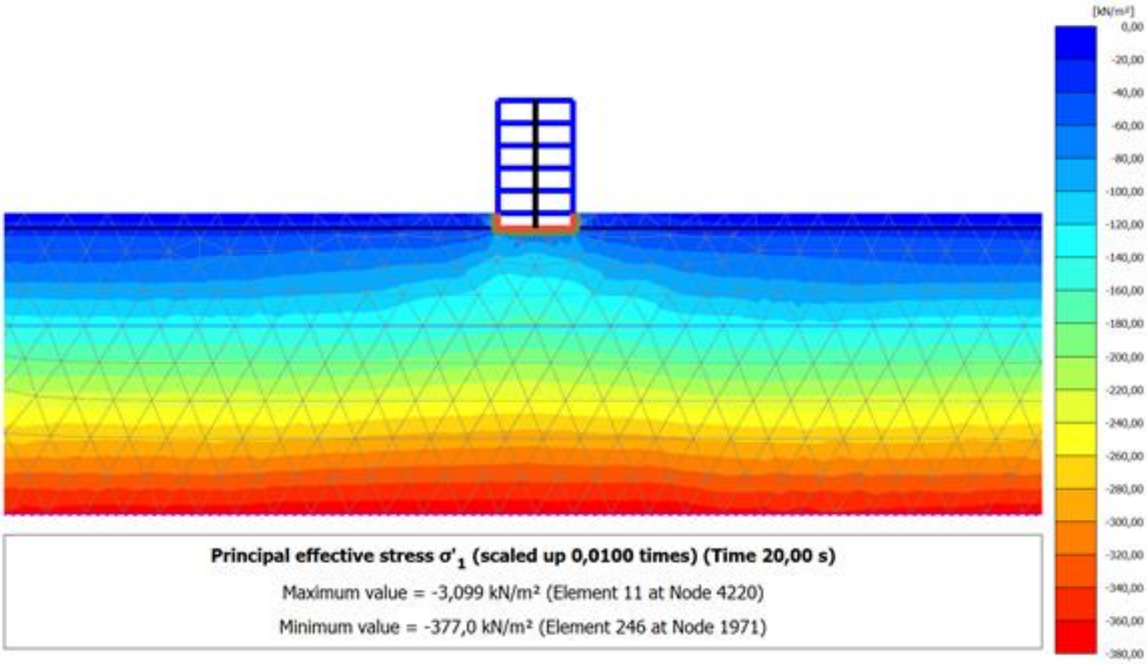

Fig. 8. The stress results (σ_1') of the seismic analysis for the model RCA

Mixing in RCA raises the in-situ stiffness so that no tensile effective stress zones develop beneath the foundation, and it yields a smoother, more uniformly compressive stress distribution. This behavior signals both reduced risk of liquefaction-induced uplift and improved overall bearing performance under seismic loading. Fig. 9 and Fig. 10 presents the effective stress results (σ_3') of the seismic analysis for the NRCA and RCA models.

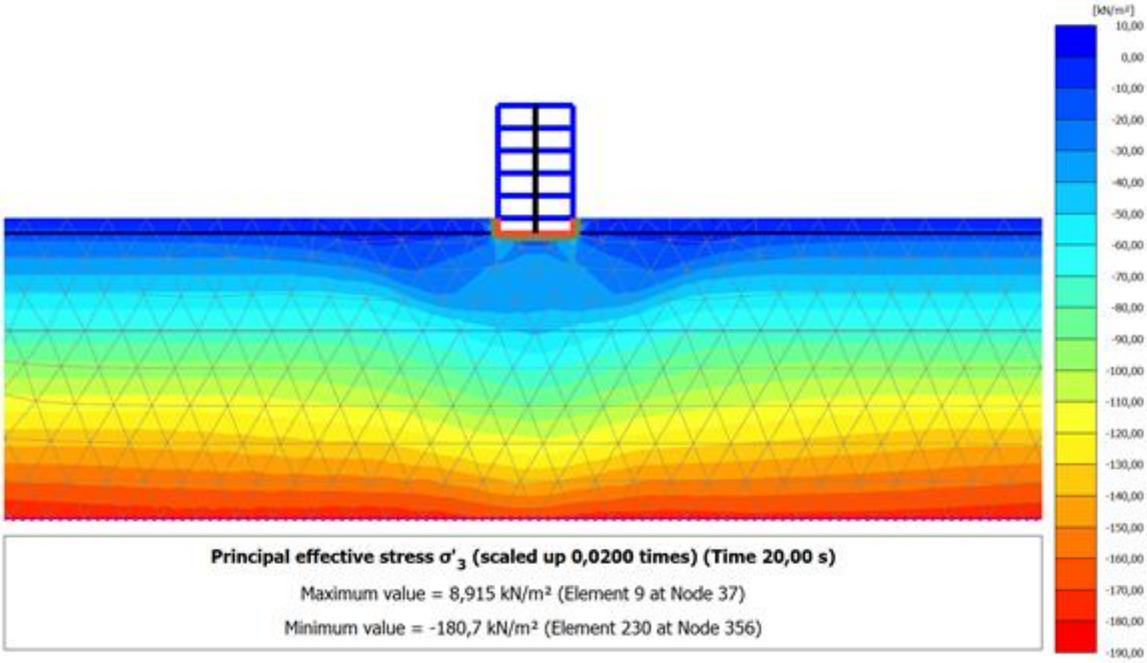

Fig. 9. The stress results (σ'_3) of the seismic analysis for the model NRCA

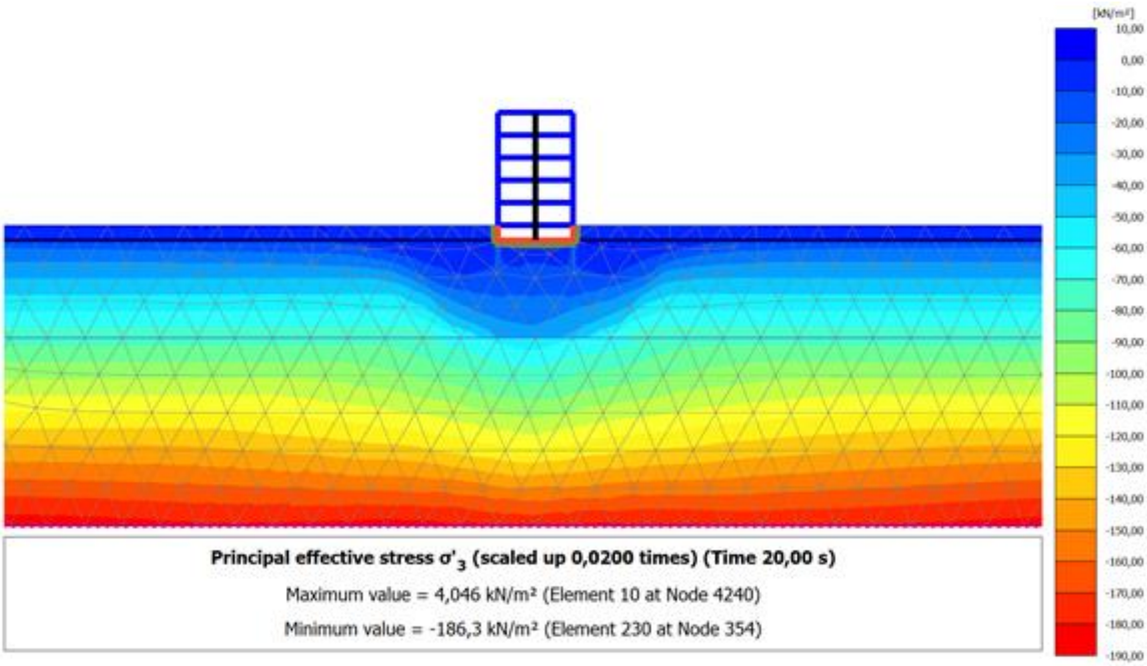

Fig. 10. The stress results (σ'_3) of the seismic analysis for the model RCA

Incorporating RCA into the soil largely eliminates tensile effective stresses beneath the foundation while slightly increasing maximum compression. This behavior indicates that RCA both mitigates uplift risk and enhances the stiffness and load-bearing efficiency of the soil under seismic excitation.

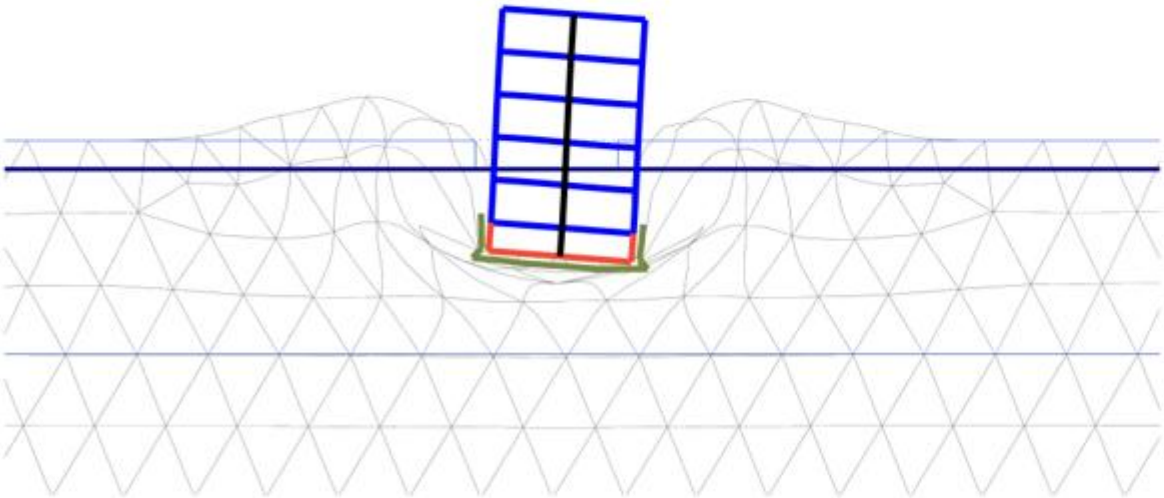

Fig. 11. The soil settlements for the analyses NRCA model

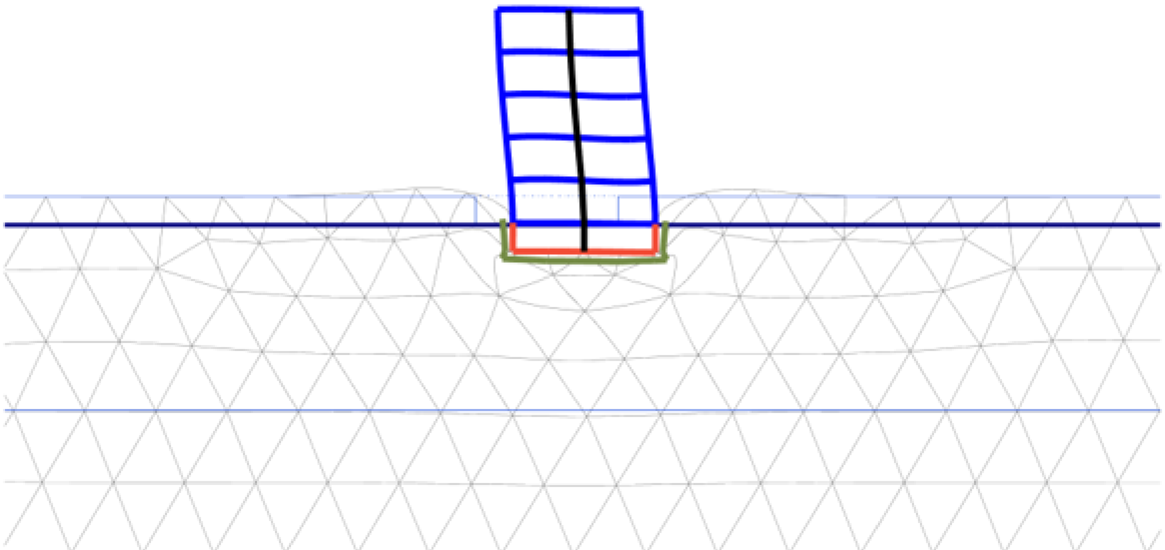

Fig. 12. The soil settlements for the analyses RCA model

Figs. 11 and 12 visualize the soil settlements for the analyses NRCA and RCA models, respectively. RCA reinforcement decreased the peak settlement by about 82 %, from 13.58 cm to 2.485 cm, indicating a substantial increase in soil stiffness and bearing capacity. In the unreinforced model, the settlement trough spreads deeply and laterally over a wide area, whereas in the RCA-reinforced model the settlement is confined to a shallow, narrow band directly beneath the foundation. This indicates a significant reduction in differential settlement and a more controlled load distribution to the soil. Limiting the maximum settlement also minimizes lateral displacements at column–slab connections, thereby reducing additional moments and shear forces on the column–shaft system. As a result, both seismic performance and long-term serviceability of the structure are enhanced.

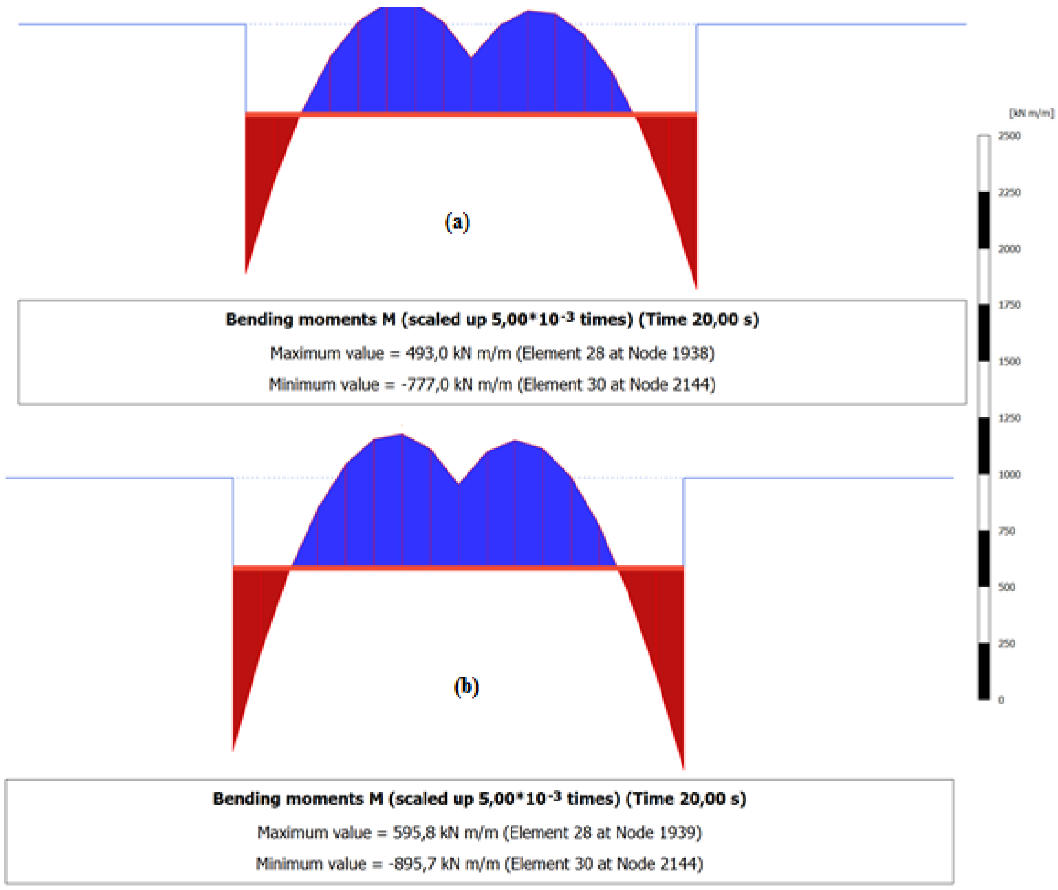

Fig. 13. The obtained moment diagrams for the models NRCA and RCA

As a result of the seismic analyses, moment and shear force diagrams at the bottom of the structure were generated for both the models NRCA and RCA. The obtained moment diagrams are presented in Fig. 13 (a-NRCA model, b-RCA model). The obtained shear force diagrams are presented in Fig. 14 (a-NRCA model, b-RCA model).

Both positive and negative peak moments rise by roughly 15–21 % in the reinforced model. NRCA shows two symmetric “humps” of positive moment with narrow negative triangular zones at the edges. RCA displays wider, more pronounced positive moment caps and deeper/asymmetric negative zones at the ends. The RCA layer stiffens the foundation soil, channeling higher bending demands into the footing. Shear peaks rise moderately in the reinforced case. NRCA shows two separate positive (upward) lobes on either side of the foundation and a central negative lobe. RCA consolidates the positive shear into one strong lobe shifted left and extends the negative shear region to the right in a deeper triangular profile. RCA reinforcement redistributes horizontal demands, increasing shear at the footing edges. The reinforced soil generates substantially larger bending and shear forces, demanding greater stiffness and strength from the foundation elements. Reinforcement focuses loads into narrower bands beneath the footing, suggesting a review of crack-control reinforcement and shear detailing in the foundation design. To accommodate increased moments and shears, consider optimizing foundation depth, reinforcement layout, or RCA layer thickness, and verify soil–RCA modulus and interface conditions in the model.

RCA reinforcement raises the end-span hogging moment by about 3.8 %, from 87.24 to 90.54 kN·m/m. Mid-span sagging deepens by ~6.1 %, from –40.14 to –42.60 kN·m/m. The peak uplift shear drops by ~2.7 % (76.58 → 74.52 kN/m). The downward shear lobe is effectively unchanged (–79.36 → –79.47 kN/m). In summary, adding recycled concrete aggregate increases bending moments at the top slab, while shear demands stay constant or decrease slightly—requiring only minor adjustments to flexural design.

As a result of the seismic analyses, moment and shear force diagrams at the top of the structure were generated for both the models NRCA and RCA. The obtained moment diagrams are presented in Fig. 15 (a-NRCA model, b-RCA model). The obtained shear force diagrams are presented in Figure 16 (a-NRCA model, b-RCA model).

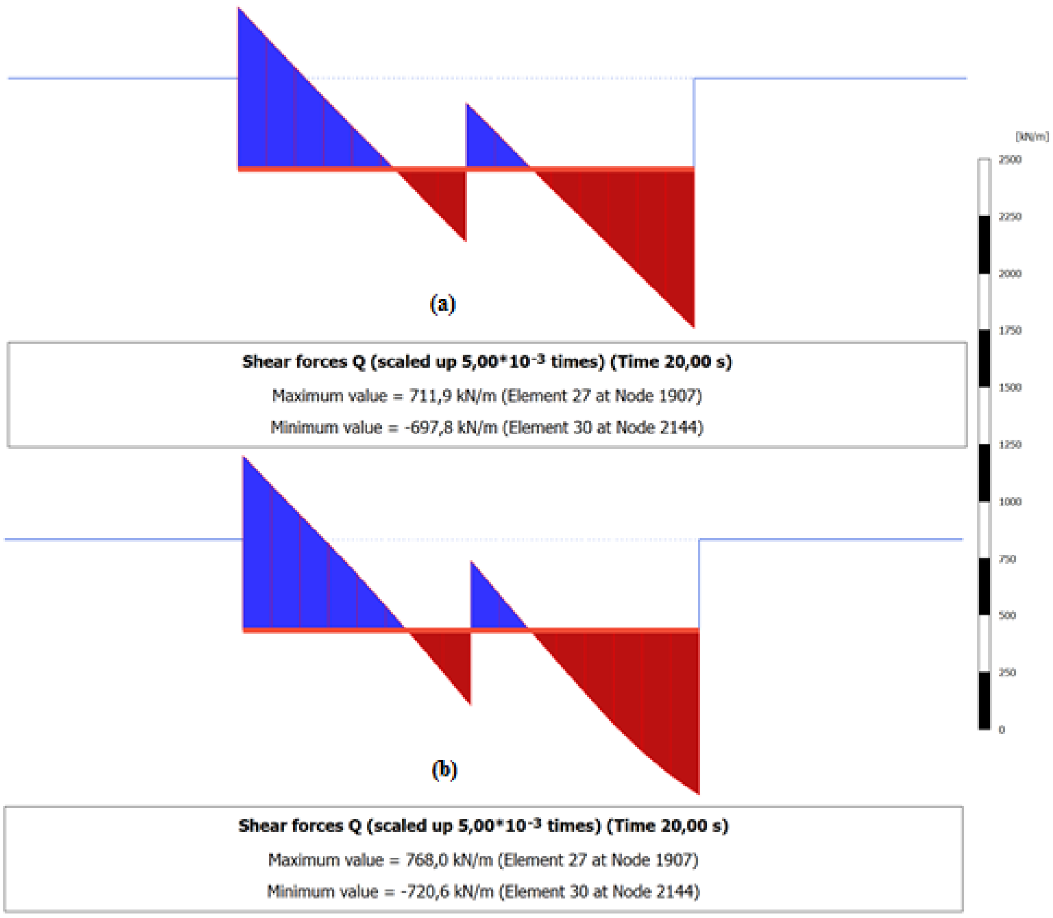

Fig. 14. The obtained shear force diagrams for the models NRCA and RCA

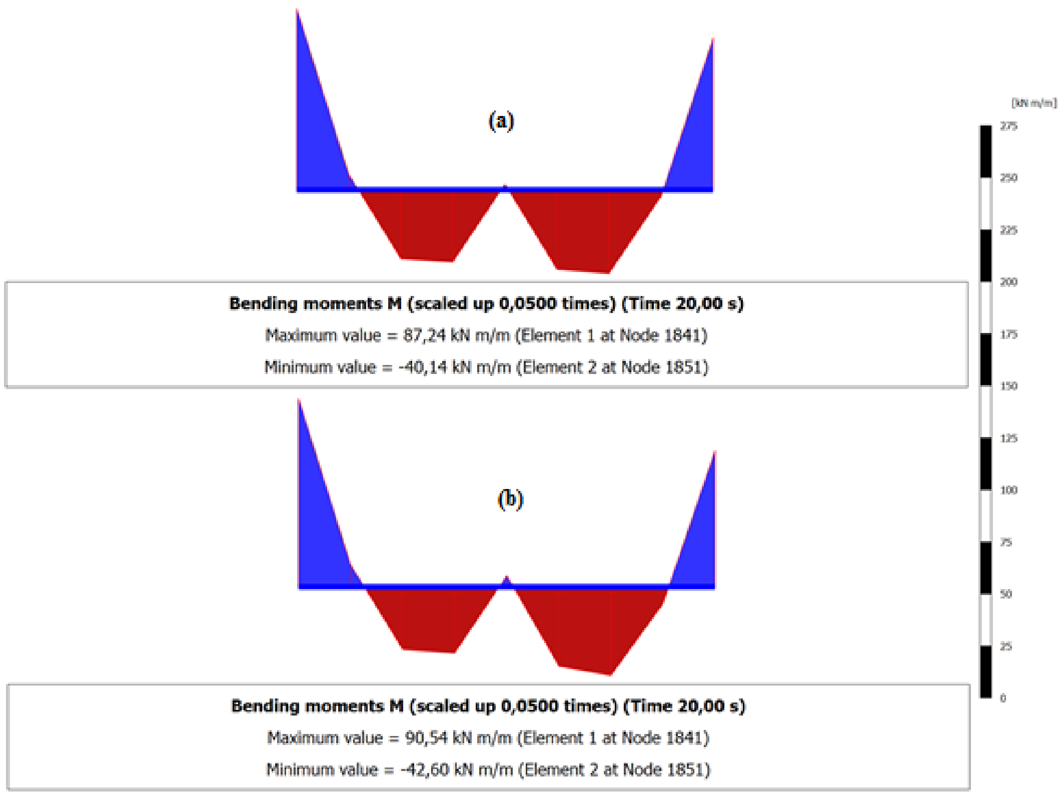

Fig. 15. The obtained moment diagrams for the models NRCA and RCA

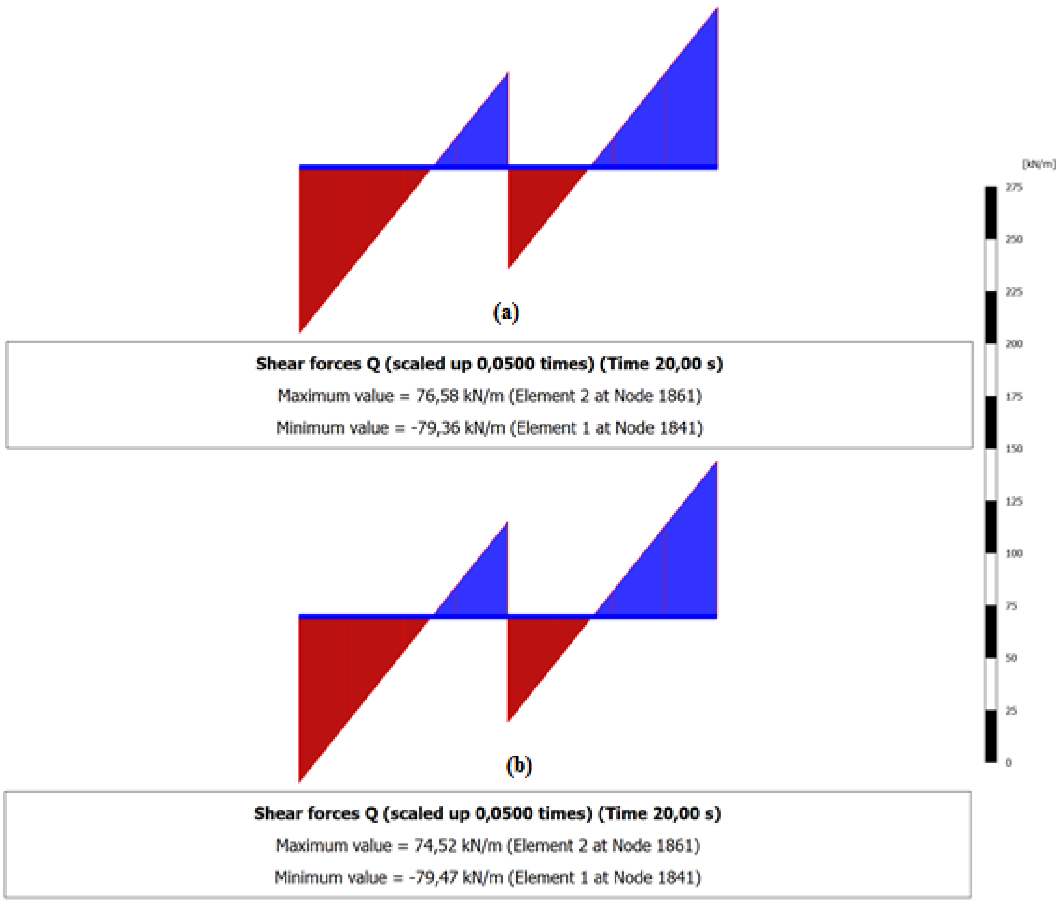

Fig. 16. The obtained shear force diagrams for the models NRCA and RCA

4. Conclusions

This study has demonstrated that mixing recycled concrete aggregate (RCA) into a fully saturated, liquefaction-prone sand significantly enhances seismic performance by substantially reducing vertical deformations and smoothing stress concentrations under dynamic loading. Numerical Plaxis 2D analyses show that RCA reinforcement limits maximum settlement beneath a six-story mat foundation from approximately 13.6 cm to 2.5 cm and confines deformation to a narrow, shallow zone, thereby mitigating differential settlement and preserving bearing capacity. Principal stress distributions likewise become more uniform: peak compressive and tensile stresses under the footing decrease by up to 28 kN/m² and 8 kN/m², respectively, and uplift-induced tensile lobes at foundation edges are markedly attenuated. At the superstructure level, top-slab bending moments increase modestly (≈4–6 %), while shear demands remain unchanged or decline slightly (≈3 %), indicating that only minor flexural design adjustments are required. These results confirm that RCA can serve as an eco-efficient ground improvement agent—enhancing stiffness and strength without compromising structural demand thresholds. Future work should extend this framework through large-scale experimental validation, long-term performance monitoring, and parametric studies of RCA gradation and content to optimize design guidelines for seismic regions.

Investigation of the variation of micro-pile parameters under moment effect with length variation

Betül Çağdaş*[1], Baran Toprak[1]

[1] Kırıkkale University, Department of Civil Engineering, 71451 Kırıkkale, Türkiye

Abstract. Micro-piles are one of the ground improvement methods made of steel materials in order to reduce settlement and increase bearing capacity with diameters smaller than 30 cm. Micro piles have gained a wide range of usage as drilling equipment and injection techniques vary and most of the load on the piles is borne by high-strength steel. In this study, the parameter changes calculated with the change in length of micro-piles manufactured in different lengths were examined. In the analyses made with Geo5 Geotechnical Calculation Program; It has been revealed that the changes in the parameters of maximum settlement, minimum compressive force and maximum rotation of the pile cap show striking changes compared to other parameters. In the analyses performed for each length change, the analysis results depending on these parameters were compiled and presented in charts. It has been observed that the micro-pile length change varies significantly on these parameters.

Keywords: Micro-pile; Length variation; Rotation of the pile cap; Settlement; Geo5

1.Introduction

Nowadays, with the increase in population and urbanisation, the construction process has also accelerated and the need for high and large buildings has increased. The growth of the structures has led to the growth of the load to be transferred to the ground and led to developments in the field of geotechnics. These developments have also increased the need for construction on grounds that are not suitable for construction. In addition, it is of great importance that the soil on which the building will be constructed is determined before the problems such as bearing capacity, settlement and liquefaction are encountered and designs are made according to these analyses. Moreover, due to the development of machine and equipment technologies, foundation systems are also improving and the bearing capacity of even the most unsuitable soil for buildings is increased.

As one of the ground reinforcement techniques, micro-piles increase the bearing capacity of the soil and reduce settlement. Multi-storey and basement structures can be built even in deep excavation and narrow construction areas. Micro-pile applications have recently come to the forefront in our country due to the comfort of working in narrow areas, low cost, sensitive working areas such as historical and industrial structures. Furthermore, micro-pile technology is a reliable pile system that can endure high axial loads as they are designed to minimum damage to existing structures (Chaudhari et al., 2015). Thus, micro-piles are widely used in many soil reinforcement techniques.

Micro-piles are defined as piles with a diameter of less than 30 cm. Micro-piles usually consist of two elements: steel and injected concrete (according to project conditions). Micro-piles are manufactured by drilling the micro-pile hole, placing the specified reinforcement in the hole and filling the hole with concrete by grouting. The micro-pile drilling method is determined by considering the soil conditions of the project. When selecting the drilling technique, the method that will damage the neighbour structures and the environment should be avoided. In places where groundwater is shallow, it should be taken into consideration that fine-grained materials in the soil may flow in the hole as the bore height increases. Taking into consideration the soil and project conditions, consideration should be given to the time taken for completion of drilling, placement of steel and injection (FHWA, 2005).

In this study, micro-pile models designed in different lengths (5m, 6m, 7m, 8m, 9m, 10m, 11m, 12m, 13m, 14m, 15m) were analysed. In the analyses, the maximum settlement, minimum compressive force and maximum rotation of the pile cap were compared with the effect of the length change in the micro-piles.

2. Methodology

Geo5 geotechnical calculation program used in the study includes many various modules. Firstly, the ‘Micro-pile’ module has been selected in the study defined the problem. Afterwards, the geometry of the field was created and it was designed and analysed.

Table 1. Soil values (CL)

Low or Medium Plasticity Clay (CL, CI)	
Unit weight	γ: 21.00 kN/m^3
Angle of internal friction	φ_{ef}: 19.00 ^{o}
Soil cohesion	c_{ef}: 12.00 kPa
Saturated unit weight	γ_{sat}: 22.00 kN/ m^3
Oedometer module	E_{oed}: 4.50 MPa

Table 2. Soil values (GC)

Clayey Gravel (GC)	
Unit weight	γ: 19.50 kN/m^3
Angle of internal friction	φ_{ef}: 30.00^0
Soil cohesion	c_{ef}: 6.00 kpa
Saturated unit weight	γ_{sat}: 20.50 kN/ m^3
Oedometer module	E_{oed}: 67.50 MPa

In the study, 11 different designs including various parameters were analysed on Geo5 geotechnical calculation program. The samples were designed in different combinations where the effect of varying micro-pile lengths was investigated. In the samples, the requested changes were clearly observed by using the parameters in the same soil types. The unit weight, angle of internal friction, soil cohesion, saturated unit weight and oedometer modulus values of the two different soil types used are given in Table 1 and Table 2. Fig. 1 shows the properties of injected concrete and steel used in micro-pile design and Fig. 2 shows the standards of the materials used.

In the created models, 11 different lengths of micro-pile models were designed as 5 m, 6 m, 7 m, 8 m, 9 m, 10 m, 11 m, 12 m,13 m, 14 m and 15 m. Injected concrete and steel were used in the manufacturing of micro-piles. Concrete class C 25/30 and steel class S 235 structural steel were used. A total of 24 micro-piles were designed and analysed.

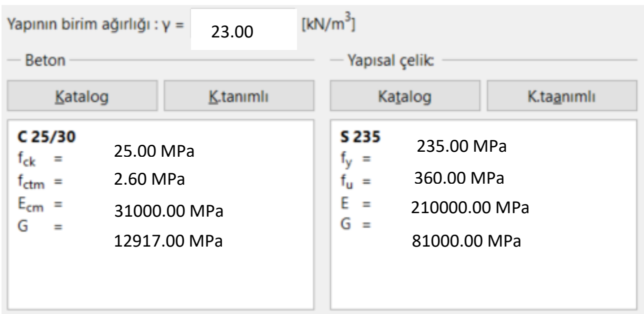

Fig. 1. Steel and injected concrete properties used in micro-pile design

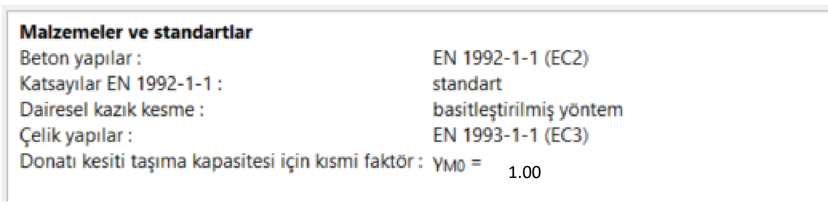

Fig. 2. Material properties and standards

The foundation geometry is designed as 24 m x 16 m. The centre to centre horizontal and vertical distances between the piles are the same and designed as 4 m. In the 24 m x 16 m foundation area, the number of micro-piles was designed as 4 on the horizontal plane and 6 on the vertical plane.

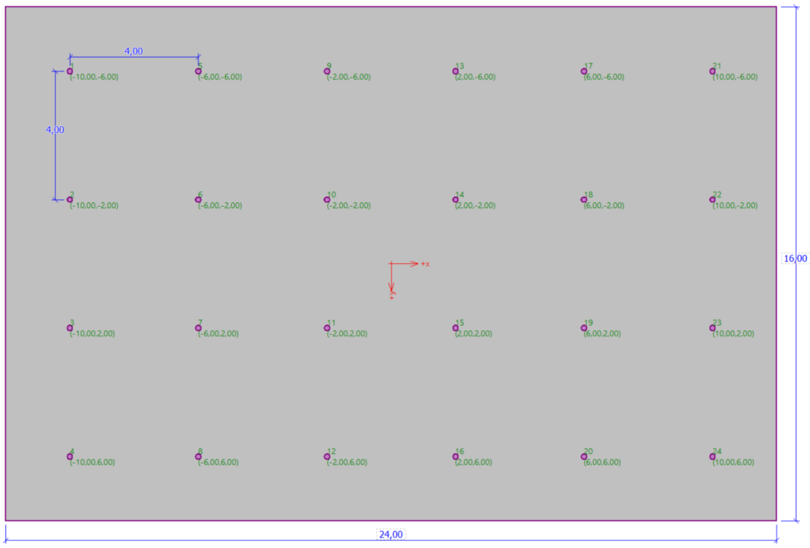

Fig. 3. Micro-pile foundation geometry plan

Fig. 3 shows the micro-pile foundation geometry plan and Fig. 4 shows the micro-pile foundation and pile information.

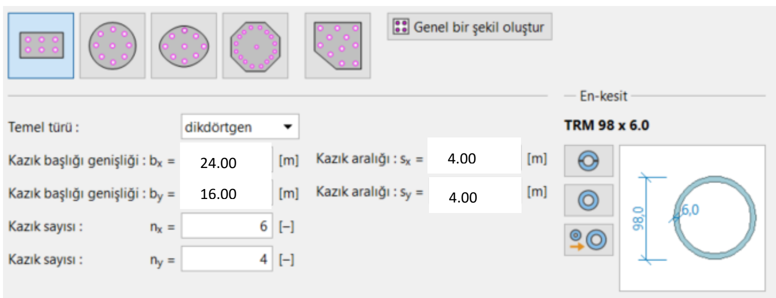

Fig. 4. Micro-pile foundation and pile information

In terms of micro-pile geometry, the starting point of the micro-piles is located at a depth of 2 m from the ground surface and the micro-pile cap is located at a depth of 1 m from the ground surface. The bottom of the ground level is designed at a depth of 18 m for all micro-pile samples. Considering the varying micro-pile lengths, it is assumed that 2 m of the micro-piles are socketed into the solid ground in each micro-pile design with the length change.

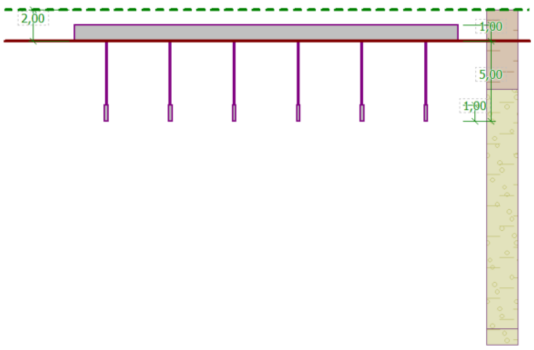

Fig. 5. Sample 5 m micro-pile profile

Similarly, in all designs, the lengths within the soil -where the micro-piles are located- were increased in parallel with the micro-pile lengths. In all micro-piles, the root region was kept constant as 1 m.

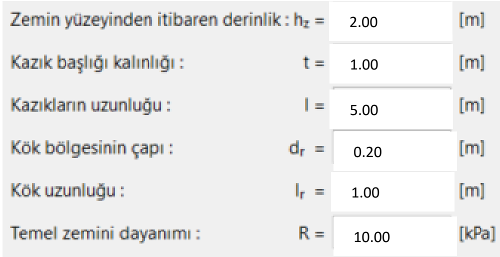

Fig. 6. Sample 5 m micro-pile properties

Exemplarily, at 5 m long micro-pile, there are 3 m clay layer and 15 m clayey gravel layer in the ground. Thus, 2 m of the 5 m micro-pile is socketed into the solid clayey gravel layer. In addition, there is no groundwater in the design. The profile and properties of the sample 5 m long micro-pile geometry design created and analysed with Geo5 geotechnical calculation program are shown in Fig. 5 and Fig. 6, respectively.

Table 3 shows the combinations of 11 different models designed in Geo5 geotechnical calculation program. Each of these designs was designed and analysed at different lengths and ground levels.

Table 3. Micro-pile models designed in the study

Model	Micro-pile length	Micro-pile ground level (Clay)	Micro-pile ground level (Clayey gravel)
Model-1	5 m	(0.00) - (-3.00)	(-3.00) – (-18.00)
Model-2	6 m	(0.00) - (-4.00)	(-4.00) – (-18.00)
Model-3	7 m	(0.00) - (-5.00)	(-5.00) – (-18.00)
Model-4	8 m	(0.00) - (-6.00)	(-6.00) – (-18.00)
Model-5	9 m	(0.00) - (-7.00)	(-7.00) – (-18.00)
Model-6	10 m	(0.00) - (-8.00)	(-8.00) – (-18.00)
Model-7	11 m	(0.00) - (-9.00)	(-9.00) – (-18.00)
Model-8	12 m	(0.00) - (-10.00)	(-10.00) – (-18.00)
Model-9	13 m	(0.00) - (-11.00)	(-11.00) – (-18.00)
Model-10	14 m	(0.00) - (-12.00)	(-12.00) – (-18.00)
Model-11	15 m	(0.00) - (-13.00)	(-13.00) – (-18.00)

3. Analyses results

In civil engineering applications and problem solutions, engineers have to think about the application as well as design. This situation is also very important in engineering applications in the field of geotechnics. Various engineering analyses of each geotechnical problem bring along soil engineering applications as well as the solution. Micro-piles are one of these application methods.

The biggest advantage of these micro-piles, which are ground improvement methods, is that they have a fast-manufacturing process and low-power light machine equipment. Compared to bored piles, it is more advantageous in terms of manufacturing process in narrow or closed areas, especially inside the building.

In this study, the maximum settlement, minimum compressive force and maximum rotation at the pile cap were analysed for different micro-pile lengths. In total, 11 analyses of 11 different lengths of micro-piles were performed in Geo5 geotechnical calculation program.

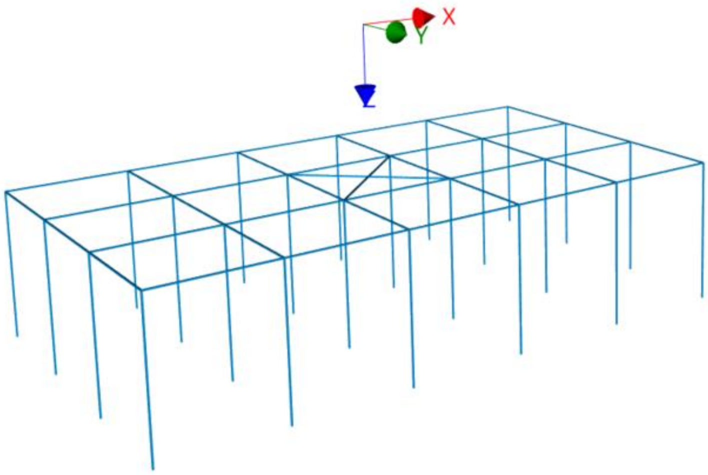

Fig. 11. Micro-pile analyses scheme

The analysis results obtained from the designs are shown in Table 4, Table 5 and Table 6. Fig. 11 shows the micro-pile schematic obtained from the analyses.

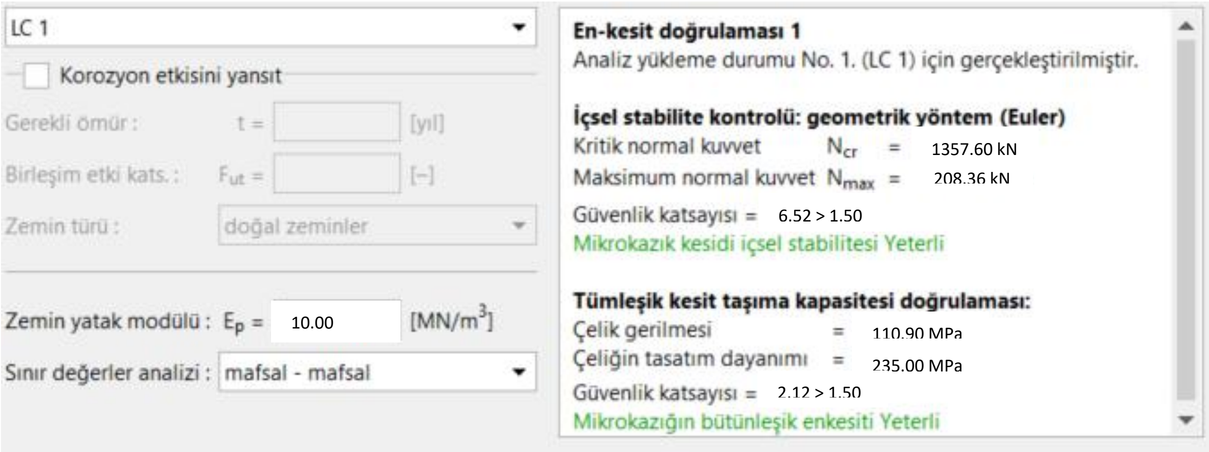

Fig. 12. Micro-pile analyses results

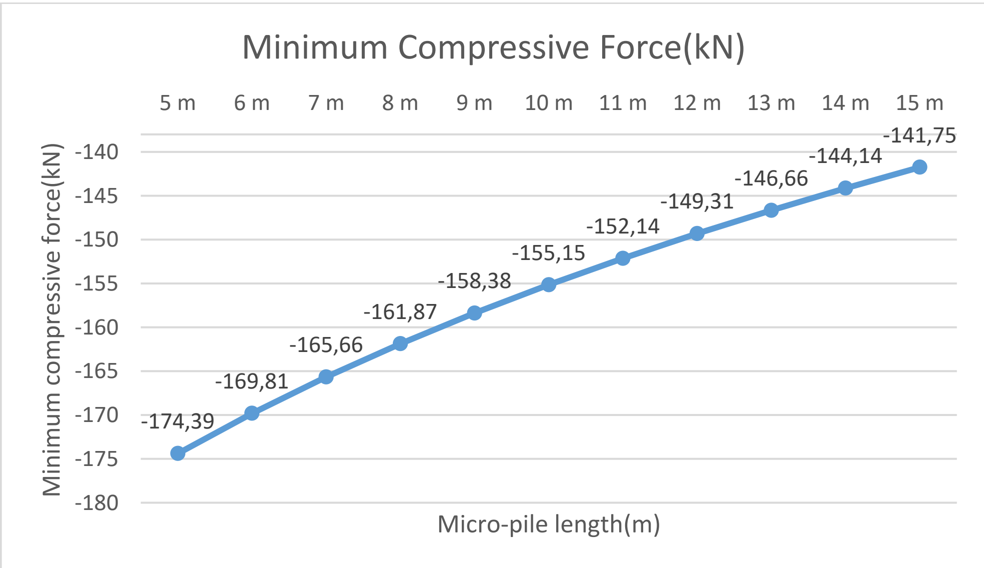

Fig. 16. Micro-pile length-minimum compressive force

3.3. Micro-pile length and maximum rotation of pile cap

Fig. 17 shows the variation of pile cap maximum rotation for piles with micro-pile lengths between 5 m and 15 m.

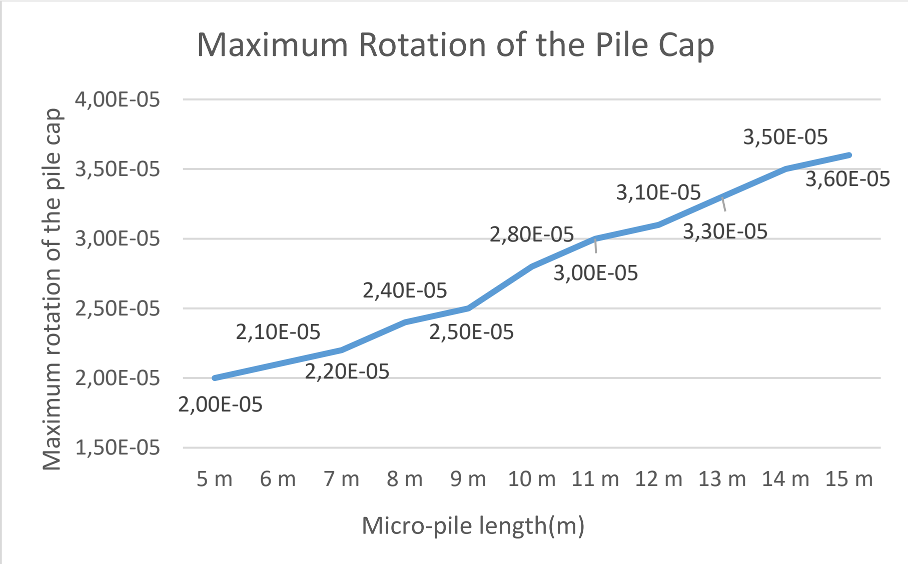

Fig. 17. Micro-pile length - maximum rotation of the pile cap

As can be seen from the results of the analyses, it was observed that the micro-piles designed in different lengths with the same soil properties significantly affected the parameters of maximum settlement, minimum compressive force and maximum rotation at the pile cap. Maximum settlement, minimum compressive force and maximum rotation at the pile cap increased with the increase in pile length. The changes in these parameters by keeping the root region length constant and increasing the micro-pile length are presented in tables. As a result of the analyses, it was observed that the selection of micro-pile lengths has an important place in micro-pile manufacturing.

4. Conclusions

In this study, the analyses of piles with the same soil properties, different soil layer thicknesses and different micro-pile lengths were investigated. A total of 11 different designs were made as micro-pile lengths (5 m, 6 m, 7 m, 8 m, 9 m, 10 m, 11 m, 12 m, 13 m, 14 m, 15 m). Designs were made in Geo5 geotechnical calculation program. The results of the analyses were mainly analysed micro-pile length-maximum settlement variation, micro-pile length-minimum compressive force and micro-pile length-micro-pile cap maximum rotation variations. The results of the analyses obtained from the study are given below:

- The maximum settlement (mm) in the analyses increased as the pile length increase from 5 m and the smallest length selected in the micro-pile design of 15 m as the longest length.
- The maximum settlement was 2.00×10^{-05} at a minimum length of 5 m and 3.60×10^{-5} at a maximum length of 15 m.
- The minimum compressive force (kN) in the analyses increased as the length of the pile increased from 5 m, the shortest length selected in the micro-pile design of 15 m as the longest length.
- The minimum compressive force was -174.39 kN at the minimum 5 m micro-pile length and -141.75 kN at the maximum 15 m micro-pile length.
- It is seen that the maximum rotation of the pile cap increases in the analyses performed as the pile length increases from 5 m, which is the shortest length selected in micro-pile designs, to 15 m, which is the longest length.
- The maximum pile cap rotation was 2.00x10-5 at a minimum of 5 m micro-pile length and 3.60x10-5 at a maximum of 15 m micro-pile length.
- Considering the parameters that are affected as the micro-pile length increases, the studies show that the quality of the micro-pile elements should be designed with a more resistant micro-pile element.
- It should not be overlooked during manufacturing and design that all the mentioned parameters will increase with the increase in the micro-pile length.

As a result, the variations of different micro-pile lengths on the maximum settlement, minimum compressive force and maximum rotation at the pile cap were analysed. Micro-piles designed with the same soil properties, same socket length in the root region and different soil layer heights increase these parameters with different length changes.

Alkali-activated by-product materials as alternative binders in deep soil mixing applications

Önder Akçakal*[1], Mustafa Hatipoğlu[1]

[1] *Istanbul Technical University, Department of Civil Engineering, 34467 Istanbul, Türkiye*

Abstract. Industrial by-products such as fly ash and ground granulated blast-furnace slag (GGBS) bring significant environmental challenges globally. Mitigation efforts focused on reintroducing these materials into the economy through their application in the construction industry as alternative resources. Since these materials do not provide sufficient binding properties when used independently, alkali activators can be used as a promising technique to improve binding properties of these waste materials. This process allows us to utilize GGBS and fly ash, as a result it is possible to reduce carbon emissions and to promote environmental sustainability. This study focuses on the application of fly ash and GGBS in ground improvement techniques, specifically targeting their use in deep mixing methods (DSM). Deep soil mixing is one of the effective soil improvement techniques in which soil is mixed with binder slurry with the help of blades. The research aims to enhance the binding properties of by-product materials through alkali activation, making them more applicable for geotechnical applications. Unconfined compression strength (UCS) tests were performed on the alkali-activated mixed samples. The increase in strength of the mixed samples was evaluated. As a result of the study outcomes of the ground improvement with alkali-activated GGBS and fly ash materials are discussed. These by-products can play an important role in reducing the carbon footprint of the geotechnical applications besides providing cost-effective solutions. This research highlights the potential of alkali-activated GGBS and fly ash in ground improvement applications. Alkali-activated by-products can be used as sustainable and efficient alternative binders in the construction industry.

Keywords: Deep Soil Mixing; By-Products; GGBS; Fly Ash; Alkali Activation

1. Introduction

High amounts of carbon dioxide emission in cement production process brings significant environmental concerns which led society to think about the reliance of construction industry on traditional cement. Global cement production is over 4 billion metric tonnes annually and Türkiye is in the fifth rank with 79 million metric tonnes (Hatfield, 2024). This quantity decreased during the pandemic period however there is a significant growth trend in the last decades which increases the concerns about environmental impacts. With 7-8% cement production is one of the major contributors of global greenhouse gas (GHG) emissions (Barbhuiya et al., 2024). Alkali activated binders with industrial by-products such as fly ash (FA) and ground granulated blast furnace slag (GGBS) have emerged in recent decades as promising alternatives of traditional cement to mitigate these concerns. When it is compared with ordinary Portland cement (OPC), alkali activated materials provide comparable technical solutions while reducing the environmental drawbacks (Cristelo, et al., 2013; Arulrajah et al., 2018).

Beside the environmental advantages of reuse of the industrial wastes, technique offers also more durable and chemically resistant binder materials (Mohammadinia et al., 2019). As a result, researchers' interest on alkali activated binders progressively increased in the last years. Studies continue various civil engineering applications and ground improvement is one of these important areas.

Deep Soil Mixing (DSM) is a ground improvement technique where a stabilizing binder slurry is mixed with soil by means of rotating blades in place. Blades mix the soil and binder slurry mechanically and form a circular column with enhanced engineering properties. Blades rotates in the soil and reaches to the required depth with mixing the soil with binder (Porbaha, 1998). It is a rapid technique and can be successfully applied in a wide range of projects, including foundations, embankments and retaining structures. (Sargent et al., 2013).

Traditional binders, cement and lime are widely used in DSM to improve the strength of the soil with hydration and pozzolanic reactions (Arulrajah et al., 2018; Sargent et al., 2013). However, production process of cement-based binders has great impact on environment, and this motivates researchers to study on alternative green stabilizers.

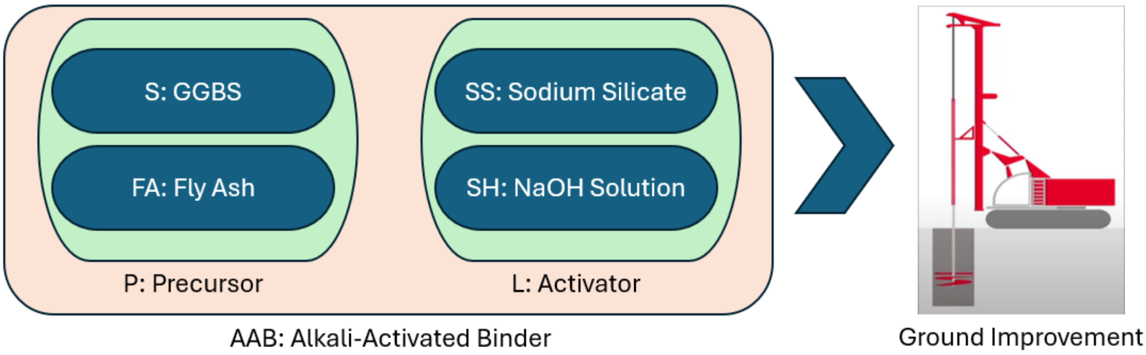

Fig.1. Ground improvement applications with alkali-activated binders

Geopolymerization is the fundamental process of the alkali-activated binders which consist of chemical reactions between aluminosilicate-rich materials and an alkaline activator. Alumina and silica dissolve into the alkaline solution in this process and then polycondensation occurs to form a three-dimensional network of sodium aluminosilicate hydrate (N-A-S-H) or calcium aluminosilicate hydrate (C-A-S-H) gels (Xu & Van Deventer, 2002).

Final properties of the geopolymeric matrix are affected by several factors like chemical composition of the precursors, concentration and composition of the alkaline activators, the ratio of liquid and binder quantities and curing conditions of the samples (Hardjito & Rangan, 2005; Al Bakri et al., 2012; Phetchuay et al., 2016). To achieve suitable mechanical properties and durability, optimization of these parameters becomes important.

Workability problems and potential carbonation or efflorescence are the main drawbacks of the technique (Palacios & Puertas, 2006). However, alkali-activated binders can be used with DSM applications and provide a sustainable alternative for ground improvement with an environmental-friendly approach (Fig. 1.)

Demand for the environmentally sustainable ground improvement techniques is increasing and the use of alkali-activated by-products such as fly ash (FA) and ground granulated blast furnace slag (GGBS) is investigated in this study as an alternative for traditional cement binder. These materials were mixed with sand under alkaline conditions in the laboratory. To evaluate the mechanical performance of the technique the unconfined compressive strength of the mixed samples was tested.

2. Investigation program

Unconfined Compression Strength (UCS) of the columns are the major performance indicators and investigation programme was determined as focusing on this parameter. As many researchers (Hardjito & Rangan, 2005; Al Bakri et al., 2012; Phetchuay et al., 2016; Mohammadinia et al., 2019) have demonstrated in their studies these parameters are affected by the concentration and composition of the alkali binder therefore different precursor dosages (P/Ws ratio 10, 15, 20, 25, 30, 35%) with varying ratios of the liquid activators were investigated.

Before the main test sets with varying dosages, a coherent set of other variables as activator ratio, sodium silicate to sodium hydroxide ratio, molarity of the sodium hydroxide and sodium silicate modulus ratio have been investigated. As geopolymerization occurs with the alkaline activation of the aluminosilicate precursors sodium hydroxide concentration gains importance (van Deventer et al. 2010; Mohammadinia et al., 2019) however to reduce the safety risks in nature of highly corrosive sodium hydroxide solution molarity needs to be optimized (Arulrajah et al, 2018). Modulus ratio (M_s) of the sodium silicate solution is the ratio of SiO_2 to Na_2O components. Sodium silicate quantity in the mixture is also important and related with the acceleration of the geopolymerization (Arulrajah et al, 2018; Shen et al., 2013; Phoo-ngernkham et al., 2015). Sample preparation sequence and material properties were investigated carefully. These parameters were determined with a series of preliminary batches and compression tests.

The utilization of the alkali activated precursors as a binder in ground improvement works was investigated with prepared samples in the laboratory. As performed in other researches (Sargent et al., 2013; Arulrajah et al, 2018; Mohammadinia et al., 2019) alkali activated binder is mixed with soil where samples were prepared with different precursor dosages. Mechanical performance of the samples was investigated with performed UCS tests (BS 1377: Part 7: Clause 7, BSI, 1990). 72 samples were prepared in total with precursor to soil weight (P/W_s) ratios varying between 0.1 to 0.35. Samples were planned to be tested after different curing times as 1, 4 and 16 weeks. Test program and the sample numbers are listed in Table 1.

Table 1. Number of samples prepared with alkali activated binders

	P/Ws (Precursor/Soil Weight)					
Curing Time	0.1	0.15	0.20	0.25	0.30	0.35
1 week	4	2	4	2	4	2
4 weeks	4	2	4	2	4	2
16 weeks	4	2	4	2	4	2
Total	12	6	12	6	12	6

3. Materials

Utilization of the by-products as precursors in alkali activated binders reduces the necessity of traditional cement in construction industry and considerably brings down the CO_2 emissions (Phair, 2006; Mohammadinia et al., 2019). Ground granulated blast furnace slag (GGBS) and fly-ash (FA) are the major by-products which can be used as aluminosilicate sources in geopolymerization process (van Deventer et al. 2010; Mohammadinia et al., 2019). GGBS is the by-product of steel manufacturing process. Molten slag floats on top of the iron ore, coke and limestone used in the blast furnace. Then it is dried and granulated and finally grinded to form a powder state. In Türkiye there are several sources of this by-product like furnace steel plants (mainly electric arc furnaces -EAF's) in Zonguldak, İskenderun, Çanakkale, Bursa and Kocaeli regions and total annual production is approximately 5 million tonnes (Yonar, et.al, 2015).

Fly-ash (FA) is also a by-product but generated by thermal power plants. They are generated from burning pulverized coal. It is collected by various methods (like electrostatic precipitators, baghouse filters or cyclone separators) to prevent environmental pollution and these methods allow its re-use in the industry (Blicharz and Franus, 2023). Fly ash output of these thermal power plants is over 20 million tonnes in Türkiye (Felekoğlu, 2006) and only 30% of the output can be re-used in the industry. Beside the economic and environmental benefits, severe stockpiling or landfill problems motivate researchers to find new ways to return this by-product to the industry (Blicharz and Franus, 2023).

GGBS and FA materials which used in this laboratory studies are received from the local plants in Türkiye (Fig. 2). F-type Fly ash was used in the studies which is originated from anthracite and bituminous coals. F-type fly ashes SiO_2+Al_2O_3+Fe_2O_3 percentage is over 70% and CaO percentage is less than 10% (Görhan et al., 2009).

To provide the alkaline environment for the geopolymerization process sodium hydroxide (NaOH) beads were diluted into a 10 Molar solution. Since this process was an exothermic reaction, in the laboratory study sodium hydroxide solution was prepared one day before the mixing phase. As the second component of the liquid activator, sodium silicate (Na_2SiO_3) solution with modulus ratio of (M_s) 3 was used to accelerate the geopolymerization process (Fig. 3).

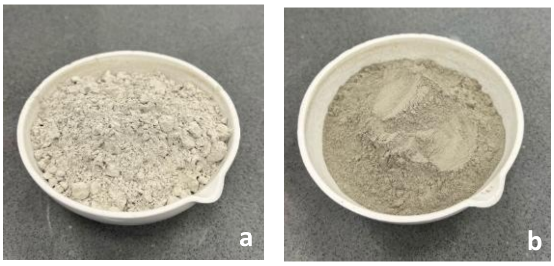

Fig.2. (a) GGBS sample, (b) Fly ash sample

Fig.3. (a) Sodium hydroxide beads, (b) Sodium silicate solution

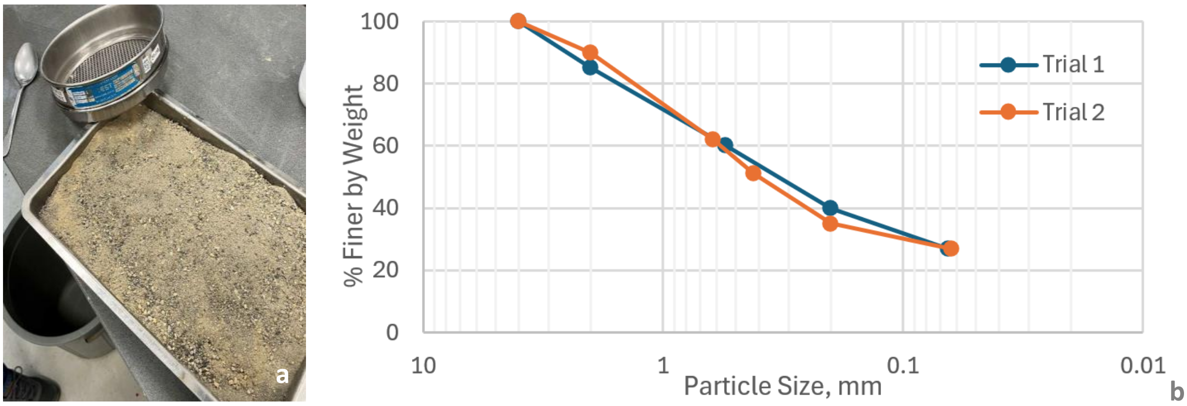

Fig.4. (a) Soil sample, (b) Sieve analysis results of the trials

Soil samples were collected from a current project site boreholes. Sand samples were preferred in the laboratory tests. SPT samples were selected, and they were sieved with a 4 mm aperture sieve (Fig. 4. (a)). The sieve analysis results are of the samples are given in the Fig. 4. (b). Fine content of the samples were limited to approximately 25% to demonstrate common site conditions for sandy soils. Soil samples were mixed with water to obtain 20% water content before the mixing stage of alkali activated binder.

4. Sample preparation and laboratory tests

Precursor (P) materials S (GGBS) and FA (Fly Ash) were uniformly mixed in a container. S:FA ratio was selected as 1.0. Liquid activator was prepared as a mix of sodium silicate and sodium hydroxide solutions. To increase the workability in some of the samples a portion of the water required for soil moisture was added to activator and they were all mixed with the precursor blend. Prepared alkali activated binder is mixed with soil in the laboratory with different dosages of precursors. P/W_s (where W_s is the weight of the dry soil in the mixture) ratios of the group of samples were 0.1, 0.15, 0.2, 0.25, 0.3 and 0.35 to see the effect or benefit of the increase of the precursors to the strength. Samples were stored under humid conditions to keep their water content during their curing time. Samples were subjected to UCS tests after 1, 4 and 16 weeks of curing times (Fig. 5).

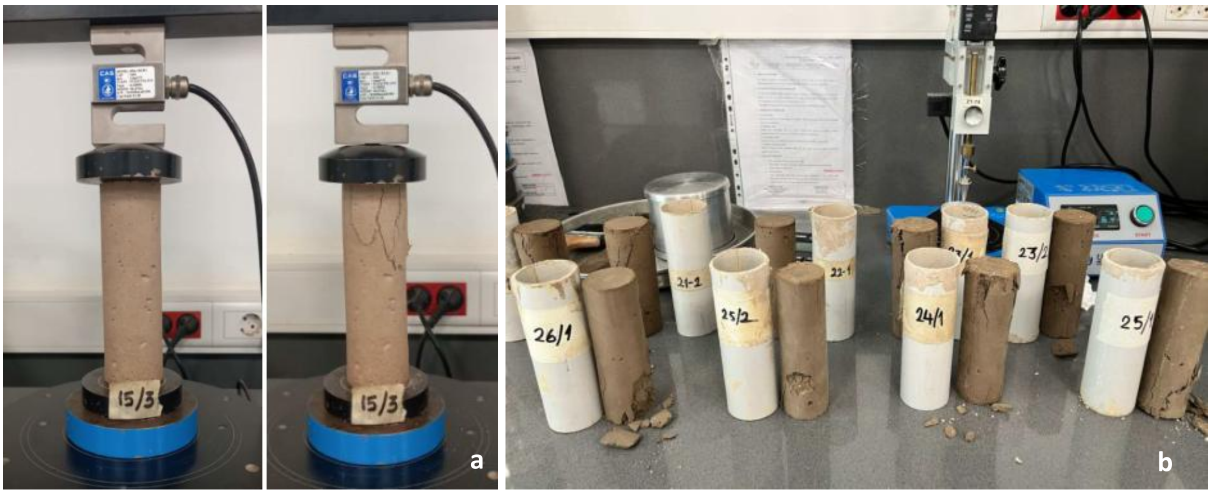

Fig.5. (a) UCS test, (b) Tested samples

5. Test results and discussion

Samples were subjected to UCS tests once the planned curing time is complete. As described in the previous section samples were prepared with two different methods. For some of the samples all the water quantity required for 20% percent water content is mixed with soil (Method A), for the rest of the samples 1/5 of the required water (4%) is mixed with the alkali activator previously to increase the workability of the binder slurry (Method B).

For every P/Ws at least 4 samples were tested, and average values were recorded and presented on Fig. 6. The results reveal that strength values increase significantly with the increase of the precursor dosage.

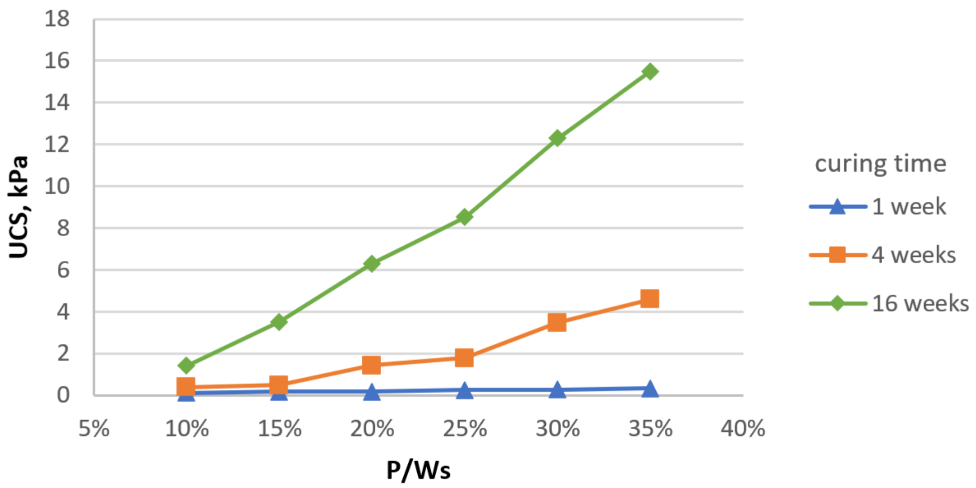

Fig.6. Average UCS results of the samples after 1 week, 4 weeks and 16 weeks curing times

Samples gained strength with the long period times and to evaluate the effect of the curing time Fig. 7 was prepared.

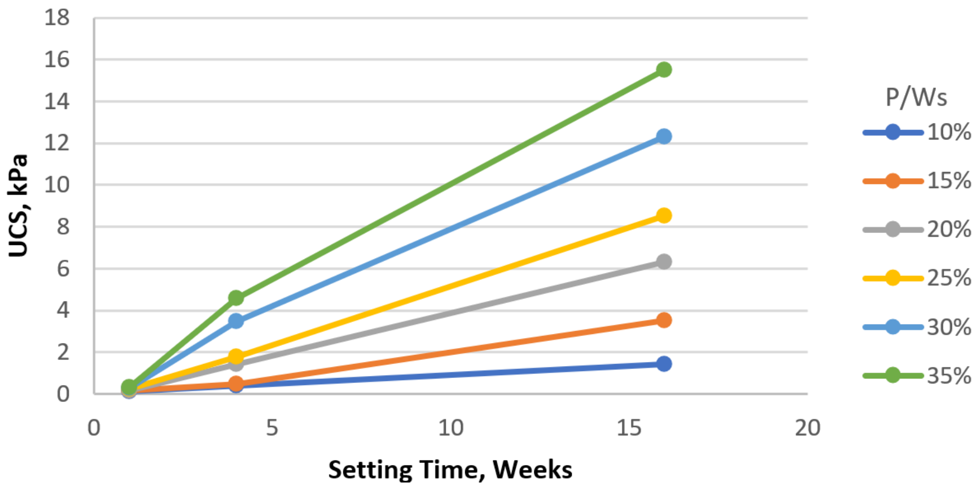

Fig.7. The increase of the average UCS Values with curing time

In general, a significant strength gain could be followed in the results with the increase of the alkali activated binder dosage. This clearly demonstrates that geopolymerization process can bring binding properties to the GGBS and FA by-products and allow them to be re-used in the industry. Despite the strength values were even less than 1 MPA after one week curing time, samples gained a significant strength in longer periods. After 4 weeks of curing time average UCS values exceeded 4 MPa and almost reached to 16 MPa after 16 weeks with 35% P/Ws ratio. However, when the average strengths compared with the curing time, the strength gain continues even after 16 weeks. Beside the strength gain, samples prepared with Method A demonstrated higher strength values when compared with the Method B. The application method and sequence of the mixing is also important for the mechanical performance of the alkali activated materials.

6. Conclusion

As a result of this study potential of the alkali activated binders prepared with by-products Fly Ash and GGBS in ground improvement works was demonstrated. Instead of traditional cement with many environmental drawbacks alkali activated binders can be utilized in geotechnical engineering especially in deep soil mixing (DSM) applications. A series of samples were prepared through the comprehensive laboratory studies with varying dosages of these by products. Mechanical performance of the samples was checked with unconfined compression tests (UCS) and evaluated within the report. The results revealed an important strength gain which can be considered as the evidence of enhanced binding capacity of these by-products. The successful results also pointed that these materials can be re-used in the industry and environmental impact of these applications can be reduced by recycling. The use of the alkali activated by-products in DSM applications can bring a sustainable approach with integration of these waste materials to the geotechnical engineering industry.

Prediction of active earth thrusts acting on a T-type cantilever retaining wall by soft computing methods

Hakan A. Kamloğlu*[1], Özge Haşlak[1]

[1] *Bayburt University, Engineering Faculty, Department of Civil Engineering, 69010, Bayburt, Türkiye*

Abstract. This study investigates the application of soft computing methods to predict active earth thrusts acting on T-type cantilever retaining walls supporting planar granular soil for active case conditions. Four different algorithms—Artificial Neural Networks (ANN), Extreme Learning Machine (ELM), Random Forest Regression (RFR), and Support Vector Regression (SVR)—were developed and compared for their predictive capabilities. A comprehensive dataset comprising 273 cases was created using Central Composite Design, where independent variables included groundwater level, saturation ratio, porosity, friction angle, wall height, heel length, and seismic coefficients. Dependent variables (lateral active earth thrust, vertical earth thrust, and application point) were obtained through finite element analyses. All algorithms were optimized using genetic algorithm to determine optimum hyperparameters. Performance evaluation using independent test cases showed that all methods could predict thrust coefficients with high accuracy (R^2 between 0.86-0.99), with SVR exhibiting superior overall performance (R^2=0.94 for lateral thrust and R^2=0.99 for vertical thrust) and minimal prediction variance. While the prediction of thrust application points remained challenging for all algorithms (highest R^2=0.64 with SVR), the study demonstrates that soft computing methods can serve as reliable and computationally efficient alternatives to complex numerical analyses for estimating earth thrusts on T-type retaining walls, particularly when optimized with genetic algorithms.

Keywords: T-type cantilever wall; Active earth thrust; Soft computing methods; FEM

1. Introduction

T-shaped cantilever walls are one of the most widely used supporting structures in civil engineering applications. The T-type walls comprise characteristic features that should be considered in lateral earth thrust calculations due to their heel configuration, which significantly influences failure surface mechanism and lateral earth pressure distribution. The main reason for this phenomenon is that the failure surface geometry behind the wall, especially in the active state, is different from other types of walls depending on the heel length (Greco, 2008). The effect of heel length on the lateral earth pressure distribution was investigated with several analytical, numerical, and experimental approaches (Chen et al., 2023; Greco, 2001; Kamiloglu, 2023). The analyses show that conventional lateral earth pressure determination methods are not accurate for T-shaped walls.

Several approaches have been employed to determine lateral earth thrust acting on the retaining structures. Although the widely used conventional lateral earth pressure determination methods are derived from analytical methods, alternative methods have been investigated to improve the calculation accuracy. These approaches can be summarized as analytical methods (Chen et al., 2025; Lin et al., 2024), numerical methods (Fan et al., 2010; Zhang et al., 2022), small-scale tests (Huali et al., 2025; Rui et al., 2024), and large-scale tests (Garrett et al., 2025). Although each method has advantages, it also has several disadvantages. Centrifuge and large-scale experiments have disadvantages based on cost and applicability. It is required to neglect or simplify some parameters to solve problems using analytical approaches. This case leads to discrepancies between analytical predictions and experimental outcomes. The numerical analyses present significant challenges, including complex mathematical modeling that requires specialized expertise and detailed soil parameters that are often difficult and expensive to obtain. Computation times can be lengthy, while boundary conditions must be precisely defined to avoid compromising results. Software costs are typically high, creating barriers to implementation for many engineers and firms. Result interpretation demands considerable experience, with misinterpretations potentially leading to serious and costly design errors. The finite element analysis method, which is classified as numerical analysis, is a good alternative to analytical and experimental methods despite having some disadvantages. In the literature, numerous studies compared finite element analyses with experimental results. The studies show that

* Corresponding author, E-mail: hkamiloglu@bayburt.edu.tr

https://doi.org/10.31462/icearc2025_ce_geo_838

finite element (FE) analysis is a highly effective method for evaluating active lateral earth pressure distribution on retaining walls (Chen et al., 2019; Fan et al., 2010; Xu et al., 2022).

In addition to conventional methods, there is an increasing number of studies analyzing retaining walls using statistical or soft computing techniques. Studies using a statistical approach usually aim to optimize parameters (Hamed et al., 2024) or to determine the effects of parameters on the result (Kamiloglu, 2023). In addition, although not used as much as others, there are also studies that aim to predict the results by establishing a relationship between independent variables and dependent variables (Lafifi et al., 2024). There are a small number of studies on lateral soil thrust estimation using soft calculation methods (Nguyen et al., 2024). It is clear that soft computing methods cannot be an alternative to traditional computing methods. However, it is also evident that some advantages can be obtained when soft computing methods are combined with complex methods such as the finite element method. Finite element analysis requires several critical competencies from a qualified expert, including the selection of appropriate calculation methods, optimization of mesh and element size, and accurate determination of material properties to be utilized in the analyses. In addition, several parameters, such as the supply of appropriate software, processor load, etc., can also make the use of the method difficult.

Hybrid applications using finite elements and soft computing methods together offer significant ease of use. In this way, users can obtain fast and reliable results on trained models without having to master the technical details of finite element analysis. This approach is not only time-efficient but also accommodates complex relationships between parameters and can provide reliable estimates for unanalyzed intermediate values. Furthermore, such hybrid models can be used with simpler hardware without needing high-performance computers or specialized software. ANN is a widely used soft computing method in lateral earth pressure estimation. However, there are many algorithms, such as Extreme Learning Machine (ELM), Random Forest Regression (RFR), and Support Vector Regression (SVR), that can be proposed as an alternative to ANN. However, there are almost no studies investigating the performance of these algorithms on a specific geotechnical problem such as horizontal soil thrust prediction.

This study is intended to compare lateral earth thrust and thrust application point estimations of four different soft computing algorithms. A T-type retaining wall supporting granular soil is considered for the active case. Lateral active earth thrust acting on the stem, vertical earth thrust acting on the heel, and thrust application points are determined as dependent variables. In the context of the study, it is aimed to estimate these dependent variables using several soft computing algorithms. Phreatic water level (PWL) (Hw), saturation ratio of the backfill above the PWL (Sr), porosity (n), internal friction angle of the backfill (ϕ), wall height (H), heel length (B), and horizontal and vertical seismic coefficient parameters (kh, kv) were determined as independent variables. A design matrix comprising lower, upper, and mean values of independent variables was created considering central composite design criteria. The design matrix was utilized as a dataset to train, test, and validate the developed algorithms. The dependent variables were determined via the finite element method by taking into account the created design matrix. Artificial Neural Networks (ANN), Extreme Learning Machines (ELM), Random Forest Regression (RFR), and Support Vector Regression (SVR) are the utilized soft computing algorithms for the estimation. Besides, the algorithms were optimized using a genetic optimization algorithm to determine optimum parameters, giving the best estimation. The comparison of the algorithms was carried out using a new data set consisting of 12 different cases, where the independent variable values were different from the data set.

2. Methods

This study aims to create AI-based algorithms predicting active lateral earth thrusts and application points of the thrusts for T-type retaining walls supporting granular backfill. The investigation was performed for planar surfaces, considering static and seismic cases. A dataset comprising a total of 273 cases was utilized by the created algorithms. Groundwater level (Hw), saturation rate of the soil layer above groundwater level (Sr), porosity (n), internal friction angle (ϕ), wall height (H), heel length (B), horizontal (kh) and vertical (kv) seismic coefficient parameters were supposed as independent variables in the dataset. Lateral earth thrust acting on the stem, vertical earth thrust acting on the heel, and application point of the thrusts were supposed to be dependent variables (Fig.1). The dependent variables were obtained with the finite element analysis method. Pseudostatic analyses were performed to consider seismic cases.

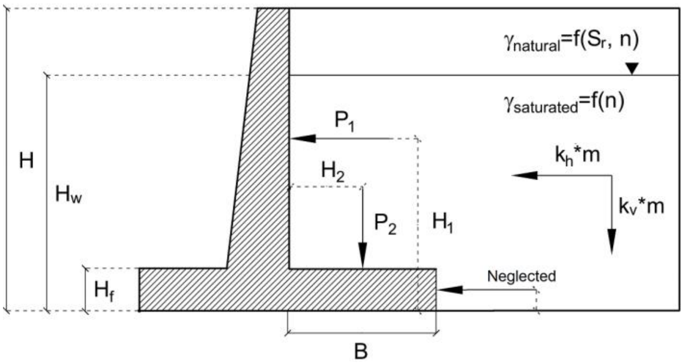

Fig. 1. Parameters considered in the created dataset

2.1. Creation of dataset

The Central Composite Design, including upper, lower points, star points, and center points of the independent variables, was employed in the creation of the dataset. The coefficient α is supposed to be 0.5 to increase data diversity. The values of independent variables used in the data set are presented in Table 1. The dataset was created by combining different values of each independent variable. As a result, a dataset comprising 273 cases was created. The dataset contains variations of the independent variables with different values (273 runs). A general view of the dataset is presented in the Appendix section.

Table 1. The upper, lower, and central values of the independent variables

Independent Variables		X_1 Hw/H	X_2 H, (m)	X_3 (B/H)	X_4 Sr	X_5 ϕ, (°)	X_6 n	X_7 kh	X_8 kv
	Coded	Actual							
Level of Factors	-1	0	3	0.1	0	28	0.15	0	0
	-0.5	0.25	4.75	0.225	0.237	32.25	0.237	0.125	0.125
	0	0.5	6.5	0.35	0.475	36.5	0.325	0.25	0.25
	+0.5	0.75	7.75	0.475	0.712	40.75	0.412	0.375	0.375
	+1	1	10	0.6	0.95	45	0.50	0.5	0.5

Dependent variables were determined with finite element analyses. Plaxis 8.6 finite element software was employed in the analyses. FE models were created considering the independent variables of the dataset. Optimum model dimensions, mesh size, and lateral translation amount to creta active state were determined with preliminary analyses. The preliminary analyses were performed for H=3 m, γ=15.4 kN/m^3, ϕ=37°, and δ/γ=R_{inter} =0.5. From the analyses, it was determined that the x and y dimensions of the model can be set as six times the wall height (H). Lateral translation leads to the occurrence of the active state, which was supposed to be 0.5% of the wall height. The optimum number and size of finite elements is 6857 elements with an average length of 60 x10^{-3} m. Parameters considered in the FE analyses are presented in Table 2.

Table 2. Parameters taken into account in the FE models.

Parameters	Backfill	Wall
Material model	Mohr-Coulomb	Linear elastic
Modulus of elasticity, (E)	40 MPa	2000 MPa
Poisson's ratio, (υ)	0.3	0.2
Dilatancy angle, (ψ)	ϕ-30 (°)	-
Saturated unit weight, (γ_{sat})	$\gamma_{unsat} = \gamma_{water} Gs(1-n) + \gamma_{water} nSr$	-
Unsaturated unit weight (γ_{unsat})	$\gamma_{sat} = \gamma_{water} Gs(1-n) + \gamma_{water} n$	24.0 (kN/m^3)
Height, (H)	–	Design matrix
Normalized heel length (B/H))	–	Design matrix
Saturation above the GWL*	Design matrix	-
Friction angle, (ϕ)	Design matrix	-
Porosity, (n)	Design matrix	-
Horizontal seismic coefficient (kh)	Design matrix	-
Vertical seismic coefficient (kv)	Design matrix	-
Normalized GWL*, (Hw/H)	Design matrix	-

The FE model was developed considering Table 2 and the independent variables given in the dataset (Appendix). As a result of plastic analyses, P_1, P_2, H_1, and H_2 parameters given in Fig. 1 were determined. Dependent variables were determined as dimensionless quantities considering the following equations.

$$y_1 = \frac{2P_1}{\gamma_{natural} H^2} \tag{1}$$

$$y_2 = \frac{2P_2}{\gamma_{natural} H^2} \tag{2}$$

$$y_3 = \frac{H_1}{H} \tag{3}$$

2.1. Soft computing methods

Within the scope of the study, it is aimed to determine the relationship between independent variables and dependent variables by soft calculation methods. At this stage, four different algorithms were determined. One of these algorithms, ANN, was chosen because it is the most widely used and most known method in geotechnical engineering. These four algorithms cover a broad spectrum of machine learning paradigms: ANNs represent neural-based learning with their multi-layer architecture; SVR leverages kernel methods and optimization theory; RFR exemplifies ensemble learning through decision trees, and ELM offers a hybrid approach with its unique random feature mapping and analytical learning.

Artificial Neural Networks (ANN), Extreme Learning Machines (ELM), Random Forest Regression (RFR), and Support Vector Regression (SVR) are the soft computing algorithms utilized for the estimation of the dependent parameters. ANN algorithms are the most widely used artificial intelligence-based prediction method in geotechnical engineering. With its ability to model the complex non-linear nature of soil behavior, simultaneously evaluate relationships between multiple soil parameters, and provide effective learning even with limited datasets, ANN is used in many studies (Thottoth et al., 2024; Yıldız et al., 2010).

Extreme Learning Machine (ELM) is a single-layer feedforward learning algorithm developed as an alternative to ANN (Hameed et al., 2024). The most distinctive feature of ELM is that input weights and hidden layer biases are randomly assigned and not updated during training; only the output weights are analytically calculated (Masood et al., 2023). This approach makes the training process of ELM much faster than ANN and eliminates the problem of getting stuck in local minima. However, it may experience stability issues due to randomly assigned weights and might not be as successful as ANN in complex problems. ELM is particularly advantageous in applications requiring fast training and low computational requirements, real-time systems, and large datasets, while traditional ANNs may perform better in complex problems requiring deep learning.

Random Forest Regression (RFR) is a robust machine learning algorithm that integrates multiple trees in the context of the ensemble learning criteria (Cutler et al., 2012). The multiple trees comprise classification and regression trees (CART), which are trained by randomly selected data. Each decision tree forming the random forest is generated in parallel, and these trees can consist of both classification trees and regression trees. The nodes in each decision tree are divided by using the best attributes that can obtain the best solution among all features. This splitting process continues until certain stopping criteria, such as maximum depth or minimum sample count, are met. In regression problems, decision trees typically use the average target variable value of samples that fall into a particular leaf node as the prediction value. One of the most important advantages of the random forest is that it can provide solutions to both classification and regression problems, which form the basis of other machine learning algorithms (Kumral et al., 2022).

Support Vector Regression (SVR), proposed by Boser et al. (1992), is an adaptation of Support Vector Machines for regression problems, creating an epsilon tube around data points while minimizing deviations outside this tube. It can be used to solve nonlinear classification, regression, and prediction problems (Kandiri et al., 2022). Unlike ANNs, which rely on interconnected neurons and backpropagation, SVR is based on convex optimization and kernel functions, generally requiring less data to achieve good results. SVR offers better interpretability than ANNs and performs efficiently on small to medium-sized datasets, showing resistance to overfitting and capturing non-linear relationships through the kernel trick. However, SVR's computational cost increases significantly with larger datasets and requires careful hyperparameter tuning. In contrast, ANNs excel with large datasets, complex relationships, and unstructured data like images and audio, though they demand more computational resources and are typically considered "black boxes" with limited interpretability.

3. Estimation of dependent variables with soft computing methods

In this part of the study, several soft computing agrorithms were developed employing Matlab R2017b software by using the dataset. A detailed explanation of the estimation methods is presented under the subheadings.

3.1. Estimation of dependent variables with ANN

The ANN network used has an input layer, hidden layers, and an output layer. The data set was divided for training, testing, and evaluation of the model. Levenberg-Marquardt (trainlm) was used as the training algorithm. The maximum number of epochs was set as 3000. An early stopping criterion was applied if the validation error did not improve for 500 epochs. The performance function is considered as Mean Squared Error (MSE). Target error, learning rate, and momentum constant criteria were set as 0.0001, 0.03, and 0.03 respectively. The performance of the trained ANN model was evaluated on training, validation, and test data sets. The metrics used for evaluation are mean absolute error (MAE), mean absolute percentage (MAPE), root mean squared error (RMSE), and regression coefficient (R^2). The workflow explaining the general structure of the implemented algorithm is presented in Fig.2.

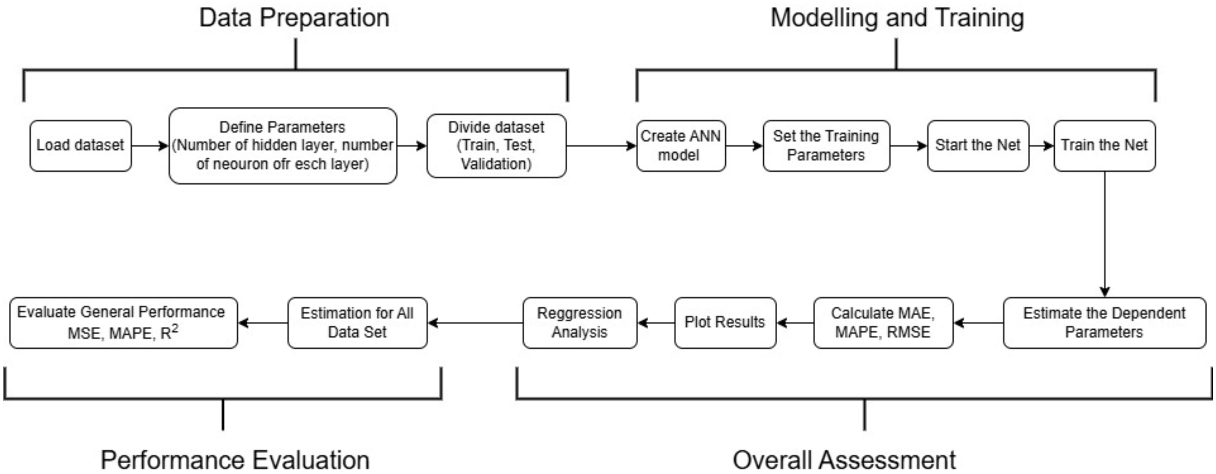

Fig. 2. Flow chart of the developed ANN algorithm

The performance of the ANNs substantially depends on parameters such as training ratio, layer number, and neuron number of each layer. It may be time-consuming and inefficient to determine the optimum values of these parameters by trial and error. Therefore, it is required to optimize the net using various optimization methods. The genetic algorithm is a powerful optimization technique that attempts to automatically find the best combination of these parameters by mimicking the process of evolution in nature. The genetic algorithm was employed to determine the optimum layer number, neuron number, and train ratio.

The optimization of artificial neural network (ANN) parameters for retaining wall analysis was conducted using a genetic algorithm (GA) approach. This MATLAB implementation employs evolutionary principles to automatically determine the optimal network architecture and training parameters. The GA operates on a population of 20 individuals across 50 generations, with each individual representing a different ANN configuration defined by a number of hidden layers (1-3), neurons per layer (5-20), and training ratio (0.6-0.9). Through iterative selection, crossover, and mutation operations, the algorithm evolves increasingly effective network configurations. The fitness evaluation function trains each candidate network using the Levenberg-Marquardt algorithm and assesses performance via a mean squared error on test data. The optimization results revealed that a network architecture with 1 hidden layer containing 6 neurons and a training ratio of 0.89 produced the best performance.

The optimized ANN model for retaining wall analysis was evaluated through multiple executions to assess its reliability and performance consistency. The code was run 10 times, each with different random initializations of network weights, to account for the stochastic nature of neural network training. For each run, key performance metrics, including mean absolute error (MAE), mean absolute percentage error (MAPE), root mean square error (RMSE), and coefficient of determination (R^2), were presented in Table 3.

Table 3. Performance metrics of the ANN algorthm

Run →	1	2	3	4	5	6	7	8	9	10	Mean	Standart Deviation
MAE	0.1456	0.09669	0.09	0.1887	0.0713	0.0843	0.1268	0.0638	0.1531	0.0859	0.1106	0.0388
MAPE	0.1065	0.0964	0.1124	0.1912	0.1269	0.1122	0.0796	0.1299	0.2124	0.132	0.13	0.0392
RMSE	0.2152	0.1205	0.1201	0.2417	0.0917	0.1049	0.296	0.0868	0.1878	0.1086	0.1573	0.0691
R^2	0.9413	0.941	0.9336	0.9199	0.939	0.9505	0.9496	0.9293	0.8654	0.9309	0.9301	0.0233

3.2. Estimation of dependent variables with ELM

In this study, an Extreme Learning Machine (ELM) approach was implemented to predict retaining wall behavior. The flow chart of the code is given in Fig. 3. The MATLAB implementation began with data preprocessing, including z-score normalization of all variables. The dataset was divided into training and testing subsets using random sampling. The ELM model utilized hidden neurons with sigmoid activation functions for optimal performance. The core advantage of ELM lies in its training approach: input weights and biases were randomly assigned. In contrast, output weights were analytically calculated using the Moore-Penrose generalized inverse, significantly reducing computational complexity. Model performance was evaluated using multiple metrics (MSE, RMSE, R^2, MAE) and visualized through scatter plots comparing predicted versus actual values. The results demonstrate that the ELM model effectively captures the complex relationships between the input parameters and the retaining wall behavior, offering a reliable and computationally efficient alternative to traditional numerical methods for engineering applications.

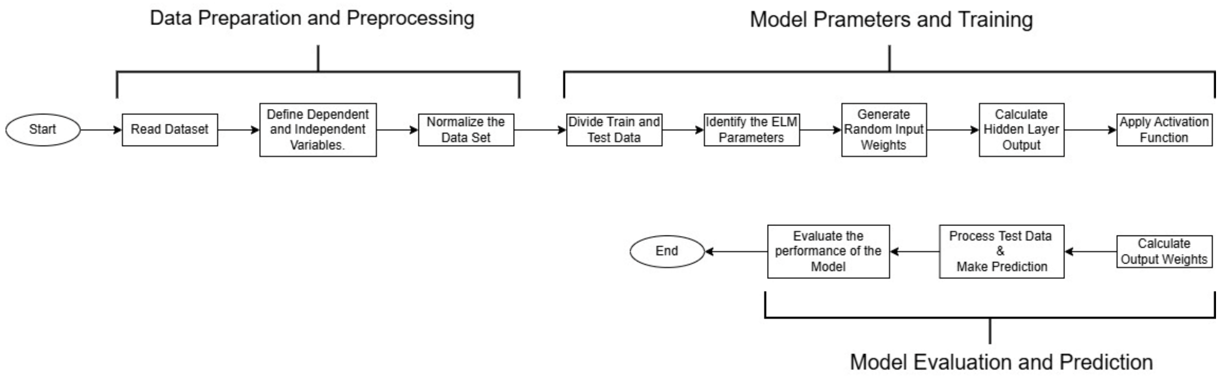

Fig. 3. Flow chart of the developed ELM algorithm

To enhance the prediction performance of the Extreme Learning Machine (ELM) model for retaining wall behavior, a genetic algorithm (GA) optimization approach was implemented to determine the optimal hyperparameters. The GA optimization considered four key parameters: the number of hidden neurons (ranging from 20 to 200), the number of hidden layers (ranging from 1 to 3), the training-testing data split ratio (ranging from 0.5-0.5 to 0.9-0.1), and the activation function type (sigmoid, sine, or radial basis). The fitness function utilized 5-fold cross-validation with the coefficient of determination (R^2) as the performance metric. After running the GA for 50 generations with a population size of 40, the optimal configuration was determined to be 127 neurons in a single hidden layer, a training-testing ratio of 0.89-0.11, and the sigmoid activation function. This optimization process significantly improved the model's predictive capability compared to the standard ELM implementation, as evidenced by enhanced performance metrics (MSE, RMSE, R^2, MAE). The optimization process effectively balanced model complexity and generalization ability while maintaining the computational efficiency that makes ELM attractive for engineering applications.

The optimized ELM model for retaining wall analysis was evaluated through multiple executions to assess its reliability and performance consistency. The code was run 10 times, each with different random initializations of network weights, to account for the stochastic nature of neural network training. For each run, key performance metrics, including Mean Square Error (MSE), Root Mean Square Error (RMSE), Mean Absolute Error (MAE), and coefficient of determination (R^2), were presented in Table 4.

Table 4. Performance metrics of the ELM algorthm

Run →	1	2	3	4	5	6	7	8	9	10	Mean	Standart Deviation
MSE	0.0703	0.0238	0.0632	0.0282	0.021	0.0451	0.0473	0.035	0.0223	0.0617	0.0418	0.0175

MAE	0.1725	0.1322	0.1385	0.1298	0.1092	0.1478	0.1695	0.1378	0.1104	0.192	0.144	0.0256
R^2	0.7416	0.9007	0.6233	0.9027	0.804	0.7747	0.7201	0.8292	0.8761	0.7888	0.7961	0.0831

3.3. Estimation of dependent variables with RFR

The provided MATLAB code implements a Random Forest Regression model to predict a dependent variable based on eight independent variables. The workflow begins by importing data and separating the features and target variables. The dataset is then randomly split into training and testing sets. The Random Forest model is trained using optimized trees with minimum leaf size while training time is measured. After training, predictions are made on the test set, and performance metrics including Mean Squared Error (MSE), Root Mean Squared Error

(RMSE), R-squared (R^2), and Mean Absolute Error (MAE) are calculated to evaluate model accuracy. Finally, the code visualizes prediction performance by plotting actual versus predicted values and displays all performance metrics along with the training duration (Fig.4).

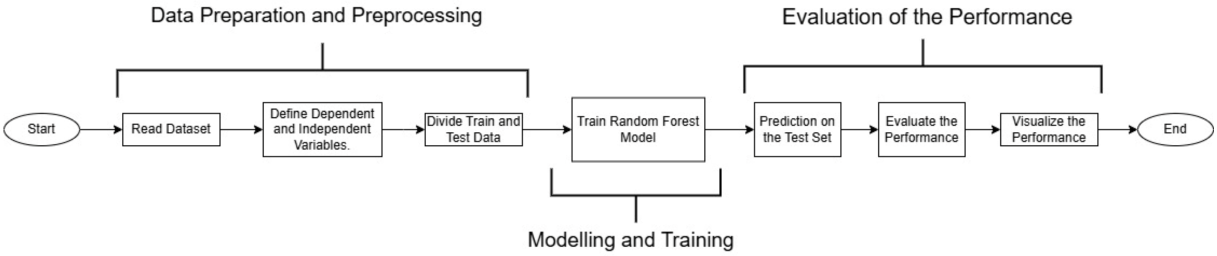

Fig. 4. Flow chart of the developed RFR algorithm

In this study, a parameter optimization approach was implemented to enhance the performance of the Random Forest Regression model for predicting retaining wall behavior. The optimization algorithm systematically explored various combinations of three critical parameters: training data ratio (ranging from 0.7 to 0.9), number of trees (from 50 to 300), and minimum leaf size (from 1 to 20). Each parameter combination was evaluated by training the model and calculating the Root Mean Square Error (RMSE) on the test dataset. The algorithm recorded all results, ranked them by RMSE, and identified the optimal parameter set that minimized prediction error. This optimization process revealed that a training ratio of 0.80, 200 trees, and a minimum leaf size of 1 yielded the best performance. These optimized parameters were subsequently incorporated into the final Random Forest Regression model, significantly improving its predictive accuracy compared to the initial configuration of 100 trees and minimum leaf size of 5. Table 5 presents the performance metrics of the optimized RFR code.

Table 5. Performance metrics of the RFR algorthm

Run →	1	2	3	4	5	6	7	8	9	10	Mean	Standart Deviation
MSE	0.0226	0.0157	0.0244	0.0253	0.0324	0.0294	0.0186	0.0336	0.0329	0.0252	0.026	0.0058
RMSE	0.1503	0.1254	0.1562	0.159	0.1801	0.1714	0.1363	0.1833	0.1815	0.1586	0.1602	0.0185
MAE	0.0835	0.0966	0.084	0.1026	0.1104	0.0984	0.0997	0.12	0.116	0.0984	0.101	0.0114
R^2	0.8771	0.9202	0.8864	0.8723	0.8467	0.8782	0.8905	0.8375	0.8677	0.8747	0.8751	0.0217

3.4. Estimation of dependent variables with SVR

The MATLAB code begins by importing data from an Excel file and separating independent variables from the dependent variable. The code then normalizes the data using z-score standardization to ensure all parameters contribute equally to the model. After dividing the dataset into training and testing portions, it constructs a Support Vector Regression (SVR) model using a Radial Basis Function kernel with epsilon=0.1 and automatic kernel scaling. The trained model predicts values for the test data, and performance is evaluated through MSE, RMSE, and R^2 metrics. Results are visualized in a scatter plot comparing actual versus predicted values. Finally, a custom function is defined for normalizing and predicting new data points, enabling quick predictions without requiring additional finite element analyses (Fig.5).

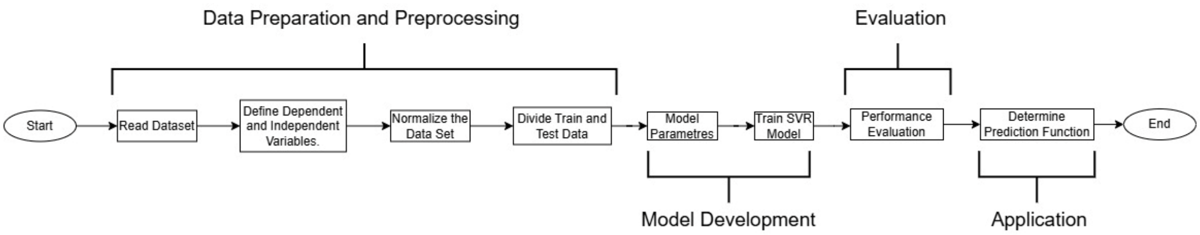

Fig. 5. Flow chart of the developed SVR algorithm

Genetic Algorithm was implemented to find the optimal hyperparameters of the estimation code for predicting retaining wall behavior. A new code was developed to optimize a Support Vector Regression (SVR) model using a Genetic Algorithm to predict retaining wall behavior from geotechnical parameters. The process involves loading and normalizing data from eight independent variables and then splitting it into training and testing sets. The code optimizes three key hyperparameters (Epsilon, Kernel Scale, and Box Constraint) through Genetic Algorithm with 5-fold cross-validation. After finding optimal values (Epsilon: 0.0049, Kernel Scale: 5.6581, Box Constraint: 10.0005), the final model is trained and evaluated, achieving excellent performance metrics (MSE: 0.0293, RMSE:

0.1712, R^2: 0.9086). This optimization significantly improves the model's ability to predict retaining wall behavior, explaining approximately 91% of the variance in the dependent variable. Table 6 presents the performance metrics of the optimized SVR code.

Table 6. Performance metrics of the RFR algorithm

Run →	1	2	3	4	5	6	7	8	9	10	Mean	Standart Deviation
MSE	0.0059	0.0273	0.0292	0.0117	0.0118	0.0268	0.0216	0.0111	0.0187	0.0232	0.0187	0.0077
RMSE	0.0765	0.1653	0.1708	0.1081	0.1084	0.1639	0.1469	0.1056	0.1368	0.1523	0.1335	0.0303

4. Comparison of the estimations of the algorithms

When the performance metrics obtained over the test and validation data in the networks trained within the scope of the study are examined, it is seen that the predictions are at statistically acceptable levels. In this part of the study, the predictive performance of the networks trained for a new set of independent variables with random values (Table 7), which was not used in the network training, was compared.

Table 7. Independent variables used for comparion of the algorithms.

Runs	X1 (Hw/H)	X2 (H)	X3 (B/H)	X4 (Sr)	X5 (ϕ)	X6 (n)	X7 (kh)	X8 (kv)

Fig.6 presents the comparison estimation power of the algorithms considering the new cases. The estimations of the algorithms were compared with FE analysis results. The dependent variables to be estimated by the algorithms were determined as lateral active soil thrust coefficient ($P_1/\gamma H^2$), vertical soil thrust coefficient ($P_2/\gamma H^2$), and the application point coefficient of lateral soil thrust (H_1/H). Since the application point of the vertical soil thrust to the wall heel is approximately half of the wall heel length, this dependent variable was not considered in the comparisons. The algorithms were run 10 times, and the means and standard deviations of the results were determined. The mean values were compared with the results of the finite element analyses. The horizontal active earth thrust acting on the stem of the wall, the vertical load acting on the wall heel, and the point of application of the horizontal thrust were considered dimensionless variables. Regression analyses were performed on the graphs obtained. In addition, the uncertainty values in the predictions are expressed by error bars.

Fig. 6a-6c compares estimations of the ANN algorithm with FE analysis results. The regression coefficients of the horizontal active thrust coefficient acting on the wall (Fig. 6a) and the horizontal thrust coefficient acting on the wall (Fig.6b) foundation are high values of approximately 91% and 98%. The regression coefficients of the horizontal active thrust coefficient acting on the wall (Fig. 6a) and the horizontal thrust coefficient acting on the wall heel (Fig. 6b) are approximately 91% and 98%, respectively. This high R^2 value indicates a strong linear relationship between the calculated and predicted values, which are approximately 91% and 98%, respectively. As a result of the examination of Fig. 6c, it is seen that the calculated and estimated coefficient values are between 0.35 and 0.5. However, although the estimated and calculated values are close to each other, the agreement is insufficient. Especially in Figures 6a and 6b, it can be seen that the magnitudes of the error bars showing the uncertainties are quite high.

In Figures 6d-6f, the prediction power of the ELM algorithm is compared with the finite element analysis results, and similar results are obtained with the ANN algorithm. In Figures 6d and 6e, the regression coefficients of the horizontal and vertical earth thrust coefficients were determined as 0.91 and 0.98. This value shows that the ELM algorithm has a very high prediction power. However, as can be seen from the R^2=0.58 value given in Figure 6f, the prediction of the point of impact of the earth thrust on the wall is not reliable. Compared to the error bars in the predictions made with the ANN algorithm, it is seen that the predictions made with the ELM algorithm give results in lower ranges.

Fig.6g-6i presents a comparison of estimation results of RFR algorithms with FE results. Although at lower levels than the ANN and ELM algorithms, the lateral and vertical soil coefficient estimates of the RFR algorithm are significant (R^2=0.87 and R^2=0.86). Fig. 6i shows that although there is no significant difference between the predicted and calculated values, the R^2 value of 0.3842 indicates that the relationship between the predicted and calculated values is weak. In addition, it is seen from the error bars that the prediction uncertainty is lower in this application compared to the ANN algorithm.

Fig.6j-6l shows the relation between the FE analysis result and the estimation of the SVR algorithm. Relatively high regression coefficients for lateral earth thrust and vertical earth thrust coefficient estimations were determined with R^2=0.94 and R^2=0.99 respectively. Although the predictions made for the H_1/H value are not considered to be sufficiently compatible with the finite element solution, they are higher than the other algorithms (R^2=0.64). In addition, the fact that the t-bars showing the estimation variances are almost negligible indicates that the standard deviation of the estimations is very small.

5. Conclusions

This study aims to compare four different soft computing algorithms (ANN, ELM, RFR, and SVR) for estimating active erath thrust and vertical earth thrust acting on the stem and heel of the T-type retaining wall respectively. In addition, the application point of the active alteral earth thrust was also tried to be estimated within the relevant algorithms. Within the scope of the study, the data set was prepared with a central composite design. Groundwater level (Hw), saturation rate of the soil layer above groundwater level (Sr), porosity (n), internal friction angle (□), wall height (H), heel length (B), horizontal (kh) and vertical (kv) seismic coefficient parameters were supposed as independent variables in the dataset. Lateral earth thrust acting on the stem, vertical earth thrust acting on the heel, and application point of the thrusts were supposed as dependent variables. The data set comprises 273 cases, which are various values of independent variables. The dependent variables in the data set were obtained by analyzing each case using the FE method. Training was done with different algorithms using the data set and the prediction capacities of these algorithms were compared using new independent variable sets. Based on the comprehensive analysis, the following conclusions can be drawn:

- All four soft computing algorithms demonstrated high accuracy in predicting lateral active soil thrust coefficients ($P_1/\gamma H^2$) and vertical soil thrust coefficients ($P_2/\gamma H^2$), with regression coefficients ranging from 0.86 to 0.99 when tested against FE analysis results.
- The SVR algorithm exhibited superior performance overall, achieving the highest regression coefficients for lateral earth thrust (R^2=0.94) and vertical earth thrust (R^2=0.99) predictions, while also showing the most consistent prediction capability with minimal variance across multiple runs.
- All algorithms struggled with accurately predicting the application point coefficient (H_1/H), with SVR performing relatively better (R^2=0.64) than the other methods (ANN: R^2=0.42, ELM: R^2=0.58, RFR: R^2=0.38).
- The ELM algorithm provided comparable accuracy to ANN for thrust coefficient predictions but with significantly reduced computational complexity and training time, making it a viable alternative for practical applications.
- The RFR algorithm, while showing slightly lower accuracy than the other methods, demonstrated good stability with consistent predictions across multiple runs.
- The genetic algorithm optimization significantly improved the performance of all four soft computing methods by identifying optimal hyperparameters, particularly for the SVR and ANN models.

Abstract. Cemented paste backfill (CPB) has become a popular choice for underground filling in the mining industry because of its ability to provide strong support and enhance safety in underground operations. Evaluating the performance of these backfill types is of great importance, especially in terms of parameters such as water permeability, strength and microstructural properties. In this context. the k_{sat} (k_{sat} Saturated Permeability Test) is an effective method for determining the permeability properties of CPB. In this study, it was aimed to determine the permeability properties of CPB mixtures prepared with different sand replacement ratios (15%. 30%. 45% by weight) and to investigate their effects on CPB performance. The mechanical (uniaxial compression, UCS), microstructure (scanning electron microscope, SEM) and permeability (k_{sat}) properties of CPB samples prepared with constant cement content/type (5%/CEM I), solid content (75% by weight) at different curing days (3-28) were investigated in detail. As a result of the study, it was observed that permeability properties directly affect the backfill strength. In addition, microstructural investigations revealed that pores and crack structures in the internal structure of the backfill material are directly related to permeability. The results of the study also detailed the effect of curing times on permeability values. These findings highlight the importance of the KSAT test in the design and application processes of CPBs and suggest that microstructural and mechanical parameters should be carefully considered to optimize CPB performance.

Keywords: Cemented paste backfill; Hydraulic conductivity; Mechanical, Sand content

1. Introduction

The mining industry is currently focusing on developing innovative technologies and methods that promote sustainable and safe operations (Keskin et al., 2024). One of the biggest challenges in underground mining is the safe and effective filling of post-excavation voids. Filling these voids with appropriate materials both ensures the continuity of mining operations and increases structural integrity and safety within the mine (Đurđevac et al., 2022). Cemented paste backfill (CPB) is one of the most common and effective filling materials developed for this purpose. In addition to providing an economical solution by minimizing environmental impacts. it is widely used in the mining industry due to its superior properties such as high strength capacity and low water permeability (Li et al., 2020).

CPB is considered to be one of the most effective waste disposal methods in terms of soil reinforcement, waste storage and operational efficiency (Fall et al., 2010). CPB consists of a mixture containing 70-85% tailings material, 3-7% cement and water by weight (Sari et al., 2023a). The mineralogical and chemical properties of the tailings used play a decisive role on the strength of the backfill. In particular, sulfur compounds and fine-grained structures can weaken the strength by negatively affecting the hydration process (Liu et al., 2020a). In addition, environmental factors such as acid mine drainage can seriously threaten the long-term stability of cemented paste backfills (Sari et al., 2022; Kasap et al., 2022a). Therefore, not only the early age strength but also the long-term strength under environmental conditions should be considered as a basic criterion in the performance evaluation of CPB systems. The formation of a durable backfill structure in the long term depends primarily on ensuring the microstructural integrity of the mixture and the resistance of this structure to environmental effects (Liu et al., 2020b). The microstructural development within the CPB is directly related to the quality, continuity and distribution properties of the products formed as a result of the hydration processes. Quality hydration products increase strength while reducing permeability. Therefore, parameters such as binder type, additive content and waste particle size should be carefully optimized. In order to provide better performance in the long term and to

golden light publishing

strengthen the microstructural integrity of the filler, the use of fly ash, slag, aggregate and various waste-based materials in the CPB composition are considered as effective alternative methods (Kasap et al., 2022b).

Sand, which is widely used in the construction sector, can be evaluated as an alternative aggregate in mining applications and has the potential to improve the mechanical properties of the fill. Aggregates directly affect the permeability, strength and rheological behaviors of cementitious mixtures depending on their physical parameters such as grain size, shape, surface roughness, density, water absorption capacity and thermal properties. (Lyu et al., 2023). Particularly, grain shape and distribution significantly shape the engineering performance of cementitious backfill by determining the friction and shear forces developed in the internal structure of the mixture (Kasap et al., 2022c). In this direction, applications aimed at the use of sand as an aggregate replacement in order to improve the performance of CPB systems are gaining more and more importance. Magmatic, sedimentary and metamorphic rocks, which are widely found in different regions of Türkiye, constitute the main geological main sources from which sands that can be evaluated for this purpose can be obtained. Magmatic rocks (e.g. granite, basalt and andesite) are formed by the cooling and solidification of molten rocks in the earth's crust and generally attract attention with their durable and hard structures. Sedimentary rocks (e.g. sandstone and limestone) are formed as a result of the accumulation of organic and inorganic substances, while metamorphic rocks are transformed under high temperature and pressure to form durable species such as marble and quartzite (Xue et al., 2014; Mibei et al., 2014). The mineralogical and petrographic properties of these rocks should be evaluated according to whether they are compatible with cementitious systems and the contributions of these materials to the CPB performance should be determined accurately.

The performance of cemented paste backfill may vary significantly depending on the properties of the materials used in their composition and environmental conditions. In particular, critical parameters such as water permeability, mechanical strength and microstructural factors are among the main elements affecting the long-term stability and durability of CPB (Sari et al., 2023b). In this context, the properties of the sand used in the mixture also play an important role. The polyhedral and rough surface texture of sand particles can increase the water requirement of cement mixtures and negatively affect workability (Kasap et al., 2023). Therefore, maintaining optimum particle fineness and sand ratio is important both in terms of workability of the mixture and final performance. In recent years, sand has started to be widely used as a binder or aggregate in the production of CPB. Due to its lower cost compared to cement and its potential to improve gradation disorders caused by tailings, sand is considered an important additive material in cemented paste backfill mixtures. However, the effectiveness of this additive depends on the careful selection of the physical and mineralogical properties of the sand; because these properties can directly affect the permeability and mechanical strength of the backfilling (Fall et al., 2009; Zhou et al., 2020).

In underground mining, the permeability properties of backfill materials play a critical role in both maintaining the structural integrity of the backfill and controlling environmental impacts (Ghirian & Fall, 2017). The movement of water in backfill systems can not only weaken the physical strength, but can also lead to the transport of harmful chemicals into underground water resources. This makes it important to control the pore structure and void continuity in the embankment. In particular, fillings with high permeability values allow water and dissolved ions to be easily transported within the structure, weakening both the mechanical properties of the material and threatening its long-term stability (Liu & Deng, 2023). Therefore, the determination of the permeability properties of backfills by reliable methods is recognised as a fundamental requirement for the success of mining applications (Yilmaz et al., 2011). In this context, the k_{sat} (saturated hydraulic permeability) test is a standardised method for quantitatively evaluating the water resistance and porosity structure of the CPB material. The data obtained with k_{sat} contribute to the design of filling materials in accordance with lower permeability and higher strength targets (Belem et al., 2010).

When the literature is examined. it is seen that there are various studies to investigate the permeability-related properties of CPB and their effect on the performance of the backfillings: Aubertin et al. (2007), in permeability tests carried out with the addition of binder at different curing times, revealed that the use of binder reduced the saturated hydraulic conductivity of tailings up to 1 ½ order of magnitude after a period of 28 days. Yilmaz et al. (2012), investigated the effects of curing time and binder content on the one-dimensional consolidation parameters and hydraulic propertie, especially saturated hydraulic conductivity (k_{sat}) and degree of saturation (Sr) of early age CPB samples. Faraji and Fall (2025), evaluated the effects of binder content and material composition on permeability behaviour and determined the parameters required for optimum performance in their study on uncemented and lightweight cemented embankments. Qiu et al. (2022), showed that cement-sand ratio and waste rock content have significant effects on the strength and permeability properties of cemented landfills. In their study, they stated that the maximum strength was achieved at 10% level of waste rock content and the permeability reached the highest value at 30% level, and that microcrack formation increased as the cement-sand ratio decreased, which decreased the strength and increased the permeability. Ghirian and Fall (2016), investigated the effects of curing under stress on the permeability of CPB. The results showed that excessive stress, especially under undrained conditions, increased permeability and increased pore water pressure. Liu et al. (2022), investigated the effect of mixing time on the saturated hydraulic conductivity (k_{sat}) of CPB and concluded that prolonged mixing reduces the hydraulic conductivity by refining the pore structure of CPB. This reduction improves the durability and environmental performance of CPB resulting in more efficient and durable materials for mine backfilling operations.

In the existing studies in the literatüre, the effects of aggregates on permeability have not been investigated in depth enough. In this context, this research aims to make an original contribution to the field by analyzing the effects of CPB sand replacement ratios (15%. 30%. 45% by weight) on permeability and mechanical properties in detail. In particular, the effects of sand ratio on critical performance parameters such as permeability, microstructural properties and mechanical strength of cement paste backfill have generally been addressed in a limited way in the literatüre, and the aim of this study is to fill this gap. Therefore, how sand replacement will affect the long-term performance of CPB and how this interaction is reflected in the engineering properties of backfill materials is of great importance to develop more efficient and sustainable solutions in the field of application. In addition, this research aims to create a reference in order to better understand and optimize the relationship between two important parameters such as water permeability and mechanical strength of backfill materials with different sand replacement ratios.

This study analyzes in more detail how sand ratios affect the permeability properties of cementitious backfill and its contribution to the long-term durability of the material. In addition, a comprehensive investigation is presented in terms of permeability (k_{sat}), microstructural properties (scanning electron microscopy, SEM) and mechanical strength (uniaxial compressive strength, UCS) parameters of the samples prepared at different curing times (3-28 days) with constant cement content (5 wt.%) and solid content (75 wt.%). In this respect, the originality of the study, unlike other studies in the literature, provides a contribution to the optimization of material design by considering the effects of sand ratios on CPB performance in a broader way.

2. Materials

2.1. Process tailings

The mining tailings evaluated in this study were subjected to physical characterization analyses. Particle size distribution was determined using a laser granulometer (Malvern Mastersizer 2000) capable of measuring in the range of 0.02–2000 μm. The results obtained show that the fine fraction rate is below 20 μm (15–35%), which reveals that the material meets the necessary criteria for cement paste filling applications and falls into the coarse-sized tailings class.

In addition, the sufficient fineness of the material may positively affect both strength and permeability properties in terms of filling performance. According to the data presented in Table 1, the specific gravity (G_s) was measured as 3.56 m²/g. Besides, the uniformity coefficient (C_u) was calculated as 15.50 and the curvature coefficient (C_c) as 1.27, which indicate that the material has a well-graded structure in terms of granulometric. Chemical components of tailings are shown in Table 2.

Table 1. Physical properties of the components of the CPB

Physical properties	Process tailings	Limestone(LS)	OPC
D_{10}. μm	7.03	2.19	3.91
D_{30}. μm	31.20	16.55	14.01
D_{50}. μm. (average grain diameter)	78.60	55.41	24.67
D_{60}. μm	109.00	76.63	30.48
D_{80}. μm	201.00	177.60	55.69
[C_u=$D_{60}/_{10}$]	15.50	34.99	7.80
[C_c=$D_{30}^2/(D_{10}*D_{60})$]	1.27	1.63	1.65
Specific surface area, S_S. m^2/g	2.63	0.59	0.40
Specific gravity, G_s	3.56	2.74	3.14

2.2. Cement and mixing water

The basic binding material used in this study is Ordinary Portland cement (OPC) of the type CEM I 42.5R with high early strength class. Some physical properties of OPC are presented in Table 1. The specific gravity (Gs) of the cement was determined as 3.14 and the specific surface area (S_S) as 0.40 m²/g.The analysis results regarding the chemical composition of the mentioned OPC are given in Table 2. The ratios of calcium oxide (CaO) and silicon dioxide (SiO_2), which are the main oxide components of the cement, were measured as 70.87% and 14.04% respectively.

In order to prepare the CPB mixtures homogeneously, only tap water was used as mixing water. In this study, the possible effects of the mixing water used on the performance and chemical properties of the filler were excluded from the evaluation.

Table 2. Chemical properties of the components of the CPB

Chemical content (%)	Process tailings	Limestone (LS)	OPC
Na_2O	0.08	0.07	0.35
MgO	0.04	0.73	0.91
Al_2O_3	8.01	1.54	3.43
SiO_2	31.50	1.96	14.04
P_2O_5	0.03	0.08	0.25
SO_3	0.23	0.75	4.42
SrO	0.01	0.08	0.06
K_2O	0.25	0.20	0.89
CaO	3.66	53.77	70.87
TiO_2	0.29	0.08	0.34
MnO	-	0.07	0.10
Fe_2O_3	30.90	0.40	4.06
Others	25.00	40.27	0.28

2.3. Crushed sand

In the scope of the study, the sand used as a fine aggregate replacement material in CPB mixtures was analyzed in terms of its physical properties. The particle size distribution (PSD) of the material is presented in Fig.1, while its detailed physical characteristics are given in Table 1. According to the measurements, the average particle diameter (D50) of the material was determined as 55.41 µm, and the (D80) value, considered as the maximum particle size, was measured as 177.60 µm. The coefficient of uniformity (Cu) was calculated as 34.99 and the coefficient of curvature (Cc) as 1.63, indicating that the material has a well-graded particle distribution. Additionally, the specific surface area was identified as 0.59 m^2/g. and the specific gravity was found to be 2.74 g/cm^3. These data were used as a fundamental input in evaluating the usability of the sand replacement material in CPB mixtures.

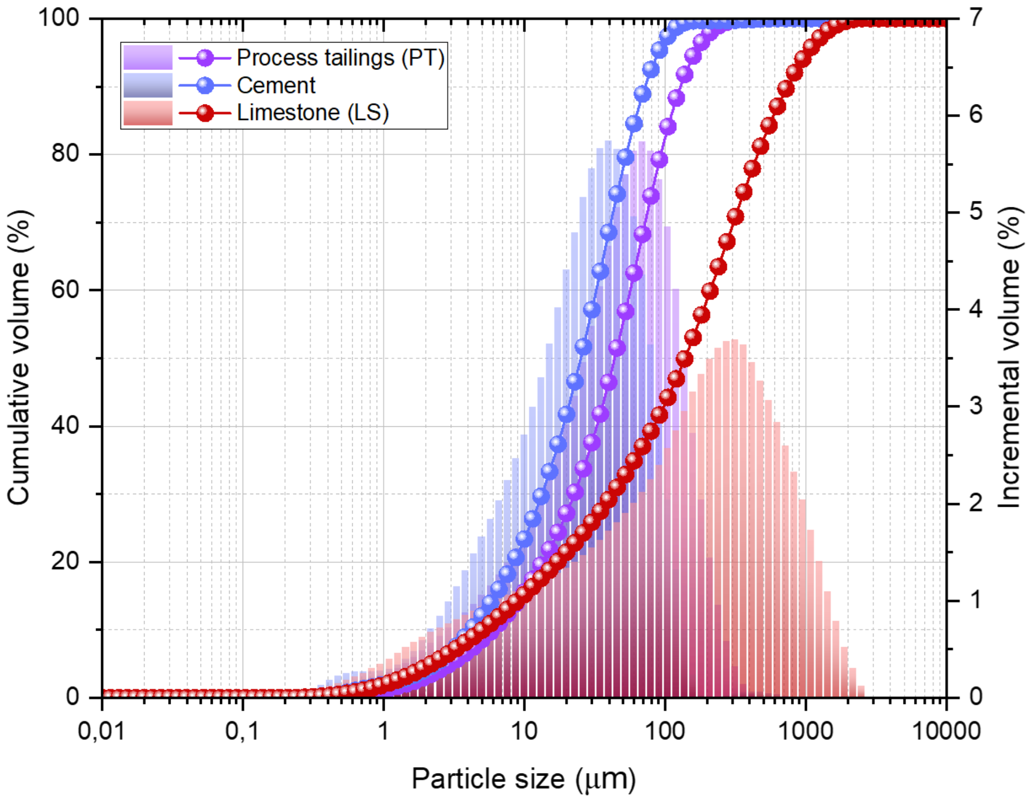

Fig.1. Particle size distribution curves of CPB components

2.4. Preparation of CPB samples

In the relevant study, CPB mixtures were prepared with a fixed 5% (by weight) Ordinary Portland cement (OPC) content and a solid concentration of 75 wt.%. To investigate the effects of sand addition on CPB performance, four different sand replacement ratios (0% – control, 15%, 30%, and 45%) were used in the tailing-sand mixtures. The detailed proportions of the mixtures are presented in Table 3.

All components (process tailings, sand, cement, and water) were weighed using precision laboratory scales and mixed for approximately 10 minutes in a 10-liter mechanical mixer to achieve a homogeneous mixture. The prepared mixtures were then poured into cylindrical plastic molds with a diameter of 5 cm and a height of 10 cm, featuring perforated bases, in accordance with the targeted solid content and consistency properties. The specimens were cured for periods ranging from 3-28 days under controlled conditions representing underground environments, with a relative humidity of 90 ± 5% and a temperature of 22 ± 3 °C.

Table 3 CPB design summary

Sample Name	Process tailings (%) (PT)	Sand (%) (LS)	Solid content (wt.%)	OPC	Curing (days)
PT100/LS0	100	-	75	CEM I/5	3-28
PT85/LS15	85	15	75	CEM I/5	3-28
PT70/LS30	70	30	75	CEM I/5	3-28
PT55/LS45	55	45	75	CEM I/5	3-28

3.Methods

3.1. Uniaxial compressive strength (UCS**)** test

The mechanical properties of CPB samples containing different proportions of sand and tailing material were evaluated in detail within the scope of uniaxial compressive strength (UCS), elastic modulus and stress-strain behaviors. Experimental studies were carried out using a UTEST Multiplex brand fully automatic electronic pressure testing device with a capacity of 50 kN and a constant loading rate of 1 mm/min. The samples were prepared in a cylindrical form with a height/diameter ratio of 2:1 in accordance with ASTM C39/C39M standards. This ratio allows the deformation and strength behaviors to be determined consistently and reproducibly.

Three samples with the same content were prepared and tested for each cure period (3-28 days). The results obtained were calculated by taking the average values of these three samples. Thus, the reliability of the experimental data was increased and the effects of different sand replacement rates on the mechanical performance of CPB were analyzed comparatively.

3.2. Saturated hydraulic conductivity (Ksat) test

In the CPB samples prepared for the purpose of determining permeability properties, sand was used as aggregate material in different proportions. Saturated permeability tests on the samples that completed the curing process were performed using the k_{SAT} (saturated hydraulic conductivity test) device belonging to Meter Group. The k_{SAT} device is a sensitive analysis system designed to measure the hydraulic conductivity coefficients of low permeability samples in a laboratory environment under constant temperature and humidity conditions.The samples were fully saturated before the test, Fig. 2 shows the k_{SAT} device and the experimental setup used.

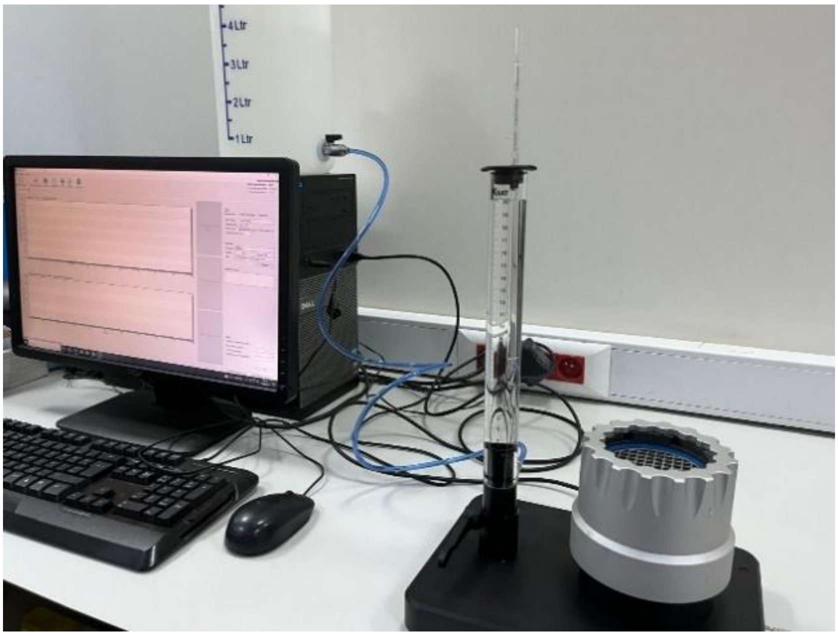

Fig. 2**.** Saturated hydraulic conductivity test setup

3.3. Assessing CPB's SEM micrographs

The microstructural characterization of the CPB specimens after the completion of the curing process was carried out using the scanning electron microscopy (SEM) method. For this purpose, a JEOL JSM-6610 model SEM device was used. Samples were taken from the center of the fractured specimens after strength testing, then immersed in an alcohol-based solution to inhibit further hydration reactions, and subsequently dried in a vacuum oven at 50 °C for 24–48 hours. The surfaces of the dried specimens were coated with gold (Au) to ensure conductivity.

SEM analyses were performed under an acceleration voltage range of 10–25 keV, a beam current of 0.9 nA, and a working distance of 35 mm. A maximum magnification of ×500 and a resolution of approximately 3 nm, adjusted based on the specimen type, were used during the measurements. Under these conditions, SEM imaging enabled detailed observation and evaluation of hydration products, microcracks, pore structures, and aggregate–matrix interactions within the CPB.

4. Results and discussion

4.1. Uniaxial compressive strength test results of CPB sample

Fig.3 presents the uniaxial compressive strength (UCS) test results of the sedimentary rock type limestone substituted in sand form on 3-28 day cured paste fill samples with different amounts of tailings/sand ratios (100/0 control sample 85/15, 70/30, 55/45). The obtained data show that the addition of sand to CPB mixtures at certain rates has positive effects in terms of UCS. The optimum strength value was obtained especially in the mixture containing 30% sand (1052 kPa) and a gradual decrease in strength was observed at sand contents above this rate.

This shows that the addition of sand up to a certain level supports the binding mechanism by improving the grain size distribution, but when this limit is exceeded, the binding matrix weakens and thus the strength is negatively affected. As a matter of fact. the replacement of limestone at high rates due to its high calcite content weakens its binding properties and disrupts the continuity of the cement matrix, leading to a decrease in strength (Irassar, 2009). This reveals the reason for the decrease in UCS values.

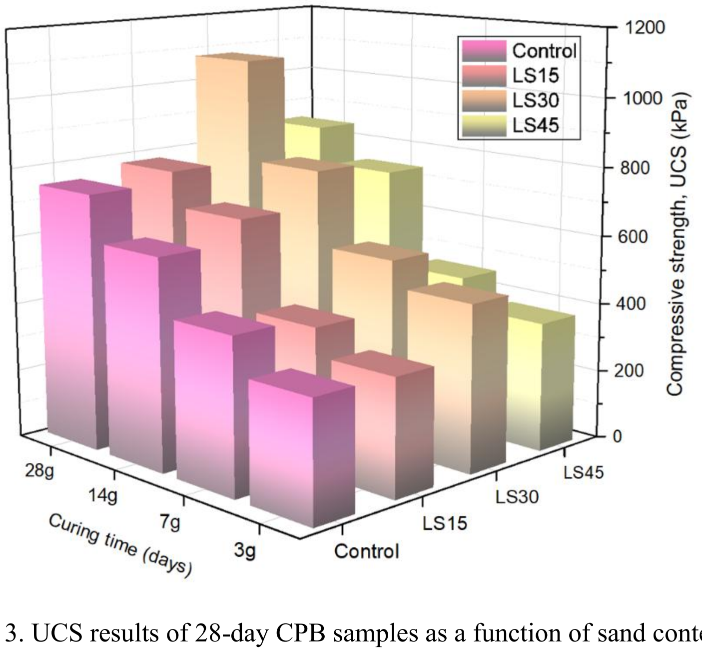

Fig. 3. UCS results of 28-day CPB samples as a function of sand content

4.2. Permeability results of CPB sample

According to the findings obtained in this study, it was observed that the use of limestone as an aggregate replacement in cement paste fillings created limiting effects on permeability properties. As a result of limestone replacements at 15%. 30% and 45% by weight, a decrease trend was observed in saturated hydraulic conductivity (k_{SAT}) values up to 30% replacement rate. As seen in Fig. 4. 30% replacement rate stands out as the point where the lowest ksat value is obtained in terms of permeability. This situation is associated with the limestone grains creating a more homogeneous structure in the cement matrix, limiting the void ratio and increasing impermeability. However, an increase occurred in permeability values again when the replacement rate was increased above 30%. It is thought that this increase is related to the weakening of the binding capacity of the limestone due to its high calcite content and the increase in microcrack formation during the solidification process. The spread of microcracks and the increase in porosity increased the hydraulic conductivity by facilitating the movement of water within the filling. Accordingly, since the use of limestone as an aggregate substitute at high rates may negatively affect the permeability performance of cement paste fillings, optimum usage rates should be determined carefully. In addition, the fact that this change in permeability is parallel to the strength values reveals that limestone provides a limited contribution in terms of both mechanical and hydraulic conductivity properties.

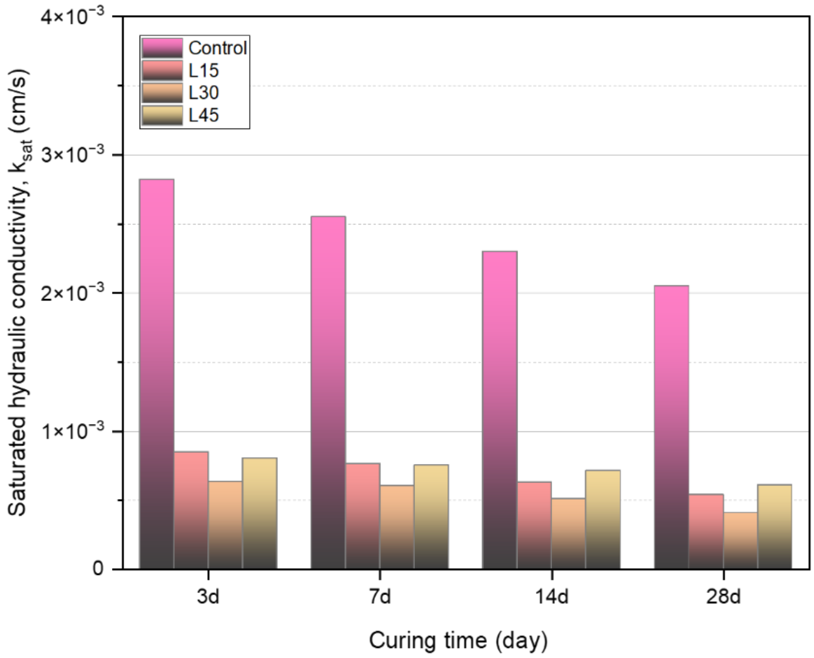

Fig. 4. Saturated hydraulic conductivity results of 28-day CPB samples as a function of sand content

4.3. Evaluation of SEM micrographs of CPB samples

Scanning electron microscopy (SEM) method stands out as an important analysis tool in the evaluation of microstructural properties of CPB samples. In SEM analyses, which allow detailed examination of hydration products that develop depending on the type and amount of components such as cement and aggregate, mixtures with 30% aggregate replacement by weight that showed optimum performance were included in the evaluation scope.

Fig. 5 presents SEM images of CPB samples prepared with these mixtures and cured for 28 days under 1000x magnification. The images revealed that calcium hydroxide [$Ca(OH)_2$], ettringite, voids and calcium silicate hydrate (C-S-H) gels were commonly found in the microstructure of the samples. It was observed that the increase in the density of C-S-H gels positively affected the strength of the filling system, and short-term ettringite formations also supported the mechanical properties (Chen et al., 2017). SEM findings show that aggregate replacement directly affects not only the macroscopic engineering properties but also the hydration process and microstructure development.

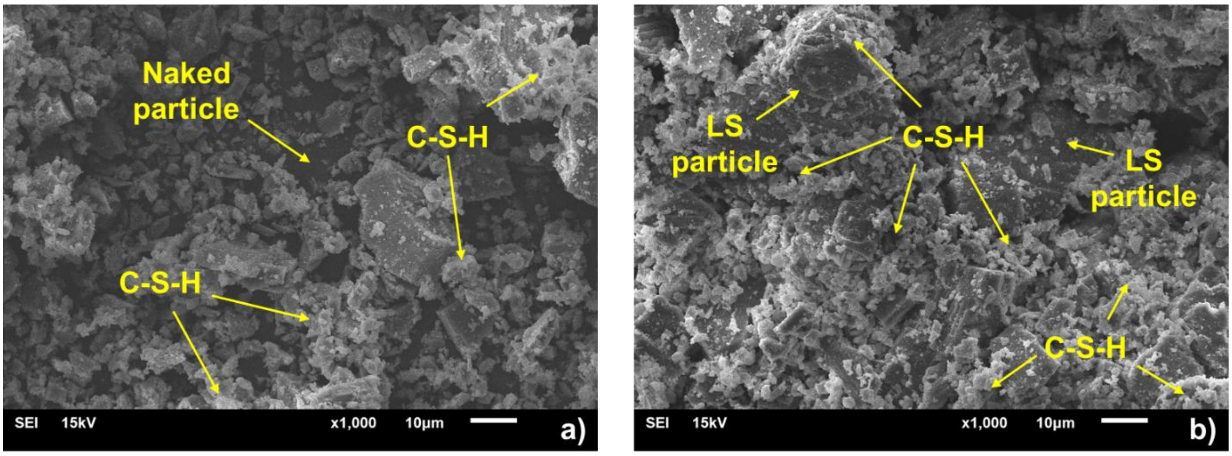

Fig.5. SEM micrographs of 28-day cured CPB samples: a) Control sample. b) 28-day cured limestone sample

5. Conclusions

In this study, sand was used in different proportions (15%, 30% and 45% by weight) as an aggregate substitute in CPB mixtures and the effects of this change on the strength and permeability properties of the fill were examined in detail. Along with the applied UCS and saturated hydraulic conductivity tests, microstructural changes were analyzed with SEM imaging technique to reveal the relationship between the development of pore structure and permeability. In the light of the obtained findings, the following conclusions were reached:

- The use of sand as an aggregate replacement has shown positive effects in terms of both strength and permeability at rates up to 30%. Especially at the 30% replacement rate, the 28-day UCS value reached the maximum level and the ksat value decreased to the lowest level. This rate stands out as the rate at which optimum engineering performance is achieved. This finding shows that the inclusion of sand in the material mixture can improve mechanical and hydraulic performance at certain rates.
- At sand ratios above 30%, the binding weakened and more voids and micro cracks formed in the microstructure. This situation caused the UCS value to decrease and the k_{sat} value to increase. These findings reveal that excessive use of sand as aggregate can negatively affect the general strength of the material by weakening the binding properties. In addition, these ratios show that the permeability values of CPB materials increase in parallel with the deterioration in their microstructure.
- SEM analyses show that the cases where the density of C-S-H gels increases and short-term ettringite formations support the strength are more pronounced, especially at optimum replacement rates. This finding reveals that the rates where sand is used as aggregate replacement cause positive changes in the microstructure strengthening the strength of the material and that the microstructure supports this strength. The increase in the density of C-S-H gels can be considered as a factor that increases the mechanical strength of the cementitious filling material.
- It has been determined that pore structure has a direct effect on permeability, and permeability values are parallel to changes in microstructure. The effect of changes in pore structure on permeability shows that the material becomes more permeable to water with the increase in voids and cracks in the microstructure. This condition may influence the long-term performance of the backfill material and should be considered as a critical factor in engineering applications.

As a result, the use of sand as an aggregate replacement improved the CPB performance up to a certain rate (especially 30%). However, if this rate was exceeded, the deterioration in the microstructure increased the permeability and negatively affected the engineering performance. Therefore, the optimum replacement rates should be carefully determined when using sand as an aggregate replacement in CPB samples.

Abstract. Pipelines for transporting natural gas, oil, water, and wastewater are widely used in the energy sector and municipal implementation and play an increasingly important role in people's lives; therefore, pipelines are a crucial component of urban underground infrastructure. But, damage to underground pipelines caused by traffic or construction activities is a frequent phenomenon around the world, resulting in considerable economic losses and environmental pollution. Several techniques have recently been proposed to reduce and control these financial losses and environmental pollution, including geosynthetic-reinforced soil platforms. Thus, it is crucial to possess a comprehensive understanding of the soil-pipe interaction to assess buried pipelines' stability accurately. The present study investigates the findings derived from numerical analysis of a flexible pipe buried in both unreinforced and geogrid-reinforced soils, with the additional consideration of surface surcharges. The aim of this research is to determine the effect of geogrid reinforcement configuration on the deflection of flexible pipe and soil settlement against applied pressure. In this context, a series of numerical analyses were carried out. The result of this study showed that the deflection of the pipe and soil settlement were strongly influenced by the configuration of geogrid reinforcement. In this way, some essential guidelines for selecting the reinforcement configuration to design the soil-pipe systems have been established through these numerical studies.

Keywords: Buried pipes; Geogrid reinforcement; Soil-pipe systems; Numerical analysis; Reinforcement configuration

1. Introduction

In geotechnical engineering, a variety of challenges arise from the interaction between soil and structures, either placed on or embedded within it. Among these, one of the most intricate problems involves understanding the behavior of buried pipelines. Subsurface piping systems have been utilized for various functions since ancient times. While initially developed for the conveyance of potable water and sewage, modern applications extend to the transportation of energy resources such as electricity, oil, and natural gas, among others. To fulfill their intended roles effectively, pipes must possess sufficient structural integrity and stiffness. They are also required to maintain durability throughout their expected service life. In this context, 'strength' refers to the pipe's capacity to resist different forms of loading, including internal pressure, overburden from soil, external structural loads, differential settlements, and longitudinal bending stresses (Moser & Folkman, 2008). The interaction between soil and buried pipes has been a subject of investigation since the early 20th century, and continues to be an active area of research today (Jeyapalan & Hamida, 1988; Selig et al., 1990; Masada et al., 2002; Won et al., 2004; Sargand et al., 2005; Kawabata et al., 2006; Talesnick and Xia, 2011; Naggar et al., 2015, Guha et al., 2016; Robert et al., 2016; Abuhajar et al., 2016; Wang et al., 2017).

Given the loads transmitted from traffic or nearby structures to closely spaced buried pipes, it is essential to account for these pipes within the framework of soil–structure interaction. Since the installation of subsurface infrastructure typically involves excavation and backfilling, the use of geogrid reinforcement can be implemented both efficiently and without requiring substantial additional effort (see Fig. 1 and Fig. 2). However, research addressing the role of geogrid reinforcement in soil–structure–pipe interaction remains relatively limited (Won et al., 2004; Tafreshi & Khalaj, 2008; Palmeira & Andrade, 2010; Zhou et al., 2017a, 2017b; Corey et al., 2014; Ahmed et al., 2015; El-Naggar et al., 2015; Hedge & Sitharam, 2015; Wang et al., 2017; Ni et al., 2018; Elsheseny et al., 2019; Placido & Portelinha, 2019; Abdollahi et al., 2019).

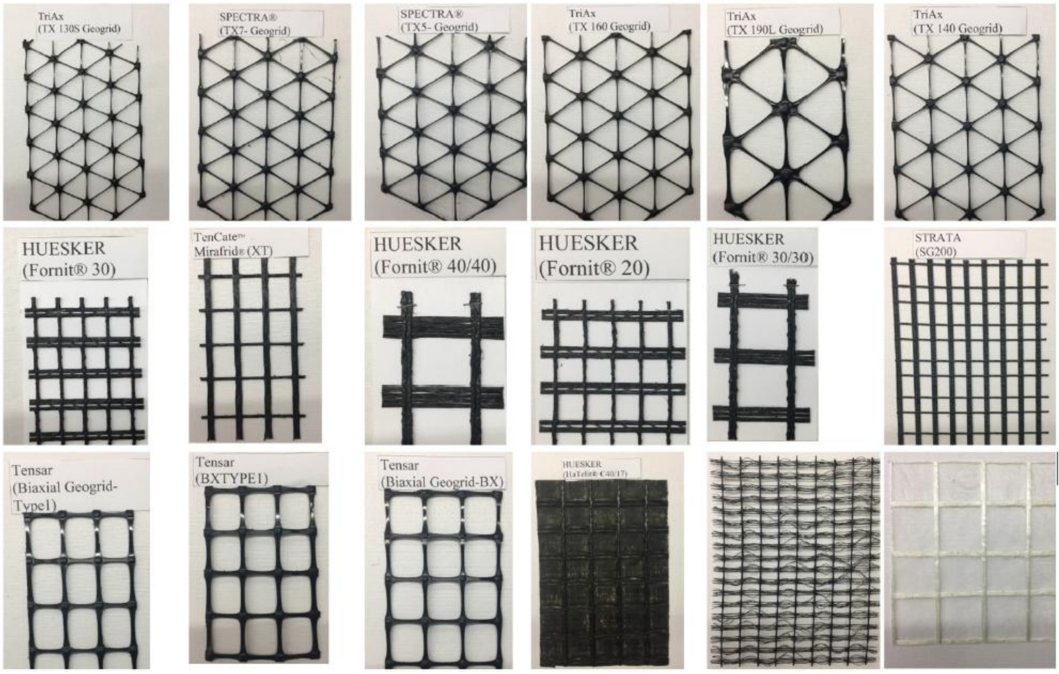

Fig. 1. Various types of geogrid materials are currently manufactured to meet diverse performance requirements in geotechnical engineering (Al-Barqawi et al., 2021)

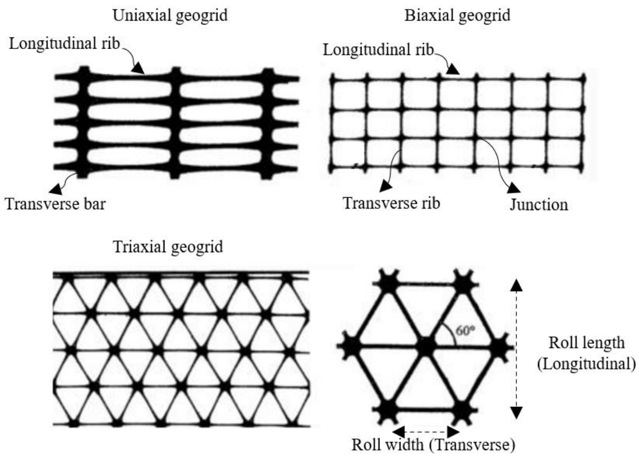

Fig. 2. Representation of various types of geogrids (Das B. M., 2013)

Tafreshi and Khalaj (2008) conducted laboratory-scale model tests to evaluate the impact of repeated loading on buried pipes. Their findings indicated that both the pipe's diameter deformation and the settlement of the surrounding soil were notably influenced by the presence of geogrid soil reinforcement. Similarly, Palmeira and Andrade (2010) employed a combination of geotextile and biaxial geogrid in their experimental models to enhance the protection of buried pipelines. They concluded that this reinforcement configuration provided effective resistance against sharp, intrusive objects, thereby mitigating the risk of accidental damage to the pipes. In another study, Asakereh et al. (2013) examined the protective role of biaxial geogrid-reinforced sand beds over continuous circular voids, simulating a strip footing centered above the void. Their results demonstrated a significant reduction in settlement, with optimal performance achieved using two to three reinforcement layers depending on the depth of the void. Corey et al. (2014) examined the influence of geosynthetic layers on the mechanical response of buried pipelines subjected to static loading conditions. Their experimental investigation involved two types of base materials and geogrids positioned both within and above the trench. The findings demonstrated a notable reduction in longitudinal deformations due to the inclusion of geogrid reinforcement. Similarly, Hedge and Sitharam (2015) carried out both experimental and numerical analyses to study the behavior of buried pipes installed in geocell-reinforced sand beds. Their results indicated that the use of reinforcement led to a reduction of approximately 50% in the pressure exerted on the pipe and around 40% in the deformation levels. Ahmed et al. (2015) conducted both experimental and numerical investigations on the contact pressure distribution around rigid pipes using tactile sensing technology. Their findings demonstrated that the inclusion of reinforcement significantly reduced radial pressures surrounding the pipe. In another study, Ni et al. (2018) performed numerical analyses to assess the viability of tire-derived aggregate (TDA) as a compressible medium in induced trench installations of rigid pipes under plane strain conditions. They found that the effectiveness of TDA in reducing earth pressures was highly dependent on the stiffness contrast between the soil and the aggregate. Kou et al. (2018) explored the response of a 160 mm PVC pipe subjected to loading from a 75 mm strip footing aligned with the pipe's centerline and buried in poorly graded sand reinforced with geogrid. Their results indicated a 20% reduction in vertical pressure at the pipe crown and a 21% decrease in footing settlement compared to the unreinforced scenario. Elshesheny et al. (2019) carried out large-scale laboratory tests to examine the response of HDPE pipes in both unreinforced and geogrid-reinforced sand subjected to incrementally increasing cyclic loading. The results showed that pipe strain and deformation decreased with increasing burial depth, with the most significant reduction in footing settlement observed up to a burial depth of H/D = 2.5. They also noted that reinforcement layers contributed to a redistribution of transferred stresses, leading to reduced strains and deformations, with a settlement reduction ratio reaching up to 50%. Abdollahi et al. (2019) combined large-scale experimental tests and three-dimensional finite element analyses to evaluate the performance of EPS post-and-beam systems for pipe protection. Their study concluded that increased soil cover reduced the stress levels on the EPS beam and that adding a single geogrid layer to the cover soil significantly enhanced the system's effectiveness. Zhou et al. (2020) investigated the mitigation of soil subsidence effects by applying woven geotextile and geogrid reinforcements both above and below buried pipes. Their results indicated that placing reinforcement beneath the pipe was particularly effective in minimizing vertical displacements.

The literature review reveals that numerous studies have addressed both reinforced and unreinforced soils in geotechnical engineering applications. However, the distinguishing feature of the present study lies in its comprehensive examination of the role of geogrid reinforcement on soil–structure–pipe interaction, with particular emphasis on the influence of different reinforcement configurations. This approach enables a more effective utilization of geogrid capacity tailored to the interaction mechanisms involved.

2. Material and method

Numerical methods are widely preferred in geotechnical engineering due to their efficiency in terms of cost, time, and versatility. Among the commonly used numerical approaches, the Finite Difference Method (FDM) and the Finite Element Method (FEM) are predominant for solving complex geotechnical problems. The FEM, in particular, involves discretizing a complex domain into smaller finite elements interconnected at nodes. This approach allows the solution of complex problems governed by partial differential and integral equations. In this study, the commercially available FEM-based software PLAXIS 2D (version 8.6), which supports plane strain and axisymmetric conditions, was employed to analyze the deformation, stress distribution, strain behavior, and failure mechanisms associated with buried pipelines. A series of two-dimensional finite element simulations were performed to investigate the structural response of a buried pipe embedded in soil with and without geogrid reinforcement. The model domain consisted of a soil bed measuring 15 meters in width and 10 meters in depth. These dimensions were determined through a sensitivity analysis aimed at assessing the influence of model boundaries on numerical outcomes. A uniform vertical surface surcharge load of 200.0 kN/m² was applied to simulate overburden pressure.

Figure 3 illustrates the geometry of the model and the configurations of the geogrid reinforcement. Three reinforcement arrangements were considered: (1) a horizontal geogrid layer placed 200 mm (equivalent to one time the pipe diameter) above the pipe crown with a length of 1200 mm (equivalent to six times the pipe diameter), (2) an inverted-U configuration where the geogrid encased the upper sides of the pipe, and (3) a full-encasement configuration in which the geogrid completely enveloped the pipe. The geogrid used in the models had a tensile strength of 30 kN/m. The objective of this modeling effort was to evaluate the performance of buried pipelines resting on sandy soil under different reinforcement scenarios.

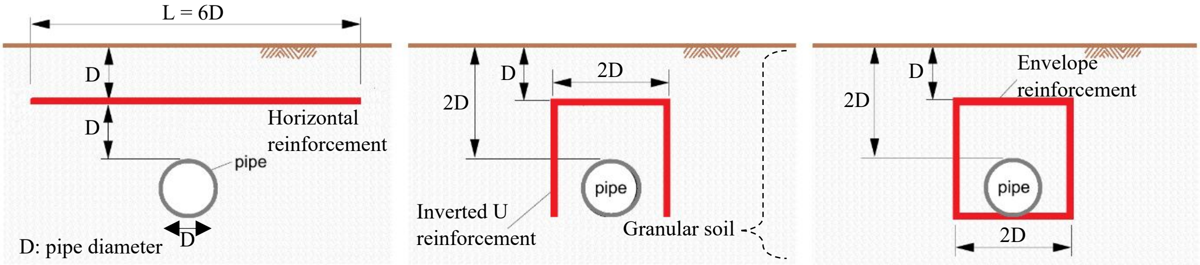

Fig. 3. Schematic diagram of geometry model and reinforcement arrangements

Finite element (FE) analyses of a buried pipe subjected to vertical loading on granular soil were conducted using PLAXIS 2D, a widely adopted, user-friendly commercial FE software package commonly used in geotechnical engineering practice. PLAXIS 2D operates using an implicit time integration scheme, which enables faster and more stable computations compared to software utilizing explicit schemes, particularly for problems involving soil–structure interaction. Designed specifically for analyzing deformation and stability in geotechnical applications, the software also provides comprehensive post-processing capabilities, allowing for a detailed interpretation of stress, strain, and displacement distributions within the model. The default boundary conditions available in PLAXIS 2D, which restrict the horizontal deformations at the side boundaries and both horizontal and vertical deformations at the bottom boundary, were used. The dimensions of boundaries were determined by conducting convergence studies by varying the model dimensions. The dimensions and initial mesh configuration of the numerical model, developed based on the cross-sectional geometry illustrated in Fig. 3, are presented in Fig. 4. A comparative analysis using a finer mesh was also performed, which yielded results within a 2% margin of difference, indicating negligible sensitivity to mesh refinement. The numerical domain measured 15 m in width and 10 m in height. Boundary conditions were defined such that the lateral boundaries were restrained against horizontal displacement, while the base of the model was fixed in both horizontal and vertical directions. The pipe, with an outer diameter of 0.20 m, was modeled using the built-in structure designer tool. A 15-node triangular element mesh was employed to improve accuracy in stress and deformation predictions. Following pipe generation, the soil within the pipe boundary was removed to simulate a hollow structure. Groundwater conditions were not considered in the present analysis.

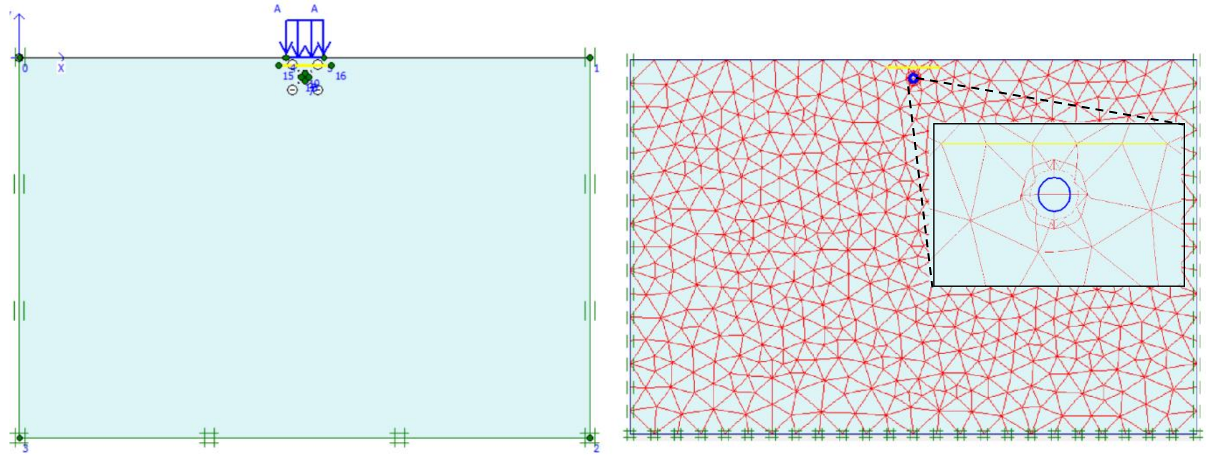

Fig. 4. Numerical model illustrating the mesh configuration for the very fine mesh case

To model the behavior of sandy soils, the Hardening Soil Model (HSM) was chosen, as it is well-suited for granular soils subjected to monotonic loading and limited unloading stress paths. When compared to other models, such as the linear elastic and perfectly plastic models based on the Mohr-Coulomb (MC) criterion, several limitations of the MC model become apparent. These include its bilinear nature (constant values for modulus of elasticity and Poisson's ratio), unlimited dilation, isotropy, and perfect plasticity assumptions. In contrast, the HSM offers a more comprehensive approach by incorporating plasticity theory and soil dilatancy, similar to the MC model, but also introduces a yield cap and a stress-dependent elastic modulus. A key distinction of the HSM is that the elastic domain is not fixed; instead, it can expand depending on both volumetric and deviatoric plastic strains. Furthermore, the model accounts for two separate yielding mechanisms: one for shear and another for compression, as depicted in Fig. 5. Irreversible deformations due to initial deviatoric loading are captured through shear hardening, whereas plastic strains arising from primary compression—such as those occurring under oedometer or isotropic loading—are accounted for by compression hardening mechanisms (Schanz et al., 1999).

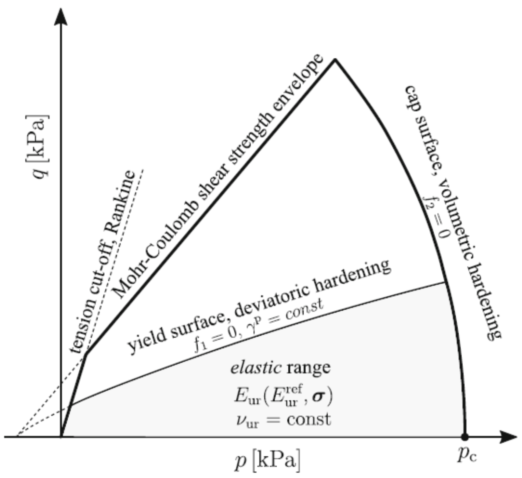

Fig. 5. Stress yield boundary and elastic behavior domain in the standard Hardening Soil (HS) model (Cudny & Truty, 2020)

A key difference between the two models lies in the parameters they utilize. The Mohr-Coulomb elastic-perfectly plastic model is governed by a limited set of fundamental parameters, including the internal friction angle (φ), dilatancy angle (ψ), cohesion (c), Poisson's ratio (ν), and a constant stiffness modulus (E). Conversely, the Hardening Soil (HS) model employs a more advanced formulation that considers the stiffness of the soil to be stress-dependent, allowing for a more realistic representation of soil behavior under diverse loading scenarios. The HS model typically requires a broader set of input parameters—at least twelve—including the unsaturated and saturated unit weights of the soil (γ_{unsat} and γ_{sat}), initial void ratio (e_{init}), Poisson's ratio (ν), cohesion (c), friction angle (φ), dilatancy angle (ψ), reference secant stiffness from a drained triaxial test (E_{50}^ref), tangent stiffness for primary oedometer loading (E_{oed}^{ref}), unloading/reloading stiffness (E_{ur}^{ref}), stress-dependency exponent (m), and the interface strength reduction factor (R_{inter}). Laboratory studies show that plastic deformations in soils begin from the initial stages of loading. Constitutive models that utilize a hardening law after early yielding are required to take into account such properties of soils. The hardening soil model can also be used for softer soils such as silts and clay in addition to sand and gravel because there are three elastic modules in the HS model, and the hardening soil model also accounts for the stress-dependency of stiffness moduli. Therefore, all three input stiffnesses are referenced to a reference stress, typically set at 100 kPa (1 Bar). In addition to the model parameters previously mentioned, the initial soil conditions, such as consolidation, are crucial in many soil deformation problems. These conditions are often incorporated into the model through the initial stress state, which plays a significant role in accurately simulating soil behavior under loading. As a result, the HS model gives more realistic results in FEM simulation than the Mohr-Coulomb model. Therefore, in the numerical simulations conducted for this study, the properties of soils were represented using the Hardening Soil (HS) constitutive model. Table 1 summarizes soil properties used in the numerical modeling.

Table 1. The input parameters for Hardening soil material model (Bildik & Tanrıöver, 2023)

Soil Parameters	Definition	Value
material model	hardening soil material model	-
γ_{unsat}	soil unit weight above phreatic level (kN/m$^{3)}$	18.40
γ_{sat}	soil unit weight below phreatic level (kN/m$^{3)}$	20.36
e_{init}	initial void ratio	0.5
ϕ	internal friction angle (degree)	37
ψ	dilatancy angle (degree)	8.625
E_{50}^{ref}	secant stiffness in standard drained triaxial test (kN/m^2)	5.1x10^4
E_{oed}^{ref}	tangent stiffness for primary oedometer loading (kN/m^2)	5.1x10^4
E_{ur}^{ref}	unloading/reloading stiffness (kN/m^2)	1.5x10^5
c	cohesion (kN/m^2)	1.00
m	power for stress-level dependency of stiffness	0.43
R_{inter}	strength reduction factor inter	1.0
$k_x = k_y$	permeability (m/day)	10.00

PLAXIS 2D finite element software offers a dedicated feature called the tunnel designer, which facilitates the modeling of circular structures such as tunnels and pipes. This tool assembles the structure by generating interconnected plate elements arranged in a ring. Following the simulation, internal forces acting on these elements can be extracted and analyzed. Each plate element is defined by five primary parameters: (1) axial stiffness (EA), (2) bending stiffness (EI), (3) equivalent thickness (t), which is derived automatically from EA and EI, (4) unit weight (γ), and (5) Poisson's ratio (ν), which is generally assumed to be zero in cases where the structural component (e.g., pipe wall) occupies a negligible portion of the model's cross-sectional area. The mechanical properties assigned to the HDPE pipe are summarized in Table 2. These parameters, based on a 200 mm diameter pipe, correspond to the assumptions of a Linear Elastic Material Model used to represent the behavior of a typical HDPE pipe

Table 2. Engineering properties of the HDPE* pipe

Pipe Parameters	Definition	Value
LE	linear elastic	-
EA	normal stiffness, (kN/m)	6.372
EI	flexural rigidity, (kNm^2/m)	0.126
υ	poisson's ratio, υ	0.40

HDPE: high-density polyethylene

3. Results

The numerical analysis results concerning the displacement behavior of a flexible pipe embedded in granular soil and the stress distribution developed on the pipe surface are presented and discussed in this section. A series of numerical analyses were carried out using a 200.0 kN/m^2 nominal surcharge load. The variations in displacement and stress within the buried pipe, as influenced by the reinforcement configuration, were also evaluated. The reinforcements were applied to the soil in three distinct configurations, as illustrated in Fig. 4. The initial and most straightforward reinforcement setup (denoted as HL) consisted of a single horizontal layer placed 200 mm above the crown of the pipe. The second arrangement (IU) involved installing the reinforcement in an inverted U-shaped configuration encircling the pipe, which can be realized by excavating trenches along both sides of the pipe. However, this method is generally less feasible in practical field applications compared to the horizontal layout. The final configuration (ENV) featured a fully enclosed reinforcement layer encapsulating the entire pipe, as illustrated in Fig. 4. In this setup, the terminal ends of the reinforcement were firmly joined to prevent slippage, thereby preserving the structural integrity and functional performance of the reinforcement. A geogrid reinforcement with 30 kN/m tensile rigidity was used to reinforce the granular soil. Thus, the values of the soil surface settlement depending on reinforcement configuration were obtained. Considering the behavior of the pipe embedded in unreinforced soil, the inclusion of geogrid reinforcement led to a noticeable reduction in vertical surface settlement. Specifically, the decrease in settlement was quantified as 40.8%, 57%, and 61% for the HL, IU, and ENV reinforcement configurations, respectively, as illustrated in Fig. 6.

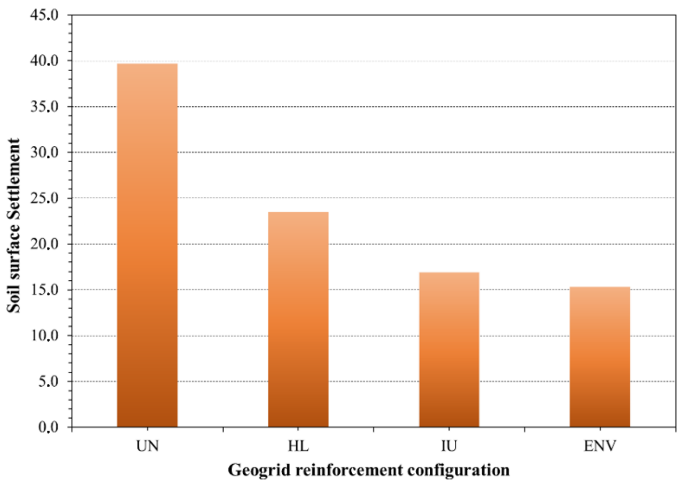

Fig. 6. Settlement at the soil surface for a surface surcharge of 200 kN/m^2

The effectiveness of the reinforcement in minimizing the deflections of the pipe can be characterized as;

$$E_D = 100 \text{ x } (\Delta D_{unr} - \Delta D_r) / \Delta D_{unr} \text{ (\%)} \quad (1)$$

where E_D represents the efficiency of the reinforcement in reducing pipe deflections, ΔD_{unr} is the pipe deflection in unreinforced soil, and ΔD_r is the pipe deflection in reinforced soil. The effectiveness of the reinforcement in alleviating the vertical compression of the pipe at the conclusion of the numerical analysis, considering different configurations, is illustrated in Fig. 7. When comparing the pipe's performance in unreinforced soil, the inclusion of reinforcement led to a reduction in vertical deflections by 40.7%, 59.9%, and 64.7%, corresponding to the results obtained for reinforcement configurations HL, IU, and ENV, respectively (see Fig. 7)

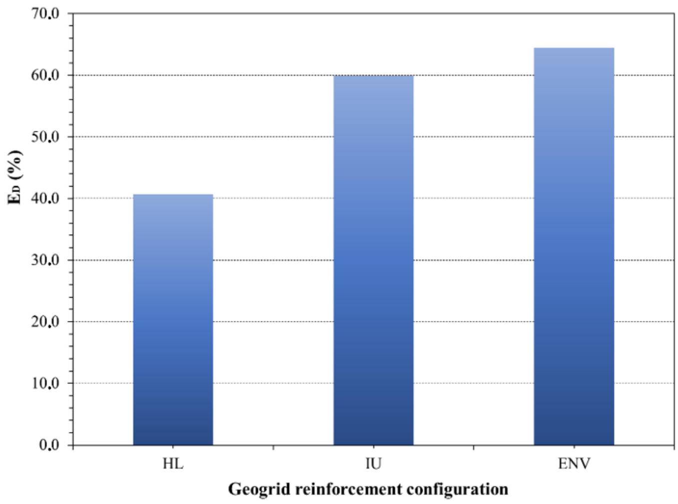

Fig. 7. The effectiveness of the reinforcement in reducing the deflections of the pipe

The surface settlements observed for reinforced soils with different configurations are presented in Fig. 8. In general, the placement of geogrid reinforcement in the subgrade reduced the ground displacements. It is clearly observed that the various reinforcement configurations have limited the displacements and effectively restrained soil movement.

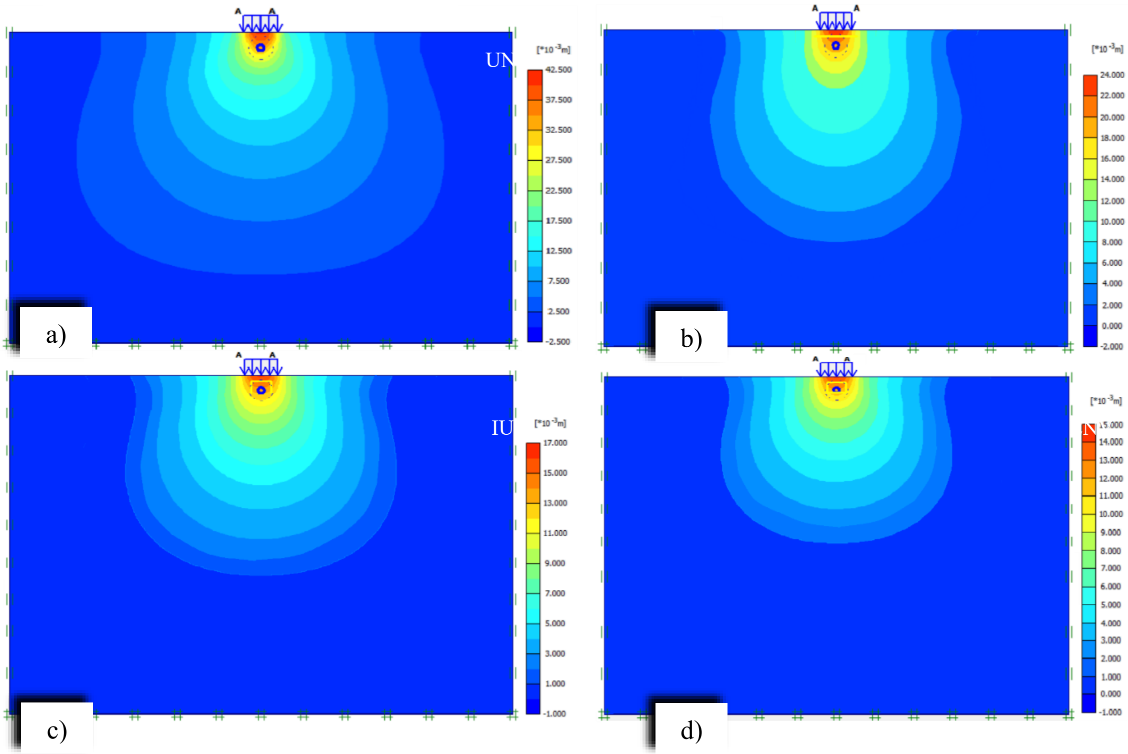

Fig. 8. Total displacement at the soil surface for a surface surcharge of 200 kN/m^2 (a) Unreinforced arrangement, (b) Horizontal reinforcement layer arrangement, (c) Shape of an inverted U reinforcement arrangement, (d) Enveloped reinforcement arrangement

4. Conclusions

Geogrids can efficiently protect buried pipelines. This research investigates the use of reinforcement methods to shield a pipe from the effects of localized surcharges applied to the soil surface. Various reinforcement types and configurations were examined. As part of the investigation, a series of finite element analyses was conducted using the commercial software PLAXIS 2D to evaluate the behavior of a buried pipe both with and without geogrid reinforcement. The key findings from this study are summarized below.

- A reduction in the overall settlement of the pipe was also observed in the reinforced soil conditions.
- The enveloping configuration was found to be the most effective in maximizing the advantages offered by the geogrid reinforcement.
- Considering the pipe's performance in unreinforced soil, the inclusion of geogrid reinforcement led to a reduction in vertical soil surface settlement ranging from 40.8 to 61%, corresponding to the HL, IU, and ENV reinforcement configurations, respectively.
- In comparison to the pipe behavior in unreinforced soil, the incorporation of geogrid reinforcement resulted in a reduction of the pipe's vertical deflections by 40.7%, 59.9%, and 64.7% for the HL, IU, and ENV configurations, respectively.

Abstract
Mechanical behavior and integrity of construction materials and civil structures made of geo-materials like soil, clay, concrete, cement and mortars is affected by the environmental conditions. Repeated freezing & thawing mechanism is among the natural phenomena that can generally reduce the overall strength properties (such as fracture toughness) of the civil structures and geomaterials and finally can accelerate the rate of damage and associated failure. Material type and state of applied external loads and deformations may affect the fracture toughness of geo-materials exposed to freezing-thawing periods. There are very limited data in the literature for investigating the influence of tensile or shear type loads (i.e., modes I and II) and numbers of freeze/thaw cycles on the fracture toughness values of geomaterials. Hence, in this research, using edge cracked semi-circular bend specimens made of soil, clay and cement concrete the impact of freezing-thawing (FT) mechanism and the number of applied FT cycles are investigated experimentally on the fracture toughness behavior. Such tests were conducted under both pure modes I and II conditions and it was observed that FT mechanism can reduce generally the fracture toughness (K_{Ic} and K_{IIc}) of both soft and tight geo-materials. However, the destructive impact of this mechanism on the tested soil materials was significantly greater than its effect on the cement concrete. For example, after performing 6 FT-cycles the fracture toughness of the soil material was reduced to approximately 50% of the fracture toughness of control soil material with no FT cycles. Such reduction for the cement concrete was only about 7%. In addition, the reduction of fracture toughness after exposing to the freeze/thaw cycles was more pronounced for the tensile type (mode I) failure mechanism compared to the shear mode II case. Due to significant influence of FT mechanism on soft geomaterials (like soils), this phenomenon should be considered as important issue in service life assessment of civil structures such as earth-rock fill dams or sub-base parts of roads at cold regions and during winter season.

1. Introduction

Construction and geomaterials such as soil, concrete, rock, asphalt mixtures and etc., are subjected to different and complex environmental and mechanical loading conditions (Baradaran & Ameri, 2023; Ayar et al., 2022; Niri et al., 2024; Pargar et al., 2024; Shojamoghadam et al., 2024; Erarslan, 2023a; Erarslan 2023b). indeed, in many field and practical applications such as underground mines, tunnels, pavement and road structures, dams, among others, soil and concrete materials are the main structural material for and element for bearing the applied loads and stresses. some issues including environmental conditions (such as temperature, humidity and moisture) may affect noticeably the structural integrity and service life of the structures made of soils, concrete and rock (Tareghian et al., 2024; Yazdi et al., 2024; Yeganeh et al., 2024; Baradaran & Ziaee, 2025; Baradaran et al., 2023; Rajaee et al., 2025; ad Miri et al., 2024; Haghighatpour & Aliha, 2023; Ghamgosar et al., 2017; Erarslan & Çavdar, 2024). In general, such parameters either under static or cyclic conditions (i.e., fluctuation of temperature or moisture) may have negative effects on the strength and mechanical property indexes. On the other hand, most of geomaterials used in civil and construction engineering projects are categorized as brittle and quasi-brittle materials and the presence of cracks and flaws or structural discontinuities and faults may increase significantly the risk of overall or catastrophic failures due to sudden growth of cracks in such materials (Berto & Lazzarin, 2014; Sharafisafa et al., 2021). Hence, it is necessary to investigate the fracture and crack growth characteristics of structural civil and

https://doi.org/10.31462/icearc2025_ce_geo_929

geo-materials under real field situations. Cracks in the structural components can be subjected to different loading modes and deformations. Among them mode I (tensile deformation) and mode II (in-plane shear deformation) are the most failure modes observed in the fractured structures. The failure of geo and construction materials under any modes I and II conditions are determined experimentally using different testing methods (Mahdavi et al., 2023; Najjar et al., 2022; Reza Karirmi et al., 2023). disc type samples and cylindrical shape specimens are favorite test samples to conduct fracture toughness (as the most important and key index in fracture mechanics) tests on geo-materials. some test configurations such as semi-circular bend (SCB) sample (Baradaran et al., 2024a; Baradaran et al., 2024b; Baradaran & Aliha, 2025; Aliha et al., 2025; Ghodratnama et al., 2025), Brazilian disc (BD) sample (Ayatollahi & Aliha, 2008; Li et al., 2022), Edge notch disc bend (ENDB) sample (Pournoori et al., 2024; He et al., 2022; Eghbali et al., 2019), three or four point bend beam (Aliha et al., 2019), center cracked ring (CCR) sample (Gu et al., 2023) are among the more common test samples for determining K_{Ic} (mode I fracture toughness) and K_{IIc} (mode II fracture toughness) values in rocks, soils, concrete and other geomaterials.

Most of the fracture experiments on these materials have been performed on control conditions (Fakhri & Ahmadi, 2017; Karimi et al., 2021; Haghighatpour & Aliha, 2022; de Jesús Arrieta Baldovino et al., 2021; Fakhri et al., 2020; Hou et al., 2021) and the effect of freezing/thawing mechanism on the crack growth resistance of construction materials has received less attention in the literature. Freezing and thawing mechanism (FTM) is one of the major degradation sources in geo-structures. This can be occurred due to change in temperature from subzero to medium temperatures and vice versa at a day or at a season. Thermal stresses and deformations induced by this mechanism can increase the risk of fracture and crack growth by weakening the material. amplitude of each freezing and thawing cycle (i.e. the difference between the maximum and minimum value of temperature) as well as the number of freeze/thaw cycles applied to geo-materials are two main affecting parameters some limited works are available in the previous works dealing with the effects of FTM on the mechanical performance of asphalt concrete mixtures. In the current research, the influence of different freeze/thaw cycles are investigated experimentally on the trends of variations for K_{Ic} and K_{IIc} values of two construction and civil materials (i.e. a soft geo-material (clay) and a tight geo-material (cement concrete)). The fracture tests are conducted on a simple and suitable specimen under both mode I and mode II conditions and the effect of material type, loading mode and number of freezing-thawing cycles are investigated on the fracture resistance (or fracture toughness) values.

2. Materials and methods

Kaolinit clay and cement concrete were considered as the materials to manufacture the test samples and conduct the fracture toughness tests. The physical and geotechnical properties of soil material (that is classified as low plasticity clay) are presented in Table 1. The cement concrete mixture was composed of Portland Cement Type II conforming to ASTM C150, potable water, and lime aggregate with a continuous aggregate gradation with 19.5 mm (maximum nominal aggregate size, NMAS, for coarse aggregates) in accordance with ASTM C33. The coarse and fine aggregate gradations used in this study are shown in Table 2. The water-to-cement ratio (w/c) was maintained at 0.4 to achieve a balance between workability and compressive strength development.

For conducting the mode I and mode II fracture tests, the SCB sample with symmetric and asymmetric loading rollers relative to the crack plane (as shown in Fig. 1) were utilized and selected. Based on the previous papers the symmetric SCB can provide pure mode I condition and asymmetric SCB is able to introduce pure mode II fracture condition (Aliha & Ayatollahi, 2013; Aliha et al., 2025; Erarslan & Aliha, 2025). The fracture toughness value that is equal to critical value of stress intensity factor under mode I and mode II conditions are determined for the SCB specimen using the below equations:

$$K_{\mathrm{IC}} = \frac{P_{max}}{2Rt}\sqrt{\pi a}\, Y_I \quad (1)$$

$$K_{\mathrm{IIC}} = \frac{P_{max}}{2Rt}\sqrt{\pi a}\, Y_{II} \quad (2)$$

where, P_{max} is the maximum peak load applied to the SCB sample at the onset of fracture (crack initiation), R, a, t are the radius of SCB, crack length and thickness of SCB specimen, respectively. S, S_1 and S_2 are also the bottom loading spans. The properties of the SCB samples made of the clay and cement concrete are illustrated in Table 3. For determining the corresponding values of fracture toughness using the SCB sample, it is required to know the values of mode I and mode II geometry factors (Y_I and Y_{II}). These parameters that are related to crack length ratio (a/R) and span ratio (S/R, S_1/R and S_2/R) have already been determined numerically in the literature for different geometry and loading conditions. The related values of Y_I and Y_{II} parameters for the test conditions of the current research (extracted from Ayatollahi & Aliha, 2007) are equal to 4.85 and 1.78, respectively. Accordingly, several SCB samples were manufactured for conducting fracture toughness tests.

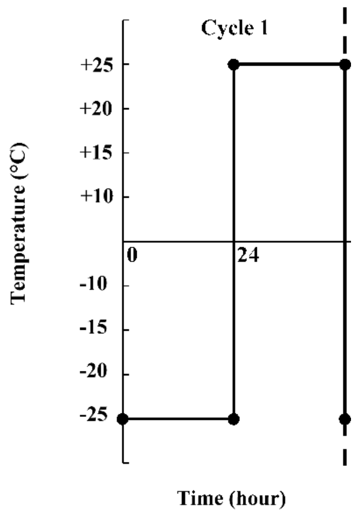

Fig. 2. Profile of thermal cycle for applying a freezing and then thawing cycle on the test samples.

Before K_{Ic} and K_{IIc} testing on the manufactured soil and cement concrete samples, they were exposed to different freezing/thawing cycles. Each cycle was consisting of a freezing period at -25°C for 1day (24 hours) following a thawing cycle inside the moisturized bath for 24 hours at temperature of +25°C. Several freeze/thaw cycles (i.e., 0 cycle (control), 1 cycle, 2 cycle, 3 cycle, 4 cycle, 5 cycle and 6 cycle) were applied to the soil and cement concrete samples and then the fracture toughness experiments were done on the SCB samples (Fig. 2). To do that, the test samples were put inside the three-point bend fixture with the loading support distances (S_1 and S_2) given in Table 3 for both modes I and II. The samples were loaded monotonically with the constant loading rate of 3 mm/min using a servo hydraulic testing machine with the capacity of 5 kN. The corresponding values of modes I and II fracture toughness were determined by importing the critical or maximum peak experimental load of each sample into Equations 1 and 2. The obtained results are illustrated and discussed in the next section.

3. Results and discussion

The variations of fracture toughness (K_{Ic} and K_{IIc}) for the tested soil and concrete materials are illustrated in Fig. 3 for different freeze/thaw cycles. Based on this Figure and obtained experimental results the fracture toughness value decreases by increasing the number of freeze/thaw cycles and compared to control condition without exposing to freezing and thawing mechanism the cracking resistance of geomaterials is reduced for both tensile and shear type failure modes. However, the reduction of fracture toughness for the soil material is more visible than the cement concrete material. After six freeze/thaw cycles, the fracture toughness of soil is reduced to 0.5 and 0.4 times of its value at control condition for both modes I and II. This reveals the significant impact of such environmental agent on the overall load bearing capacity of the soft geomaterials (such as soils and clays). Based on the obtained results, fracture toughness of shear mode case is more sensitive to the freezing thawing mechanism compared to the tensile type failure mode.

In addition, the tight cement concrete material was not so sensitive to the freeze/thaw cycles and a reduction up to 7% was only observed in the K_{Ic} or K_{IIc} values after five freeze/thaw cycles. Other similar research works, have also outlined and emphasized the reduction of cracking resistance of engineering construction materials subjected to different freeze-thaw cycles. For example, Haghighatpour & Aliha (2022), Fakhri et al. (2025), have shown that the fracture toughness of hot or warm mix asphalt concrete materials (HMA and WMA) is reduced by applying different cycles of freezing-thawing. Such materials (that are made of visco-elastic bitumen or binder) may show high dependency to the changes in environmental conditions such as temperature variations or thermal stresses. Hence, according to the available relevant studies, freezing-thawing mechanism can reduce significantly the fracture toughness of asphalt mixture up to 50% of the control condition's strength and load bearing capacity. However, compared to the bitumen or asphaltic binder, the cement used in the mixture of cement or plain concrete has lesser sensitivity to the temperature changes in the range of ±25°C.

Therefore, the research investigated cement concrete material showed lower variation in the value of fracture toughness by applying the freeze/thaw cycles relative to the HMA or WMA mixtures. In order to better compare the trends of fracture toughness variation under repeated freezing/thawing mechanism Fig. 4 presents the normalized fracture toughness data versus the number of applied freeze/thaw cycles to the tested soil and concrete geomaterials. Indeed, in this figure the fracture toughness data of different freeze/thaw cycles were normalized to the corresponding value of K_{Ic} or K_{IIc} obtained at control condition (i.e. with no application of freezing-thawing cycles). This figure clearly shows the sensitivity of cracking resistance value to the material type and loading mode in the investigated geo-materials. While, for the cement concrete material, the fracture toughness reduces dominantly by a linear trend when the number of cycles is increased, the first cycles of freezing/thawing mechanism have much more impact on the reduction of both K_{Ic} and K_{IIc} and by increasing the number of cycles (for instance, greater than 4 cycles), the fracture toughness reduction curves show a power law form. In addition, mode I fracture case has more sensitivity to the freezing/thawing mechanism compared to the mode I case.

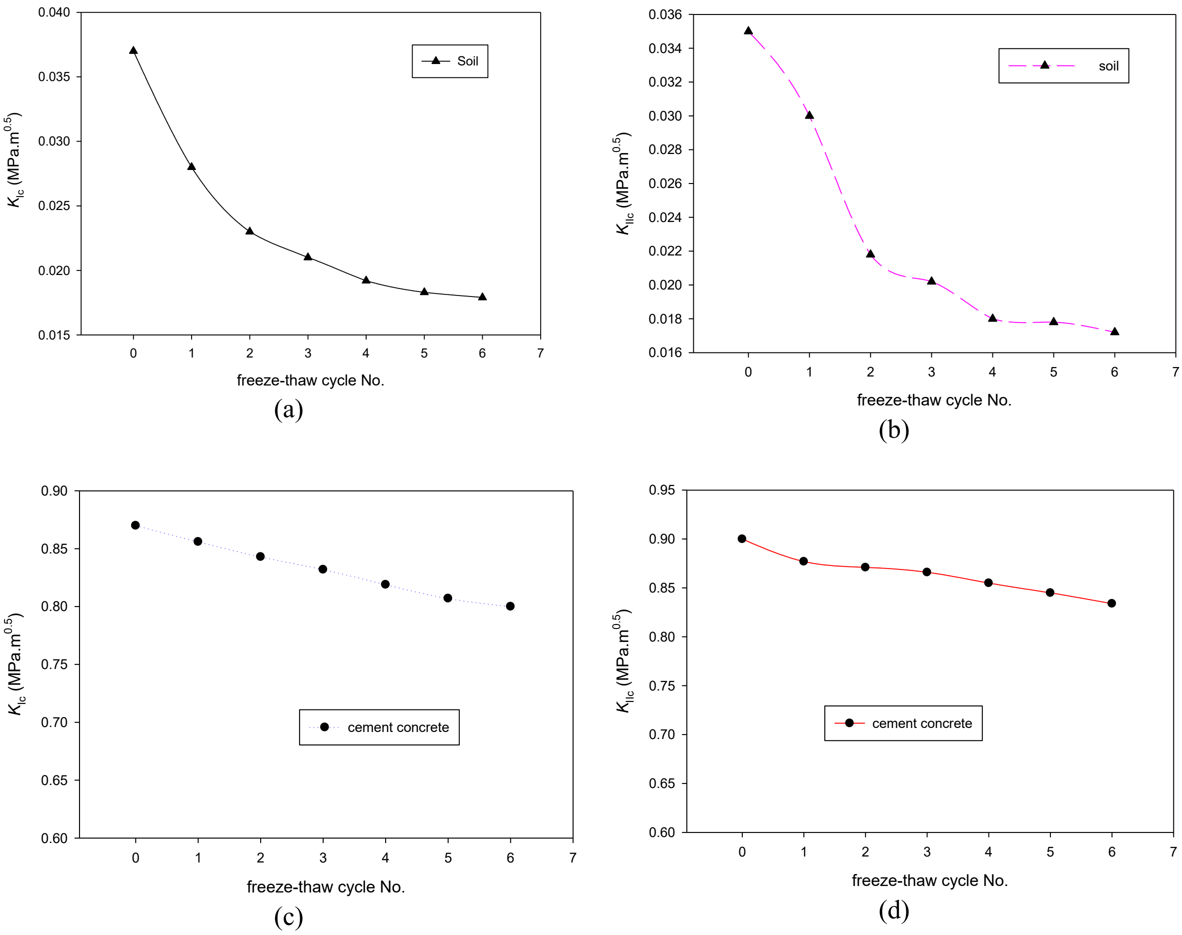

Fig. 3. Variations of fracture toughness (a) and (b): modes I and II results of soil material with the number of freeze/thaw cycles, (c) and (d): modes I and II results of cement concrete material with the number of freeze/thaw cycles.

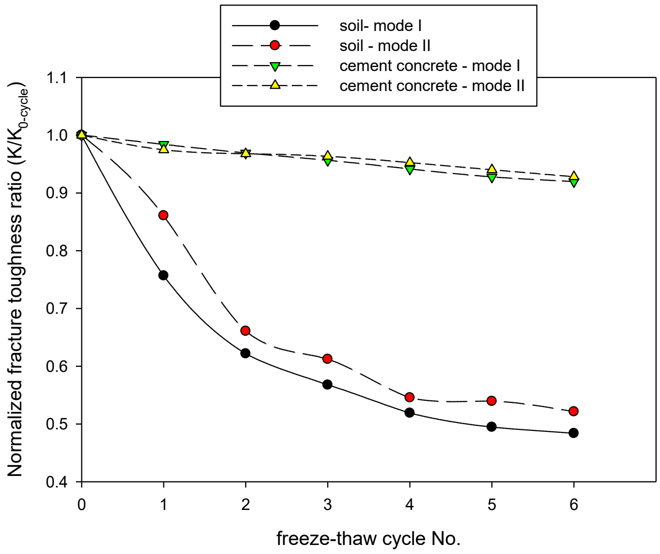

Fig. 4. Variations of normalized fracture toughness ratios with the number of freeze/thaw cycles for the tested soil and concrete materials under mode I and mode II conditions.

4. Conclusions

This study aimed to investigate the fracture toughness of two key geo-materials—soft soil and cement concrete - under freeze/thaw conditions, commonly encountered in civil and construction engineering projects. By experimentally determining the fracture toughness under both mode I (K_{Ic}) and mode II (K_{IIc}) loading conditions using a semi-circular bend (SCB) sample and both symmetric and asymmetric three-point bending setups, valuable insights were obtained regarding the materials' performance in environments subjected to freeze/thaw cycles. The results revealed that both the K_{Ic} and K_{IIc} values decreased with an increasing number of freeze/thaw cycles. However, the effects were markedly different for the two materials. For the soft soil material, the reduction in fracture toughness was more pronounced, reaching up to 40% after six freeze/thaw cycles, while cement concrete exhibited a much smaller decrease of less than 10%.

This suggests that soft soils are significantly more susceptible to freeze/thaw damage than cement concrete. Additionally, the trend of fracture toughness reduction followed distinct patterns for the two materials. For cement concrete, the fracture toughness reduction was nearly linear across the cycles, indicating a gradual degradation. In contrast, the soft soil material exhibited a power-law type reduction, with the most significant decrease occurring during the initial freeze/thaw cycles.

This behavior indicates a higher sensitivity of the soil material to early freeze/thaw damage. In conclusion, the findings of this study underscore the vulnerability of soft soil materials to freeze/thaw cycles, highlighting the need for careful consideration of material selection in construction projects exposed to such environmental conditions. The results also provide a foundation for further research into improving the durability of geo-materials, particularly soft soils, in freeze/thaw scenarios. These insights are essential for the design and long-term performance assessment of civil engineering structures, ensuring greater reliability and safety in environments subject to freeze/thaw stress.

Evaluation of the bearing capacity of strip footings on cohesionless sloped soils by finite element analysis

Burak Akçay*[1], Osman Sivrikaya[1a]

[1] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. In this study, a series of numerical analyses of strip foundations on cohesionless sloping soils were performed using PLAXIS 2D finite element method. The relationship between key parameters influencing the bearing capacity of strip footings on sloping soils and the bearing capacity factor ($N_{\gamma q}$) is investigated. These parameters include the slope angle (β), the distance from the strip footing to the top of the slope (b), the internal friction angle (ϕ), and the unit weight of the soil (γ). The soil has a slope angle (β) of 10˚ 20˚ and 30˚, distance of the footing to the slope crest to the width of the footing (b/B) of 0, 0.5, 1, 1.5, 2, 3, 4, 5, 6 and an internal friction angle (ϕ) of 30˚, 34˚ and 40˚ representing loose, medium dense and dense sands . Depending on the angle of internal friction angle, the unit volume weight was chosen to be 16 kN/m^3, 18 kN/m^3 and 21 kN/m^3 respectively. The footings on the surface (D_f=0),. the slope height (H=2 m) and the footing width (B=2 m) were taken as constant value. In addition, an empirical correlation was developed to estimate the bearing capacity coefficient ($N_{\gamma q}$). As the distance from the edge of the slope increases (i.e. as the b/B ratio increases), it can be observed that at a certain distance the bearing capacity of the footing approaches that of footings placed on horizontal level ground. Beyond this threshold, the bearing capacity remains constant regardless of further increases in the b/B ratio and the influence of the slope on the bearing capacity becomes negligible. Consequently, the footing behaves as if it were placed on horizontal level ground.

Keywords: Slope; The bearing capacity; FEM; Strip footing; Plaxis 2D

1. Introduction

The performance of the footings is affected by their bearing capacity and settlement behavior. Thus, a key challenge in geotechnical engineering is designing footings that satisfy both bearing capacity and displacement safety criteria. Several factors, including soil stratification, geotechnical properties, footing geometry and loading conditions, influence the bearing capacity of the foundation. Also, the estimation of bearing capacity becomes significantly more challenging in the presence of a slope. Critical parameters, including slope inclination (β), soil internal friction angle (ϕ), footing-to-crest distance (b), footing width (B), and embedment depth (D_f), collectively influence the bearing capacity behavior of shallow foundations on sloped soil (Meyerhof, 1957; Hansen, 1970; Vesic, 1973; Akcay, 2023).

A variety of methodological approaches have been used in the literature to study this phenomenon, including theoretical analyses, numerical simulations and experimental investigations. The theoretical framework was developed in particular by the contributions of Meyerhof (1957), Hansen (1970) and Vesic (1973). While these methods provide valuable analytical frameworks, their applicability is constrained to specific ranges of foundation placement and embedment depth. In particular, Meyerhof (1957) introduced a theoretical solution for determining the ultimate bearing capacity (q_u) of strip foundations located either on the slope face or at the crest. The equation developed by Meyerhof (1957) is as follows:

$$q_u = cN_{cq} + 0.5\gamma BN_{\gamma q} \tag{1}$$

where N_{cq} and $N_{\gamma q}$ are the bearing capacity factors, which are functions of the soil internal friction angle (ϕ), the slope angle (β) and the depth to width ratio (D_f/B), c is the soil cohesion, γ is the unit weight of the soil and B is the width of the footing. For cohesionless soils, Eq. (1) simplifies to the following:

$$q_u = 0.5\gamma BN_{\gamma q} \tag{2}$$

*Corresponding author, E-mail: burak.akcay@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_geo_962

According to the results of the study by Meyerhof (1957), the relationship between the bearing capacity factor ($N_{\gamma q}$) and various parameters such as the slope angle (β), the internal friction angle of the soil (ϕ) and the distance/width ratio of the foundation to the crest of the slope (b/B) is shown in Fig. 1.

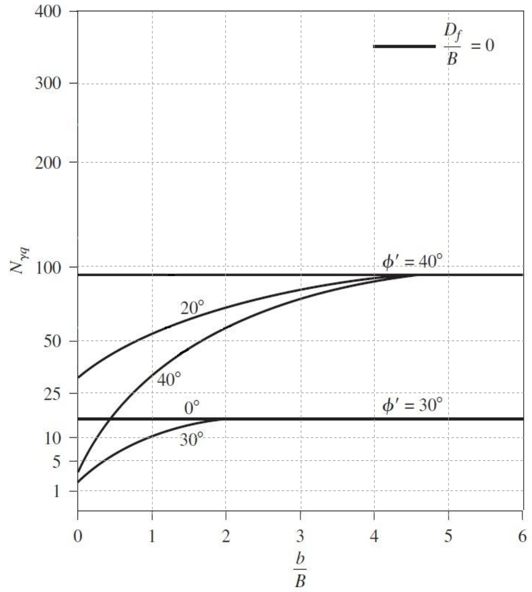

Fig. 1. The relationships between the factor $N_{\gamma q}$ of the strip footing built on top of cohesionless sloping soil with β, ϕ and b/B (Meyerhof, 1957)

In addition, numerical approaches have significantly advanced the understanding of the bearing capacity of strip footing on slopes, with contributions including the works of Lysmer (1970), Davis and Booker (1973), and Chen (1975), followed by later developments from Kusakabe et al. (1981), Michalowski (1989), Krabbenhoft et al. (2005), Farzaneh et al. (2008), Georgiadis (2008), Shiau et al. (2011), Keskin and Laman (2013), and Mofidi et al. (2014). Complementing these numerical studies, experimental investigations by Gemperline (1988), Shields et al. (1990), and Castelli and Motta (2010) have provided crucial validation of both theoretical and numerical predictions. While these studies have contributed significantly to the understanding of the slope-footing interaction, there are still some critical research gaps that have not been addressed in the literature (Akcay, 2024).

This study investigates the bearing capacity of strip footings on cohesionless slopes through a comprehensive parametric analysis using finite element modelling. A series of finite element analyses were performed to systematically evaluate the influence of key geotechnical parameters on both the ultimate bearing capacity (q_u) and the corresponding bearing capacity factor ($N_{\gamma q}$). The numerical analyses were performed using PLAXIS 2D. In addition, the empirical correlation for the bearing capacity factor ($N_{\gamma q}$) was developed by performing non-linear regression analysis. The developed empirical correlation was validated by comparing the finite element method and the Meyerhof (1957) method.

2. Materials and methods

The numerical simulations were performed with PLAXIS 2D, using the Finite Element Method (FEM) to analyze the bearing capacity of footings on slopes. The investigation considered variable parameters, including the slope angle (β), the horizontal distance between the footing and the slope crest (b), the unit weight of the soil (γ), and its internal friction angle (ϕ) (Fig. 2).

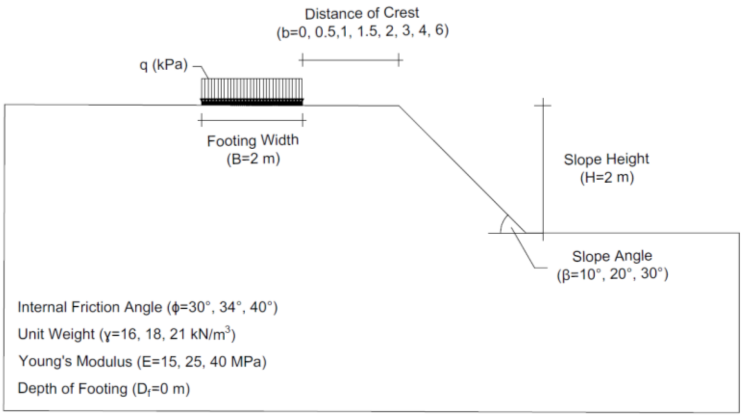

Fig. 2. Geometric presentation of the parameters on model

Meanwhile, the constant parameters included the footing width of B=2 m, the slope height of H=2 m and depth of footing of D_f=0 m. Slope angles (β) were systematically chosen as 10°, 20° and 30° an internal friction angle (ϕ) of 30˚, 34˚ and 40˚ representing loose, medium dense and dense sands. Depending on the angle of internal friction angle, the unit volume weight was chosen to be 16 kN/m^3, 18 kN/m^3 and 21 kN/m^3 respectively. The selected values for b/B included 0, 0.5, 1, 1.5, 2, 4, and 6.

The finite element analyses were conducted under plane-strain conditions, employing 15-node triangular elements to ensure high accuracy in stress and deformation calculations. The soil was modeled using the Mohr-Coulomb constitutive model with drained conditions, while groundwater not considered. The key soil parameters implemented in the analyses are comprehensively given in Table 1. The strip footing was assumed as an elastic, isotropic plate element, with applied loading represented as a concentrated point load acting at the center of the footing.

Table 1. Soil parameters used in the FEM analyses

Cases	I	II	III
Internal friction angle, (ϕ′), deg.	30	34	40
Unit weight of soil, (γ), kN/m^3	16	18	21
Young's modulus, (E′), MPa	15	25	40
Dilatancy angle, (ψ′), deg.	0	4	10

3. Results and discussions

A systematic numerical study was performed using a series of PLAXIS 2D models to examine the behavior of a strip footing positioned at the slope crest. The analysis primarily focused on evaluating the impact of fundamental dimensionless parameters, including the normalized distance from the slope crest (b/B), slope angle (β), footing depth ratio (D_f/B), and internal friction angle of the soil (ϕ) on the bearing capacity factor ($N_{\gamma q}$). The results indicate that $N_{\gamma q}$ is highly sensitive to changes in these parameters, and a detailed evaluation of their effects is presented in the following sections.

The results indicate that the bearing capacity increases proportionally with the internal friction angle (ϕ). For cohesionless sloped soils, lower values of ϕ allow the bearing capacity to reach that of horizontal ground conditions at relatively smaller normalized distances (b/B). Conversely, soils with higher internal friction angles require larger b/B ratios to achieve the same capacity. For instance, the bearing capacity does not vary beyond b/B = 2 for ϕ = 30°, whereas this threshold increases to b/B = 3 for ϕ = 34°, and to b/B = 4 for ϕ = 40° (Fig. 3).

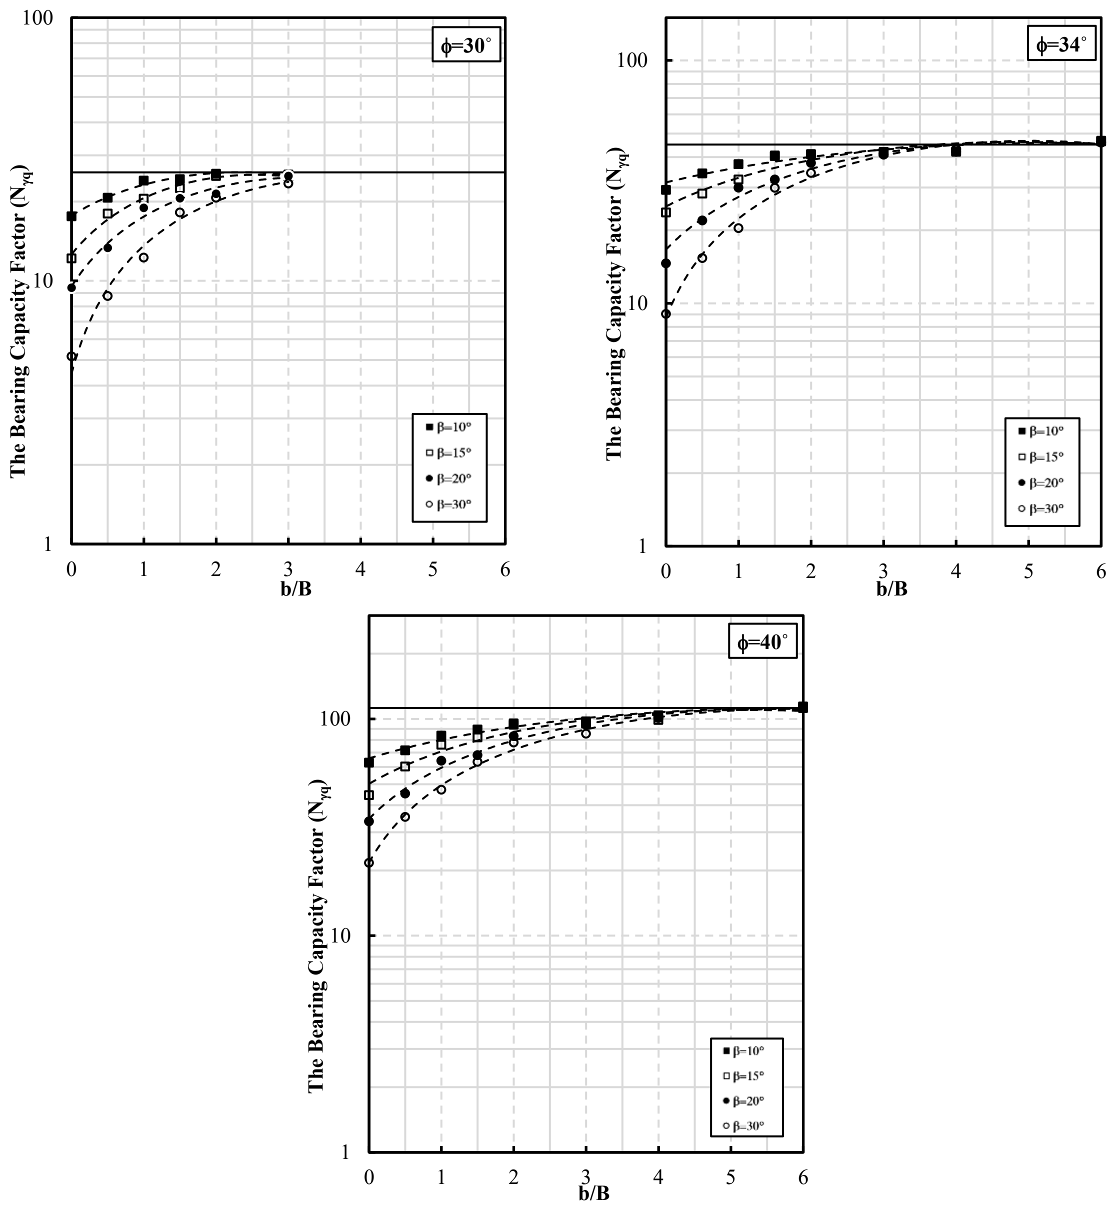

Fig. 3. Relationship between different slope angles (β) and $N_{\gamma q}$ factor at different internal friction angles (ϕ)

In contrast to the internal friction angle (ϕ), the slope angle (β) exhibits an inverse relationship with the bearing capacity (q_u). For relatively gentle slopes, the footing with smaller normalized setback distances (b/B) are sufficient to attain the bearing capacity corresponding to horizontal ground conditions. However, as the slope angle increases, a larger b/B ratio is required to reach this capacity. This trend is observed consistently across all values of internal friction angle (ϕ), but becomes particularly significant in soils with higher ϕ (e.g., ϕ > 34°). For instance, when ϕ=40°, the influence of the slope becomes negligible beyond b/B = 4 for β = 10°, while the corresponding threshold increases to b/B = 5 for β = 30° (Fig. 4).

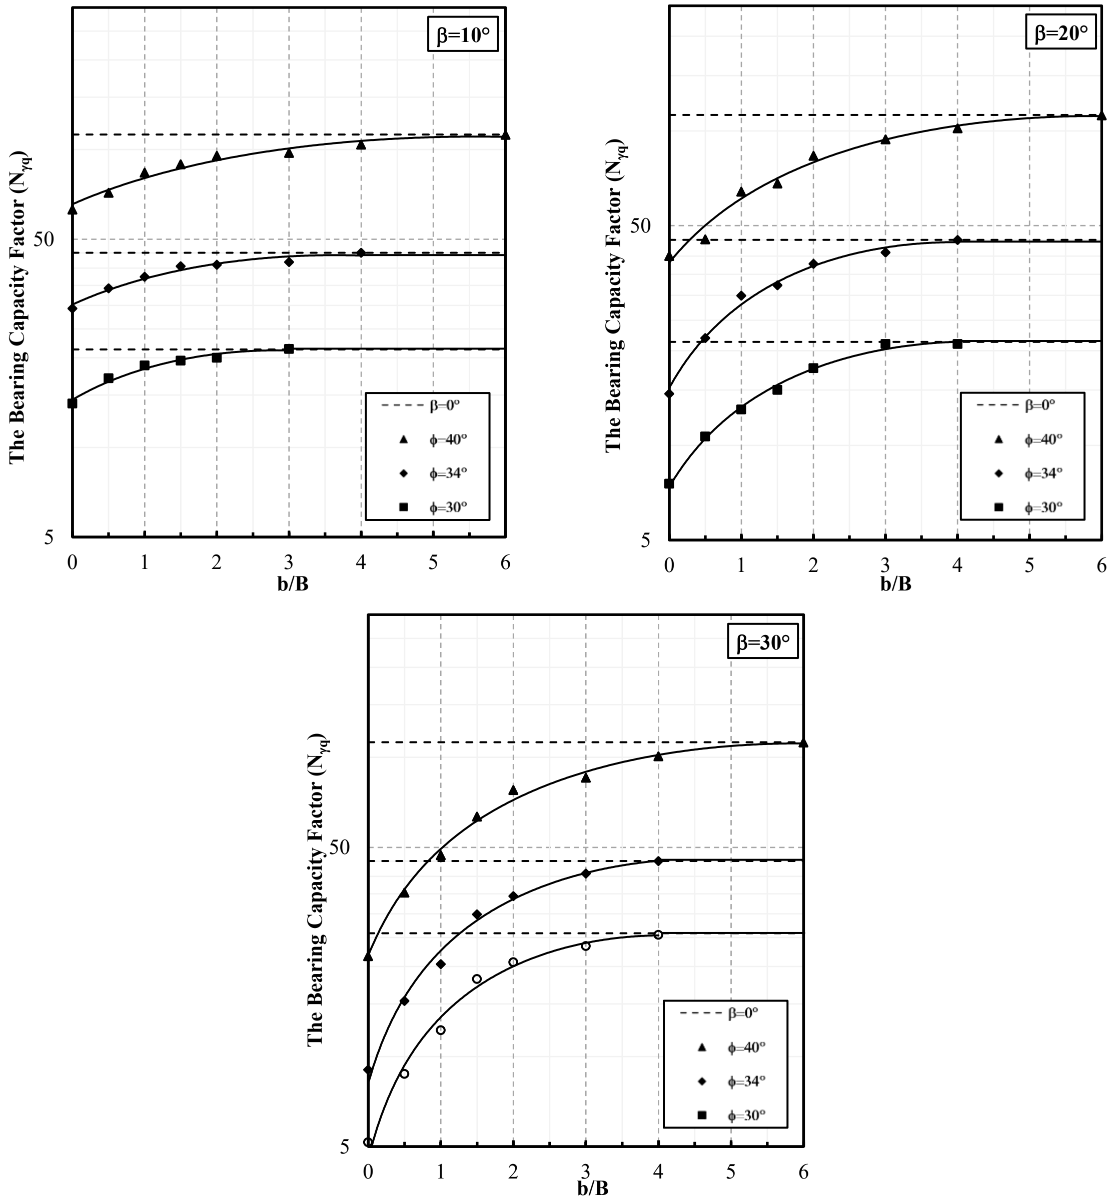

Fig. 4. Relationship between different internal friction angles (ϕ) and $N_{\gamma q}$ factor at different slope angles (β)

3.1. Comparison of empirical correlation and FEM with Meyerhof method

A nonlinear regression analysis was conducted using IBM SPSS V23, incorporating four independent variables (unit weight (γ), distance from the slope crest (b/B), internal friction angle (ϕ), and slope angle (β)) to predict the bearing capacity factor ($N_{\gamma q}$) as the dependent variable. The developed empirical correlations are given in Eq. 3:

$$\begin{aligned} N_{\gamma q} &= -1310.7\times\gamma - 2246.4\times\frac{b}{B} + 417.1\times\phi - 18.4\times\beta + 2224\times\gamma\times\frac{b}{B} \\ &-18.6\times\gamma\times\phi + 19.5\times\gamma\times\beta - 1111.1\times\frac{b}{B}\times\phi + 0.2\times\frac{b}{B}\times\beta - 9.8\times\phi\times\beta \\ &+237.2\times\gamma^2 - 1.4\times\left(\frac{b}{B}\right)^2 - 49.7\times\phi^2 + 0.1\times\beta^2 + 1371.3 \end{aligned} \quad (3)$$

(R^2 = 0.987)

The resulting empirical correlation was subsequently compared with theoretical predictions based on the method proposed by Meyerhof (1957) and results of FEM anaysis. The comparison revealed a strong agreement between the developed empirical correlation, FEM analysis and the theoretical approach, validating the reliability of the developed correlation. This consistency is especially notable for cases involving higher internal friction angles (e.g., ϕ ≥ 34°) and lower slope angles (e.g., β ≤ 20°). Overall, the accuracy and reliability of the empirical correlation improve as the bearing capacity factor increases, resulting in enhanced agreement with the Meyerhof (1957) method and more consistent predictive performance (Fig. 5).

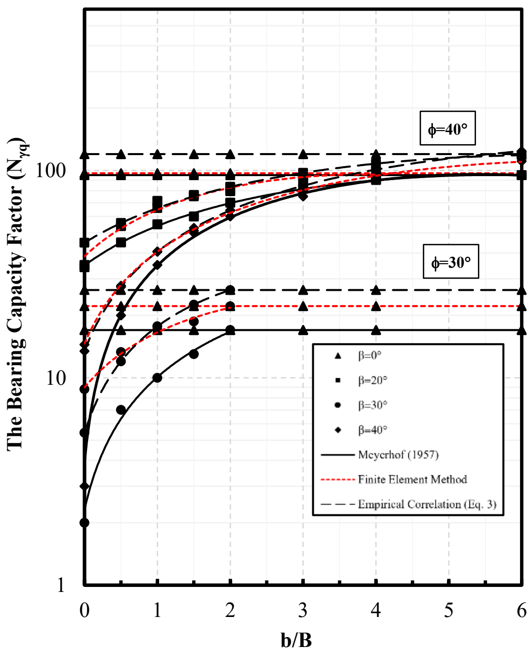

Fig. 5. The comparison of the empirical correlation, FEM analysis and Meyerhof (1957) method

4. Conclusions

A series of numerical analyses were performed to evaluate the bearing capacity of a strip footing constructed on cohesionless sloped soil. The study considered several key parameters influencing bearing behavior, including the horizontal distance from the slope crest to the footing (b), the unit weight of the soil (γ), the slope angle (β), and the internal friction angle of the soil (ϕ). In addition, a nonlinear regression analysis was performed to derive an empirical correlation for the bearing capacity factor. As a result of this study, the following conclusions are reached.

- The bearing capacity of the footing significantly increases by reducing the slope angle (β), increasing the internal friction angle (ϕ), and increasing the horizontal distance between the footing and the slope crest (b).
- If the b/B ratio increases as the footing moves away from the slope crest, it is observed that after a certain distance, the bearing capacity factor of the footing in sloped conditions reaches that of horizontal soils. Beyond this critical distance, the bearing capacity factor reaches a constant value and shows no further variation with additional increments. At this stage, the effect of the slope on the bearing capacity is negligible and its residual effect is insignificant. As a result, the footing behaves in the same way as a foundation placed on a flat, horizontal layer of soil.
- An increase in the angle of internal friction (ϕ) results in an increase in the bearing capacity factor ($N_{\gamma q}$). The soils with higher internal friction angles require larger crest distances (b/B) to achieve the bearing capacity equivalent to that of horizontal soil conditions (β=0°), whereas soils with lower internal friction angles achieve this capacity at relatively smaller b/B values.
- In contrast to the influence of the internal friction angle (ϕ), the slope angle (β) has an inverse relationship with the bearing capacity factor ($N_{\gamma q}$). The results indicate that as β increases, the bearing capacity factor remains constant only at a greater distance from the crest (b/B). In particular, for gentle slopes (low β values), the effect of the slope on the bearing capacity factor of the footing becomes negligible at a relatively small b/B ratio. Conversely, for steeper slopes (high β values), a larger b/B ratio is required to eliminate the influence of the slope and achieve bearing capacity factor conditions comparable to those of a horizontal soil surface (β=0°).
- The empirical correlation exhibits notable deviations from Meyerhof (1957) method in cases involving sloping soils with low internal friction angles (ϕ). In contrast, for higher ϕ values, the empirical correlation and FEM analysis results align closely with theoretical method (Meyerhof, 1957), highlighting the enhanced predictive capability of the model under such conditions.

Non-stationarity assessment of intensity-duration-frequency (IDF) curves of standard duration rainfall in the Eastern Black Sea Region, Türkiye

Nagehan Şahin*[1], Murat Şan[1], Murat Kankal[2]

Abstract. Intensity-Duration-Frequency (IDF) curves used in the design of hydraulic structures are traditionally based on stationary frequency analyses with fixed parameters. However, temporal changes in extreme rainfall caused by climate change have made the validity of the stationary approach questionable. Recent studies have focused on updating IDFs under non-stationary conditions to understand the time-varying behaviour of extreme rainfall better. In this context, this study, which aims to examine the hydrological impacts of climate change in the Eastern Black Sea region, estimated IDF curves by performing non-stationary frequency analysis for six stations. Both stationary and non-stationary models of the generalized extreme value (GEV) distribution were used to determine extreme rainfall intensities, and the results of both models were compared in terms of the effects of non-stationarity on infrastructure design. It was concluded that the stationarity assumption is still valid in stations such as Akçaabat, Giresun, and Ordu. At the same time, the effects of non-stationarity are evident in Bayburt, Gümüşhane, and Hopa stations.

Keywords: The Eastern Black Sea Region; Intensity-duration-frequency curves; Non-stationarity; Rainfall frequency

1. Introduction

Climate change has significant consequences worldwide, including sea level rise, extreme rainfall, drought, and increased heat waves (Ahmed vd., 2018; Shiru vd., 2019; Şan vd., 2023). Although these impacts vary regionally, they directly affect each region's infrastructure systems and natural resource management. Accurately identifying the impacts of climate change at the local level is critical for developing adaptation strategies (An vd., 2023).

Some studies have identified increasing trends in the frequency and intensity of extreme rainfall (Swain vd., 2020; Tabari vd., 2021). In particular, Asadieh & Krakauer (2015) revealed a global increase of 8.5 percent in annual maximum daily rainfall between 1901 and 2010. Similar findings have been reported in regions such as the Americas, Africa and the Mediterranean (Douglas vd., 2023; Shang vd., 2011; Tramblay & Somot, 2018). Türkiye is a country open to the effects of climate change due to its location in the Mediterranean basin. Touhedi vd. (2023) revealed that the increasing trend in extreme rainfall is evident throughout Türkiye, and this increase is particularly concentrated in the Black Sea, Marmara, and Aegean regions.

IDF curves, which are important design tools used in the sizing and risk analyses of engineering structures, relate rainfall intensities of certain durations to return periods and are traditionally obtained under the assumption of stationarity by statistical analysis of past extreme rainfall data. However, due to climate change effects, the assumption of stationarity used in classical hydrological analyses is losing its validity (Cheng vd., 2014). This makes it necessary to question the existing hydrological design criteria. In this context, there are various studies for non-stationary modeling of extreme climate events worldwide (Cheng vd., 2014; Gao vd., 2016; Lee vd., 2020; Mondal & Mujumdar, 2015; Sugahara vd., 2009; Vasiliades vd., 2015; Wi vd., 2016). Considering the climate diversity of Türkiye, it is of great importance to study the impacts of climate change on non-stationarity in small and medium-sized regions (Aziz & Yucel, 2021). Aziz and Yucel (2021) examined the temporal variability of annual and seasonal extreme rainfall across Türkiye using stationary and non-stationary frequency analyses. According to the percentage differences calculated over 30-year return levels, the non-stationarity effect reached 35%, 30%, 25%, and 20% in the Mediterranean, Aegean, Marmara, and Black Sea regions, respectively. In

https://doi.org/10.31462/icearc2025_ce_hwr_052

contrast, more complex and unclear non-stationarity effects were observed in the Central, Eastern and Southeastern Anatolia regions. Similarly, in a study conducted in the Black Sea Region, in addition to the stationary model, a non-stationary model with parameters varying with time and hydrometeorological variables, frequency analysis of extreme rainfall was performed, and IDF curves were created in this context (Aksu vd., 2025). Oruc (2021) used two non-stationary equations in the Black Sea region and observed higher magnitude non-stationary effects for the Eastern Black Sea Region and the coastline. However, there may also be a scenario of equations with the non-stationary parameter being affected in different forms over time.

This study performed an IDF analysis based on the generalized extreme value (GEV) distribution using annual maximum precipitation data of standard duration recorded between 1980 and 2020 from six stations in the Eastern Black Sea Region of Turkey. GEV is the most suitable distribution for the Black Sea (Aksu et al., 2022). Within the scope of the analysis, nine different models, i.e., one stationary and eight non-stationary models with time-varying parameters, were evaluated. The Corrected Akaike's Information Criterion (AICc) and Likelihood Ratio (LR) tests were used to select the best GEV model. IDF curves were generated using the selected models. Thus, regional impacts of climate change were evaluated more precisely, and hydrological design criteria specific to the Eastern Black Sea Region were obtained.

2. Materials and methods

2.1. Study area and data

This study was conducted in the Eastern Black Sea Region in the north-east of Türkiye. The region covers Rize, Artvin, Trabzon, Giresun, Gümüşhane, and Bayburt provinces. Geographically, it has temperate and humid climate characteristics. The Eastern Black Sea Region, one of the areas with the highest total annual rainfall in Türkiye, is frequently subjected to floods due to its topographical structure. Since the residential areas in the region are generally located near floodplains, many material and moral losses occur due to floods (Anik vd., 2021). Floods caused by excessive rainfall are among the most destructive natural disasters in the region, which is very rich in water resources due to its topography, mountainous terrain, and typical climatic character (Aksu vd., 2025).

Hopa, Akçaabat, Giresun, Ordu, Ordu, Gümüşhane, and Bayburt meteorological stations in the Eastern Black Sea Region, which have 30 years of records between 1980 and 2020, were selected in this study (Fig. 1). Time series containing annual maximum rainfall with standard duration (5, 10, 15, 30 m and 1, 2, 3, 4, 5, 6, 8, 12, 18, 24 h) of the selected stations were obtained and evaluated within the scope of the study.

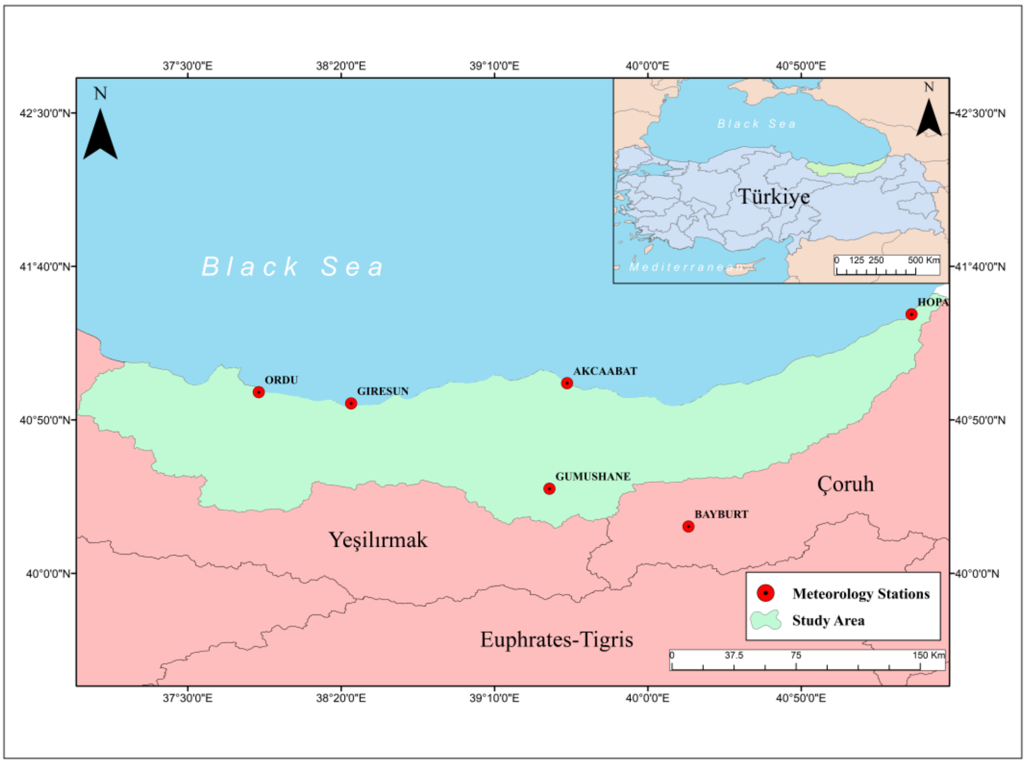

Fig. 1. Location of the provincial centres where the stations are located in the Eastern Black Sea Region showing the study area.

2.2. Generalized Extreme Value distribution

The study used generalized extreme value (GEV) distribution to model the temporal variation of extreme rainfall. This distribution is defined by the parameters of location (μ), scale (σ), and shape (ξ) (Coles, 2001) :

$$F(x, \mu, \sigma, \xi) = \exp\left\{-\exp\left[-\left(1+\xi\frac{x-\mu}{\sigma}\right)\right]\right\},\ 1+\frac{\xi(x-\mu)}{\sigma} > 0 \quad (1)$$

In stationary models these parameters are constant, whereas in non-stationary models they are a function of time. In this case the cumulative distribution function takes the following form:

$$F(y; \mu(t), \sigma(t), \xi(t)) = \exp\left\{-\left[1+\ \xi(t)\frac{y-\mu(t)}{\sigma(t)}\right]^{-\frac{1}{\xi(t)}}\right\} \quad (2)$$

A total of nine different GEV models were constructed, and these models are presented in Table 1. Parameter estimation was performed by the maximum likelihood estimator (MLE).

Table 1. Time-varying nonstationary models

Model	Location	Scale
I	μ (constant)	σ (constant)
II	μ0 + μ1*t	σ (constant)
III	μ0 + μ1*t	σ0+ σ1*t
IV	μ0 + μ1*t	exp(σ0+ σ1*t)
V	μ (constant)	σ0+ σ1*t
VI	μ (constant)	exp(σ0+ σ1*t)
VII	μ0 + μ1*t + μ2*t^2	σ (constant)
VIII	μ0 + μ1*t + μ2*t^2	σ0+ σ1*t
IX	μ0 + μ1*t + μ2*t^2	exp(σ0+ σ1*t)

The most appropriate model for each station and rainfall period was selected using the Corrected Akaike’s Information Criterion (AICc). Differences between models were determined by calculating Δi = AICc - min(AICc), and models with Δi ≤ 2 were considered appropriate (Burnham & Anderson, 2004). The Likelihood Ratio (LR) test compared stationary and non-stationary models. Then, non-stationary models were considered statistically significant if $p<0.05$ (Katz, 2013). The R code used for generating GEV models was utilized from the work of Silva and Simonovic (2020).

2.3. Generating IDF curves

Based on the selected best GEV model, stationary and non-stationary return levels were calculated for different return periods (2, 5, 10, 20, 50, and 100 years). With the help of the GEV distribution, the depth of rainfall (z_p) corresponding to the return level as a function of the return period T years, calculated as

$$z_p = \mu\frac{\sigma}{\xi}\left[1\left\{-ln\left(1\frac{1}{T}\right)^{-\xi}\right\}\right] \quad (3)$$

If the best GEV model is chosen as a non-stationary model, the location and/or scale parameters must change over time. In this framework, based on the low-risk approach (Cheng vd., 2014), time-varying parameters are calculated using the 95th percentile values. The calculated model parameters are then adapted into Equation 4 to predict the depth of rainfall under non-stationary conditions.

$$I = A(d+C)^B \quad (4)$$

Where I is the rainfall intensity (mm/hour), A, B, and C are the coefficients determined for each return period (T). In addition, the parameter d indicates the rainfall duration in hours.

3. Results

In this study, stationary and non-stationary IDF curves were constructed for six meteorological stations, i.e., Hopa, Akçaabat, Giresun, Ordu, Gümüşhane, Bayburt, located in the Eastern Black Sea Region of Türkiye with return levels calculated for 2, 5, 10, 20, 50, and 100 years. The AICc values of the equations that satisfy the Δi ≤ 2 condition and pass the LR test for each standard period as a result of the analysis made with the annual maximum precipitation amount recorded at the stations to generate the IDF curves and the best GEV model selected according to the minimum value of these values are given in Table 2. The stationary model I is the majority for all stations. For 12-h rainfall, non-stationarity was detected at any station. In 6 of the standard durations, the non-stationary GEV model was found to be the best model in only one station, while in 7 of the standard durations, the non-stationary GEV model was selected as the best model in two stations. Gümüşhane station, where non-stationary GEV model was detected in 5 of the standard durations, was the station with the highest non-stationarity. Ordu province was the station with the least non-stationarity by providing only one non-stationary GEV model. At Ordu station, except for 18 h of rainfall, the stationary state dominates the other durations.

Table 2. The best GEV model and AICc values selected for each station and standard times. (AICc value of the selected GEV model is marked in bold.)

In Fig. 2, the best GEV model selections by station for different rainfall durations from 5 minutes to 24 hours in the Eastern Black Sea Region are presented spatially. Non-stationary models appear in inland areas for short durations (5m-3h), while they start to emerge in coastal areas as the duration increases.

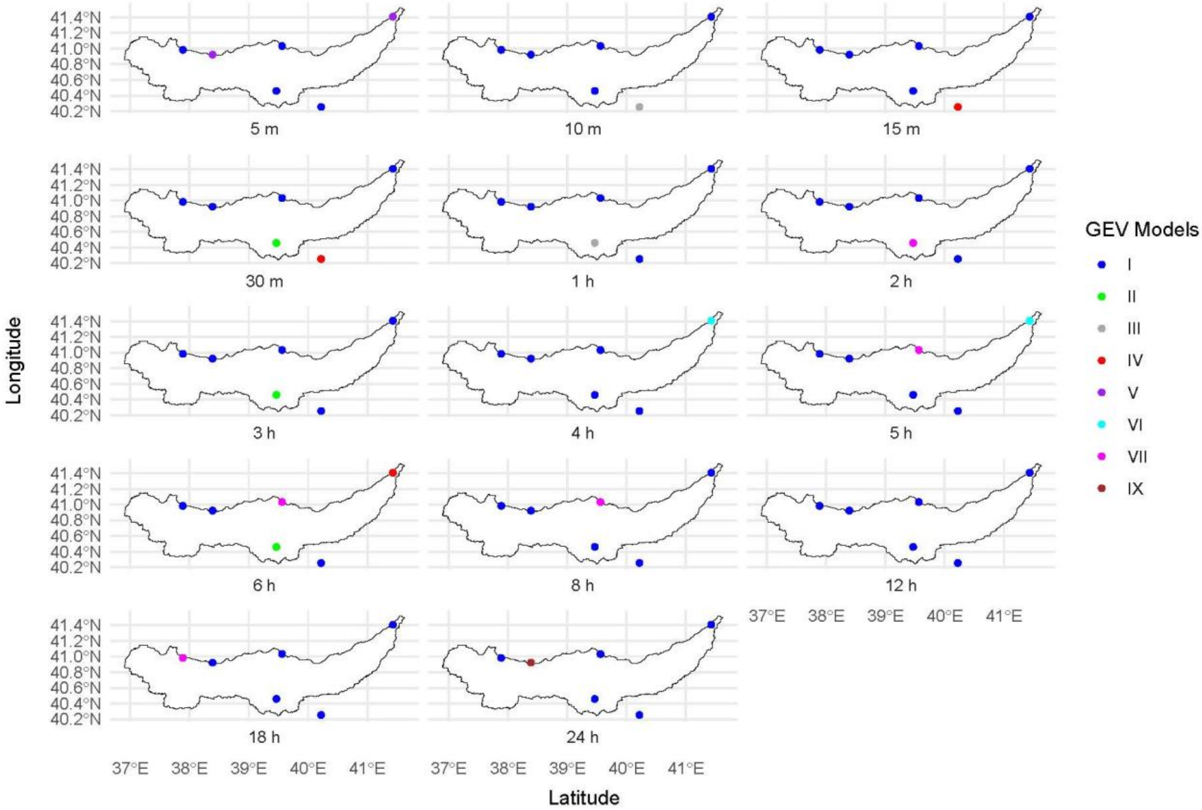

Fig. 2. The best GEV models in the map of the Eastern Black Sea Region

Calculations are made with equation I for the cases where the stationarity assumption is valid. On the other hand, in case of a non-stationary situation for different standard durations, calculations are made through non-stationary GEV model equations (model II-IX). Then, the 95th percentile values of non-stationary IDF curves are presented with the stationary IDFs at different return periods. (

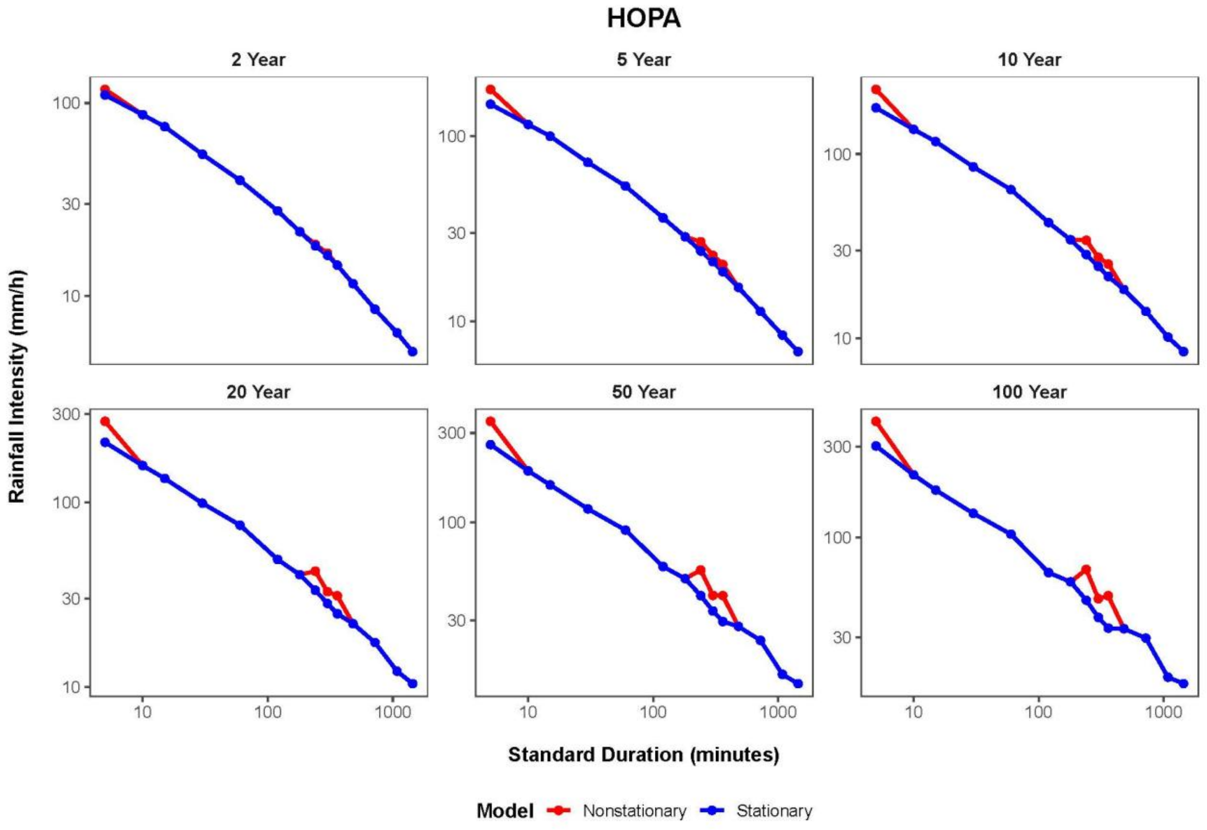

Fig. 3-8). The results of the different return periods for each station are summarized below.

At Hopa station, non-stationary models produced higher rainfall intensities than stationary models for very short rainfall duration (5-30 minutes) (

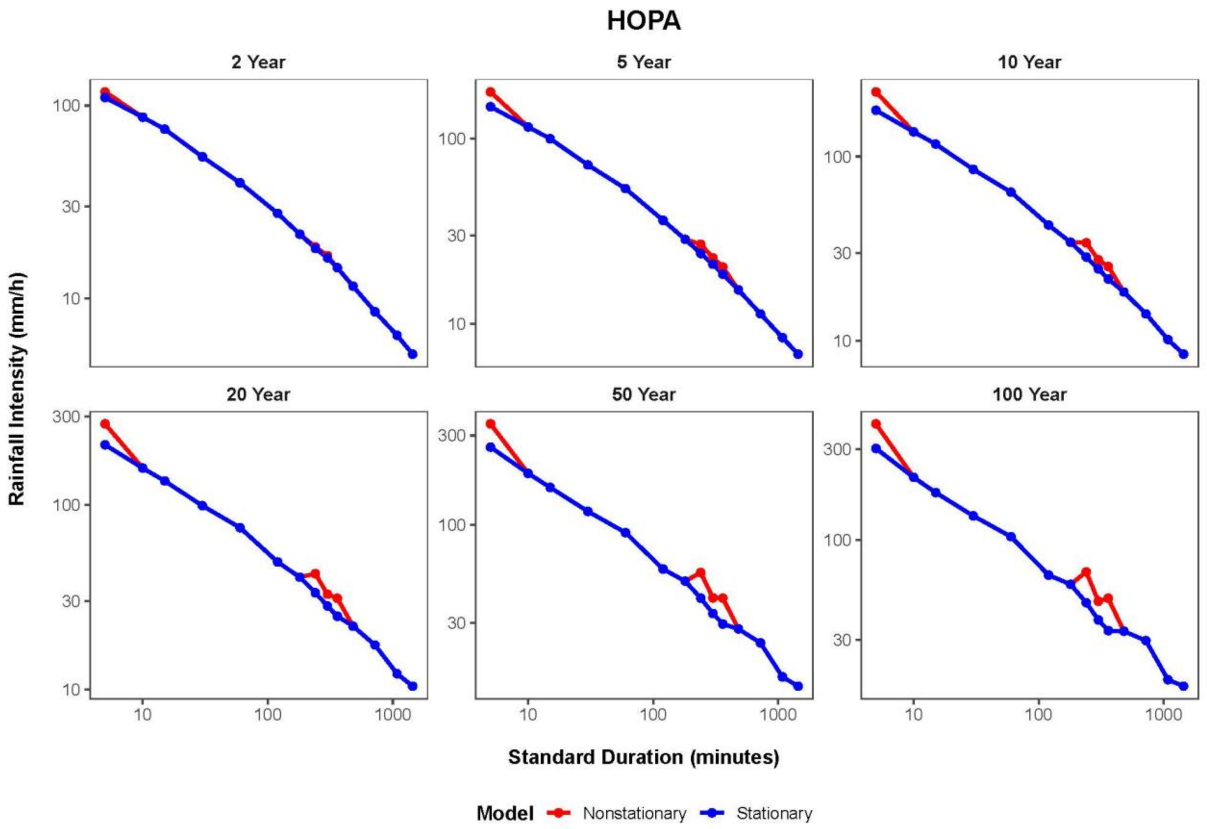

Fig. 3). In long-duration rainfall, stationary effects dominate, especially at low return periods. Non-stationary models in the range of 4-6 hours provided an increase in rainfall intensity with the return period. At 5 m, 4 h and 5 h, the GEV models (V and VI) that provide non-stationarity keep the position parameter constant while changing the scale parameter with time. Similarly, at 6 h, the model (IV), which is selected as the best model, increases the position parameter linearly while the scale parameter increases exponentially. This can be interpreted that the non-stationarity for Hopa station is primarily due to changes in the scale parameters (Table 2).

Minor differences between stationary and non-stationary IDF curves were detected at the Akçaabat station (

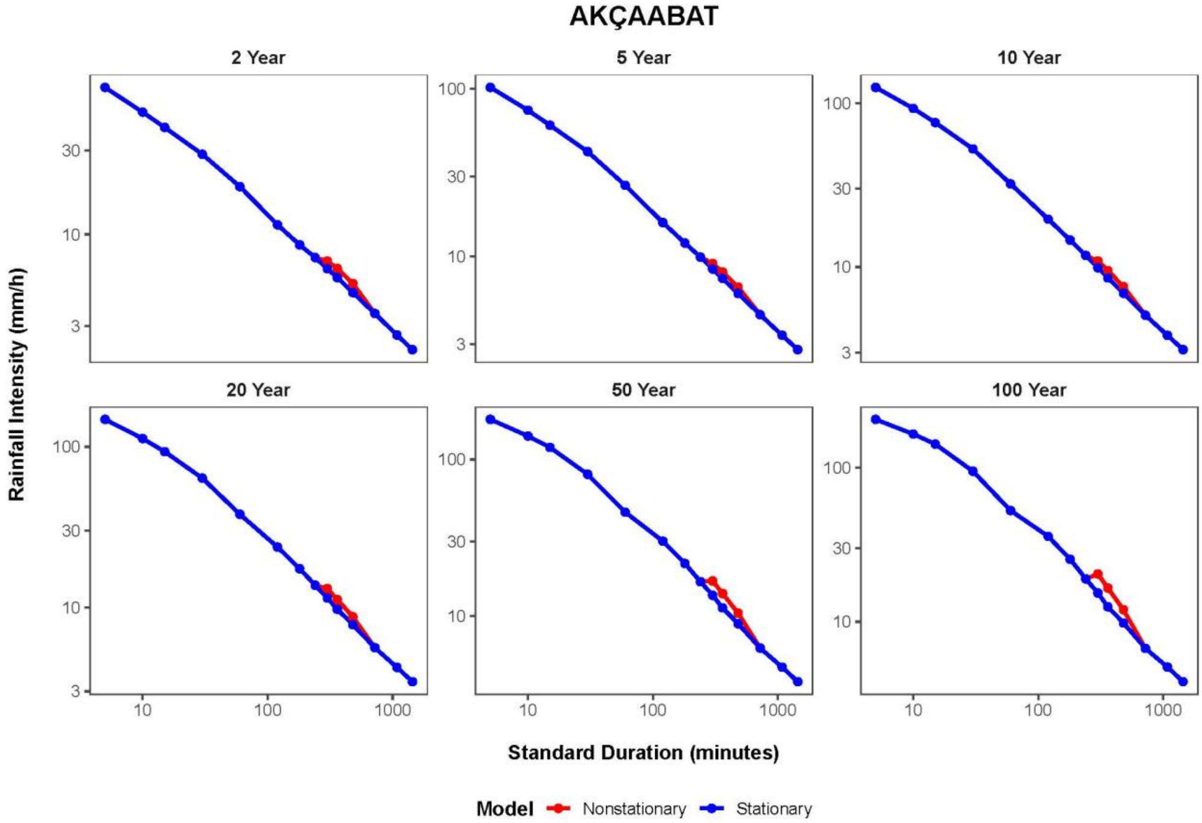

Fig. 4). Especially in short durations (5-60 minutes), stationarity is dominant, while non-stationary models in the 5-8 hours range show a slight increase in rainfall intensity compared to stationary models. Although it can be argued that this variation is due to the position parameters, it should be noted that the GEVIII model, in which the position and scale parameters change linearly in 5h, also fulfils the $\Delta i \leq 2$ condition (Table 2). However, the general pattern remained essentially parallel between both models.

Differences between stationary and non-stationary models were limited at the Giresun station (Fig. 5). Only in 5 minutes and 18 hours of rainfall was the non-stationary model prominent, and this model showed lower rainfall intensities than the stationary model in 5 minutes of rainfall, while it showed significantly higher intensities than the stationary model in 24 hours of rainfall. The changes at 5 min are due to the scale rather than the position parameters, since the two smallest AICc values that satisfy the condition $\Delta i \leq 2$ are those for equations in which the position parameter remains constant and the scale parameter varies with time (Table 2).

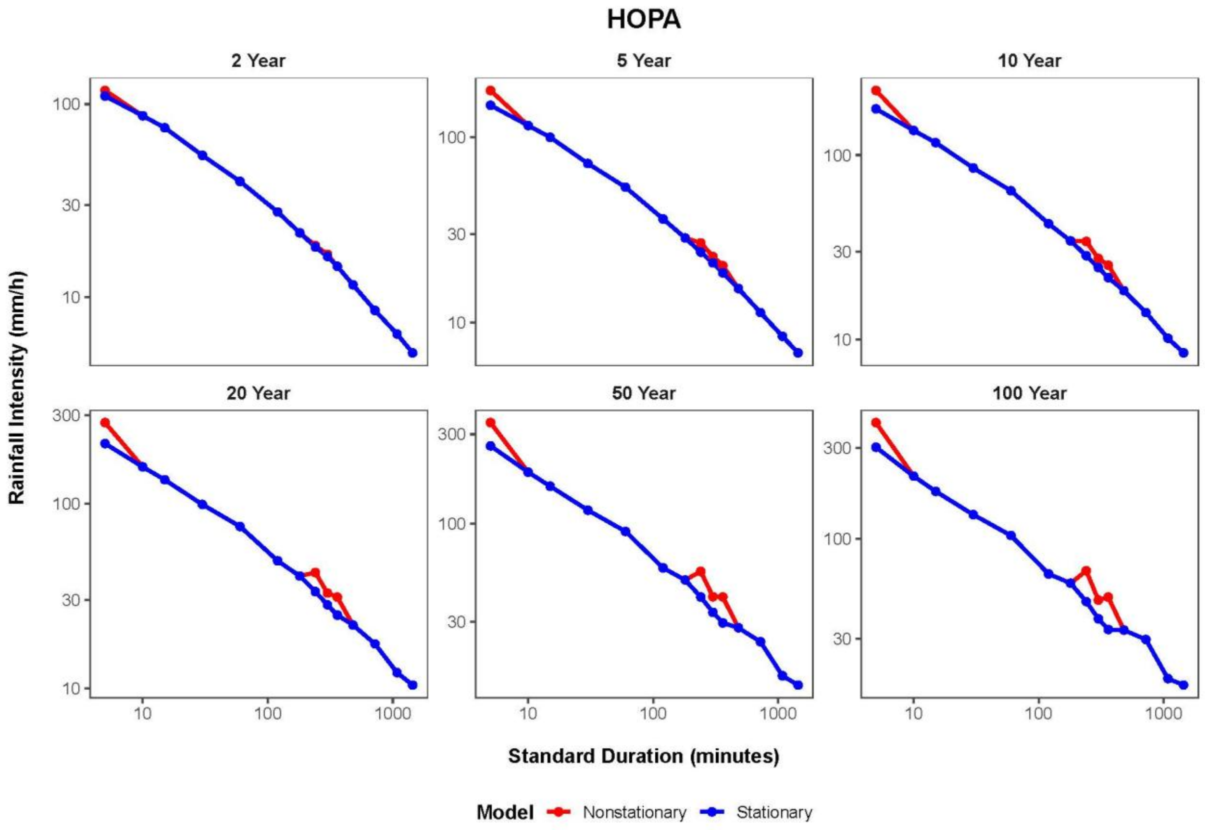

Fig. 3. Stationary and non-stationary IDF for different return periods for Hopa station

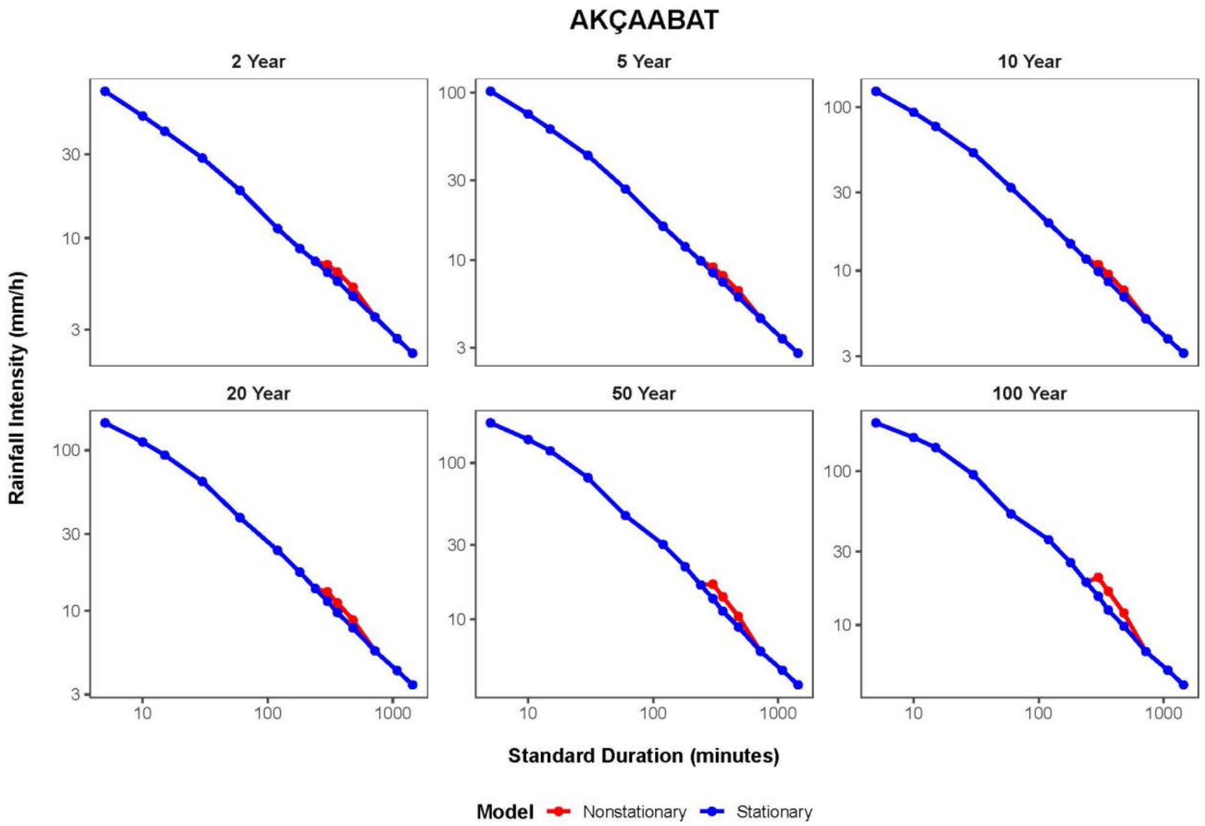

Fig. 4. Stationary and non-stationary IDF for different return periods for Akçaabat station

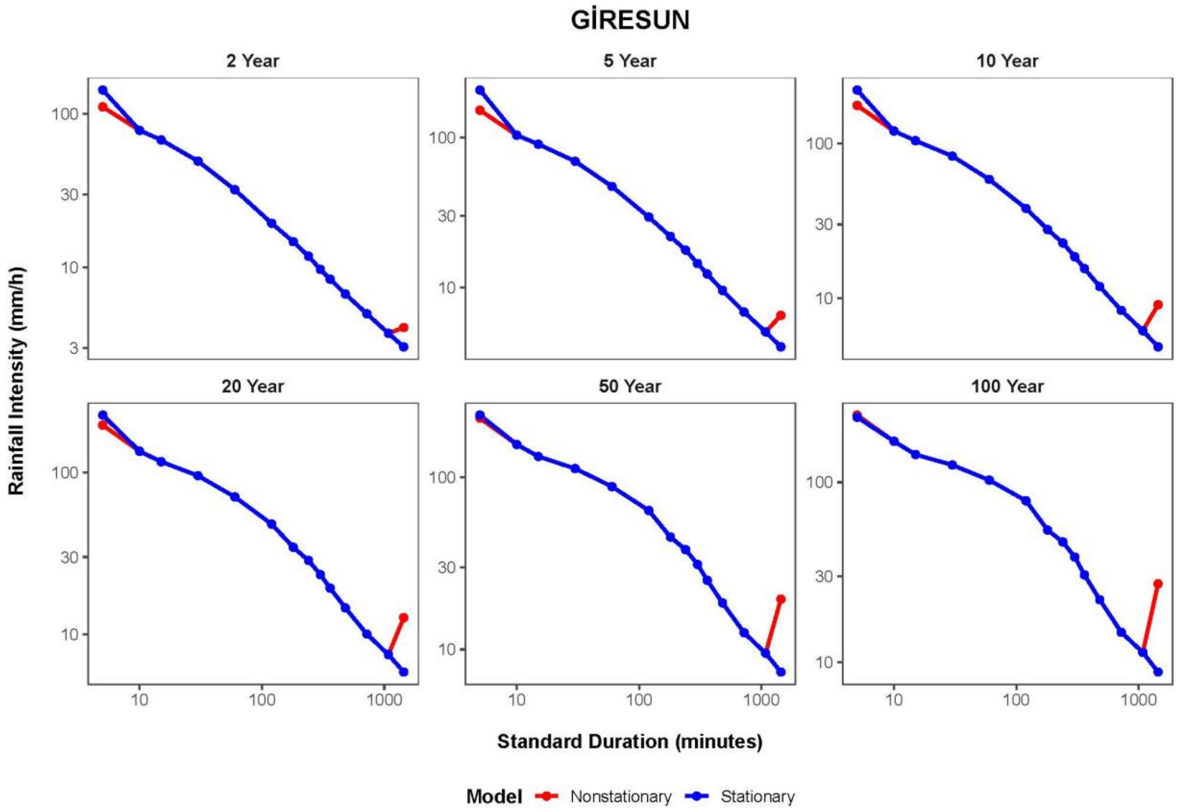

Fig. 5. Stationary and non-stationary IDF for different return periods for Giresun station

Although non-stationarity effects due to change of location parameters (Table 2) are observed only in 18-hour rainfall in Ordu, this effect is minimal at high return periods (10-100 years) (Fig. 6).

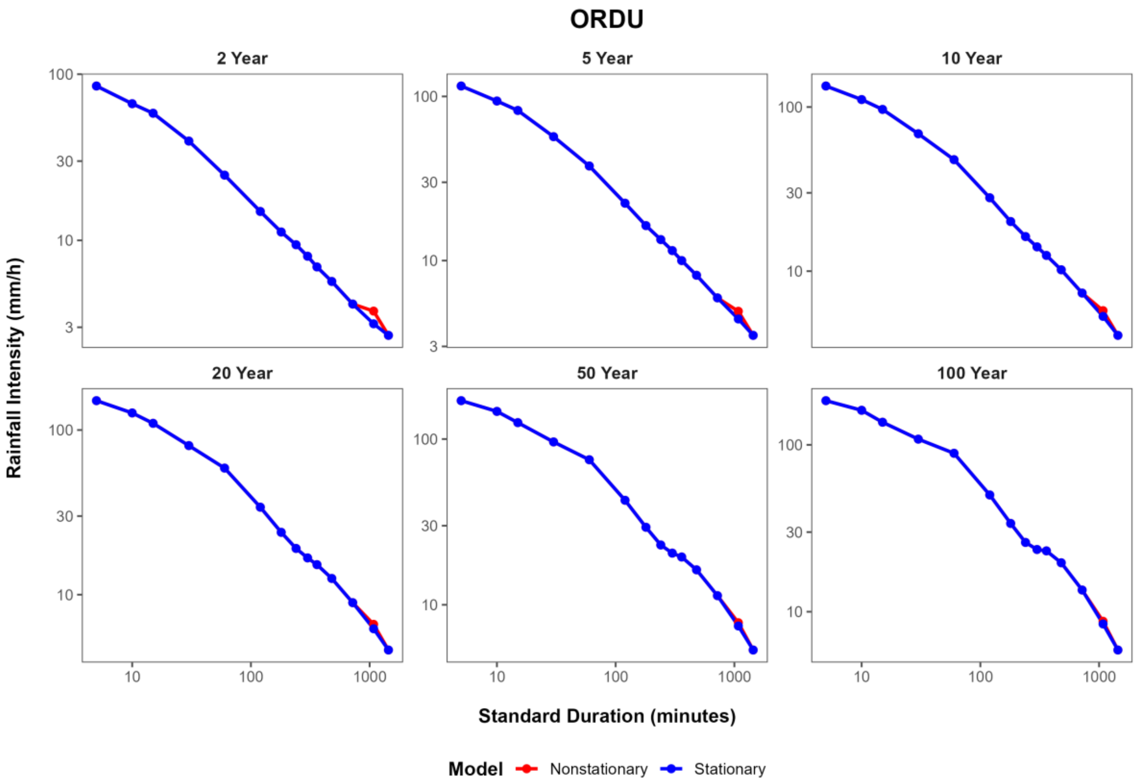

Fig. 6. Stationary and non-stationary IDF for different return periods for Ordu station

Between stationary and non-stationary IDF curves in Gümüşhane, non-stationary models, due to changes in location parameters (Table 2), produced higher intensity values in all return periods, especially in rainfall durations between 30 minutes and 6 hours (

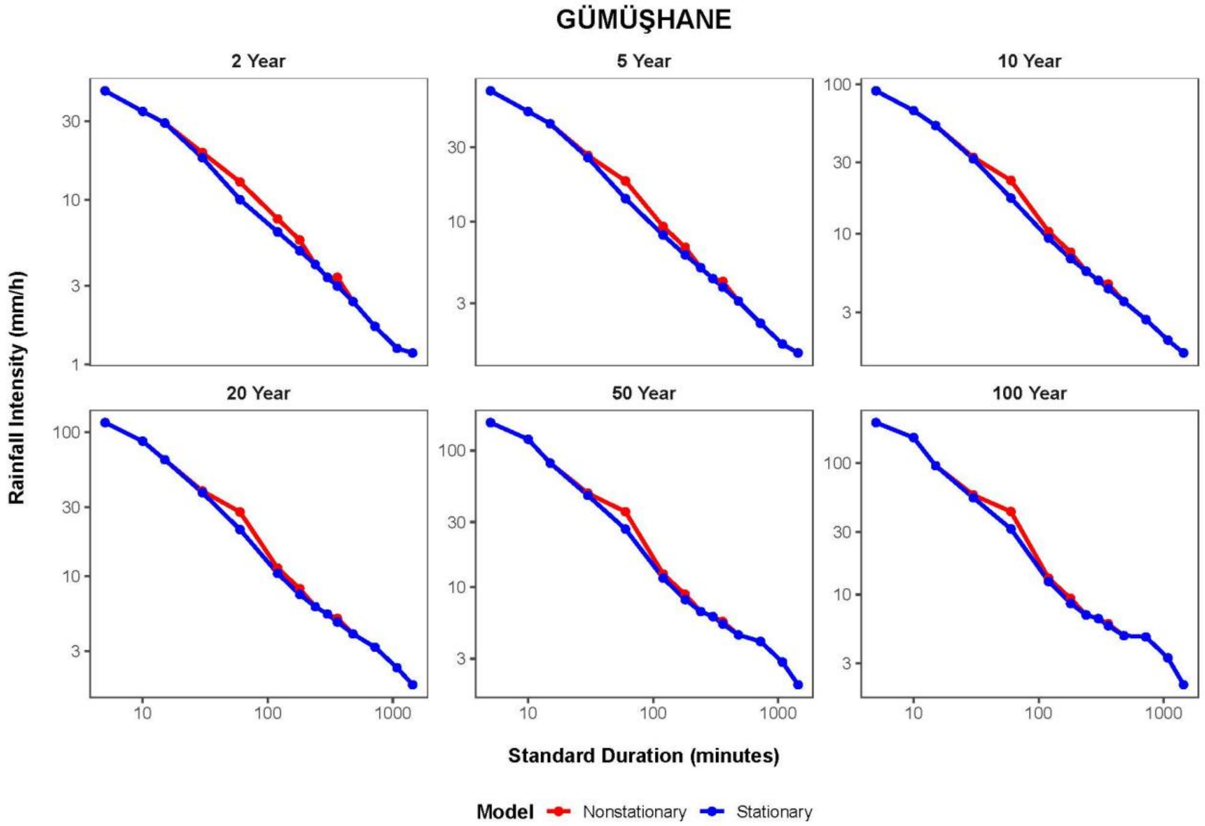

Fig. 7). However, when the AICc values are examined, it should be noted that the GEV models (III and IV) in which the scale parameter is changed also fulfil the Δi ≤ 2 condition and there is not much difference between the AICc values of the other models (Table 2).

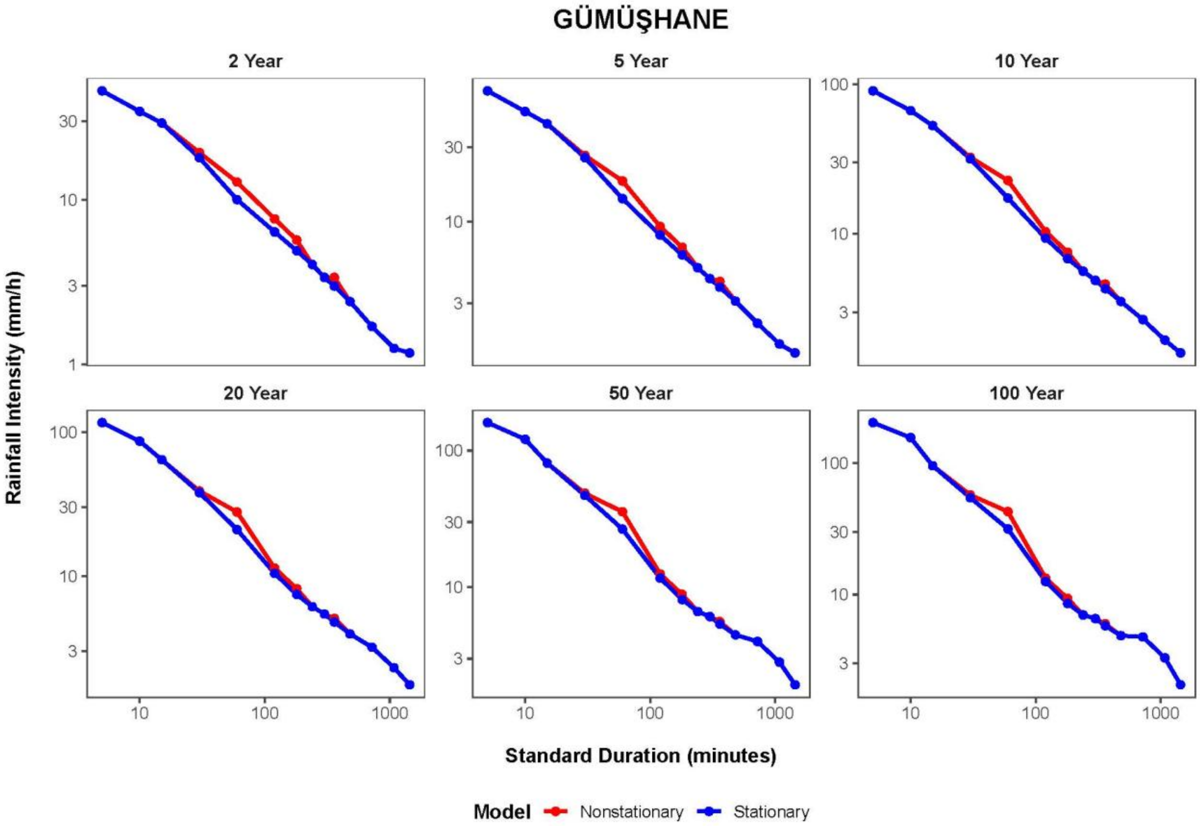

Fig. 7. Stationary and non-stationary IDF for different return periods for Gümüşhane station

At Bayburt station, non-stationary models predicted significantly higher rainfall intensities than stationary models for short-duration and low return periods (2-20 years) (Fig. 8). The difference was especially evident for periods below 60 minutes, indicating that short-term extreme precipitation tends to increase in the short duration. These changes are due to both location and parameters (Table 2).

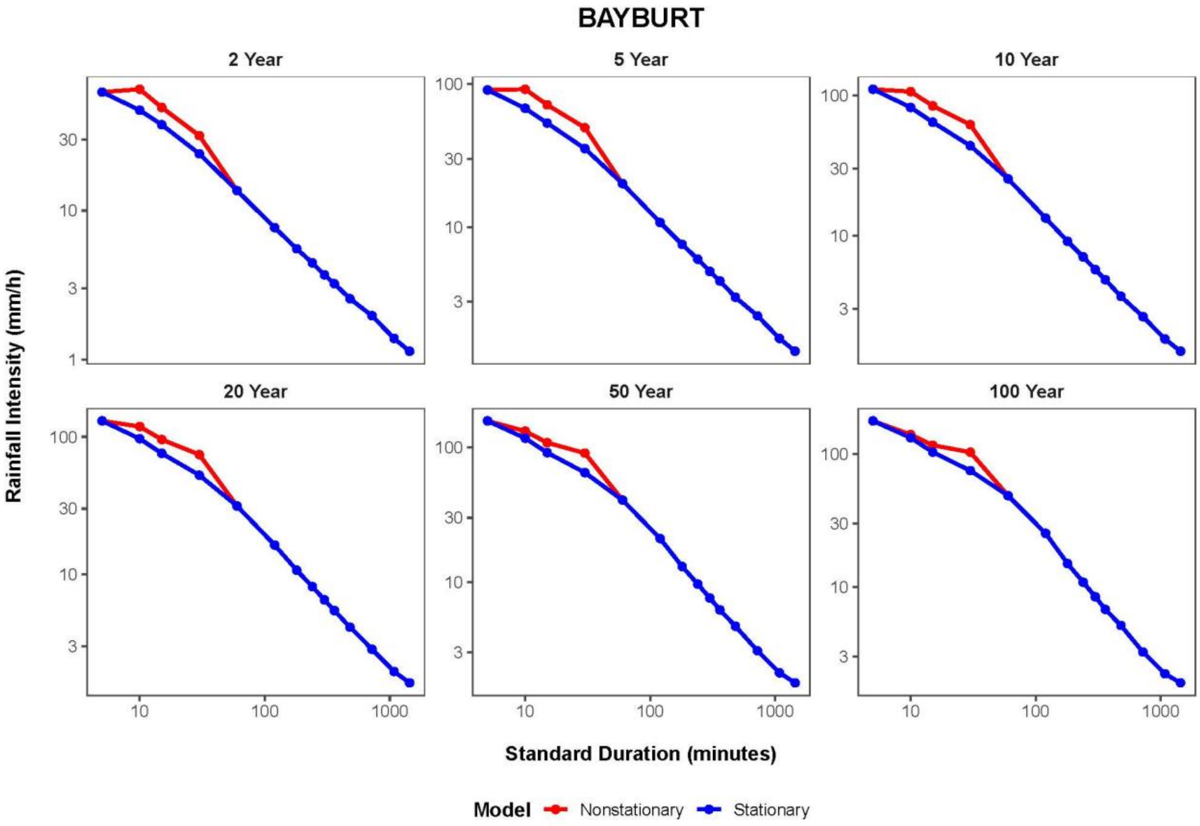

Fig. 8. Stationary and non-stationary IDF for different return periods for Bayburt station

Non-stationary models generally predicted higher rainfall intensities for short-duration and low-medium return periods. The non-stationarity effects were especially evident at the Bayburt, Gümüşhane, and Hopa stations. The stationarity assumption still seems valid at stations such as Akçaabat, Giresun, and Ordu. These results indicate that climate change-induced instability should be considered in infrastructure projects and urban planning in the Eastern Black Sea Region.

4. Conclusions

Stationary and non-stationary intensity-duration-frequency (IDF) curves of maximum standard duration rainfall at six stations were obtained using the Generalized Extreme Value (GEV) distribution in the Eastern Black Sea Region. Non-stationary conditions are characterized by short-duration rainfall in the region's interior and long-duration rainfall in the coastal areas. In the region, non-stationary issues emerge mostly due to location changes. According to the results, the stationary situation is still valid, but a non-stationary situation cannot be ignored. So, the non-stationary effects of climate change ought to be considered when planning and constructing infrastructure projects in the Eastern Black Sea Region.

Enhancing model performance: calibration of SWAT+ model for the İznik Lake Watershed

Anıl Çalışkan Tezel*[1], Adem Akpınar[1]

[1] *Bursa Uludağ University, Department of Civil Engineering, 16059 Bursa, Türkiye*

Abstract. Hydrological modeling is a crucial tool for understanding and managing the hydrological processes within a watershed. In this study, the Soil and Water Assessment Tool-Plus (SWAT+), an advanced version of the SWAT model, was employed to model the hydrological processes of the İznik Lake Watershed, a region of significant environmental and social importance in the Marmara Region of Türkiye. The sensitivity analysis, calibration, and the validation were conducted using the SWAT+ Toolbox to accurately simulate the hydrological processes within the watershed. SWAT+ Toolbox is designed to work with SWAT+ model, offering enhanced flexibility and efficiency for hydrological studies. Given the limited studies on the application of SWAT+ Toolbox, the present study aims to provide valuable insights into the calibration process and the parameters sensitive to streamflow. The model was calibrated for 2007-2016 and validated for 2017-2021, including two years of warm-up period. The model's performance was evaluated using Nash-Sutcliffe efficiency (NSE), Kling-Gupta efficiency (KGE), coefficient of determination (R^2), and the percent bias (PBIAS). The observed flow data from two streamflow gauging stations were compared with the simulated values. The results revealed that the SWAT+ model can represent the hydrology of the study region, with satisfactory to very good model performance. The calibrated model can be applied to assess the impacts of climate and land use/land cover changes for better management strategies, and will guide further studies in hydrological modelling.

Keywords: İznik Lake Watershed; SWAT+ model; Hydrological modeling; SWAT+ Toolbox

1. Introduction

Hydrological models are excellent tools for analyzing, forecasting, and effectively managing water resources (Aragaw et al., 2021). Without numerical models, predicting hydrological processes in large-scale watersheds is highly challenging due to the complexity of interactions among climate, land use, soil properties, and topography. However, the calibration and the validation of hydrological models need to be implemented carefully since poorly calibrated or unvalidated models can lead to significant uncertainties in model predictions. If the model does not accurately represent real-world hydrological processes, subsequent studies on water resource management, climate change impacts, and land-use planning within the study area may lack reliability. A well-calibrated model enhances predictive capabilities, allowing for more reliable hydrological assessments and future scenario analyses. Numerous studies affirm that well-calibrated models improve accuracy and reliability (Abbas et al., 2024; Mei et al., 2023; Wang et al., 2024).

In this study, the Soil and Water Assessment Tool-Plus (SWAT+) model, an advanced version of the widely used SWAT model, was employed to simulate the hydrological processes of the İznik Lake Watershed. This watershed, located in the Marmara Region of Türkiye, holds significant environmental and hydrological importance, as it serves as a critical water resource for the surrounding region. There are a large number of SWAT-related studies conducted to assess the model's stability and usefulness (Abbaspour et al., 2018).

SWAT+ Toolbox was selected as the calibration tool, which is a C#-based software designed to work with the SWAT+ model (Chawanda 2021). It enables sensitivity analysis, as well as both manual and automatic calibration and validation. By calibrating and validating the SWAT+ model, this study aims to improve the accuracy of streamflow simulations and provide insights into key parameters influencing hydrological processes. The primary goal of this study is to calibrate the SWAT+ model for the İznik Lake Watershed using the SWAT+ Toolbox, focusing on streamflow simulation. The findings of this study will contribute to a deeper understanding of the SWAT+ calibration process and support future hydrological modelling efforts in similar watersheds.

2. Material and methods

2.1. Description of the study site

The study site is the İznik Lake Watershed located in the Marmara Region of northwestern Türkiye (Fig. 1). İznik Lake is the largest lake in the Marmara Region and the fifth largest in Türkiye. The watershed covers an area of approximately 1,400 km^2, extending from latitude 40° 20′ to 40° 35′ N and longitude 29° 10′ to 29° 55′ E. The lake has an elliptical shape, with a surface area of 313 km^2, an average depth of 40 m, and a maximum depth of 80 m (Viehberg et al., 2012; Oğuz et al., 2020). It is a freshwater lake of tectonic origin. The region's climate is typically Mediterranean, characterized by a mean annual temperature of approximately 14°C and an average annual precipitation of around 630 mm (Franz et al., 2006). The lake's water level varies seasonally, rising during winter and spring (February to April), declining throughout the summer, and reaching its lowest level in autumn (September). The lake is located at 85 m above sea level, with the temperature of the bottom water dropping to 5°C in spring due to the inflow of cold snowmelt (Oğuz et al., 2020).

The İznik Lake Watershed plays a vital role in supporting various activities such as agriculture, industry, tourism, and fishing in the surrounding areas. The dominant land use types within the watershed are agricultural lands, forests, and urban areas. The watershed is primarily located within the borders of Bursa province, with parts extending into Kocaeli and Yalova provinces. To the west of the basin lie Erikli Mountain and Gemlik Bay, while the Samanlı and Karlık Mountains are situated to the north (Garipagaoglu and Uzun, 2019). In the northeast of the study area, the İznik Dam has been under construction since 2017. The lake is surrounded by picnic areas, sightseeing spots, and tourist facilities, and it is home to a rich diversity of flora. Additionally, the İznik Basilica, a monumental structure, is located 20 meters from the shore of İznik Lake. In recognition of its ecological and cultural significance, the İznik Lake Watershed was designated as a "Protected Area" in 1990. The main rivers feeding the lake include Sölöz, Olukdere, Kırandere, and Karasu, with Karsak Stream serving as the lake's outlet (Kaya, 2022). Among these, Karasu (also known as Karadere) in the northeast and the Sölöz in the southwest are the most significant. Karadere Stream is the largest stream flowing into the lake, with a drainage basin of 273 km^2 and an average flow rate of 2.4 m^3/s, while Sölöz Stream has a basin of 92 km^2 and an average flow rate of 1.06 m^3/s. The location of major rivers, meteorological stations, and gauging stations within the İznik Lake Watershed are illustrated in Fig. 2.

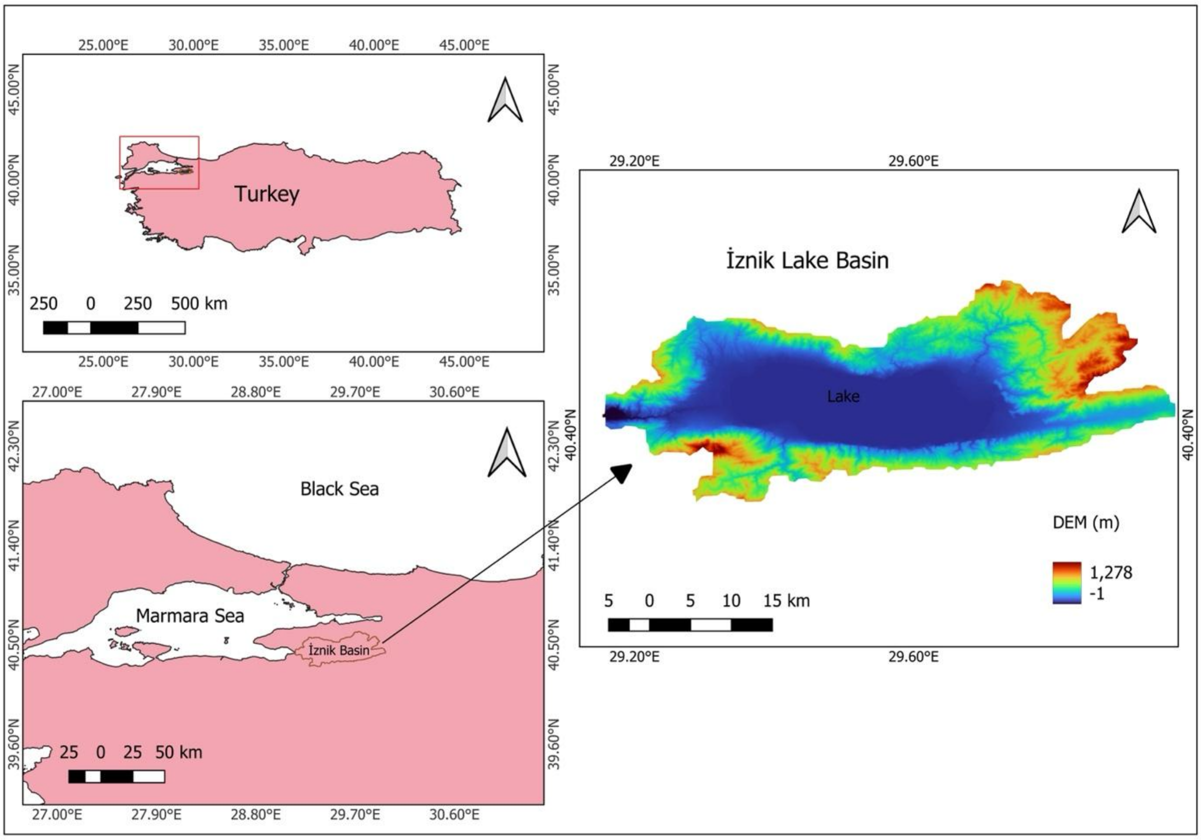

Fig. 1. Study area location and elevation map (Tezel et al., 2025)

Fig. 2. Map showing gauging stations, rivers, and meteorological stations (Tezel et al., 2024)

2.2. SWAT+ hydrological model

The SWAT+ model, version 61.0.1, was used in this study to simulate streamflow in the İznik Lake Watershed. Since the model operates within the QGIS interface, QGIS version 3.40.4 Bratislava (Long Term Release) was used in this study. The SWAT+ model is a widely used physically based hydrological model (Bieger et al., 2017) developed by Dr. Jeff Arnold for the USDA Agricultural Research Service (ARS). SWAT+ is an enhanced version of the original SWAT model, offering improved flexibility and modularity in simulating watershed processes. Being an open-source model, SWAT+ provides access to its source code, documentation, and updates through its official GitHub repository (https://github.com/swat-model/swatplus), ensuring continuous improvements and community contributions. The SWAT+ model is designed to simulate hydrological processes in watersheds on a daily time step under varying land use, soil types, and management practices. The key hydrological components, including surface runoff, lateral flow, groundwater flow, evapotranspiration, and streamflow are simulated. The SWAT+ model divides the watershed into sub-basins, which are further delineated into hydrological response units (HRUs) based on unique land use, soil type, and slope combinations. The simulations are based on the water balance equation, and the hydrological cycle for each HRU is simulated using the water balance equation (Basu et al. 2022):

$$SW_t = SW_0 + \sum_{i=1}^{t}\left(R_{day} - Q_{surf} - E_a - w_{seep} - Q_{gw}\right) \quad (1)$$

where SW_t is the final soil water content (mm H_2O), SW_0 is the initial soil water content on day i (mm H_2O), R_{day} is the amount of precipitation on day i (mm H_2O), Q_{surf} is the amount of surface runoff on day i (mm H_2O), E_a is the amount of evapotranspiration on day i (mm H_2O), w_{seep} is the amount of water entering the vadose zone from the soil profile on day i (mm H_2O), Q_{gw} is the amount of return flow on day i (mm H_2O), t is the time (days) (Neitsch et al. 2011).

2.3. Model input data

The SWAT+ model requires a diverse set of input data to represent the physical characteristics of the watershed. Model input data can be categorized into two main groups: spatial and temporal data. Spatial data include the digital elevation model (DEM), land use/land cover (LULC), and soil data, which are essential for defining HRUs. Runoff is predicted individually for each HRU and routed to obtain the total runoff for the watershed (Neitsch et al., 2011). The temporal input data include precipitation, maximum and minimum air temperature, relative humidity, solar radiation, and wind speed.

The DEM is a critical dataset for watershed delineation and river network definition, as it determines key topographical characteristics such as slope classes, channel length, channel width, and channel depth. For this study, the Shuttle Radar Topography Mission (SRTM) 1 Arc-Second Global dataset (~30 m resolution) was utilized to extract watershed characteristics and delineate the drainage network (https://earthexplorer.usgs.gov/). The DEM map of the İznik Lake Watershed is presented in Fig. 1.

Land use/land cover (LULC) data are essential for simulating hydrological processes within the watershed. In the present study, the Coordination of Information on the Environment (CORINE) land cover dataset was utilized, generated using Geographic Information Systems (GIS) and remote sensing techniques. This dataset has a spatial resolution of 100m x 100m. The Corine Land Cover (CLC) dataset has a minimum mapping unit of 25 hectares (ha) for areal features and a minimum width of 100 m for linear features. The data is available in both vector and 100 m raster formats. As illustrated in Fig. 3, the LULC map of the İznik Lake Watershed identifies 20 different land cover types. The dominant LULC classes in the watershed include agricultural areas, forests, bushlands, and grass.

Another essential dataset required for the SWAT+ model is soil data. The Major Soil Groups (BTG) Map of Türkiye, which was originally created at a scale of 1:100,000 by the General Directorate of Rural Services in the 1970s, was utilized in the study. These maps have been updated and modified over time. The BTG soil data was pre-processed in QGIS for use in the model. BTG soil types vary based on several factors, including slope-depth combination (EDK), degree of erosion (ERZ), land use type (SAK), land use capability (AKK, ATS), and other soil properties, such as salinity and alkalinity. The watershed contains various soil types, including Brown Forest Soil, Red-brown Mediterranean Soil, Rendzina, Alluvial, and Colluvial Soils (Table 1). A soil look-up table was developed to determine the soil parameters for BTG soil maps. Some parameters are optional, as indicated in Table 2. The necessary soil parameters were derived from field studies and soil sample analyses conducted in Bursa province (Özsoy, 2007; Aksoy et al., 2007; Özcan, 2021). Based on the BTG soil data, the required soil parameters were identified, and the soil map was reclassified into unique soil units. The spatial distribution of soil types within the İznik Lake Watershed is shown in Fig. 4.

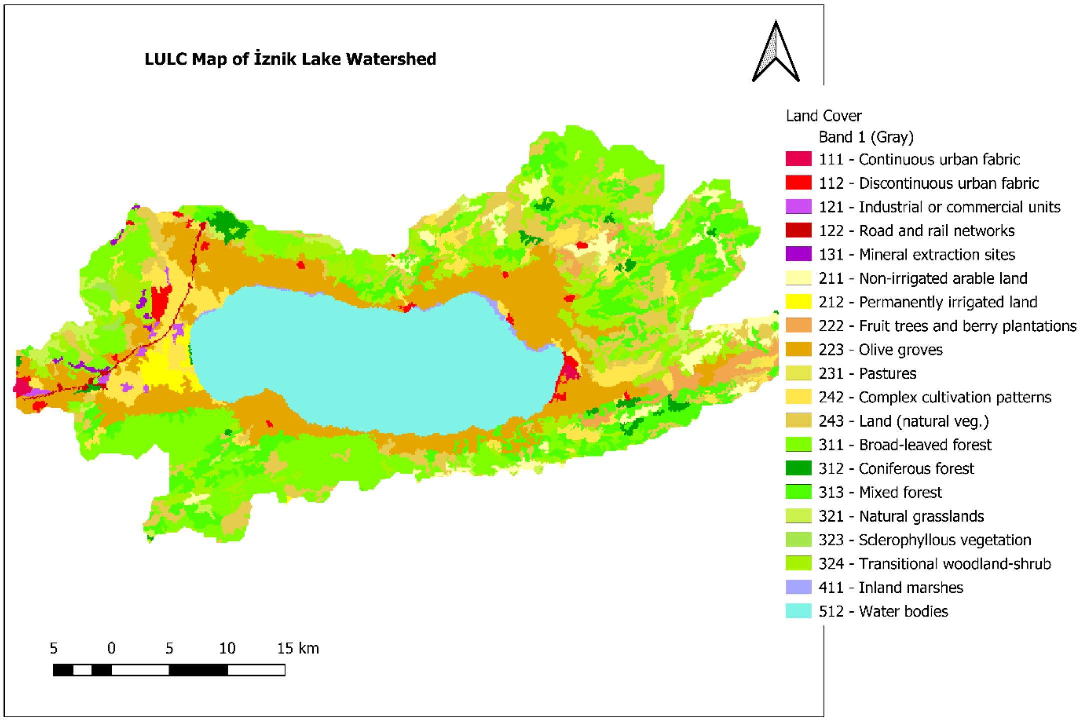

Fig. 3. LULC classification of the İznik Lake Watershed (Tezel et al., 2024)

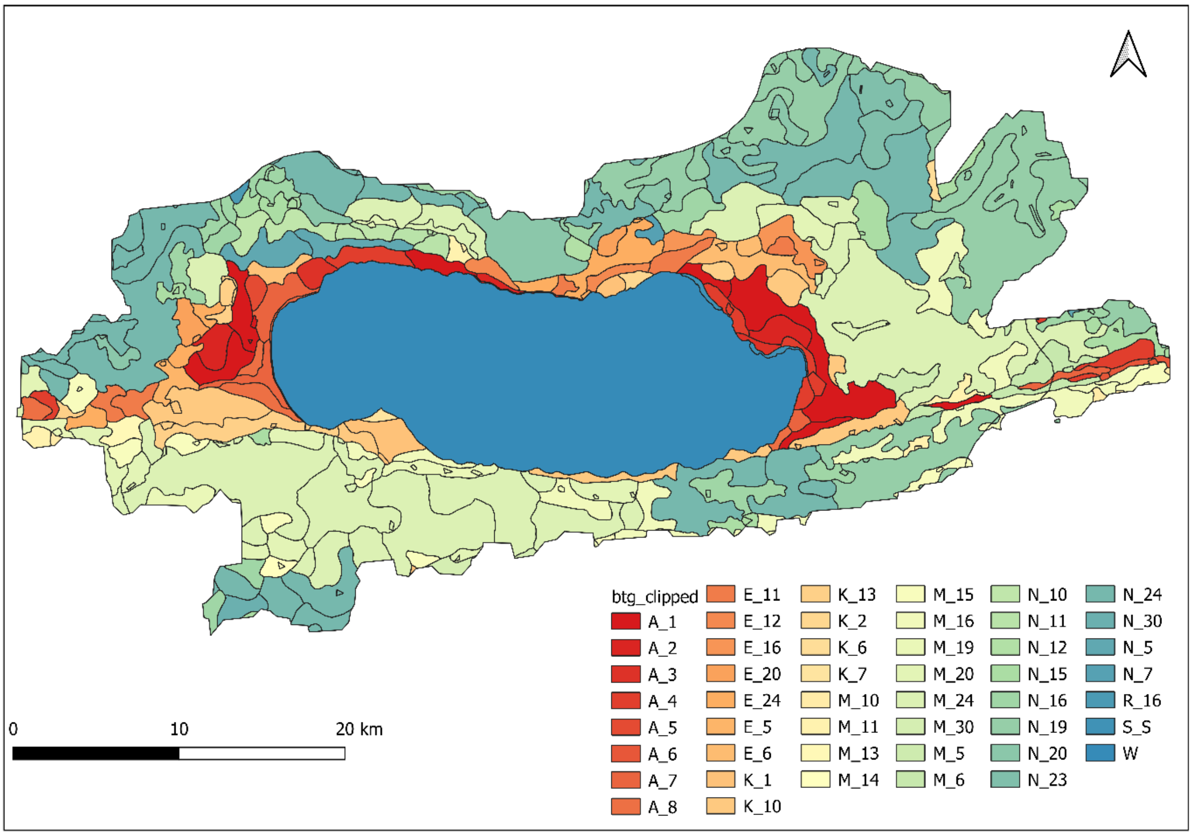

Fig. 4. Major Soil Groups (BTG) of İznik Lake Watershed (Tezel et al., 2024)

Table 1. BTG soil types of İznik Lake Watershed (Tezel et al., 2024)

Symbol	Soil Type
M	Brown Forest Soils
N	Brown Forest Soils with No Lime
E	Red-Brown Mediterranean Soils
R	Rendzinas
A	Alluvial Soils
S	Alluvial Coastal Soils
K	Colluvial Soils

Meteorological data is a crucial input for the SWAT+ model as it determines the water balance and hydrological parameters in the watershed. The required meteorological data include daily precipitation, maximum and minimum air temperature, wind speed, solar radiation, and relative humidity. Wind speed and solar radiation data were sourced from NASA's Prediction of Worldwide Energy Resources (https://power.larc.nasa.gov), while the other weather parameters were acquired from the General Directorate of Meteorology. There are three meteorological stations within the basin, referred to as İznik, Bursa Radar, and Orhangazi. Since the İznik meteorological station has the most comprehensive and continuous dataset, the data from it was used in the study (Fig. 2). Furthermore, SWAT+ includes a weather generator option, which is one key component for providing daily weather inputs when observed data is not available or to fill in gaps in the data.

The streamflow records obtained from the General Directorate of State Hydraulic Works (DSI) were used to calibrate and validate the performance of the SWAT+ model.

Table 2. Soil data input variables for SWAT+ model (Tezel et al., 2025)

Parameter Name	Definition
HYDGRP	Soil hydrologic group (A, B, C, or D). Required only for the SWAT ArcView interface)
ZMX	Maximum rooting depth of soil profile (mm)
ANION_EXCL	Fraction of porosity (void space) from which anions are excluded
CRK	The potential or maximum crack volume of the soil profile expressed as a fraction of the total soil volume
TEXTURE	Texture of soil layer
Z (layer #)	Depth from soil surface to bottom of layer (mm)
BD (layer #)	Moist bulk density (Mg/m^3 or g/cm^3)
AWC (layer #)	Available water capacity of the soil layer (mm H_2O/mm soil)
K (layer #)	Saturated hydraulic conductivity (mm/hr)
CBN (layer #)	Organic carbon content (% soil weight)
CLAY (layer #)	Clay content (% soil weight)
SILT (layer #)	Silt content (% soil weight)
SAND (layer #)	Sand content (% soil weight)
ROCK (layer #)	Rock fragment content (% total weight)
ALB (Top layer)	Moist soil albedo.
USLE_K (Top layer)	USLE equation soil erodibility (K) factor (units: 0.013 (metric ton m^2 hr)/(m^3-metric ton cm)).
EC (layer #)	Electrical conductivity (dS/m) (Not currently active).
CAL (layer #)	Soil CaCo3 (%) (0-50%)
PH (layer #)	Soil Ph (3-10)

2.4. SWAT+ model setup, calibration, and validation

The SWAT+ model setup involves several steps, including watershed delineation, the creation of HRUs, and editing inputs. First, watershed delineation was performed using DEM data, and 13 sub-basins were created within the watershed based on flow direction. The SWAT+ model setup requires the delineation of the watershed into sub-basins and the further division of these sub-basins into HRUs, which represent unique combinations of land use, soil, and slope. The SWAT+ model created 259 channels, 259 landscape units (LSUs), and 8969 HRUs for the watershed, which were utilized in the model simulations. After the watershed delineation and HRU definition, the model input files were generated based on the prepared spatial and temporal datasets.

Model calibration is particularly important to minimize the differences between the observed and simulated streamflow. The more reliable the calibration is, the more accurate the model predictions (Ozdemir & Akbas, 2023). In this study, the SWAT+ model was calibrated and validated using observed monthly streamflow data from two gauging stations, Karadere-Çakırca and Fındıcak-Bayırköy, operated by DSI. Model simulations were conducted for the period 2007-2021, which was divided into three phases: 2007 to 2009 warm-up period, 2010 to 2016 calibration period, and 2017 to 2021 validation period. SWAT+ Toolbox version 2.4 was utilized for sensitivity analysis, calibration, and validation of the model.

The sensitivity analysis was performed to identify the most sensitive parameters for streamflow simulation, which helps reduce the number of parameters requiring calibration. Previous studies have been reviewed to identify parameters which are sensitive to streamflow (Ren et al., 2022; Zeiger et al., 2021; Zhang et al., 2020). Using these approaches, 11 parameters were identified as the most sensitive for streamflow simulation. The model was subsequently calibrated using both manual and automatic procedures. The sensitivity ranking and corresponding fitted values are presented in Table 3, with the three most sensitive parameters identified as the percolation coefficient (perco), depth of the soil layer (z), and SCS curve number (Cn2), respectively.

Three commonly used statistical metrics: Nash-Sutcliffe Efficiency (NSE), Kling-Gupta Efficiency (KGE), and Percent Bias (PBIAS) were selected (Moriasi et al. 2007; Thiemig et al. 2013; Kouchi et al. 2017). NSE was selected due to its capability to quantify the overall agreement between observed and simulated data (Nash & Sutcliffe, 1970). KGE was included as it decomposes the model performance into correlation, bias, and variability (Gupta et al. 2009). Lastly, PBIAS was employed to assess the model's tendency to overestimate or underestimate streamflow predictions (Moriasi et al. 2007). These three metrics were calculated and compared for both the calibration and validation periods to assess the model's ability to accurately simulate streamflow under different conditions.

$$\mathrm{NS}E = 1 - \frac{\sum_{t=1}^{T}\left(Q_m^t - Q_o^t\right)^2}{\sum_{t=1}^{T}\left(Q_o^t - \overline{Q_o}\right)^2} \tag{2}$$

$$PBIAS = \left[\frac{\sum_{t=1}^{T}(Q_o^t - Q_m^t)x100}{\sum_{t=1}^{T}(Q_o^t)}\right] \tag{3}$$

$$KGE = 1 - \sqrt{(r-1)^2 - \left(\frac{\sigma m}{\sigma o} - 1\right)^2 - \left(\frac{\mu m}{\mu o} - 1\right)^2} \tag{4}$$

Where Q_o^t and Q_m^t are the observed and the modeled flow, and $\overline{Q_o}$ is the mean value of observed and modeled flow respectively, for a specific time (t), r is the Pearson correlation coefficient between the observed and modeled, σ is the standard deviation, and μ is the mean. Table 4 presents the model performance ratings for evaluation metrics.

Table 3. Calibrated SWAT+ parameters

Parameter	Definition	Sensitivity Rank	Change Method	Fitted Value
perco	Percolation coefficient	1	Replace	0.02
bd	Bulk density (mg/m^3)	8	Percent	-5
cn3_swf	Pothole evaporation coefficient	6	Replace	1
cn2	The SCS Curve number is a function of the soil's permeability	3	Percent	-15
clay	Clay content (%soil weight). The percentage of soil particles that are <0.002 mm in equivalent diameter	4	Percent	-40
z	Depth from soil surface to bottom of layer (mm)	2	Percent	140
esco	Soil evaporation compensation factor	5	Replace	-0.1
k	Saturated hydraulic conductivity (mm/hr)	9	Relative	350
canmx	Maximum canopy storage (mm H2o)	10	Replace	100
chk	Effective hydraulic conductivity in main channel alluvium (mm/hr)	11	Relative	-50
lat_len	Slope length for lateral subsurface flow (m)	7	Percent	-38

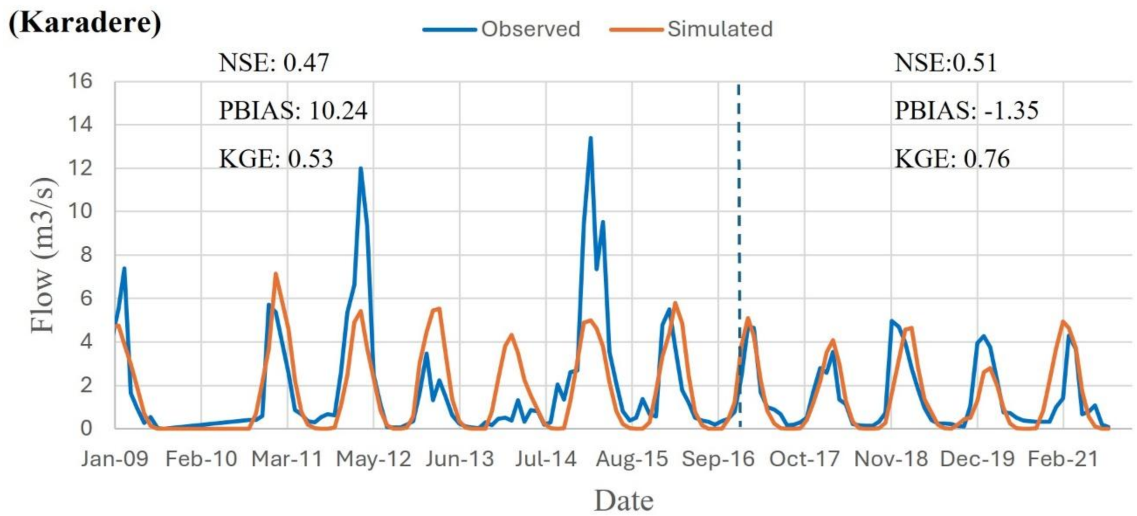
Table 4 Model performance ratings (Moriasi et al.2007; Thiemig et al.2013; Kouchi et al.2017)

Performance Rating	NSE	PBIAS (%)	KGE
Very good	0.75<NS≤1.00	PBIAS<±10	0,9 ≤ KGE ≤ 1
Good	0.65<NS≤0.75	±10≤PBIAS<±15	0,75 ≤ KGE < 0.9
Satisfactory	0.50<NS≤0.65	±15≤PBIAS<±25	0,5 ≤ KGE < 0.75
Unsatisfactory	NS≤0.50	PBIAS≥±25	KGE <0.5

3. Results and discussion

The comparison of observed and simulated flow during the calibration and validation periods for each gauging station is shown in Fig. 5, along with the corresponding error statistics. According to the statistical metrics, PBIAS values are classified as "very good" in all cases except for the validation period at the Fındıcak station. KGE values range from 0.53 to 0.76, indicating performance levels between "satisfactory" and "good" for both calibration and validation periods. For the Karadere station, NSE values were 0.47 and 0.51 during calibration and validation, respectively, indicating "satisfactory" model performance, while these values were lower at 0.44 and 0.40 for the Fındıcak station. Overall, the model demonstrated performance ranging from 'satisfactory' to 'very good' based on PBIAS and KGE values. However, NSE values at the Fındıcak station were slightly below the recommended threshold of 0.50. The İznik meteorological station is located near the Karadere gauging station but at a considerable distance from the Fındıcak station. This spatial discrepancy may have introduced higher uncertainty in precipitation input data, contributing to the lower model performance at the Fındıcak station.

The largest discrepancies between the modeled and the observed values were mostly during peak flow periods, particularly in March-April 2012 and February-April 2015 at the Karadere station, as well as in January 2010, and January-February 2015 at the Fındıcak gauging station. The model also overestimated the low observed flows from December 2013 to February 2014 for both stations. The observed flow and the precipitation data are consistent with each other during the peak flow periods in Karadere and Fındıcak stations. Additionally, the streamflow was measured to be low in the early months of 2014, when low precipitation was observed during the same periods supporting the consistency between the observed flow and precipitation data. Her and Jeong (2018) highlighted potential prediction issues in the SWAT+ model, showing multiple peaks in sub-daily hydrographs due to its newly implemented HRU-level flow routing scheme. A study conducted in the Uruguay River Basin using the SWAT+ model reported a systematic underestimation of peak discharges, despite adequate flow fluctuation representation (Barresi Armoa et al., 2023). On the other hand, the model simulated the low flows well during the simulation for both stations, except for the overestimation in early 2014. The observed flows were smaller than 1 m^3/s, while the simulated values were between 2 and 4 m^3/s during this winter period of 2014. The high flow estimates during low-flow periods may be attributed to the inaccurate modeling of the snowmelt processes. Errors in temperature or solar radiation data can lead to such discrepancies (Debele et al. 2010, Myers et al. 2021). In another study by Kardhana et al. (2024), the limitations of the SWAT+ model in watershed management and water resource optimization, particularly under low-flow conditions, were discussed. In general, the SWAT+ model was able to capture the seasonal dynamics of the hydrology in the watershed reasonably well, reproducing the annual cycle of streamflow and the timing of high and low flows periods.



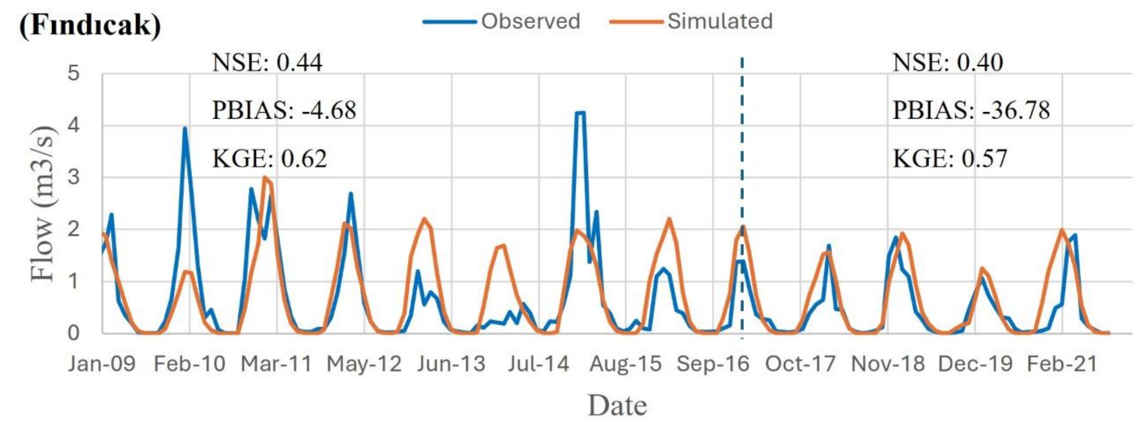


Fig. 5. Comparison of the observed and the modeled monthly streamflow for the Karadere-Çakırca, and Fındıcak- Bayırköy gauging stations (the dotted vertical line shows the boundary between the calibration and the validation periods) (Tezel et al., 2025).

4. Conclusions

The SWAT+ model was used to simulate streamflow in the İznik Lake Watershed, an important water resource for the surrounding area. The newly released SWAT+ Toolbox, a free calibration tool specifically designed for the SWAT+ model, was utilized for sensitivity analysis, calibration, and validation. Compared to other calibration tools, SWAT+ Toolbox has been frequently applied in the literature, making this study valuable for SWAT+ model users.

The model was calibrated and validated using observed monthly streamflow data from two gauging stations, achieving satisfactory to very good performance based on multiple statistical metrics, including NSE, KGE, and

PBIAS. However, some discrepancies were observed during peak flow periods and low-flow conditions, especially at the Fındıcak station, which may be attributed to uncertainties in meteorological data and the complex hydrological process in the watershed.

The calibration parameters and methodological approach used in this study can guide researchers and practitioners effectively utilizing the SWAT+ model for similar watersheds. Additionally, as one of the relatively few studies employing the SWAT+ Toolbox, this research provides valuable insights for model users. This study will also serve as a baseline for future research on climate change impacts on water resources, land management practices, and water quality modeling in the region.

Acknowledgements

We would like to thank the General Directorate of Meteorology (MGM) and the General Directorate of State Hydraulic Works (DSI) for providing the data that significantly contributed to this study. We also extend our gratitude to Prof. Dr. Ertuğrul Aksoy and Dr. Gökhan Özsoy for their valuable contributions to the preparation of the soil data.

Examination of existing buildings for rainwater harvesting system and feasibility of the system

Murat Ay*[1]

[1]*Yozgat Bozok University, Department of Civil Engineering, 66000 Yozgat, Türkiye*

Abstract. This present study consists of the importance, cost, benefit, environmental effects of rainwater harvesting system (RHS), which is a hydrological variable, and RHS's ability to be used as an alternative to existing water resources, and its storage function against to drought. In this context, RHSs are analyzed based on the regulations (DIN1989 (Germany), Turkey (Official Gazette in Turkey, 2017; Official Gazette in Turkey, 2021), BS8515 (England)). The results regarding the applicability and efficiency of RHSs in two existing traditional/typical reinforced concrete frame buildings in Yozgat province in Turkey are discussed. The results showed that RHSs are not economically advantage for these buildings in today conditions for short term. Therefore, some additive reforms can change this issue the terms of the associated financial cost as well as the efficiency of the technology behind rainwater collection. It has been seen that the storage costs constitute approximately 50%-80% of cost of the total system. In this direction, different storage forms and materials can be considered and state-supported payments or incentives can be made to the RHS projects. Considering the reasons such as the high initial investment and labor costs, the long amortization period of the system (9-25 years) and the laborious, costly and risky construction of the RHS in such buildings whose construction is completed, it can be said that the possibility of the RHS being implemented in our country is low. However, it can be said that such reasons are weaker reasons than risks such as drought danger and quality water shortage that threaten living beings. This study may also be a good preliminary starting point for a cost-benefit analysis because it states some associated pros and cons for financial issues, environmental issues, and practicality issues of installing RHSs.

Keywords: Benefit; Cost; Feasibility; Rainwater harvesting system (RHS); Yozgat

1. Introduction

Water is very important for all living things on our planet; however, most people generally prefers to act when a disaster happens to them. The scarcity, untimeliness and irregularity of water in future periods highlight the need for rainwater harvesting to be used in many sectors and for different purposes. Rainwater discharges to groundwater, and feeds the soil in especially during drought times. Moreover, when energy costs and facilities are considered, the RHS has many positive effects on water, carbon and ecological footprints (Ball, 1999; Şen, 2002; Ay, 2013; Haque et al., 2016; Çakar, 2022; SYGM, 2023; Dağ and Ay, 2024). Rainwater, which is a clean and easily accessible asset, has always maintained its effectiveness and priority due to the concern of water shortage or shift. Urbanization, increasing in population, globalization and extreme events cause natural water resources to be consumed carelessly and recklessly (Sazakli et al., 2007; Jha et al., 2014; Almazroui et al., 2017; Kılınç et al., 2023). These conditions have led societies to seek different ways to meet their water needs with natural and quality water resources (Uba and Aghogho, 2000; Zavala et al., 2018; Ay, 2021, 2022; Almeida et al., 2023; Kılıç et al., 2023).

Using rainwater for drinking, industry and agriculture sectors is a rational and economical solution. Moreover, RHSs can be also used in areas such as vehicle washing, irrigation, flushing water, floor cleaning, indoor heating, and groundwater. Especially the change in rainfall regimes and the serious decrease in rainfall in some regions bring the use of rainwater to the forefront. In our country, rainwater is used in agriculture, workplaces and buildings in many provinces and it is becoming increasingly widespread. Recently, in some countries (such as Germany (2000), England, Australia, America (1992)), tax reductions and financial aids have provided for people who install rainwater systems. RHSs are also evaluated within the scope of green building certificate and buildings with this system are given additional points within the scope of the green building concept. In Turkey, there are buildings having green building certificate in İstanbul and Ankara. The Water Efficiency Regulation, published in the Official Gazette on December 27, 2024, can be an important turning point for the sustainable management and

*Corresponding author, E-mail: murat.ay@bozok.edu.tr

https://doi.org/10.31462/icearc2025_ce_hwr_139

golden light publishing

efficient use of water resources in Turkey. The regulations compliance with the ISO 46001: Water Efficiency Management Systems Standard a legal requirement in related sectors. The regulations used for rainwater harvesting systems are DIN1989 (Germany), Turkey (T.C. Official Gazette 2017; T.C. Official Gazette, 2021), BS8515 (England). In addition, there are national and international companies that install, assemble and operate rainwater harvesting systems well. Thus, there is enough experience to build a RHS any region of the world.

Many national and international researchers indicate that rainwater harvesting is among the important and necessary works (Musayev et al., 2018; Mattos et al., 2019). For example, Zavala et al. (2018) tested the reliability of rainwater harvesting systems to meet 100% of the water demand of a transportation logistics company in Mexico City. Haque et al. (2016), Almazroui et al. (2017) and Zhang et al. (2019) analyzed the effects of climate change on rainwater harvesting in Australia, Saudi Arabia, and China, respectively. Khanal et al. (2020), Üstün et al. (2020), Raimondi et al. (2023), Lepcha et al. (2024) and Gupta et al. (2025) conducted a comprehensive review of rainwater harvesting and treatment systems. Kılıç et al. (2023) examined the installation of a rainwater harvesting system for the Faculty of Theology at Bursa Uludağ University campus in Turkey. In another study (Kılıç and Abuş 2018), they made calculations for rainwater harvesting of a house with a garden. Kilinc et al. (2023) analysed payback periods RWHS and GWR in Antalya, Turkey. Sultana (2022) researched the optimum tank size for RWHS university campus in USA. She concluded that payback period of the RWHS was 52-75 years for 100% tank capture efiicincy and zero spills. Kahn et al. (2022) stated that structures having a green roof connected to a small rainwater storage tank is recommended. Kapitan et al. (2024) conducted economic effectiveness and cost-efficiency of four selected sustainable rainwater harvesting designs for shopping mall under climatic and financial conditions of Lublin, Poland. Dağ and Ay (2024) prepared the RHS cost table of a shopping mall located in Çorum province of Turkey and stated that the amortization period is 92-year. On the other hand, it can be seen that geographic information systems (GIS) (Singh et al., 2017; Baby et al. 2019; Preeti and Rahman, 2021; Suhara and Haghi, 2025) are also used in the calculation of rainwater potential.

In this study, Engineering-Architectural Faculty (EAF) of Yozgat Bozok University (YOBU) and a typical reinforced building roof plans located in Yozgat were used as a sample case. Current material, labor costs, water prices and rainwater potential caluculation according to different storages, rainfall scenarios and usage of rainwater were done for both buildings in the following titles of the study.

2. Material and method

Yozgat province has a continental climate and receives snowfall in the winter months (T.C. Ministry of Agriculture and Forestry, (MGM) 2025). Rainfall amounts (mm) can be seen from the Table 1. Two reinforced concrete buildings located in Yozgat were examined (see Fig. 1 and Fig. 2). The potential of rainwater that can be obtained from their roofs was calculated in Table 1. Then, the quantities and rainfall scenarios of RHSs of both buildings were considered and their costs were calculated in Table 2 and Table 3. The roof area of the Engineering-Architecture Faculty is calculated as 15365 m^2. The roof area of another building is calculated as 785 m^2.

In the calculations, the measurements of the roof areas of the buildings were made based on the projects of the buildings. The "rainwater yield (RWY)" equation (Equation 1) was used to calculate the amount of rainwater that can accumulate on the roofs of the buildings (DIN 1989).

$$RWY = A \times P \times R_k \times F_k \quad (m^3) \tag{1}$$

In Equation 1, rain collection area, A (m^2): Indicates the roof area of the building. P (mm) represents the monthly rainfall. Roof efficiency coefficient (R_k): It is the coefficient specified as 0,6 - 0,9 by German standards in DIN1989 (page 26). Filter efficiency coefficient (F_k): It is the coefficient (0.9) specified by German standards in DIN1989 (page 26). It is the efficiency coefficient of the first filter through which rainwater obtained from the roof is passed to separate visible solid matter. According to the precipitation data obtained from the General Directorate of Meteorology (MGM, 2025) (measurement period: 1929-2023), it was seen that the annual total precipitation amount for Yozgat province was 571,4 mm (Table 1). In addition, monthly total rainwater yields for both buildings are given separately in Table 1. The total rainwater yields in all months are 7.111,44 and 322,96 m^3. It can be said that keeping these water volumes in a tank, using for irrigation, cleaning and making them usable as grey water may be an important option. However, it can be said that controlling these collected waters with smart automation systems is more prominent thing in addition to determining the tank volume well. This issue is also a difficult process for these buildings in terms of construction. Another aspect for this, rainwater can be divided into some sectors such as grey water, washing machine according to control devices. For example, excess rainwater can be discharged to underground with a T-connection and can be stored here. In this way, this process can also contribute to the feeding of groundwater. In this point, it can be said that sustainability of water resources by using RHSs having some criteria, which are technical, economical, environmental, and social, should be considered all together.

3. Application

RHSs generally include six components: catchment area, roof-wash system, rainwater conveyance system, cistern, delivery system, and water treatment system. In this context, the performance of rainwater harvesting and storage systems depends on the roof area, roof covering material, amount of rainfall coming to the roof, amount of ambient evaporation, wind direction and intensity, pipe fittings, tank shapes and volumes, maintenance and operation of the treatment/filter system (DIN 1989; BS 8515 2008; T.C. Official Gazette 2017; T.C. Official Gazette 2021). The roof areas of the examined buildings were calculated based on their projects. The annual calculated potential rainwater amounts from the roofs of both buildings were calculated in Table 2 according to four different scenarios using Table 1. Because the storage volumes that could occur according to the calculated RWYs are high, it is thought that it would be more rational and logical to choose the most suitable storage volume and therefore to prefer scenario 4 (December) when storage costs are considered as one of the largest costs in the system. This situation is generally taken into consideration in studies and applications. At this point, the rainwater yields calculated by taking the maximum monthly rainfall total in December (75.3 mm) can be used for the tank volumes (937.16 m^3 and 42.56 m^3) according to the scenario 4. The calculations of tank volumes and below and above these values can be compared with the other volume values in Table 2. In addition, where and how the tanks will be placed is also another important issue. It is preferred that the tanks are hidden underground and protected from external environmental conditions (temperature, risk of freezing, material life and vandalism). The tank volumes were selected according to the maximum total rainfall height for December, and as there will be rainfall below this volume in other months, it was generally thought that the tank volumes would be sufficient (Fig. 3). In case the water in the tank runs out, the water will have to be taken from the water pipeline in the city.

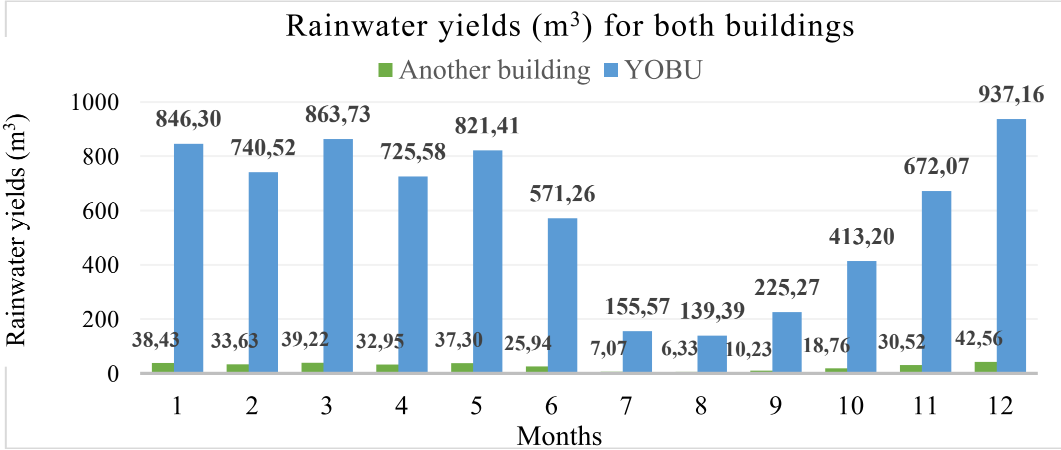

Fig. 3. Rainwater yields (m^3) for both buildings (DIN1989) from Table 1

According to the 2025 unit prices in Table 3, it has been determined that 900-tons (900 m^3 in total) storage tanks will be sufficient for the Engineering-Architecture Faculty (EAF). If the project, labor, transportation, personnel and unforeseen costs are added to the cost amount calculated with the use of the equipment in Table 3, the total cost of the system to be established can be determined as approximately 10.500.000,0 TL. These calculated costs are valid for 2025, and it can be said that these costs will increase in the following years according to the inflation rates. When the m^2 cost of this type of rainwater harvesting system is calculated, it is seen as 10.500.000,0 TL / 15.365 m^2 = 683,37 TL/m^2. For the other building, it can be determined that 50-tons (50 m^3 in total) storage tank will be sufficient. If the project, labor, transportation, personnel and unforeseen costs are added to the cost calculated by using the equipment in Table 3, the total cost of the system to be installed is determined as approximately 1.100.000,0 TL. When cost of the m^2 of such a rainwater harvesting system is calculated, it is seen as 1.100.000,0 TL/ 785 m^2 = 1401,27 TL/m^2.

When the annual water amounts consumed in these buildings were examined for the year 2024, the annual water amounts were determined as approximately 12000 m^3 and 4800 m^3, respectively. The m^3 prices of water from the related places are determined as approximately 35 TL in Yozgat campus and 24 TL in the city center. When these prices are multiplied by the annual water amounts consumed above, they are calculated as 420.000 TL(35x12000) and 115.200 TL(24x4800), respectively. When these prices are compared with the costs of the system, it can be calculated that the system will amortize itself in 10.500.000 TL/420.000 TL= 25 years and 1.100.000 TL/115.200 TL= 9,54 years, respectively. In case of decreases in rainfall, these amortization periods will also be extended more.

4. Conclusions

Rainwater harvesting from roofs of many buildings is very important and meaningful case in terms of water control and saving in these days. It is seen that manufacturing and installing of the RHSs, especially during the construction phases of buildings, is much more economical and rational (Sultana, 2022; Raimondi et al., 2023; Dağ and Ay, 2024; Kapitan and Widomski, 2024) than the applying to existing buildings. These items, which are also mentioned in sustainable development goals of the United Nations in Europe, are of course vitally important as it has been known for years. In feasibility reports and project planning of any a building, it is now necessary to support the rainwater harvesting system, which should be in every building, and to implement it very carefully in the construction phase. The regulations (DIN 1989; BS 8515 2008; SYGM, 2022; SYGM, 2023; United Nations Sustainable Development Goals, 2023; ISO 46001, 2024) also completely supports this idea.

A senior, an experienced team and quality materials are required for installing the RHS. In this case, it can be said that applying rainwater harvesting systems to existing buildings in many countries is a difficult and expensive process. In our country, it can be said that the possibility of implementing rainwater harvesting systems especially for small roof areas (500-800 m^2) is low. In the following years, if there may be an increase in demand for rainwater harvesting systems according to climate scenarios of decreasing rainfall, the supply-demand balance for the markets should also be controlled. In addition to these results, the following results can also be stated.

- The calculated annual total rainwater yields from the roofs of both buildings are 7.111,44 m^3 and 322,96 m^3, respectively. It is seen that these water amounts are not enough for the annual water needs of both buildings (12.000 m^3 and 4.800 m^3).
- It can be said that the yields of the water amounts that come from the rainwater harvesting system will annually provide an additional water saving to the buildings approximately 7.111,14/12.000= 59,2% (YOBU) and 322,96/4.800= 6,7% (another building), respectively.

- Architectural and static aspects of the building have to be designed as a green building concept in these current days anymore. Moreover, this green concept should be considered together in designing RHSs and renewable energy types such as sun and wind.

Rainfall intensity-duration-frequency analysis in the Eastern Black Sea Basin

Ömer Yüksek*[1], Osman Yüksek[2]

[1]Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye
[2]Bursa Uludağ University, Department of Civil Engineering, Görükle Campus, 16059 Nilüfer, Bursa, Türkiye

Abstract. Rainfall intensity-duration-frequency (IDF) relationship is one of the most commonly used tools in water resources engineering, either for planning, designing and operating of water resource projects, or the protection of various engineering projects against floods. Civil infrastructure such as storm sewers, storm water management ponds, culverts and bridges are commonly designed using IDF curves. In this study, IDF curves for Eastern Black Sea Basin (EBSB), the rainiest basin in Türkiye, were developed. The maximum rainfall intensity values for 14 rainfall durations (D=5, 10, 15, and 30 minutes, and 1, 2, 3, 4, 5, 6, 8, 12, 18 and 24 hours) were used. The data of 2 Meteorological Stations (Trabzon and Rize) of Turkish State Meteorological Service (MGM, in Turkish), of which observation durations were 60 and 80 years and located in EBSB, were employed. Since various studies have favored the use of Log Pearson Type 3 (LP3) Distribution for annual maximum precipitation data in Türkiye; this distribution was used for the analysis. The rainfall intensity values for each station and for 7 return periods (T = 2, 5, 10, 25, 50, 100 and 500 years) was calculated by LP3 Distribution. Multi-nonlinear regression analysis was carried out by using nine kinds of IDF formulas, which were taken by using various IDF formulae in the literature and newly generated formulae. In order to test the reliability of the functions, two criteria were used: The determination coefficient and the mean relative error. It has been concluded that the reliability of the results is high enough and that this study will motivate and open new horizons to detailed studies on IDF analysis.

Keywords: Rainfall intensity-duration-frequency analysis; Eastern Black Sea Basin; Nonlinear regression analysis

1. Introduction

The most important meteorological factors in the formation of disasters of atmospheric origin are precipitation and features of precipitation. The intensity, duration and frequency of precipitation are the main characteristics. Heavy rainfall can cause sudden floods by increasing peak discharges. Intense rainfalls not only cause flooding; additionally, the water droplets with increased kinetic energy intensify the soil erosion that progresses at normal speed, destroy the natural vegetation and agricultural fields and shorten the dam life as it leads to siltation. The interpreted hydro climatological data produced by statistical studies are a source of light for the decision-makers in the planning and operation of water resources.

Rainfall is of particular importance in hydrology. Specifically, it is necessary to determine the rainfall intensity for various probabilities or return periods in many hydrological models, in addition to water quality and quantity calculations. For example, engineers must calculate the frequency of rainfall intensity to design hydraulic structures (bridges, dams, etc.). To realize this aim, IDF functions and curves are frequently used for the hydrologic design of small and medium sized catchments. The IDF curves provide estimates of the rainfall intensity for any given duration, corresponding to different probabilities of exceedance values.

The rainfall IDF relationship is one of the most commonly used tools in water resources engineering, either for planning, designing and operating of water resource projects, or the protection of various engineering projects against floods (Chow et al., 1988; Şengül and Can, 2011; Can et al. 2012). Civil infrastructure such as storm sewers, storm water management ponds, culverts aend bridges are commonly designed using IDF curves, which assume that the occurrence of precipitation is in the form of rainfall and immediately available for the rainfall-runoff process (Tekkant, 2015). The appropriately sized capacities of these civil infrastructure are so important to avoid overdesign which could lead to economic losses and/or increased property damage and possibly increased risk of loss of life. Thus, obtaining reliable estimates of IDF curves is essential (Anılan, 2014).

* Corresponding author, E-mail: yuksek@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_hwr_201

The IDF relationship is a mathematical relationship between the rainfall intensity I, the duration D, and the exceedance frequency F (F=1/T, T is return period). This relation is usually obtained as curves, and each curve shows the change of intensity of rainfall with respect to a frequency (or return period). These curves are generally obtained by empirical and statistical approaches (Karahan et al., 2007).

IDF functions are used for quantifying the magnitude of rainfall events that are used in the design of a variety of civil infrastructure, especially in an urban environment. These relationships of extreme rainfall intensities are one of the most used tools in water resources engineering for planning, design, and operation of water resources projects (De Vyver, 2015). IDF curves for a location are generally obtained by fitting a theoretical probability distribution, such as Gumbel (GM), Generalized Extreme Value (GEV), Log Pearson Type III (LPT3), Log Normal (LN), to the extreme rainfall data.

The typical procedure involves the following: steps (i) fitting a probability distribution to the annual maximum rainfall intensity values for several rainfall durations, (ii) estimating extreme rainfall quantiles for each rainfall duration for a number of return periods, and (iii) fitting a relationship between rainfall intensity and rainfall duration, for each frequency, based on the rainfall intensity quantiles estimated for each rainfall duration. The resulting relationships between rainfall intensity and rainfall duration constitute the IDF curves for the given location (Anılan, 2014).

The establishment of IDF relationships goes back to the 1930s (Bernard, 1932). Since then, different forms of relationships have been constructed for several regions of the world up to today. A general IDF relationship formula, consistent with the theoretical probabilistic foundation of the rainfall data, was provided by Koutsoyiannis et al., 1998. Okonkwo and Mbajiorgu (2010), analyzed rainfall data and characteristics for locations in seven states of Southeastern Nigeria and developed IDF curves for these locations using graphical and statistical methods. There are also several studies about IDF in Turkey. Karahan et al,(2008), applied a solution algorithm that solves IDF relationship by using Genetic Algorithm (GA) optimization technique to four city centers in the Southeastern Anatolia Project (GAP) region. Their results showed that the developed solution algorithm that is alternatively proposed to determine IDF relationship gives accurate results for the cities located in the GAP region. Ghiaei et al. (2018) analyzed rainfall intensity-duration-return period data in the Eastern Black Sea Region by using L-moments and artificial neural networks (ANN). Based on the distribution functions, they extracted the governing equations for calculation of intensities of 2, 5, 25, 50, 100, 250, and 500 years return periods (T). Then, T values for different rainfall intensities were estimated using data quantifying maximum amount of rainfall at different times. Yavuz (2018) calculated the parameters of five different potential analytical equations for IDF relationship of annual extreme rainfalls at each one of the seven geographical regions of Türkiye. In the study, a single IDF equation was obtained using all the 22 stations, and by the same criteria, the most appropriate expression valid for all of Türkiye has been determined.

Eastern Black Sea Basin (EBSB) is frequently exposed to floods due to its topographic structure. In case of floods, many casualties, injuries and property damages occur as the settlements are generally located in floodplains. The dimensions of these floods incurred in the basin, both in terms of economics and of loss of life, are greater than those in other basins in Turkey due to the physical and climatic conditions (Anılan, 2014). The effective factors that make the EBSB a natural disaster area are, the geological structure and characteristics of the basin as well as the increasing slope values of morphology with increasing slope values with the sharp elevation of the mountains from the shore, the erosion of the streams with strong flow on this slope and the high precipitation values (Nemli, 2017). In Turkey, IDF analyses have been developed only for local sites and analysis with the current data encompassing the whole country is needed (Yüksek, et al., 2022).

In this study, IDF curves for Eastern Black Sea Basin (EBSB), the rainiest basin in Türkiye, were developed. The maximum rainfall intensity values for 14 rainfall durations (D=5, 10, 15, and 30 minutes, and 1, 2, 3, 4, 5, 6, 8, 12, 18 and 24 hours) were used. The data of 2 Meteorological Stations (Trabzon and Rize) of Turkish State Meteorological Service (MGM, in Turkish), of which observation durations were 60 and 80 years and located in EBSB, were employed. Since various studies have favored the use of Log Pearson Type 3 (LP3) Distribution for annual maximum precipitation data in Turkey; this distribution was used for the analysis. The rainfall intensity values for each station and for 7 return periods (T = 2, 5, 10, 25, 50, 100 and 500 years) was calculated by LP3 Distribution. Multi-nonlinear regression analysis was carried out by using nine kinds of IDF formulas, which were taken by using various IDF formulae in the literature and newly generated formulae. In order to test the reliability of the functions, two criteria were used: The determination coefficient and the mean relative error. IDF functions for the used stations were also calculated and presented both as equations and graphics It has been concluded that the reliability of the results is high enough and that this study will motivate and open new horizons to detailed studies on IDF analysis, which is an important issue to optimum design of various kinds of hydraulic structures.

2. Study area and used data

In Türkiye, there are significant differences in climatic conditions from one region to the other because of the existence of the mountains that run parallel to the coasts and the diverse nature of the landscape. Due to geographical location, geology and hydrological properties, Türkiye has a potential risk of mainly three different types of natural disasters related to gravity flows: Floods, landslides and snow avalanches. Floods are the second important natural hazards after earthquakes and destructive flood events have occurred in various river basins of Türkiye, especially in The Black Sea coast, which receives the greatest amount of rainfall. In last 100 years 66 extremely severe floods took place and caused great life and economic losses (Anılan et al., 2016). EBSB is also the only region of Turkey that receives rainfall throughout the year. Very major and destructive floods have occurred in the EBSB. The data used in this paper are annual maximum precipitation depth values, measured at 2 meteorological stations (MS),Trabzon and Rize,which are equipped with pluviographs. Thus, by measuring precipitation depths for several time intervals it is possible to calculate rainfall intensities. The observation periods of the data are 60 years and 80 years for Trabzon and Rize, respectively.

3. Methodology

3.1. Obtaining IDF values

To obtain IDF values, the best statistical distribution for the data must be determined and by using this distribution, an intensity-frequency analysis must be carried out for the selected standard rainfall durations. There are several statistical distributions that might be suitable for rainfall intensity-frequency (or return period, T=1/F) analysis. Various studies have favored the use of three suitable distributions for annual maximum precipitation (and also flood) data in Türkiye: Log-Normal Distribution (LN2), Gumbel Distribution (GM) and Log-Pearson Type 3 Distribution (LPT3). Since various studies have favored the use of Log Pearson Type 3 (LP3) Distribution for annual maximum precipitation data in Türkiye (Yüksek et al. 2022); this distribution was used for the analysis and the rainfall intensity values were calculated.

3.2. The used IDF functions

There are a number of formulae to determine IDF relationship. In general, return period (T=1/F) is used instead of frequency. General structure of these formulae is as follows (Yüksek et al. 2022):

$$I(D,F) = \frac{A(F)}{B(D)} \tag{1}$$

Where I(D,F) is rainfall intensity (mm/hour) as a function of frequency (1/year) and rainfall duration (D, hour). A number of functions have been given in the literature for the A(F) and B(D) functions. A list of these are presented in Table 1. By combining these functions, 9 IDF functions are obtained and are given in Table 2.

Table 1. Functions for A(F) and B(D)

	No	Function	References

3 and 4	$I(D,F)=\dfrac{a+b*\ln(\ln(1/F)}{D^c}$	8
3 and 5	$I(D,F)=\dfrac{a+b*\ln(\ln((1/F)}{D^c+d}$	9
3 and 6	$I(D,F)=\dfrac{a+b*\ln(\ln(1/F)}{(D+d)^c}$	10

4. Results

4.1. Reliability of the IDF functions

By using SPSS program, regression coefficients are calculated and IDF functions, Eq. 2 to 10, were obtained. Then, in order to test the reliability of the functions, two criteria have been used. The first criteria is the determination coefficient (R^2, square of correlation coefficient, R) and the second one is the mean relative error (RE, %) among the calculated IDF values both by the best distribution and by SPSS program. RE is calculated by:

$$RE=\frac{1}{N}\sum\left(\frac{IDF_1-IDF_2}{IDF_1}\right)*100 \tag{11}$$

where, IDF_1 and IDF_2 are calculated IDF values by the best distribution and SPSS program, respectively, and N is the number of data. Although there no strict criteria on what the minimum acceptable RE is, it is obvious that this value should be as low as possible. A summary of R^2 and RE values and for Trabzon and Rize are given in Table 3. Finally, success rating (SR) of the functions (from 1, the best to 9, the worst) are given as the last column of Table 3. As can be seen functions of Trabzon with higher R^2 and lower RE values are more reliable than that of Rize. However, it has been concluded that the IDF functions for both MS are reliable.

4.2. Equations and their graphics

As can be seen from Table 3, Eq. 7 and Eq. 6 are the best functions and are presented in Eq. 12 and Eq. 13 for Trabzon and Rize, respectively. The IDF functions are given in Eg. 12 and 13 and Fig.1 and 2, for Trabzon and Rize, respectively:

$$I(D,F)=\frac{18.991+16.507*\ln(1/F)}{(D+0.354)^{0.937}} \tag{12}$$

$$I(D,F)=\frac{37.361+15.432*\ln(1/F)}{D^{0.581}+0.174} \tag{13}$$

Table 3. Summary of R^2, RE and SR values for the used equations

Eq. No	Trabzon			Rize		
	R^2	RE	SR	R^2	RE	SR
2	0.963	0.550	8	0.980	0.339	8
3	0.990	0.092	4	0.984	0.239	2
4	0.989	0.087	3	0.982	0.270	5
5	0.966	0.515	7	0.984	0.321	7
6	0.993	0.077	2	0.987	0.218	1
7	0.993	0.073	1	0.986	0.250	4
8	0.943	0.552	9	0.970	0.340	9
9	0.968	0.172	6	0.973	0.242	3

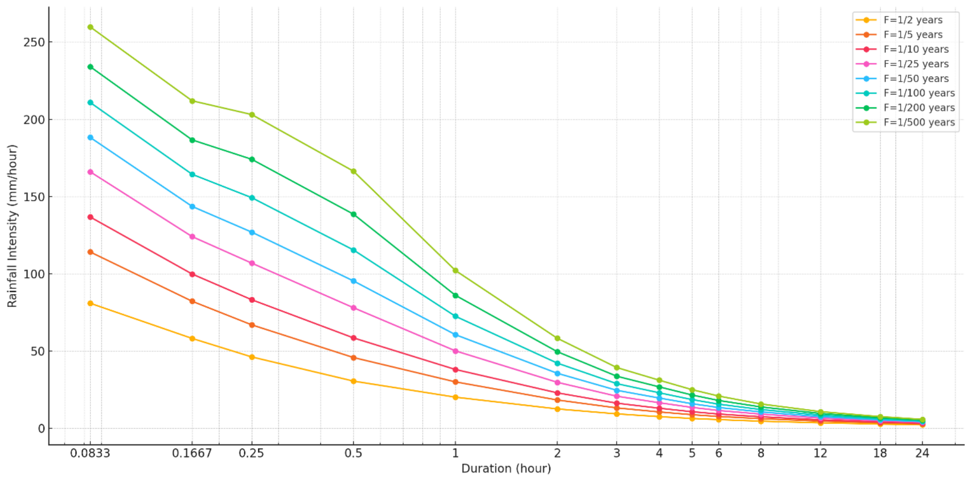

Fig. 1. IDF graphics for Trabzon

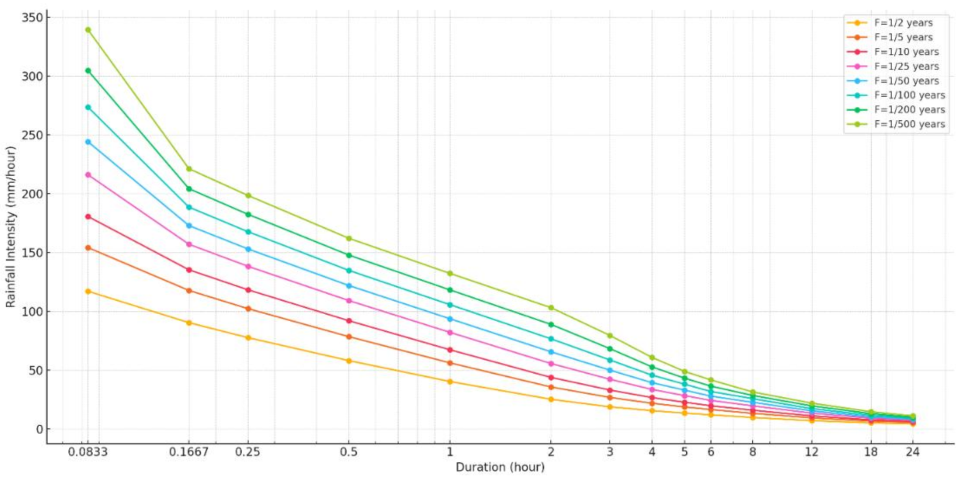

Fig. 2. IDF graphics for Rize

5. Conclusions

In this study, by using the annual maximum rainfall depth values in 2 MS in the EBSB, maximum intensity values for various durations are calculated and analysed. Rainfall intensity (I) values are estimated for various rainfall duration (D) and frequency (F) values according to the LPT3 distribution. Multi-nonlinear regression analysis has been carried out by using nine kinds of IDF formulas and various regression coefficients are obtained. The best formula for each MS is determined depending on R^2 and RE between intensity values, one with maximum R^2 and the minimum RE. The studied 9 functions are analyzed in detail. In this context, the numerator A(F) and denominator B(D) functions of Equation 1, have been evaluated in the context of their reliabilities in predicting rainfall intensities. A success rating list of nine functions is presented. Functions of Trabzon with higher R^2 and lower RE values are more reliable than that of Rize. In the final phase of the study, IDF functions for Trabzon and Rize, are presented both as equations and graphics.

Cost analysis of small hydroelectric power plants: a case study Euphrates and Tigris Basins

İbrahim Yüksel*[1], Ersal Yılmaz[2], Fatih Çıbuk[1], Merve Terzi[1]

[1] Istanbul Rumeli University, Department of Civil Engineering, 34445 Istanbul, Türkiye
[2] Marmara University, Department of Construction and Technical Works, 34445 Istanbul, Türkiye

Abstract. Energy costs in the world are directly related to energy capacity. As the energy capacity increases, the investment cost of the hydroelectric power plant also increases. Because if the energy capacity is high, the energy production will also be high and the investment cost will be amortized in a short time. In this study, 10 small streams on which hydroelectric power plants are designed were selected, and then the investment costs were analysed for these small streams which are in the Euphrates and Tigris Basins. There is a flow observation station (FOS) in only two of these 10 selected streams (Baskoy and Celebiyan Streams). The flow values of the other 8 small streams were estimated by using the basin characteristics and flow values of Baskoy and Celebiyan streams. In addition to many technical and economic parameters, flow values are the most effective parameters for energy production in hydroelectric power plants. Therefore, cost analyses of small hydroelectric power plants were performed by using flow values.For the cost analyses; SMART Mini Hydro Tool Program was used. Because this program includes many technical and economic parameters as well as the most effective hydrological parameters.

Keywords: Small hydroelectric power plants, Hydrological models, Cost analysis, Energy efficiency, Euphrates and Tigris Basins.

1. Introduction

The subject of this study is the cost analysis of small hydroelectric power plants without reservoirs (without storage). Therefore, hydroelectric power plants with reservoirs and micro hydroelectric power plants established for domestic wastewater are not included in this study. However, some suggestions are included at the end of the study for hydroelectric power plants with reservoirs and micro hydroelectric power plants established for domestic wastewater.

In the studies conducted to date, a comprehensive analysis of the investment costs and efficiency issues of small hydroelectric power plants without reservoirs has not been made. One of the aims of this study is to close this deficiency in the literature.

Some hydraulic-hydrological simulation-optimization models such as Watershed Modelling System (WMS), The Hydrologic Engineering Center Hydrologic Modelling System (HEC-HMS) are used in system designs for integrating hydroelectric power plants with reservoirs into the ecosystem.

However, it has not been seen that simulation-optimization models are used in small hydroelectric power plants without reservoirs. Therefore, this study, which analyses small hydroelectric power plants technically and economically for an ideal optimization, is an important and new study.

In this study, it is aimed to optimize small hydroelectric power plants in terms of cost-benefit factor and to add these plants to the ecosystem.

On the other hand, the results obtained from this study, which demonstrated the feasibility of small hydroelectric power plant projects in terms of both ecosystem and economy, were generalized and it was suggested that they could be applied to SHPPs to be established in different basins.

There are two basic parameters in the economic analysis of small hydroelectric power plant projects. These are the investment cost and the annual cost, and these parameters are necessary to obtain the total cost of the project. On the other hand, some indirect costs such as construction costs, electromechanical equipment costs, energy

* Corresponding author, E-mail: ibrahim.yuksel@rumeli.edu.tr

https://doi.org/10.31462/icearc2025_ce_hwr_371

transmission costs are considered as investment costs, while equipment depreciation, maintenance, operation and replacement costs are considered annual costs (Moldoveanu & Popescu ,2018; Singal et al., 2010).

2. Method and materials

2.1. Selecting model for estimating cost of the small hydropower plants

In this study, the SMART Mini Idro Tool Program, which includes important hydrological parameters such as discharge, minimum flow, turbine flows, etc. as well as many other technical and economical parameters, was used.

Therefore, it was concluded that the SMART Mini Idro Tool Program is a good option to use in the cost analysis of hydroelectric power plants.

SMART Mini Idro is a tool that evaluates hydropower project parameters using some values such as Flow Continuity Curve (FCC), net head, turbine types and discharge interval (Yuksel, 2024; McEnroe, 2010).

The main task of the SMART Mini Idro Tool, which uses hydrological data as input data; It is to make a preliminary assessment of the environmental flow of a stream, taking into account the daily average flows, to select the appropriate turbine type and to make an estimated economic analysis.

There are some assumptions for the annual costs of small hydroelectric power plant projects used within the scope of the SMART Mini Idro Program. In this study, these assumptions were taken into account while making cost-benefit analysis of hydroelectric power plants. These are:

- Project life as 30 years,
- Management and maintenance costs as 3% of the investment cost,
- Energy fee as 0.07 €/kWh and
- Green certificate fee is accepted as 0.137 €/kWh for 15 years.

One of the most important elements in hydropower cost analysis is the hydrological model factor. Therefore, hydrological models of hydroelectric power plants must be established before construction. Because thanks to the hydrological model, all risks such as deficiencies, errors, inconsistencies, etc. that may arise in a hydroelectric power plant can be determined, and these are solved at the project stage.

Otherwise, it is not possible to eliminate the negativities in a hydroelectric power plant built without establishing a hydrological model. This means that a lot of money and labour will go to waste.

For the analyses in this study, 10 streams were selected from the Tigris and Euphrates Basins, and since only Baskoy and Celebiyan streams have flow observation stations, the flow values of the remaining 8 streams were estimated by calculating them with regression analysis. Regression analysis is widely used in solving these types of problems in water resources.

There are different types of regressions such as Linear Regression (Simple Regression), Linear Multiple Regression, Nonlinear Multiple Regression.

Many problems in engineering cannot be solved with simple regression. Because most of the events in engineering are either complex problems (such as the components of an earthquake) or random events (such as the rate of rainfall).

2.2. Multiple nonlinear regression

Multiple Nonlinear Regression is a form of regression analysis in which the data is modelled by a multiple function that is a nonlinear combination of the parameters in the event to be modelled and depends on more than one independent variable (Beyazit, 1981).

Multiple nonlinear regression is an analysis that easily estimates models that have arbitrary or random relationships between the independent and dependent variables. A multiple nonlinear regression is expressed as Eq. 1:

$$\log(Y) = \log(a_0) + a_0 \log(X_1) + a_0 \log(X_2) + \cdots a_0 \log(X_n) \quad (1)$$

Here:

In the Equation 1, $\log(Y)$ on $\log(X_1)$, $\log(X_2)$, …, $\log(X_n)$ is used to estimate the parameters a_0, a_1,…and a_n. Where:

- Y: Dependent Variable
- X_1-X_n: Independent Variables
- a_0 - a_n: Are the equation parameters for the nonlinear relation

It is known that variables affecting many events or problems are not linearly related to each other and that variables in engineering problems are multiple nonlinear. For this reason, multiple nonlinear functions are widely used in engineering fields. In this study, multiple linear and multiple nonlinear regression were used.

2.3. Design parameters of cost analysis for small hydropower plants

One of the most important factors affecting the benefit/cost value in a hydro power plant is turbines. The size of the turbines is directly related to the diameter of the turbine wheel, and the working order of the power plant is determined by the diameter of the wheel. The following equations are used to determine the diameter of the impeller (Fujii et al., 2017).

$$D = \frac{84.6 * \theta_3 * \sqrt{H}}{N} \tag{2}$$

$$\theta_3 = 0.0223 * \sqrt[3]{N_s^2} \tag{3}$$

$$N_s = \frac{1.358 * N * \sqrt{P}}{\sqrt[4]{H^5}} \tag{4}$$

Within the scope of the SMART Mini Idro Program, the following equations are used for the construction works and the costs of different equipment in small hydroelectric power plants, and the plant's retinue is calculated according to Eq. 2, which is the installed power function.

$$C_{CE}(€) = a * P(kW)^2 + b(kW) + c \tag{5}$$

The water intake structure of the plant is calculated according to the Eq. 3, which is the maximum discharge function.

$$C_P(€) = a * Q(m^3/s)^2 + bQ(m^3/s) + c \tag{6}$$

The transmission channel entourage of the power plant is calculated according to Eq. 4, which is the maximum discharge and maximum length function.

$$C_{CA}(€/m) = a * Q(m^3/s)^2 + bQ(m^3/s) + c \tag{7}$$

The penstock cost is calculated according to the Eq. 5, which is the function of diameter and maximum length.

$$C_{CF}(€/m) = a * D(m)^2 + bD(m) + c \tag{8}$$

In the equations: 2-8:

- N_s: The specific speed of the turbine (rpm),
- N: Turbine rotation speed (rpm),
- H: Net head (m),
- P: Power (kW),
- Q: Flow,
- C_{CA}: Transmission channel cost,
- C_{CE}: Plant cost,
- C_{CF}: Penstock cost,
- C_P: Water intake structure cost,
- a, b and c are the coefficients.

The most important parameter to be determined in order to make cost analysis in hydroelectric power plants is the gross hydropower potential. For this reason, it is necessary to know which methods are used for calculating of the gross energy potential. The potential taken as basis in the calculations in hydropower projects is the gross hydropower potential.

2.4. Gross power and gross energy potential

When the total efficiency (η) obtained from the equation 7 is written in its place in the power equation, gross power is obtained by using the Eq. 9: Gross Power,

$$P_{gross} = \gamma * Q_m * H * \eta \tag{9}$$

The equation is obtained and using this equation the gross energy potential is found by using the Eq. 10: Gross Energy potential is obtained.

$$E_{gross} = \gamma * Q_m * H * \eta * 24 * 365 \tag{10}$$

In the Equations 9 and 10:

- P_{gross}: Gross power (kW),
- E_{gross}: Gross energy (kWh),
- γ : Water specific gravity (kN/m^3),
- Q_m: Average flow rate (m^3/s)
- H: Net head (m),
- η : Total efficiency (%)

The most important parameter in hydropower capacity calculations is the flow rate. In open channel flows and streams, the flow rate can be determined precisely with the help of velocity measurements on the cross section. For this purpose, the stream cross section is divided into slices (Fig. 1).

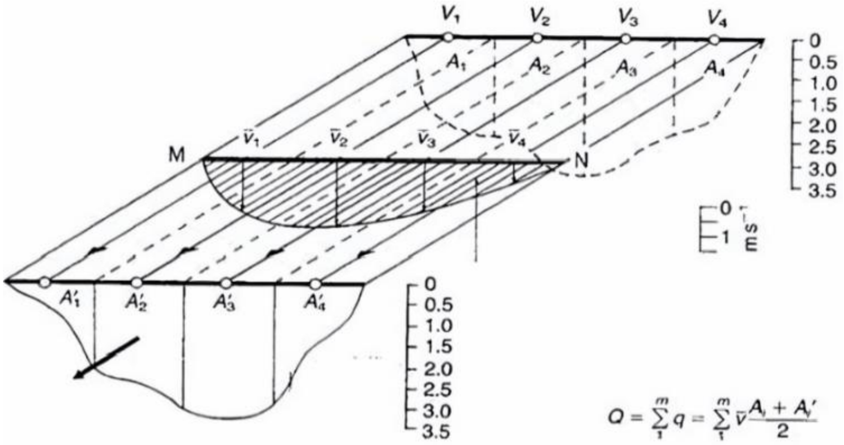

Fig. 1. Measurements of flow along the cross-section in open channels and streams

The average velocity V_i (m/s) and the cross-sectional area A_i (m^2) in each of these slices are measured. The flow rate (Q) is calculated by using the obtained values in the Eq. 11:

$$Q = \sum V_i A_i \tag{11}$$

Here:

- Q: Flow rate (m^3/s),
- Vi: Speed at the measurement point (m/s),
- Ai: Cross-sectional area at the measurement point (m^2)

2.5. Cost analysis for small hydropower in selected streams

Only Baskoy and Celebiyan streams have flow observation stations from the 10 selected streams. By using these two streams' data, the flow values of the other 8 streams were calculated by using numerical and statistical methods.

In a previous study (Yuksel, 2024; McEnroe, 2010; Beyazit, 1981; Fujii et al, 2017; Demirel, 2021), in order to work at the same gross load for all streams, 12 different scenarios with gross head values ranging from 15, 20, 25, 30, 35, 40, 45, 50, 55, 60, 80 and 100 m have been created. However, it is mentioned that SHP projects can be developed in these streams with a head of 15 m and above in the study.

Although it was concluded that SHP projects could be developed for the selected streams using these 12 scenarios, both the maximum total benefit-cost ratios and the capacity factor values were observed as the ideal values for 100 m. Therefore, the cost-benefit analyses calculated for 100 m gross head for selected streams were taken into account.

The cost-benefit analyses calculated for 100 m gross head for the selected streams are given in the Table 1.

Table 1. Cost analysis for all selected streams

Stream	Gross Head (m)	Net Head (m)	Max kW	MWh	Number of Operation Days	Investment Cost (€)	Annual Cost (€)	Total Cost (€)	Payback Period (Year)	Benefit-Cost Ratio	Capacity Factor (%)
Han	100	98	6035	21834	201	12.547.746	518.090	13.065.836	2,28	5.29	0.41

3. Conclusion and discussion

When Table 1 is analysed, it is seen that flow and head load amounts have a great effect on the power produced and the cost-benefit ratios change with the increase in the low values.

On the other hand, cost analysis table (Table 1) for all streams is examined, it is seen that the capacity factors are close to each other for all streams and these values vary between 0.37% and 0.48%. In this case, the average capacity factor for the selected streams is 0.42.

Considering that the average capacity factor in hydroelectric power plants in Turkey is 37% and 44% in the world (Yuksel, 2024; McEnroe, 2010; Beyazit, 1981; Fujii et al., 2017; Demirel, 2021), it is seen that the capacity factor of 0.42 obtained in this study is above the Turkish average and very close to the world average.

Considering all the costs analysed in this study, it has also been determined that the SHPPs to be established on the selected streams will make profits by financing themselves for periods varying between 2.28-4.79 years.

As a result of the calculations, it has been determined that the SHPPs to be built according to parameters and criteria's in this study will be efficient and the self-financing period of these power plants will be between 2.28-4.79 years.

Small streams located in the Euphrates and Tigris basins, whose flow values are unknown due to the lack of measurement stations but have a certain potential, have been highlighted and their potential has been included in hydropower production. Based on this study, it is strongly suggested that this method can also be applied to small streams in different basins.

In order to further improve the cost-benefit analysis of small hydroelectric power plants by using different hydraulic and hydrological characteristics, this study will be an important reference.

Essentials of manifold flow hydraulics-II: Energy-gradient ratio (EGR) approach

Gürol Yıldırım*[1]

[1] Giresun University, Engineering Faculty, Civil Engineering Dept., 28100, Giresun, Türkiye.

Abstract. This paper presents a new analytical procedure based on Energy-Gradient Ratio (EGR) approach, identifying different types of energy head profiles for a given pipe design slope, and determining unknown hydraulic characteristics through the energy-grade line (EGL). The present technique is simple, direct, and sufficiently accurate for a wide range of water application uniformity, and can be efficiently implemented for different types of pressure head profiles for different line slope situations.

Keywords: Manifolds; Steady-state analysis; Fluid mechanics; Energy Gradient Ratio (EGR); Fluid flow

1. Theoretical background

The Energy-Gradient Ratio (EGR) approach is a useful tool to identify first which type of pressure profile occurs for a given uniform design slope with other hydraulic variables initially known, then comprehensively evaluate its definite hydraulic characteristics along the line (Sadeghi & Peters, 2011). The most important difficulty when recognizing the type of pressure profile is the determination of energy-grade line slope (or friction slope) (S_f), which depends on the total inlet discharge (Q) and pipe diameter (D), since Q and D are unknown parameters in most design cases (Hathoot et al. 1993). Knowing the hydraulic properties for any type of pressure profile regarded enables the design engineer to evaluate pressure parameters through the line sections in a simple way based on the proposed EGR approach. The EGR approach is essentially based on a simple ratio, defined as "the energy-gradient ratio (K_S)" which can be explained as "the ratio of uniform pipe slope (S_0) to the friction slope (S_f) [or energy-gradient line (EGL) slope] (KS = S_0/S_f)". Through the following analysis, the improved EGR approach, based on the recent analytical development (Yıldırım, 2006a; 2007a,b) to cover different types of pressure head profiles (Type-I, Type-II.a, Type-II.b, Type-II.c and Type-III) concerning different uniform line slope situations (Barragan & Wu, 2005), will be presented.

This paper presents a new analytical procedure based on Energy-Gradient Ratio (EGR) approach, identifying different types of energy head profiles for a given pipe design slope, and determining unknown hydraulic characteristics through the energy-grade line (EGL) (Sadeghi & Peters, 2013; Singh et al., 2000).The present technique is simple, direct, and sufficiently accurate for a wide range of water application uniformity, and can be efficiently implemented for different types of pressure head profiles for different line slope situations. The proposed method offers considerable flexibility by directly computing values of the required hydraulic variables along the energy profile, incorporating different uniformity patterns and without requiring any additional hydraulic variables, such as pipe diameter, total inlet discharge, required average outflow, downstream end pressure head, total friction drop or outlet characteristics (Sadeghi et al., 2016; Singh & Mahar, 2003).

2. Analytical energy-gradient-ratio (EGR) approach

Assuming that outlets along the pipeline have uniform outflow, neglecting the change in kinetic head and local head losses, the operating inlet pressure head, H0I, for a multi-outlet pipeline is approximated by Keller and Bliesner (1990) as:

$$H_{0I} = \overline{H} + k \times h_{f(L)} + \frac{1}{2} \times (S_0 \times L) \tag{1}$$

where k = the fraction of the total pipe friction head loss; the suggested values of factor k are 0.75, 0.63 and 0.5, for a multioutlet pipe with single-diameter, two-diameter and more than two diameters, respectively (Keller & Bliesner, 1990; Mahar & Singh, 2003). The traditional formulation, Eq.(1) cannot be easily applied to determine H_{0I}, since $\overline{H}$ and S_0 are known a priori, whereas H_d and/or $h_{f(L)}$ cannot be determined in advance, because pipe diameter, D, is an additional unknown parameter for the required operating inlet pressure head, H_{0I}, in most usual design cases. As a useful reference, to overcome the implicit procedure given by Eq. (1), Yıldırım (2023a) recently

https://doi.org/10.31462/icearc2025_ce_hwr_417

golden light publishing

proposed an improved direct computing technique to determine H_{0I} for a single line size system which incorporates different uniformity patterns for water application. In this analysis, first, simple mathematical expressions are deduced to relate uniformity parameters; then H_{0I} is simply reformulated by taking into account a multiplification factor , for the required average outlet pressure head, and β^*, for the potential energy head change due to uniform line slope. However, the applicability of this procedure is only limited for the design case of a Type-I pressure profile for horizontal or uphill slope situation. Eq. (1) can be rewritten for a single line size system (k = 0.75), and suitable for the general slope situations (p = 0 and p = 1 for zero and upslope, p = -1 for downslope) as follows:

$$H_{0I} = \overline{H} + L\left(\frac{3}{4}S_f + \frac{1}{2}(pS_0)\right) \tag{2}$$

In this section, the computing technique (Yıldırım, 2008) based on the recent analytical development (Yıldırım, 2023a; 2023b) which evaluates the operating inlet pressure head, H_{0I} for a single line size system (k = 0.75), will be improved and extended to encomapss different types of pressure profiles concerning different uniform line slope situations, and various design combinations. In the analysis, first the friction slope (S_f) is formulated in terms of dimensionless physical mumbers ($\lambda_1, \lambda_2, \lambda_3, \lambda_4, \lambda_5$), introduced into Eq. (2), and then H_{0I} can be directly determined as follows.

3. Steps of algorithm

For the sake of comparison between the formulations derived for design parameters [the friction slope, S_f, fraction of the required average pressure head, δ_H , and multiplication factors (α and β^*) for operating pressure], regarding the five types of pressure profiles (Type I, Types II.a, II.b, II.c and Type III), all formulations are sythesized and are shown in Fig. 1.

Energy-Grade Line Slope, S_f (%)

Type of Pressure Profile(s)	Design Coefficients (k_1, k_2, k_3, k_4)			
	k_1	k_2	k_3	k_4
Type-I	4.357	3.477	2.745	2.92
	$S_f = k_1 \times \lambda_1 \times \lambda_5 - S_0 = k_2 \times \lambda_2 \times \lambda_5 - S_0 = k_3 \times \lambda_3 \times \lambda_5 - S_0 = k_4 \times \lambda_4 \times \lambda_5 - S_0$			
Type-II.a	4.357	3.477	2.745	2.92
	$S_f = S_0 + k_1 \times \lambda_1 \times \lambda_5 = S_0 + k_2 \times \lambda_2 \times \lambda_5 = S_0 + k_3 \times \lambda_3 \times \lambda_5 = S_0 + k_4 \times \lambda_4 \times \lambda_5$			
Type-II.b	2.178	1.738	1.372	1.459
	$S_0 = S_f = k_1 \times \lambda_1 \times \lambda_5 = k_2 \times \lambda_2 \times \lambda_5 = k_3 \times \lambda_3 \times \lambda_5 = k_4 \times \lambda_4 \times \lambda_5$			
Type-II.c and **Type-III**	4.357	3.477	2.745	2.92
	$S_f = S_0 - k_1 \times \lambda_1 \times \lambda_5 = S_0 - k_2 \times \lambda_2 \times \lambda_5 = S_0 - k_3 \times \lambda_3 \times \lambda_5 = S_0 - k_4 \times \lambda_4 \times \lambda_5$			

Fraction of Required Average Pressure Head: δ_H (%)

Type of Pressure Profile(s)	Design Coefficients (k_1, k_2, k_3, k_4, k_5)

	$\alpha = 1 + c_1 \times k_1 \times \lambda_1 = 1 + c_1 \times k_2 \times \lambda_2 = 1 + c_1 \times k_3 \times \lambda_3 = 1 + c_1 \times k_4 \times \lambda$				$-\frac{0.75}{F_S}$ ($F_S \neq 1.0$)	$\frac{0.75}{F_S} - \frac{1}{2}$ ($F_S \neq 1.0$)

Dimensionless Physical Numbers: $\lambda_1 = \frac{(1-U_C)}{x}$, $\lambda_2 = \frac{CV_q}{x}$, $\lambda_3 = \frac{(1-EU)}{x}$, $\lambda_4 = \frac{(1-DU)}{x}$, $\lambda_5 = \frac{\overline{H}}{L}$; and F_S = Enlargemet factor, to take into account the effect of local losses [$F_S = 1 + (l_e / s)$].

Fig. 1. Relationships for the Energy-Grade Line Slope: S_f (%), Fraction of Required Average Pressure Head $(\overline{H})$: δ_H (%), Multiplication Factors: α and β^*, to Determine the Operating Inlet Pressure Head (H_{0I}) with Related Design Coefficients (c_1, k_1, k_2, k_3, k_4, k_5) for Five Types of Pressure Profiles [*Type-I, Types II.a, II.b, II.c* and *Type-III*]

Before starting the present algorithm, the following input data for hydraulic variables are assigned in advance to finally evaluate the required pressure parameters along the profile.

Input (initially known) parameters: S_0: pipe slope which is assumed to be uniform along the line (%), L: total length of the submain line (m), $\overline{H}$: required average pressure head (m), (U_C, CVq, E_U or D_U): uniformity parameters for the desired level of water application unformity (%), l_e: equivalent length (m) to determine the enlergement factor (F_S), s and x: outlet spacing (m) and outlet discharge exponent, respectively.

Output (required) parameters: S_f: the friction slope (or the slope of EGL) (%), $K_S = S_0/S_f$: the dimensionless "energy-gradient ratio", which primarily identifies the type of pressure profiles, $h_{f(L)} = S_f \times L$: the total friction drop at the end of line (m), H_{max}, H_{min}: the extreme pressure heads (m) with their locations (i_{max} , i_{min}), $\Delta H_{\max}$: the maximum allowable pressure head difference along the line (m), $\delta_H = \Delta H_{\max} / \overline{H}$: the fraction of the required average pressure head (%), $\phi_H = \Delta H_{\max} / h_{f(L)}$: the relative maximum pressure variation (%), α and β^*: the multiplification factors to the operating inlet pressure (H_{0I}), H_{0I} and H_d: the operating inlet and downstream end pressure heads (m), respectively, and β: nonuniform outflow exponent to evaluate the nonumiform outflow distribution along the line. Based on the present improved EGR approach, the following calculation steps are implemented, respectively, using the related formulations for each type of pressure profile.

a) For a desired value of the uniformity coefficient (U_C, CVq, E_U or D_U), and the outlet discharge exponent (x), the related dimensionless physical numbers (λ_1, λ_2, λ_3 or λ_4) are computed for a given value of required average pressure head ($\overline{H}$) and the total length of submain line (L), the dimensionless physical number, λ_5, is also computed.
b) Select the proper formulation for Sf in accordance with the given design slope (S0) condition [zero (p = 0), upslope (p = 1), or downslope (p = -1)]. Then Sf is evaluated, depending on dimensionless physical numbers (λ1, λ2, λ3, λ4 and λ5), and certain values of design coefficients (k1, k2, k3, k4 and k5).
c) Compare the friction slope (Sf) to the uniform pipe slope (S0) with respect to the design intervals of the energy-gradient ratio (KS = S0/Sf), and make a decision about the type of pressure profile depending on the KS value assigned in Step (b). It should be noted for downslope condition, as an initial computation, the Sf formulation given for the pressure profiles Type II.c and Type III is first used; then if a negative value of Sf is reached, this would indicate that Sf is greater than the pipe slope, S0; that means the formulation for Sf deduced for Type II.a profile should be used.
d) For the type of pressure profile assigned in Step (c), select the proper formulation to evaluate the percentage of the required average pressure head (δ_H). Then, compute the total friction drop, hf(L).
e) For the type of pressure profile decided on above, compute multiplication factors (α and β^*) for the operating inlet pressure head (H0I), depending on the dimensionless physical numbers (λ1, λ2, λ3, λ4 and λ5) and certain values of design coefficients (c_1, k_1, k_2, k_3, and k_4) from Figure 1. Then, the operating inlet pressure head (H_{0I}) can be evaluated for both the design cases (considering or neglecting local losses).
f) For the above type of pressure profile, determine the extreme pressure heads (H_{max}, H_{min}) with their positions along the line (imax, imin), and evaluate the maximum allowable pressure head difference ($\Delta H_{\max}$) to check the value of δ_H computed from Step (d). Then, determine the relative pressure variation ($\phi_H = \Delta H_{\max} / h_{f(L)}$).
g) Compute the downstream end pressure head (Hd) from the conservation of energy principle or the related analytical equations derived for each type of profile. Then, set the order of operating inlet (H0I), downstream end (Hd), extreme (Hmax, Hmin) and required average ($\overline{H}$) pressure heads to check the identity for the assigned type of pressure profile from Step (c).
h) Introduce the value of Sf previously determined in Step (c) into analytical equations to reveal the certain form of the pressure head profile along the line. Then, check the identitiy of the specific hydraulic characteristics between the certain and assigned pressure profiles.

Note that if a higher precision is required, the nonumiform outflow distribution along the line should be taken into consideration. For this case the nonuniform outflow exponent, β is evaluated depending on the values, S_0, x, L, $\overline{H}$, F_S, and S_f [determined from Step (b)]. Then, Steps (f)~(h) are repeated to evaluate the nonuniform outflow distribution.

4. Conclusions

Determination of the proper operating inlet pressure head is important for hydraulic design of multi-outlet pipelines in submain lines. This paper presents an analytical energy-gradient ratio (EGR) approach which offers simple, direct but sufficiently accurate relationships to determine the operating inlet pressure head and the the required pressure parameters, incorporating different uniformity patterns for water application. For this purpose, some mathematical expressions are initially deduced to relate water application uniformity parameters; such as

Christiansen uniformity coefficient, lower-quarter distribution uniformity, coefficient of variation of outlet discharge, emission uniformity and allowable pressure head variation. Hence, the operating inlet pressure head is reformulated by incorporating different uniformity patterns, and setting a multiplification factor, α , and the required average outlet pressure head, and β *, for the change in potential energy head due to the uniform line slope. The present formulations can be efficiently used for a wide range of water application uniformity, and for different types of pressure profiles in different line slope situations, without requiring any additional hydraulic variables.

5. Appendix

5.1. Computational example for type III profile: "steep downslope" case

Based on the original data presented-above, determine the energy-gradient line (EGL) with the corresponding hydraulic variables for the steep-downslope situation, S_0 = 0.05, and for the desired level of water application uniformity, U_C = 90.5%, based on the nonuniform outflow concept ($m_\beta = \beta \times m$, $\beta \neq 1$), and neglecting the change in the kinetic energy head $(H_{VI} \cong 0)$ and local head losses (F_S = 1).

a) For U_C = 0.905, $\overline{H}$ =7.2 m, L = 151 m and x = 0.5, dimensionless physical numbers, λ_1 and λ_5 are already computed in the following: $\lambda_1 = 0.19$ and $\lambda_5 = 0.048$

b), c) The friction slope, S_f is directly computed from Figure 1 (k_1 = 4.357):

$$S_f = S_0 - k_1 \times \lambda_1 \times \lambda_5 = 0.05 - 4.357 \times 0.19 \times 0.048 = 0.0105 \rightarrow, S_f = 1.05\% \tag{3}$$

The dimensionless energy-gradient ratio, $K_S = \dfrac{S_0}{S_f} = \dfrac{0.05}{0.0105} = 4.75$ (Figure 1), therefore Type-III profile is observed along the line.

Total friction drop, m.

Total energy gain due to steep-downslope situation, m.

For the nonuniform outflow distribution along the line, the nonuniform outflow exponent, is evaluated from Eq. (4)*, depending on the values of S_0, x, L, $\overline{H}$, FS, and S_f , as follows:

$$\beta = 1 - 3.322x \log\left[1 + \frac{H_{VI}}{\overline{H}} + \frac{h_{f(L)}}{\overline{H}}\left[\left(\frac{m+3-0.5^{m+1}}{m+2}\right) - F_S\right] + \frac{1}{4\overline{H}}(p\Delta S)\right] \tag{4}$$

$$\beta = 1 - 3.322 \times 0.5 \times \log\left[1 + 0 + \frac{1.59}{7.2} \times \left[\left(\frac{4.75 - 0.5^{2.75}}{3.75}\right) - 1\right] + \frac{1}{4 \times 7.2} \times (-1) \times 7.55\right] \tag{5}$$

$\beta = 1.172$, therefore the improved value of velocity exponent, mβ : $m_\beta = \beta \times m = 1.172 \times 1.75 = 2.05$

d) For Type III profile, can be directly determined from Figure 1 (k_1 = 4.357):

$$\delta_H = k_1 \times \lambda_1 = 4.357 \times 0.19 = 0.828 ,\ \delta_H = 83\% \tag{6}$$

e) For Type III profile, multiplication factors (α and β^*) are computed from Figure 1: k_1 = 4.357, c_1 = -0.75 for F_S = 1]:

$$\alpha = 1 + c_1 \times \delta_H = 1 - 0.75 \times 0.828 = 0.379 \tag{7}$$

$$\alpha = 1 + c_1 \times k_1 \times \lambda_1 = 1 - 0.75 \times 4.357 \times 0.19 = 0.379 \text{ , and } \beta^* = 0.25 \text{ (for } F_S = 1) \tag{8}$$

The operating inlet pressure head (H_{0I}) is directly computed from:

$$H_{0I} = \alpha \times \overline{H} + \beta^* \times (S_0 \times L) \tag{9}$$

$$H_{0I} = 0.379 \times 7.2 + 0.25 \times (0.05 \times 151) = 4.617 \cong 4.62 \text{ m} \tag{10}$$

Check the value of H_{0I}, for i = 0, for S_f = 0.0105 and $m_\beta = 2.05$:

$$H_{0I} = H(l=0, i=0) = \overline{H} + H_{VI}[1-(1-i)^2] + h_{f(L)}\left[F_S[(1-i)^{m_\beta+1} - 1] + \frac{m_\beta + 1}{m_\beta + 2}\right] - p\Delta S\left(i - \frac{1}{2}\right) \tag{11}$$

$$= 7.2 + 0 + 1.59 \times \left[1 \times [(1-0)^{2.05+1} - 1] + \frac{2.05+1}{2.05+2}\right] - (-1) \times 7.55 \times \left(0 - \frac{1}{2}\right) = 4.62 \text{ m} \tag{12}$$

The downstream end pressure head, H_d, can be directly evaluated from the conservation of energy principle:

$$H_d = H_{0I} + L \times (S_0 - S_f) = 4.62 + 151 \times (0.05 - 0.0105) = 10.585 \cong 10.59 \text{ m} \tag{13}$$

Check the value of H_d, for for i = 1, for S_f = 0.0105 and $m_\beta = 2.05$:

$$H_d = H(l = L, i = 1) = 7.2 + 0 + 1.59 \times \left[1 \times [(1-1)^{2.05+1} - 1] + \frac{2.05+1}{2.05+2}\right] - (-1) \times 7.55 \times \left(1 - \frac{1}{2}\right) = 10.582 \cong 10.58\,\text{m} \quad (14)$$

f), g), h) The location of minimum pressure head (i_{min}) can be evaluated from:

$$i_{\min(DW)} = \frac{l_{\min}}{L} = 1 - 0.561 \times \left(\frac{K_S}{F_S}\right)^{0.57} = 1 - 0.561 \times \left(\frac{4.75}{1}\right)^{0.57} = -0.36 \quad (15)$$

Minus sign indicates the minimum outflow just occurs at the upstream pipe inlet point ($i_{min} = 0$), therefore the operating pressure head at the pipe inlet is just identical to the minimum pressure head along the line ($H_{0I} = H_{min}$ = 4.62 m), and the maximum pressure head occurs at the downstream closed end ($H_{max} = H_d$ = 10.58 m)

The maximum pressure head difference, $\Delta H_{\max} = H_{\max} - H_{\min} = 10.58 - 4.62 = 5.96$ m.

Check the value of from: $\delta_H = \frac{\Delta H_{\max}}{\overline{H}} = \frac{5.96}{7.2} = 0.828$, (83%)

Compute parameter, ϕ_H , to evaluate the pressure variation:

$\phi_H = \frac{\Delta H_{\max}}{h_{f(L)}} = \frac{5.96}{1.59} = 3.75$ means the excessive level for the pressure variation along the line for a given steep downslope situation (for K_S = 4.75>2.75)

Check the pressure orders for Type- III profile:

$$H_d = H_{\max} = 10.6 > \overline{H} = 7.2 > H_{0I} = H_{\min} = 4.6\,\text{m} \quad (16)$$

The distribution of pressure parameters evaluated based on the EGR approach is verified by the Type- III profile.

ı) For water application uniformity evaluation, for Type III profile (c_1 = -0.75, k_1 = 4.357 and = 0.25), regarding the design value of operating pressure head, H_{0I} = 4.62 m, and $\lambda_5 = \overline{H}/L = 7.2/151 = 0.048$, the uniformity parameters are evaluated as follows:

$$\theta = \frac{H_{0I}}{\overline{H}} - \beta^* \times \frac{S_0}{\lambda_5} - 1 = \frac{4.62}{7.2} - 0.25 \times \frac{0.05}{0.048} - 1 = -0.61875 \quad (17)$$

$$\delta_H = \frac{\theta}{c_1} = -\frac{0.61875}{-0.75} = 0.825 \cong 83\% \quad \lambda_1 = \frac{(1-U_C)}{x} = \frac{\theta}{c_1 \times k_1} = \frac{-0.61875}{-0.75 \times 4.357} = 0.1894 \quad (18)$$

$$U_C = 1 - \lambda_1 \times x = 1 - 0.1894 \times 0.5 = 0.905 \cong 90.5\% \quad (19)$$

Abstract. Acidic groundwater jeopardizes quarry wall stability, particularly in faulted regions, by promoting chemical weathering and elevating pore pressure. This study assesses the efficacy of drainage systems and lime-based chemical treatment in enhancing stability, using FLAC simulations to evaluate three scenarios: baseline acidic conditions, drainage alone, and combined drainage with lime treatment. The baseline scenario, characterized by high pore pressure (0.1 MPa) and degraded rock properties, produced a factor of safety (FOS) of 0.88, indicating instability. Drainage reduced pore pressure to 0.01 MPa, increasing FOS to 1.02, suggesting marginal stability. The combined approach, integrating drainage with lime treatment to neutralize acidity (pH ≈ 7) and improve rock properties, elevated FOS to 1.29, achieving significant stability. Results highlight that while drainage mitigates mechanical instability, lime treatment addresses chemical degradation, which offers a holistic solution for quarry operators. By incorporating site-specific fault data and chemical treatment effects into FLAC2D modeling, this study provides a novel framework for managing acid mine drainage risks in mining settings. Nevertheless, field trials are recommended to confirm these findings, with future research proposed to explore detailed chemistry modeling and long-term treatment durability.

Keywords: Acidic groundwater; Quarry wall stability; Drainage system; Chemical treatment; FLAC2D simulation

1. Introduction

Quarry wall stability is critical for ensuring operational safety and economic viability in mining operations. Unstable slopes can lead to rockfalls, landslides, and costly production delays, posing significant risks to workers and equipment. A key factor compromising stability is acidic groundwater, often with a pH around 2-4, which triggers chemical weathering of rock masses. This process, driven by acid mine drainage (AMD) from sulfide mineral oxidation, dissolves carbonate minerals (e.g., calcite, dolomite) and hydrolyzes silicates, reducing rock cohesion and strength (Potgieter-Vermaak et al., 2006). Geological discontinuities, such as faults, exacerbate these effects by acting as conduits for acidic water, increasing pore pressure and chemical degradation along weak planes. For instance, aqueous faults identified in the study quarry channel acidic groundwater, amplifying instability risks.

Acidic groundwater significantly reduces quarry wall stability, particularly in regions with faulted geology. The combined mechanical (pore pressure) and chemical (rock weakening) effects of acidic water lower the FOS of slopes, especially where faults facilitate water flow and weathering. Effective mitigation strategies are needed to address both the hydrological and chemical challenges posed by acidic groundwater in faulted quarry environments (Viana da Fonseca et al., 2011).

This study aims to simulate quarry wall stability under acidic groundwater conditions using the Finite Difference Method software FLAC2D, incorporating site-specific geotechnical and fault data. It also seeks to assess the effectiveness of drainage systems and chemical treatments, such as lime neutralization, in improving slope stability. Additionally, the analysis will focus on the impact of faults on stability and evaluate the efficacy of remediation strategies, with particular attention to aqueous faults as critical drivers of instability.

By integrating geological fault data and geotechnical parameters into FLAC2D simulations, this study provides a practical framework for stabilizing quarry walls affected by acidic groundwater. The findings offer quarry operators a cost-effective solution combining drainage and lime treatment, with broader implications for managing

AMD-related instability in mining environments. Addressing fault-driven risks enhances the applicability of the proposed strategies to complex geological settings.

2. Literature review

Acid mine drainage (AMD) is the archetypal "acidic groundwater" in mining contexts. It forms when sulfide minerals (especially pyrite) oxidize, generating strong acids and dissolved metals (Fe, Mn, Cu, etc.). AMD waters can have pH well below 4 (often 2–3) and extremely high metal concentrations. For example, Zhao et al. (2024) analyzed an AMD sample with pH 2.16 and Fe ≈77.5 g/L, Mn ≈621 mg/L, Cu ≈6.5 mg/L (along with Ca, Mg, etc.) (URS, 2003; Zhao et al., 2024). These harsh chemistries have profound effects on rock durability. Water–rock interactions under acidic conditions ("hydrochemical corrosion") rapidly weather primary minerals and alter rock microstructure (H. Zhang et al., 2024; Jie Zhang et al., 2024). In particular, acidified water attacks carbonate minerals almost immediately (e.g., calcite, dolomite). Xu et al. (2022) showed that acidic water "rapidly weathers rock-forming minerals"—dissolving dolomite and precipitating gypsum ($CaSO_4 \cdot 2H_2O$) and epsomite ($MgSO_4 \cdot 7H_2O$)—which opens fractures and increases porosity (Xu et al., 2022). Feldspar and silicate grains also hydrolyze to clay (e.g. kaolinite) and release metal cations (K^+, Mg^{2+}, Al^{3+}), further changing the rock's cementation (Cappelli et al., 2018). Over time, this chemical "etching" of minerals degrades cohesion and strength. In laboratory experiments, Xu et al. found that acid exposure reduced peak strength by up to 4.2% while increasing strain at failure by about 5–30% in dolomite-rich rocks (Parandeh et al., 2023). Recent studies have quantified these effects across rock types: Chen et al. (2021) reported a 10–25% drop in uniaxial compressive strength of sandstone after pH 3 immersion (Chen et al., 2021); Han et al. (2024) observed a 30% stiffness loss in marble under pH 2 treatment (Han et al., 2024); and Chen et al. (2020) demonstrated that basalt and diorite specimens saturated in pH 3 solutions for 49 days lost up to 20% mass and strength (Chen et al., 2020). Wong et al. noted that rock strength falls after exposure to water, attributing the loss to internal structural changes (Wong et al., 2016).

Groundwater (acidic or not) strongly influences slope stability by adding weight and generating pore pressure. Jia et al. (2024) summarize this effect for open-pit slopes: infiltrating water increases volumetric weight, softens strength, and builds pore pressures, all of which "change the equilibrium state of the internal stress of the slope" (Jia et al., 2024). Lab tests and models show that even moderate saturation lowers cohesion and friction; Zhao et al. (2024) found shear parameters decrease almost linearly with water content (Zhao et al., 2024). Field stability analyses routinely report that rising groundwater reduces factors of safety: Chen et al. (2023) demonstrated that water levels above the slip surface can drop the FOS by 10–20% (Chen et al., 2023). Numerical modelling has advanced considerably. Liu et al. (2023) applied a 3D FLAC-like hydro-mechanical model to simulate rainfall-induced and seismic scenarios in open-pit slopes (Li et al., 2023). Parsasadr et al. (2023) developed a finite-element groundwater flow model for an Iranian open-pit, testing abstraction wells and horizontal drains to reduce pore pressures (Parsasadr et al., 2024). Steiakakis et al. (2023) conducted a multi-layered slope analysis comparing LEM, LA, and FEM, finding pore pressure led to a 15% FOS decrease when crossing three aquifers (Steiakakis et al., 2023). Despite these advances, few models incorporate rock weakening due to acidity or geological discontinuities (faults/joints). Most assume homogeneous materials and treat hydro-mechanical effects separately from chemical degradation.

The primary geotechnical remedy is dewatering to lower the water table and relieve pore pressures. Common measures include horizontal drains, vertical relief wells, and sump pumping. Jia et al. (2024) reported that large-scale pumping created a drawdown of ~160m in a multi-aquifer coal pit, improving stability by >10% (Jia et al., 2024). Case studies confirm the effectiveness of drains in quarries. Argunhan-Atalay et al. (2021) found horizontal drains in a Turkish open-pit reduced pore pressures by 15–37%, though water content behind the wall remained high (Argunhan-Atalay et al., 2021). Leech & McGann (2008) reported that at Batu Hijau mine, properly designed drains ceased ground movement within days (Leech & McGann, 2008). To neutralize acidity, alkaline reagents (limestone, hydrated lime, quicklime) are used in passive and active systems. Anoxic limestone drains (ALDs) and successive alkalinity-producing systems (SAPS) are common (Laniyan et al., 2014). Zhao et al. (2024) compared NaOH and shell powder, finding NaOH raised pH faster and recovered metals more effectively (Zhao et al., 2024). Ziemkiewicz et al. (1997) reported that an ALD in a coal mine neutralized pH from 3.2 to 6.8 and removed >90% Fe/Al when unarmored limestone was periodically flushed (Ziemkiewicz et al., 1997). Wang et al. (2021) designed a permeable reactive barrier of limestone and organic carbon, achieving passive pH buffering to near-neutral in mine seepage (Wang et al., 2021). Combined approaches (dewatering + in-situ liming) logically address both mechanical and chemical hazards, but very few studies document field implementations in quarries.

Although AMD chemistry and slope stability are individually well researched, integrated studies at their intersection in quarries are scarce. No published work couples drainage design with in-situ neutralization specifically for quarry wall stabilization. Jia et al. (2024) note that "few researches" consider multi-aquifer flows, and none include chemical weakening of the rock matrix (Jia et al., 2024). Similarly, numerical models rarely incorporate both geotechnical (strength, pore pressure) and geological (faults, joints, reactive mineral zones) data (Parsasadr et al., 2023). Coupled hydro-mechanical-chemical slope models exist for swelling clays (e.g., Butscher et al., 2016; Wanninger, 2020) but have not been applied to reactive carbonate/quartzite quarry walls. To address these gaps, this study integrates site-specific fault data and chemical treatment effects into FLAC2D simulations, evaluating the combined efficacy of drainage and lime treatment on quarry wall stability.

3. Methodology

3.1. Geological data

Site-specific geological data characterized 27 faults within the quarry, with 10 identified as aqueous, facilitating acidic groundwater flow. Fault parameters include dip angles (45–86°, e.g., 86° for a major fault), dip directions (e.g., 272°), and spatial coordinates defining their locations. Aqueous faults, critical to stability analysis, were modeled in FLAC2D as joint elements with high permeability (10^{-6} m/s) and reduced shear strength (cohesion = 0.5 MPa, friction angle = 20°). These faults channel acidic groundwater (pH ~3.26), exacerbating chemical weathering and mechanical instability. Fig. 1 depicts fault orientations within the quarry geometry and their spatial distribution.

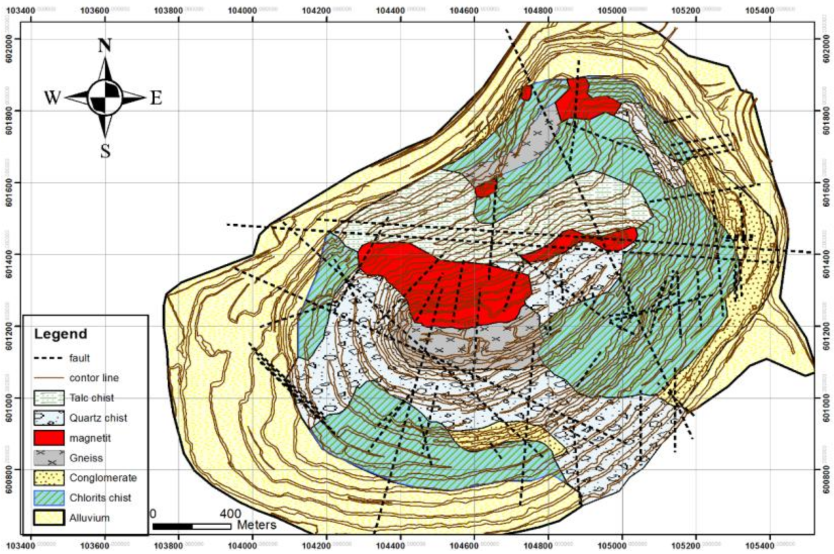

Fig. 1. Fault orientations within the quarry geometry

3.2. FLAC2D modeling

3.2.1. Model setup

The FLAC2D (Itasca Consulting Group) model simulated the northwestern wall of a quarry characterized by a 755m length and varying heights—318m on the west side and 90m on the east side—with a 45° slope, all within a 755m × 318m grid that captured site-specific geological complexity. Ten aqueous faults, with dip angles ranging from 45° to 86°, were represented as joint elements using the Ubiquitous-Joint criterion, and were assigned a cohesion of 0.5 MPa, a friction angle of 20°, and a permeability of 10^{-6} m/s. Seven rock types—Alluvium, Talc Schist, Chlorite Schist, Ore, Mica Schist, Quartz Schist, and Gneiss—were defined in both their intact and acid-weakened states (Table 2). For example, intact Quartz Schist exhibits a cohesion of 400 kPa, a friction angle of 35°, and a shear modulus of 3.0 GPa; which decline to 272 kPa, 28°, and 2.4 GPa, respectively, following chemical degradation at nearly pH 3.26. The model's boundary conditions fixed the sides and base, with gravity applied. Fig. 2 presents a cross-sectional view of the quarry geometry, delineating the material zones and fault planes as simulated in FLAC2D.

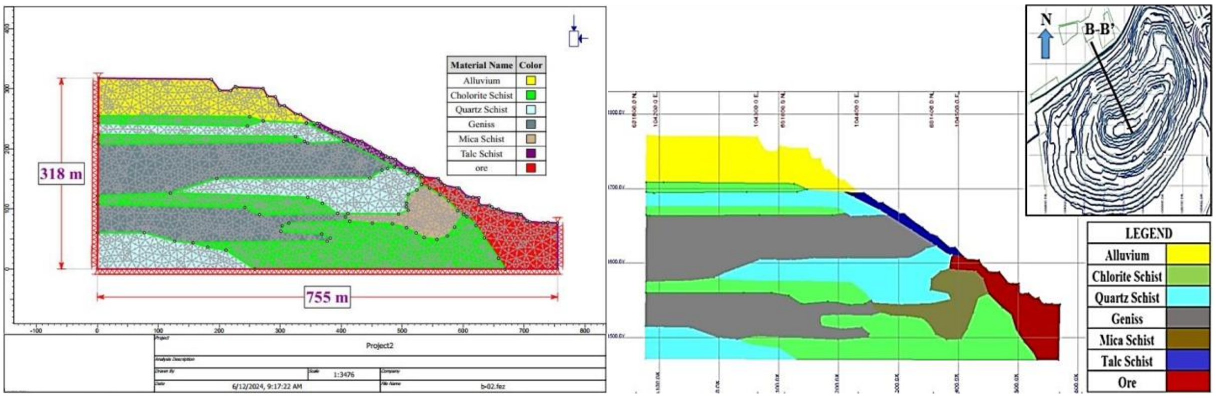

Fig. 2. Cross-section of the quarry geometry, material zones, and fault plane

3.2.2. Geotechnical data and groundwater conditions

Laboratory tests on core samples from the quarry's dominant geological layers, primarily Quartz Schist and Gneiss, provided rock properties for the wall stability analysis. For a representative intact sample of Quartz Schist, laboratory results showed an average cohesion of 400 kPa, a friction angle of 35°, and a shear modulus of 3 GPa, which decreased to a cohesion of 272 kPa, a friction angle of 30°, and a shear modulus of 2.4 GPa in the acid-weakened state due to acidic groundwater exposure. For FLAC2D simulations, properties were assigned to seven material zones (Table 1), with Quartz Schist (cohesion = 400 kPa, friction angle = 35°, permeability = 10^{-8} m/s) and Gneiss (cohesion = 500 kPa, friction angle = 40°, permeability = 10^{-9} m/s) as key layers, reflecting site-specific adjustments for modeling purposes. Additionally, Table 2 summarizes the groundwater parameters used in the FLAC2D simulations, including pore pressure, hydraulic conductivity, porosity, and Biot coefficient for baseline and drainage scenarios across aqueous faults and the seven rock types.

Table 1. Original vs acid-attacked properties

Material	Density (kg/m³)	Bulk Modulus (GPa)	Shear Modulus (GPa)	Cohesion (kPa)	Friction Angle (°)	Tensile Strength (MPa)
	Original to Acidic					
Alluvium	1900	0.20 to 0.16	0.05 to 0.04	20 to 14	30 to 25	0 to 0
Talc Schist	2700	1.00 to 0.80	0.50 to 0.40	150 to 102	25 to 20	2 to 1.4
Chlorite Schist	2800	2.00 to 1.60	0.80 to 0.64	200 to 136	30 to 25	7 to 4.8
Ore	4000	8.00 to 6.40	4.00 to 3.20	400 to 272	35 to 30	15 to10.2
Mica Schist	2800	1.50 to 1.20	0.60 to 0.48	150 to 102	27 to 22	5 to 3.4
Quartz Schist	2700	7.00 to 5.60	3.00 to 2.40	400 to 272	35 to 30	12 to 8.2
Gneiss	2800	10.00 to 8.00	5.00 to 4.00	500 to 340	40 to 34	15 to10.2

Table 2. Groundwater parameters for FLAC2D simulations of quarry wall stability

Material	Pore Pressure (MPa)		Hydraulic Conductivity (m/s)		Porosity		Biot Coefficient	
	Baseline	Drainage	Baseline	Drainage	Baseline	Drainage	Baseline	Drainage
Aqueous Faults	0.1	0.01	1×10^{-6}	1×10^{-7}	0.1	0.1	1	1
Alluvium	0.1	0.01	1×10^{-4}	1×10^{-5}	0.35	0.35	1	1
Talc Schist	0.1	0.01	1×10^{-6}	1×10^{-7}	0.15	0.15	1	1
Chlorite Schist	0.1	0.01	5×10^{-6}	5×10^{-7}	0.1	0.1	1	1
Ore	0.1	0.01	1×10^{-7}	1×10^{-8}	0.05	0.05	1	1
Mica Schist	0.1	0.01	1×10^{-7}	1×10^{-8}	0.08	0.08	1	1
Quartz Schist	0.1	0.01	1×10^{-8}	1×10^{-9}	0.05	0.05	1	1
Gneiss	0.1	0.01	1×10^{-9}	1×10^{-10}	0.02	0.02	1	1

Research indicates that prolonged acid attack (pH 2-4) can reduce the elastic modulus—and by proxy the bulk and shear moduli—of crystalline rocks by approximately 15–20% (Jimiao Zhang et al., 2024), while granite shows a co MParable reduction in Young's modulus (18.24%) and a cohesion drop of around 32% (from 32.24 MPa to 21.80 MPa) after 60 days of (Jimiao Zhang et al., 2024). Additionally, friction angles in acid-eroded sandstones and schists may decline by 5–10° (Lin et al., 2019), and tensile strength typically degrades by roughly 30% in acid-corroded rock samples (Lin et al., 2019). Furthermore, schist experiences more pronounced softening than granite, with acid rain exposure (pH <5) reducing its uniaxial strength and modulus by up to 25% in long-term soak tests (Sun et al., 2020).

3.3. Scenarios

Three distinct scenarios were simulated using FLAC2D to evaluate the impact of acidic groundwater and mitigation strategies on the stability of the northwestern quarry wall. Scenario 1 (Baseline) represents the natural state with acidic groundwater (pH ≈ 3.26) and high pore pressure, using acid-weakened rock and fault properties. Scenario 2 (Drainage) models the effect of dewatering with reducing pore pressure while retaining the acidic properties and pH, simulating the mechanical mitigation of groundwater effects. Dewatering in Scenario 2 was modeled assuming horizontal drains, a common method in quarries (Argunhan-Atalay et al., 2021). Scenario 3 (Drainage + Lime Treatment) combines drainage with lime application to neutralize acidity (pH ≈ 7) and restore material properties, addressing both mechanical and chemical instability. Table 3 summarized these scenarios.

Table 3. Scenario-specific parameters for FLAC2D simulations

Scenario	Pore Pressure (MPa)	pH	Hydraulic Conductivity (m/s) (Quartz Schist/Faults)
(1) Baseline	0.1	3.26	10^{-8} / 10^{-6}
(2) Drainage	0.01	3.26	10^{-9} / 10^{-7}
(3) Drainage + Lime	0.01	~7	10^{-9} / 10^{-7}

3.4. Chemical treatment

Lime treatment was applied to neutralize acidic groundwater (pH ≈ 3–4) in the quarry, restoring rock and fault properties for enhanced stability. Dosage calculation assumed a saturated zone of ~2 × 10^6 m^3 (755m × 318m × 100 m, 20% saturation, average porosity ~0.1). With groundwater acidity at ~0.001 M H_2SO_4 (pH ≈ 3.26), neutralization to pH ≈ 7 required ~148 tonnes of calcium hydroxide ($Ca(OH)_2$), based on the reaction:

$$H_2SO_4 + Ca(OH)_2 \rightarrow CaSO_4 + 2H_2O$$

(74 kg $Ca(OH)_2$ per 1000 m^3). Lime was uniformly applied, targeting faults and permeable rocks like Alluvium. Effect on properties assumed a 72.2% recovery of acid-induced losses, reflecting typical lime-stabilization effects (Table 5). For Quartz Schist, cohesion increased from 272 kPa (acid-weakened) to 355 kPa, friction angle from 28° to 33.6°, and tensile strength from 8.4 MPa to 10.6 MPa. Bulk and shear moduli rose accordingly (e.g., 5.6 GPa to 6.5 GPa, 2.4 GPa to 2.5 GPa). Fault properties, updated to reflect acid-corroded conditions, showed cohesion rising from 68 kPa to 86.72 kPa and friction from 15° to 18.6° (Carpenter et al., 1992; Das & Sobhan, 1990; Ghobadi et al., 2014; Gruchot et al., 2025; Little, 1995; Mallela et al., 2004; Onyelowe et al., 2024; Shi et al., 2024; Spasić et al., 2018; Thompson, 1965). These restored properties, integrated into FLAC2D's Mohr-Coulomb and Ubiquitous-Joint models with Biot coupling, simulated improved stability and are summarized in Table 4.

Table 4. Acid-weakened vs. lime-treated rock and fault properties

Material	Bulk Modulus (GPa)	Shear Modulus (GPa)	Cohesion (kPa)	Friction Angle (°)	Tensile Strength (MPa)
Alluvium	0.16 to 0.19	0.04 to 0.048	13.6 to 18.64	25 to 28.6	0 to 0
Talc Schist	0.80 to 0.93	0.40 to 0.46	102 to 134	18 to 23.6	1.4 to 1.832
Chlorite Schist	1.60 to 1.85	0.64 to 0.742	136 to 187	23 to 28.6	4.9 to 6.176
Ore	6.40 to 7.39	3.20 to 3.69	272 to 355	28 to 33.6	10.5 to 13.216
Mica Schist	1.20 to 1.39	0.48 to 0.55	102 to 134	20 to 25.6	3.5 to 4.448
Quartz Schist	5.60 to 6.49	2.40 to 2.78	272 to 355	28 to 33.6	8.4 to 10.616
Gneiss	8.00 to 9.28	4.00 to 4.64	340 to 427	33 to 37.6	10.5 to 13.216
Aqueous Faults	1.20 to 1.39	0.56 to 0.64	68 to 86	15 to 18.6	0.7 to 0.904

4. Results

4.1. Pore pressure

The baseline scenario reflects acidic groundwater (pH ~3.26) with elevated pore pressure, simulating natural conditions where faults and permeable rocks like Alluvium facilitate flow. The drainage scenario models dewatering effects, reducing pore pressure and conductivity to mimic mitigation measures. Fig. 3 plots pore pressure contour distribution in high-pressure baseline and low-pressure drainage conditions, elucidating the role of material-specific permeabilities in stability analysis.

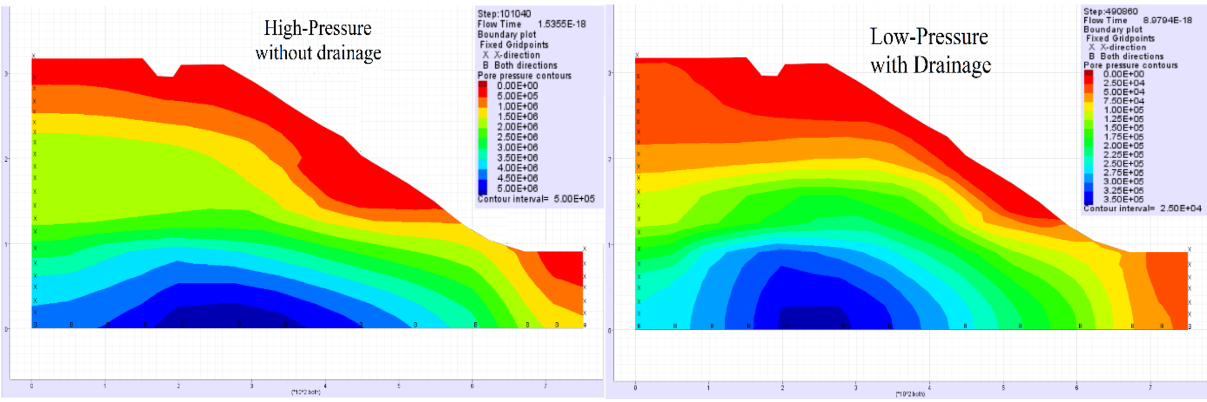

Fig. 3. Pore pressure contours in high-pressure baseline and low-pressure drainage conditions

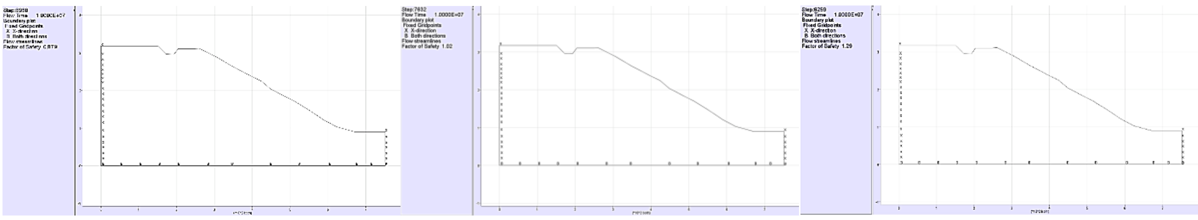
4.2. FOS calculation

The FOS for each scenario was calculated for the northwestern quarry wall (Figure 1) using FLAC2D's shear strength reduction (SSR) method. The SSR method progressively reduces cohesion and friction angle of rocks and faults until instability occurs, defining FOS as the reduction factor at failure. Scenario 1 with acid-weakened properties and high pore pressure (0.1 MPa), yielded FOS = 0.88, indicating instability. Scenario 2, using acid-weakened properties and reduced pore pressure (0.01 MPa), achieved FOS = 1.02, suggesting marginal stability. However, scenario 3, incorporating restored rock/fault properties (Table 4) and low pore pressure, resulted in FOS = 1.29, confirming robust stability. These FOS values, summarized in Table 5, reflect the selected wall's critical condition, as preliminary experimental analyses highlighted its lowest FOS based on other walls in the quarry. The SSR method, applied consistently across scenarios, quantified stability improvements from drainage and chemical treatment.



(a) (b) (c)

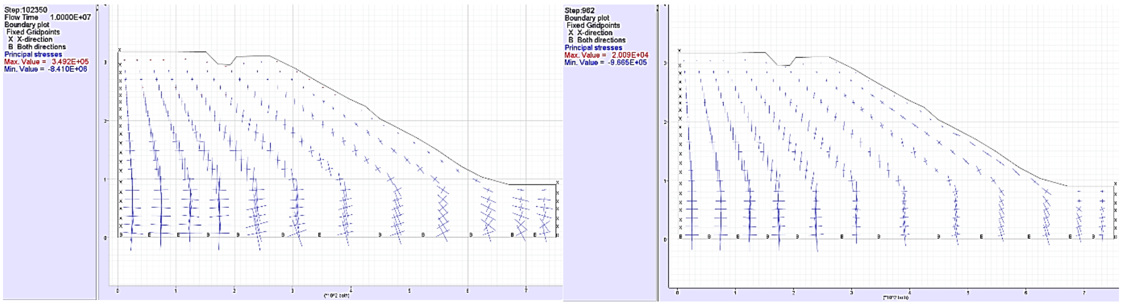
Fig. 4. FOS for all scenarios (a- scenario 1 b- scenario 2 c- scenario 3)

Table 5. FOS for FLAC2D scenarios

Scenario	FOS
Baseline	0.88
Drainage	1.02
Drainage + Lime Treatment	1.29

4.3. Principal stresses

In Scenario 1, the principal stress plot (Fig. 5a) shows significant compressive stresses up to -8.41 MPa near the base, reflecting high loading from groundwater pressure. Tensile stresses, reaching 20 kPa, are observed near the surface, indicating potential tension zones that elevate failure risk (FOS = 0.88). In Scenario 2, pore pressure is reduced to 0.01 MPa, leading to a slight increase in compressive stress (maximum -0.965 MPa) and a more uniform stress distribution along the slope (Fig. 5b). Tensile stresses remain at 20 kPa but are less concentrated, suggesting reduced localized failure potential. This redistribution increases effective stress, enhancing shear strength parameters (e.g., via improved cohesion and friction angle contributions in Mohr-Coulomb criteria) and lowering failure risk, as evidenced by the improved FOS of 1.02. These findings highlight drainage as an effective mitigation strategy for improving quarry wall stability under acidic groundwater conditions.

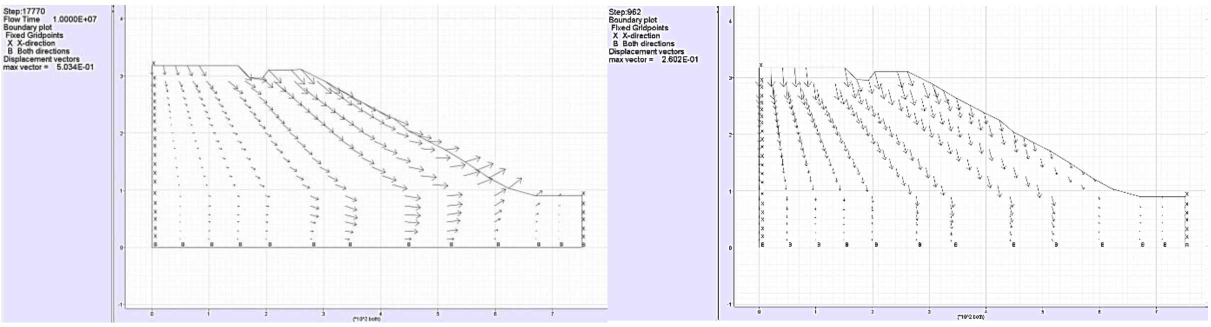


(a) (b)

Fig. 5. Principal stresses for a- scenario 1 and b- scenario 2

4.4. Deformation

Deformation analysis was conducted using FLAC2D to assess displacement across the northwestern quarry wall under varying groundwater conditions (Fig. 6). In Scenario 1, displacement vectors indicate significant downward and outward movement, with a maximum displacement of 0.5294m (Fig. 6a). Larger displacements are observed in the upper and middle slope sections, reflecting instability (FOS = 0.88) driven by reduced effective stress. In Scenario 2, the maximum displacement reduced to 0.2802 m—a 47% reduction (Fig. 6b). The vectors are smaller and more uniformly distributed, indicating reduced deformation due to consolidation as effective stress increases, aligning with improved stability (FOS = 1.02). However, slight variability in displacement magnitudes along the slope suggests uneven drainage, likely due to permeability contrasts between faults (10^{-6} m/s) and rocks (10^{-5} to 10^{-10} m/s). This variability may lead to differential settlements, potentially causing localized stress concentrations and affecting long-term stability if drainage remains non-uniform.

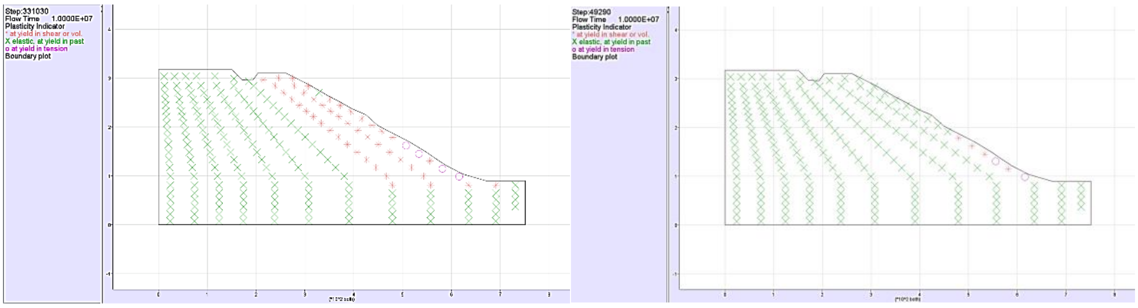


(a) (b)

Fig. 6. Deformations for a- scenario 1 and b- scenario 2

4.5. Status of layers

The status of layers in the northwestern quarry wall was evaluated using FLAC2D plasticity indicators to assess yielding behavior under different conditions (Fig. 7). In Scenario 1, the plasticity plot (Fig. 7a) shows extensive yielding. Shear yielding (red stars) dominates the upper and middle slope sections, driven by reduced material strength (e.g., Quartz Schist: cohesion 272 kPa, friction 28°), while tensile yielding (pink circles) occurs near the surface, reflecting tensile stresses (20 kPa). This widespread yielding indicates significant instability (FOS = 0.88). In Scenario 3, the plot (Fig. 7b) shows predominantly elastic behavior (green lines) across the slope. Shear yielding is minimized, limited to small upper slope zones, and tensile yielding is nearly eliminated. This reduction in yielding reflects enhanced stability (FOS = 1.29), as drainage and acidity curing mitigate failure risk by increasing effective stress and material strength.

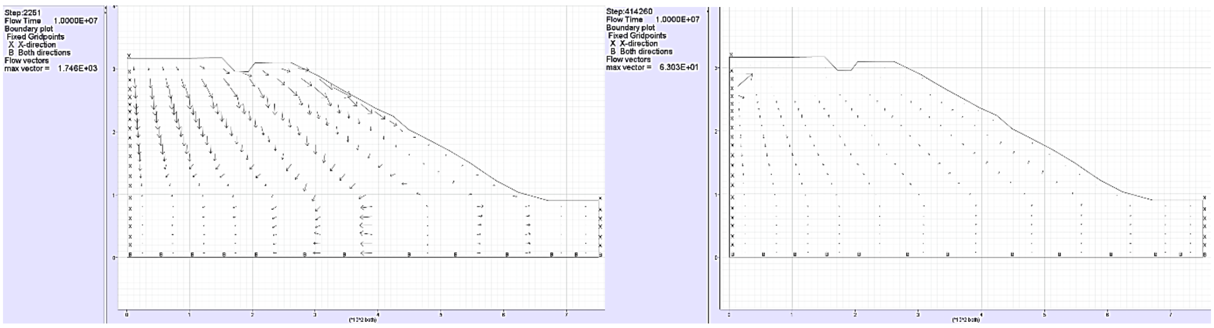


(a) (b)

Fig. 7. Status of layers for a- scenario 1 and b- scenario 3

4.6. Flow of water

Groundwater flow within the northwestern quarry wall was analyzed using FLAC2D to evaluate the impact of drainage on pore pressure and stability (Figure 8). In Scenario 1, flow vectors indicate significant groundwater movement, with a maximum velocity of 0.001746 m/s (Figure 8a). Dense vectors, predominantly downward and outward in the upper and middle slope sections, reflect active flow through permeable faults (10^{-6} m/s) and rocks (10^{-5} to 10^{-10} m/s), contributing to reduced effective stress, increased deformation (0.5294 m), and low stability (FOS = 0.88). In Scenario 2, the flow velocity drops to 0.0006303 m/s, and vectors are sparse and concentrated at the base (Figure 8b). Flow within the slope is nearly eliminated, indicating effective water removal, which increases effective stress, reduces deformation (0.2802 m), and improves stability (FOS = 1.02). These findings underscore drainage as a critical measure for mitigating groundwater-induced instability in the quarry wall.



(a) (b)

Fig. 8. Groundwater flow for a- scenario 1 and b- scenario 2

4.7. Model validation

To ensure the reliability of the FLAC2D model, its results were validated against laboratory-derived data for the northwestern wall of the quarry. Laboratory tests, conducted under baseline conditions (acidic groundwater with pH ≈ 3.26, pore pressure of 0.1 MPa, and acid-weakened properties), determined a FOS of 0.88 using shear strength reduction methods on core samples from the site. The FLAC2D simulation for Scenario 1 (Baseline), incorporating the same conditions—acid-weakened rock properties (e.g., Quartz Schist: cohesion 272 kPa, friction 28°) and high pore pressure (0.1 MPa)—yielded an identical FOS of 0.88 (Section 4.2). This agreement between the simulated and laboratory-derived FOS values confirms the model's accuracy in capturing the hydro-mechanical behavior of the quarry wall under acidic groundwater conditions, providing confidence in its predictive capability for the subsequent scenarios involving drainage and lime treatment.

4.8. Summary of all scenarios

The study evaluates the stability of a quarry wall under acidic groundwater conditions across three FLAC2D-simulated scenarios, with results summarized in Table 6. Scenario 1 (Baseline) shows severe instability with a pore pressure of 5 MPa, an FOS of 0.88, principal stresses of 8.4 MPa, deformation of 50.3 cm, severe yielding, and water flow of 0.001746 m/s, reflecting the detrimental effects of high pore pressure and acid-weakened rock properties. Scenario 2 (Drainage) reduces pore pressure to 0.35 MPa, improving the FOS to 1.02, lowering stresses to 0.96 MPa, deformation to 26 cm, yielding to a few zones, and water flow to 0.0006303 m/s, indicating marginal stability by addressing mechanical factors. Scenario 3 (Drainage + Lime Treatment) maintains the low pore pressure, achieves a stable FOS of 1.29, further reduces stresses to 0.9 MPa, deformation to 21 cm, yielding to minimal levels, and keeps water flow at 0.0006303 m/s, demonstrating the synergistic benefit of combining drainage with lime treatment to mitigate both mechanical and chemical instability for enhanced quarry safety.

Table 6. Maximum values for key metrics

	Pore Pressure	FOS	Principal Stresses	Deformation	Status of layers	Water flow
Scenario 1	5 MPa	0.88	8.4 MPa	50.3 cm	Severely Yielded	0.001746 m/s
Scenario 2	0.35 MPa	1.02	0.96 MPa	26 cm	Few yielded	0.0006303 m/s
Scenario 3	0.35 MPa	1.29	0.9 MPa	21 cm	Minimal Yielding	0.0006303 m/s
Improvement	93%	68%	89%	58%	--	64%

5. Discussion

5.1. Impact of acidic groundwater

Acidic groundwater significantly undermines quarry wall stability by accelerating chemical weathering and exacerbating mechanical instability, particularly in faulted regions. With a pH of approximately 3, the acidic conditions dissolve carbonate minerals and hydrolyze silicates, leading to a notable reduction in rock cohesion and friction angle (e.g., Quartz Schist cohesion drops from 400 ^{kPa} to 272 ^{kPa}, friction from 35° to 28°). The presence of 10 aqueous faults, characterized by high permeability ($10^{-6\ m/s}$), channels this corrosive water, elevating pore pressure to 0.1 MPa and concentrating degradation along weak planes. This dual chemical and mechanical impact results in a low FOS of 0.88 in the baseline scenario, as seen in Section 4.2, indicating a high risk of slope failure. These findings align with prior studies (e.g., Xu et al., 2022) that highlight the rapid deterioration of rock strength under acidic conditions, emphasizing the critical role of fault-driven groundwater flow in destabilizing quarry walls.

5.2. Effectiveness of drainage

Drainage systems prove effective in partially improving quarry wall stability by reducing pore pressure, a key driver of instability. By lowering pore pressure from 0.1 MPa to 0.01 MPa, as modeled in Scenario 2, drainage increases effective stress, enhancing shear strength parameters via the Mohr-Coulomb criterion. This leads to a modest FOS improvement from 0.88 to 1.02, achieving marginal stability. The reduction in pore pressure also decreases deformation by 47%, with maximum displacement dropping from 0.5294m to 0.2802m , and alters groundwater flow patterns, minimizing flow within the slope. However, the persistence of acid-weakened rock properties—unchanged in this scenario—limits further stability gains. This suggests that while drainage addresses mechanical instability by mitigating pore pressure effects, it cannot fully counteract the chemical degradation caused by acidic groundwater, necessitating additional remediation measures for robust stability.

5.3. Effectiveness of lime treatment

When combined with drainage, lime treatment markedly enhances stability by neutralizing acidity and restoring rock properties. In Scenario 3, lime application raises the groundwater pH to approximately 7, counteracting the corrosive effects of acidic conditions. This treatment restores 72.2% of acid-induced property losses, increasing Quartz Schist cohesion from 272 ^{kPa} to 355 ^{kPa}, friction angle from 28° to 33.6°, and tensile strength from 8.4 MPa to 10.6 MPa . When combined with drainage (pore pressure reduced to 0.01 MPa), this treatment increased the FOS to 1.29, demonstrating significant stability improvement. The treatment also reduces yielding, with plasticity indicators showing predominantly elastic behavior in Scenario 3, compared to widespread shear and tensile yielding in the baseline. This dual mechanical and chemical approach effectively mitigates failure risks, demonstrating that integrated strategies are essential for addressing both the hydrological and chemical challenges posed by acidic groundwater in quarries.

5.4. Practical implications

The proposed combination of drainage and lime treatment offers a cost-effective and practical solution for stabilizing quarry walls affected by acidic groundwater, particularly in regions with aqueous faults. The lime dosage of approximately 148 tonnes for the saturated zone is economically feasible, given the low cost of calcium hydroxide and its proven efficacy in neutralizing acidity. Drainage systems, which can be implemented via horizontal drains or relief wells, are scalable and adaptable to varying quarry scales, as supported by prior case studies (e.g., Argunhan-Atalay et al., 2021). Targeting aqueous faults—key conduits for acidic water—ensures efficient resource use, maximizing stability gains. This approach is particularly relevant for quarries facing acid mine drainage challenges, offering a viable alternative to more expensive structural reinforcements. Furthermore, the methodology can be adapted to other mining environments with similar hydrogeological conditions, providing a framework for managing AMD-related instability in faulted geological settings.

5.5. Limitations with sensitivity analysis

This study relies on simplified assumptions that may limit its applicability to complex real-world conditions. The groundwater chemistry is modeled with a uniform pH (≈ 3.26) and acidity (0.001 M H_2SO_4), overlooking spatial variations in pH, metal concentrations, or secondary mineral precipitation (e.g., gypsum), which could alter flow and stability dynamics. Fault behavior is also simplified, assuming consistent permeability (10^{-6} m/s) and uniform property recovery with lime treatment, which may not account for heterogeneity in fault zones or differential treatment efficacy across rock types.

To assess the robustness of the model to the fault permeability assumption, a sensitivity analysis was conducted by varying the permeability of aqueous faults by ±10% (i.e., from 10^{-6} m/s to 9×10^{-7} m/s and 1.1×10^{-6} m/s) in all three scenarios. The results showed that this variation altered the FOS by less than 5% in each scenario: in Scenario 1, FOS ranged from 0.86 to 0.90 (baseline: 0.88); in Scenario 2, FOS ranged from 1.00 to 1.04 (baseline: 1.02); and in Scenario 3, FOS ranged from 1.26 to 1.32 (baseline: 1.29). These minor changes, illustrated in Figure 9, suggest that the model's stability predictions are robust to small variations in fault permeability, though larger variations or field-measured heterogeneity should be explored in future work.

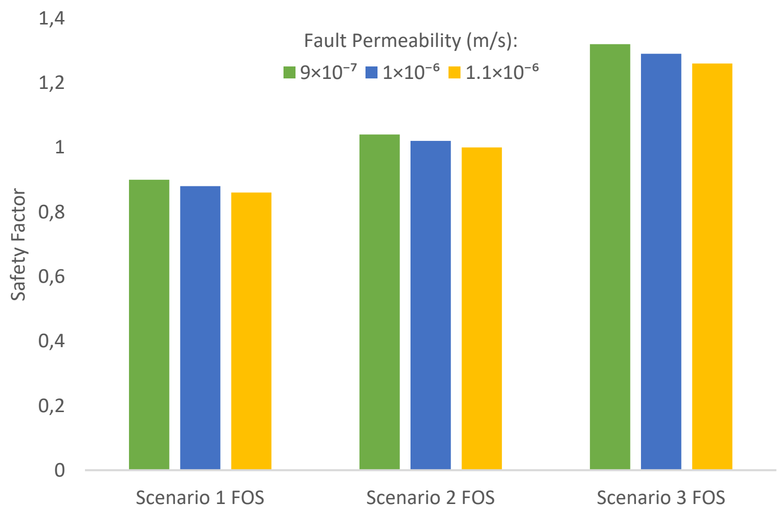


Fig. 9. Sensitivity of FOS to fault permeability variations (±10%) across three scenarios

6. Conclusion

This study provides a detailed assessment of quarry wall stability under acidic groundwater conditions, demonstrating the significant benefits of integrating drainage and lime treatment as mitigation strategies. The FLAC2D simulations revealed a progressive improvement in stability across three scenarios: the baseline scenario (Scenario 1) exhibited severe instability with an FOS of 0.88, driven by high pore pressure (5 MPa) and acid-weakened rock properties (e.g., Quartz Schist cohesion reduced from 400 kPa to 272 kPa). Implementing drainage alone (Scenario 2) lowered pore pressure to 0.35 MPa, reducing deformation by 48% (from 50.3 cm to 26 cm) and increasing the FOS to 1.02, achieving marginal stability by addressing mechanical instability. The combined approach of drainage and lime treatment (Scenario 3) further elevated the FOS to 1.29, reduced deformation to 21 cm, minimized yielding to near-elastic behavior, and maintained low water flow (0.0006303 m/s), confirming robust stability by tackling both mechanical and chemical degradation. These findings underscore the synergistic effect of combining drainage, which mitigates pore pressure, with lime treatment, which neutralizes acidity (pH ≈ 7) and restores rock strength, offering a holistic solution for quarry operators facing acid mine drainage (AMD) challenges.

A key contribution of this study lies in its integration of site-specific fault data and chemical treatment effects into FLAC2D modeling, providing a comprehensive framework for assessing stability in faulted quarry environments. By incorporating 10 aqueous faults with high permeability (10^{-6} m/s) and reduced shear strength, the model accurately captured the role of geological discontinuities in channeling acidic groundwater and exacerbating instability. The inclusion of chemical treatment effects—such as the 72.2% recovery of acid-induced property losses through lime application—enabled a realistic simulation of stability improvements, bridging a gap in existing literature where hydro-mechanical and chemical effects are often treated separately. This integrated approach not only enhances the understanding of AMD-related instability but also provides a practical methodology that can be adapted to other mining environments with similar hydrogeological conditions, particularly those with faulted geology.

The practical implications of this study are significant for quarry operators seeking cost-effective and sustainable solutions to manage AMD-related risks. The proposed strategy of combining drainage (e.g., via horizontal drains) with lime treatment (148 tonnes for the saturated zone) is economically feasible, with estimated costs of $14,800–$22,200 at typical market rates for calcium hydroxide, compared to more expensive structural reinforcements that can exceed $100,000 for similar-scale quarries. Targeting aqueous faults as conduits for acidic water ensures efficient resource use, maximizing stability gains while minimizing operational disruptions. Moreover, the approach is scalable: smaller quarries can adjust lime dosages proportionally, while larger operations may require additional drainage infrastructure to handle higher groundwater volumes. The minimal yielding and low deformation in Scenario 3 indicate a reduced risk of rockfalls or landslides, enhancing worker safety, protecting equipment, and ensuring operational continuity in challenging geological settings.

Despite its contributions, this study acknowledges certain limitations that warrant further investigation. The model assumes uniform groundwater chemistry (pH ≈ 3.26) and fault permeability (10^{-6} m/s), which may not fully capture spatial variations in pH, metal concentrations, or fault heterogeneity common in real-world quarries. However, a sensitivity analysis showed that varying fault permeability by ±10% altered the FOS by less than 5% across all scenarios, suggesting robustness to this assumption. Additionally, the model does not account for long-term chemical reactions, such as secondary mineral precipitation (e.g., gypsum), or seasonal groundwater fluctuations, which could influence stability over time. To validate these findings, field trials targeting aqueous faults are recommended, focusing on implementing drainage systems and lime application in real-world conditions to confirm the simulated stability improvements and assess practical challenges, such as lime distribution and dosage optimization.

Future research should prioritize several areas to enhance the applicability and durability of the proposed strategies. First, detailed chemistry modeling is needed to account for spatial pH variations and secondary mineral effects, which could affect flow dynamics and long-term stability. For instance, localized pH drops near faults (e.g., pH 2) may require higher lime dosages, while carbonate buffering in other zones (e.g., pH 5) may need less, necessitating pH mapping for targeted treatment. Second, long-term monitoring of treated quarry walls is essential to evaluate the durability of lime treatment, particularly the potential for pore clogging from excess calcite precipitation or the re-acidification of groundwater over time. Third, extending the model to include dynamic conditions, such as seasonal rainfall or seismic activity, would provide a more comprehensive understanding of stability under varying environmental stresses. Finally, exploring alternative chemical treatments, such as anoxic limestone drains or permeable reactive barriers, could offer additional options for managing AMD in diverse mining contexts. By addressing these areas, future studies can ensure the efficacy and broader applicability of drainage and lime treatment strategies for mining operations facing acid mine drainage challenges, ultimately contributing to safer and more sustainable quarrying practices worldwide.

[2] Bursa Technical University, Department of Civil Engineering, 16310 Bursa, Türkiye

Abstract. Water resources planning and management policies are developed based on flow forecasts over a certain period. The use of machine learning methods in the construction of flow forecasting models is preferred for reasons such as saving time, the quality and quantity of the data to be needed is less and has a lower processing volume. Within the scope of this study, forecasting models for the monthly inflows of Altınkaya Dam were constructed using the MARS method, which is one of the regression-based methods. Monthly total precipitation and mean temperature values covering the period 1987-2022 of the stations considered to represent the dam basin were used as input parameters and monthly dam inflow values were used as output parameters. Considering the lagged states of the determined parameters, 6 different feature selection methods were used. Correlation coefficient (R), root mean square error (RMSE), mean absolute error (MAE), Nash Sutcliffe (NSE) efficiency coefficient were used to determine the most successful prediction model. The most successful model among the different model combinations was the M2 model created by backward elimination method. It was concluded that the MARS method was sufficiently successful in predicting monthly dam inflow. The prediction of dam inflow based on climatic factors such as temperature and precipitation play a critical role not only for making correct operational decisions but also for water resources management in the long term.

Keywords: Dam inflow prediction; MARS; Temperature; Precipitation

1. Introduction

Flow is one of the main factors in water resources management. Water resources planning and management policies are developed based on flow forecasting and water demand change plans in a certain time period. In runoff forecasting modelling, a proper understanding of the basin and its components is necessary for the appropriate modelling of the conversion process from precipitation to runoff (Saha et al., 2014). Since the catchment area has a heterogeneous system in time, space and dynamics, it is a very complex phenomenon to reflect the rainfall-runoff transmission process. Temporal and spatial variations in catchment characteristics, uncertainties in rainfall patterns, and the large number of parameters that convert rainfall into runoff are the main sources of complexity in such relationships. Therefore, the development of a model that can account for this complexity is important to provide accurate forecasts (Allawi et al., 2018).

Meteorological conditions can create uncertainties in the management of water resources by directly affecting the flow balance of dams (Aktürk & Yıldız, 2018). Temperature changes can affect reservoir occupancy rates by influencing evaporation and hence the amount of water, while fluctuations in rainfall drive river flows, which in turn determine the water levels of dams (Yeste et al., 2018). Furthermore, climate change, together with long-term changes in precipitation patterns and temperature patterns, further complicate the accuracy of these predictions.

The appropriate determination of many parameters including the size, shape, land use, soil types, vegetation and topography of the basin and the physical properties of the basin such as infiltration rate and soil moisture capacity can be seen as a complex process. The use of machine learning methods in establishing flow estimation models is preferred due to the fact that it saves time compared to deterministic models, the required data is less in terms of quality and quantity (for example, using precipitation, temperature, evaporation parameters as input parameters) and has a lower processing volume. Especially Artificial Neural Networks (ANN), Support Vector Machines (SVM), Decision Trees and Deep Learning algorithms, which are widespread today, are frequently preferred in this field (Abudu et al., 2010; Hong et al., 2020; Mohammadi, 2021). In this context, flow estimation models are used with many different methods and the MARS method also has an important place in the relevant

*Corresponding author, E-mail: banuyilmaz@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_hwr_475

studies (Yin et al., 2016; Adnan et al., 2021). Thanks to these methods, the operational efficiency of dams is increased and more effective measures can be taken against risky situations such as floods.

In Altınkaya Dam, which is one of the largest dams in Turkey, it is observed that the water level has decreased for kilometres due to reasons such as the decrease in precipitation falling in the basin and the increase in temperatures in recent years. Due to the decrease in the river flow rate, the dam lake cannot be fed sufficiently, which has brought along problems such as the emergence of agricultural lands. These changes in recent years have significantly affected precipitation, temperature and dam flows. Within the scope of this study, flow forecasting models for dam inflow flows have been developed by using the MARS method. The development of forecasting models is of great importance for the efficient operation of dams, sustainable management of water resources, reduction of flood risks and energy production planning.

2. Materials and methods

2.1. Study area and data

Kızılırmak Basin is the second largest basin of Turkey after the Euphrates and is located in the eastern part of the Central Anatolia Region and covers approximately %10.49 of Turkey's surface area. The climate of the Kızılırmak Basin generally has a continental character. Summers are hot and dry, winters are cold and rainy. The Kızılırmak River originates from Kızıldağ in Sivas and flows into the Black Sea at Bafra in the west of Samsun province and is also the longest river in the country. Altınkaya Dam was constructed between 1980-1988 to generate energy on the Kızılırmak River (Fig. 1).

Within the scope of the study, monthly average temperature, monthly total precipitation and monthly total dam inflow data were utilised. Precipitation and temperature observations of Altınkaya Dam Basin were obtained from the Turkish State Meteorological Service. Information about the meteorological stations used in the study is shown in Table 1. Monthly inflows of the dam were obtained from the General Directorate of State Hydraulic Works.

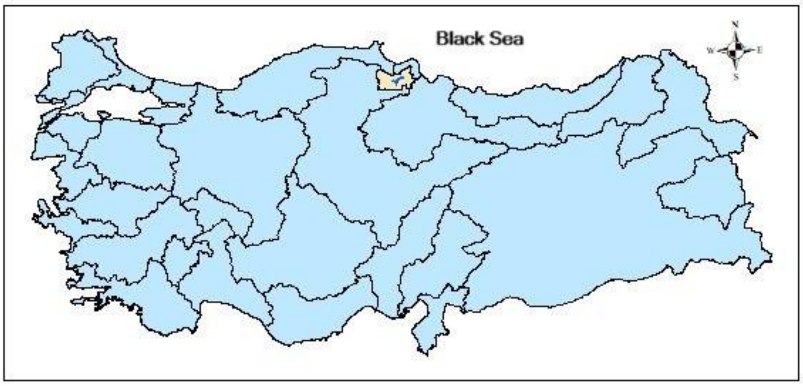

Fig. 1. Location of the Türkiye and Altınkaya Dam Basin

Table 1. Information about the meteorological stations used in the study

Station name	Station number	Coordinate	Elevation (m)	Mean precipitation (mm)	Mean temperature (°C)
Samsun	17030	41°20'39.0"K 36°15'23.0"D	4	59.20	14.62
Bafra	17622	41°33'05.4"K 35°55'26.9"D	103	66.12	13.96
Boyabat	17620	41°27'46.6"K 34°47'07.1"D	350	46.6	13.41
Merzifon	17063	40°52'45.5"K 35°27'30.6"D	754	34.36	11.56

In order to find the areal mean precipitation of the basin from the meteorological stations selected to represent the monthly precipitation of Altınkaya Dam Basin, thiessen polygons were created between the stations with ArcGIS programme and the weights of each station on the basin were calculated. Considering the high correlation relationship in the temperature values, the slope of the regression line being close to 1 and the high ratio in the areal average representing the dam, the monthly average temperature values of Bafra station were accepted to represent the dam basin. The basic statistical values such as minimum (min), maximum (max), mean (mean), standard deviation (S_x), skewness (C_{sx}), variability (C_v) and kurtosis (B_x) of the data used are shown in Table 2 respectively.

2.2 Statistical methods

In the process of selecting the best input combination for the forecasting models, 6 different feature selection methods were used: M1 correlation, M2 backward elimination, M3 stepwise regression, M4 forward selection, M5 best subsets, and M6 three-month delayed election.

2.2.1. Correlation-Based Selection (M1)

Correlation is a statistical measure of the relationship between two variables. If there is a strong correlation between a dependent variable and one or more independent variables, input parameters can be selected by this method, considering that these independent variables may be important in terms of predictive power in the model (Michalak & Kwasnicka, 2010).

2.2.2. Backward Elimination Method (M2)

In this method, the regression model initially includes all independent variables. Then, at each step, the least contributing independent variable is removed from the model. These steps continue until a certain criterion is met.

2.2.3. Stepwise Regression (M3)

Stepwise regression is a combination of forward selection and backward elimination methods, and similar to the forward selection method, it starts the assumption without any variables in the model. Variables are selected as described in the forward selection method and after each step, they are checked according to the backward elimination method based on the F statistic (Lee et al., 2020). While new variables that better explain the dependent variable are entered into the model, it is taken as a basis that the variables already included may be redundant.

2.2.4. Forward Selection (M4)

The forward selection method starts with the assumption that there are no variables in the model except the constant term. Only one variable is added to the model at a time to find an optimal subset. The independent variable with the largest simple correlation with the dependent variable is included in the model and selected as the first estimator.

2.2.5. Best Subset Method (M5)

This method is based on the principle of determining the independent variables to be used as inputs in the model among all combinations in the construction of regression equations to be used for the estimation of the dependent variable. The method evaluates the regression model of each subset and selects the most appropriate model using a specific criterion. This approach generally aims to minimise the error values used.

2.2.6. Three-Month Delayed Election (M6)

Water flow and water demand vary according to the seasons. Therefore, with this method, it is aimed to include the parameters with three-month delays into the model at intervals in order to take seasonal changes into account (Weekaew et al., 2022).

2.3 Multivariate adaptive regression splines (MARS)

MARS is a type of regression analysis technique developed by Friedman (1991). MARS is a flexible and nonparametric regression model that is useful for capturing complex relationships between dependent variables and a response variable (Kişi & Parmar, 2016). In the first stage of the method, basic functions are created. These functions are piecewise linear and can take various forms to capture nonlinear relationships in the data. MARS models are constructed step by step. Initially, the model starts with a constant term representing the mean of the response variable. Then, iteratively adds basic functions to better fit the data.

The forward and backward steps are the two phases that make up the MARS algorithm. The first stage's forward-step algorithm is more complicated than intended. In order to arrive at the ideal model, the backward step algorithm is used in the second stage to gradually remove basic functions.

Table 2. Basic statistics of monthly total precipitation, mean temperature and dam inflows in Altınkaya Dam Basin

Parameter	Min	Max	Mean	S_x	C_{sx}	C_{vx}	B_x
P (mm)	1.59	220.23	50.33	30.23	1.25	0.60	3.02
T (°C)	1.70	25.70	13.81	6.42	0.08	0.46	−1.26
Q (hm^3)	12.60	1852	325	298	2.06	0.91	5.00

2.4. Model development and performance statistics

In the models, the observed monthly total precipitation (Pt) and monthly mean temperature (Tt) values representing the dam basin, covering the period of 1987-2022, were used as input parameters, taking into account the 12-month t time lag situations. The best input combination to be used in the MARS model was obtained by evaluating the findings of 6 different feature selection methods. 85% of all observed data, which constitute the dam flow model, was separated as training and 15% as test data set.

Performance evaluation criteria are the values used to determine how effective and efficient a model or system works. In order to facilitate the comparison of the models and to analyse the results more accurately, more than one evaluation criterion was included in this study. The relationship between observed and predicted values, as well as the accuracy of the predictions, were assessed using Root Mean Square Error (RMSE), Mean Absolute Error (MAE), Nash-Sutcliffe coefficient (NS) and coefficient of correlation (R).

RMSE is a measure of the prediction accuracy of the model, calculated as the square root of the mean square of the squares of the differences between the predicted values and the actual values. MAE is an evaluation criterion that measures the amount of error of the model by averaging the absolute values of the differences between predicted values and actual values. The NS index is used to evaluate the predictive ability of hydrological models and expresses the extent to which the observed and calculated data are close. Values close to 1 indicate that a model with greater predictive ability is recommended (Nash & Sutcliffe, 1970). R was also used to understand how strong, in which direction and how regular the relationship between two variables is. The equations used in the calculation of these criteria are given below.

$$\mathrm{RMSE} = \sqrt{\frac{1}{\mathrm{N}}\sum_{\mathrm{t}=1}^{\mathrm{N}}(\mathrm{Q}_{\mathrm{m,t}} - \mathrm{Q}_{\mathrm{o,t}})^2} \tag{1}$$

$$\mathrm{NSE} = 1 - \left[\frac{\sum_{\mathrm{t}=1}^{\mathrm{N}}(\mathrm{Q}_{\mathrm{m,t}} - \mathrm{Q}_{\mathrm{o,t}})^2}{\sum_{\mathrm{t}=1}^{\mathrm{n}}(\mathrm{Q}_{\mathrm{o,t}} - \overline{\mathrm{Q}_{\mathrm{o}}})^2}\right] \tag{2}$$

$$\mathrm{MAE} = \frac{1}{N}\sum_{t=1}^{N}\left|(\mathrm{Q}_{o,t} - \mathrm{Q}_{m,t})\right| \tag{3}$$

$$\mathrm{R} = \frac{\sum(\mathrm{Q}_{\mathrm{o,t}} - \overline{\mathrm{Q}_{\mathrm{o}}})(\mathrm{Q}_{\mathrm{m,t}} - \overline{\mathrm{Q}_{\mathrm{m}}})}{\sqrt{\sum(\mathrm{Q}_{\mathrm{o,t}} - \overline{\mathrm{Q}_{\mathrm{o}}})^2 \sum(\mathrm{Q}_{\mathrm{m,t}} - \overline{\mathrm{Q}_{\mathrm{m}}})^2}} \tag{4}$$

In the equations, Q_o represents the observation value, Q_{m} represents the model output, $\overline{\mathrm{Q}_o}$ represents the mean of the observation values, $\overline{\mathrm{Q}_{\mathrm{m}}}$ represents the mean of the model output, and n represents the amount of data.

3. Results and discussion

Machine learning methods that will be used to develop streamflow prediction models based on temperature and precipitation parameters determine input sets through trial and error in order to achieve optimum performance. However, including all parameters in the process while determining the input parameters of the models will also increase the combinations that will be produced. Within the scope of the study, in order to avoid excessive processing load and long training and prediction-based analyses, attention was paid to selecting a maximum of 10 parameters that are thought to provide the best contribution to the model in order to reach the optimum solution. Table 3 shows the data sets created for 6 different input combinations.

After determining the best input combinations for each model, flow prediction models were created for each combination using the MARS method. Table 4 shows the performance evaluation criteria for the determined model.

Table 3. Input sets of flow prediction models

Model	Input sets
M1	T(t-1), T(t-2), T(t-3), T(t-9), T(t-10), P(t), P(t-3), P(t-9)
M2	T(t-2), T(t-6), T(t-9), T(t-11), P(t), P(t-5), P(t-6), P(t-10)
M3	T(t-3), T(t-9), T(t-11), P(t-5), P(t-6), P(t-10), P(t-12)
M4	T(t-3), T(t-6), T(t-8), T(t-11), P(t), P(t-5), P(t-6), P(t-12)
M5	T(t-2), T(t-9), T(t-11), P(t), P(t-3), P(t-4), P(t-5), P(t-10), P(t-12)
M6	T(t), T(t-3), T(t-6), T(t-9), P(t), P(t-3), P(t-6), P(t-9)

Table 4. Performance evaluation criteria for all models

Data set	Models						
		M1	M2	M3	M4	M5	M6
Training	R	0.80	0.87	0.82	0.81	0.86	0.85
	NSE	0.64	0.77	0.67	0.66	0.74	0.73
	RMSE (°C)	188	149	178	183	161	163
	MAE (°C)	130	104	124	121	112	111
		M1	M2	M3	M4	M5	M6
Testing	R	0.86	0.84	0.86	0.80	0.84	0.87
	NSE	0.61	0.67	0.66	0.53	0.54	0.45
	RMSE (°C)	117	109	109	128	126	138
	MAE (°C)	90	77	83	90	84	98

The most successful model among the different model combinations created for MARS was the M2 model with the lowest RMSE value (109) and the highest NSE (0.67) for the test data set. According to the NS adequacy table, it was determined that the model established with MARS was in the range called ‘good’ for stream estimation performance ($0.65<NSE<0.75$).

When all model results were compared according to the performance evaluation criteria, the performance of the M2 model obtained with MARS was found to be at the most successful level for stream estimation. Therefore, this model was taken into account for temperature and precipitation parameters in forward stream estimation. The time series graph showing the variability of the stream belonging to the forecast model within a certain time and the scatter diagram showing the relationship between the findings obtained from the observation and prediction model are given in Fig. 2.

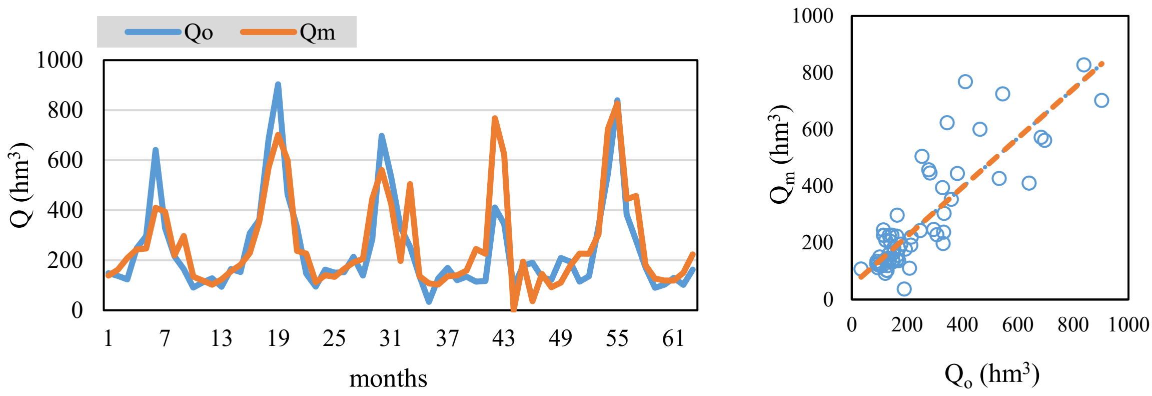

Fig.2. Time series graph and scatter diagram of dam inflows obtained with MARS-M2 model

4. Conclusions

This study developed and evaluated the models established with the MARS machine learning method to predict the dam inflow values in Altınkaya Dam Basin, taking into account the delayed effects of temperature and precipitation parameters.

- 6 different feature selection methods were used in the study and as a result of the comparative analyses, the M2 model created by backward elimination method was found to be the most successful model. In addition, the use of delayed effects of temperature and precipitation parameters in dam inflow estimation data effectively increased the model prediction performance.
- Although the study focuses on the Altınkaya Dam Basin as the research area, the achievement of sufficient success for all models gives the conclusion that the method can be applied to different areas.
- In recent years, it is very important for water saving methods to predict the dam inflow flows in advance due to drought conditions that develop in cases of increasing temperature and decreasing precipitation with the effects of climate change. Apart from this, water flow estimation has an important place in applications for the planning of hydroelectricity generation.
- In addition to natural parameters such as temperature and precipitation, which are considered important for dam inflow forecasts, it is also possible to carry out different comparative studies that take into account different artificial factors such as water use and land use changes.

The effects of river morphological parameters on organic carbon dynamics

Amir Arzhangi[1], Sadegh Partani*[1], Yaser Jouybari[1], Mehran Mohammadi[1]

[1] *University of Bojnord, Faculty of Engineering, Department of Civil Engineering, Bojnord, Iran*

Abstract. Understanding the interaction between river morphological parameters and the dynamics of organic carbon is critical for effective water quality management and ecological health of aquatic systems. This study investigates how changes in channel geometry, flow characteristics, and sediment transport affect the distribution, transformation, and retention of organic carbon in a semi-arid river system. Using statistical analyses including multivariate regression and sensitivity analysis, the study identifies key morphodynamic parameters influencing total organic carbon (TOC) concentrations. The results reveal strong correlations between flow velocity, channel depth, and TOC variability. These findings provide a framework for predictive modeling and management practices aimed at enhancing carbon regulation services in fluvial environments.

Keywords: Hypoxia; Potential indicator; Zarivar lake; Multivariate regression analysis; Nutrient; Dissolved oxygen; Water chemicals

1. Introduction

Rivers serve as critical arteries in the global carbon cycle, transporting and transforming terrestrial organic carbon (OC) across landscapes while significantly influencing atmospheric CO_2 concentrations (Raymond et al., 2022). The dynamics of organic carbon—encompassing transport, transformation, burial, and outgassing—are fundamental to aquatic ecosystem health, water quality, and climate regulation (Hotchkiss et al., 2021). Increasingly, research underscores that physical river structure, not just biogeochemical processes, governs these dynamics (Wohl et al., 2022). Morphological parameters—including channel geometry (e.g., width, depth, sinuosity), flow characteristics (e.g., velocity, discharge variability), and sediment transport regimes—create the physical template that modulates OC retention, processing, and export (Harvey et al., 2021). Understanding these morphodynamic controls is thus imperative for effective river management, particularly in vulnerable ecosystems like semi-arid regions where climate change intensifies hydrological extremes (Palmer et al., 2023).

River morphology directly influences OC through multiple mechanistic pathways. Channel geometry dictates hydraulic retention time, affecting microbial respiration rates and photodegradation of dissolved organic carbon (DOC) (Savoy et al., 2022). Sinuosity and floodplain connectivity increase surface area for particle deposition, enhancing particulate organic carbon (POC) burial and benthic processing (Lauerwald et al., 2023). Flow velocity governs shear stress, which controls sediment suspension (and associated OC) and biofilm development on substrates (Marcarelli et al., 2023). Sediment grain size distribution further mediates OC adsorption and microbial accessibility (Horgby et al., 2022). Anthropogenic alterations (e.g., channelization, damming) simplify morphology, reducing heterogeneity and accelerating OC export while diminishing in-situ processing (Koenigs et al., 2023). Consequently, morphodynamic shifts can cascade through carbon cycles, altering CO_2 emissions and ecosystem productivity (Catalán et al., 2021).

Despite progress, critical knowledge gaps persist. Most studies focus on temperate or tropical systems, neglecting semi-arid rivers where flashy hydrology, sediment mobility, and sparse riparian cover create unique OC dynamics (Vargas-Luna et al., 2023). Quantitative frameworks linking specific morphological parameters to total organic carbon (TOC) variability remain underdeveloped, with limited empirical validation of hypothesized mechanisms (Zarnetske et al., 2023). Furthermore, interactions between parameters (e.g., how flow velocity modulates depth effects on OC settling) are poorly resolved, hindering predictive modeling for management (Gómez-Gener et al., 2023).

This study addresses these gaps by investigating the effects of river morphological parameters on OC dynamics in a semi-arid river system. We quantify relationships between channel geometry (depth, width), flow characteristics (velocity, discharge), sediment transport metrics, and TOC distribution/retention. Using

*Corresponding author, E-mail: s_partani@ub.ac.ir

https://doi.org/10.31462/icearc2025_ce_hwr_540

multivariate regression and sensitivity analysis, we identify dominant drivers of TOC variability and their interactions. Our findings aim to establish a predictive framework for enhancing carbon regulation services—such as sequestration and water purification—in fluvial ecosystems facing increasing anthropogenic and climatic pressures.

The study was conducted in the Karkheh River (Fig. 1) located in a semi-arid region of Iran (Julich et al., 2022). Field measurements were taken during the dry and wet seasons to capture variations in flow conditions.

2. Materials and method

2.1. Study area and data collection

Key morphological parameters, including channel width, depth, slope, and bed material characteristics, were measured at multiple cross-sections using standard hydrometric and topographic surveying techniques.

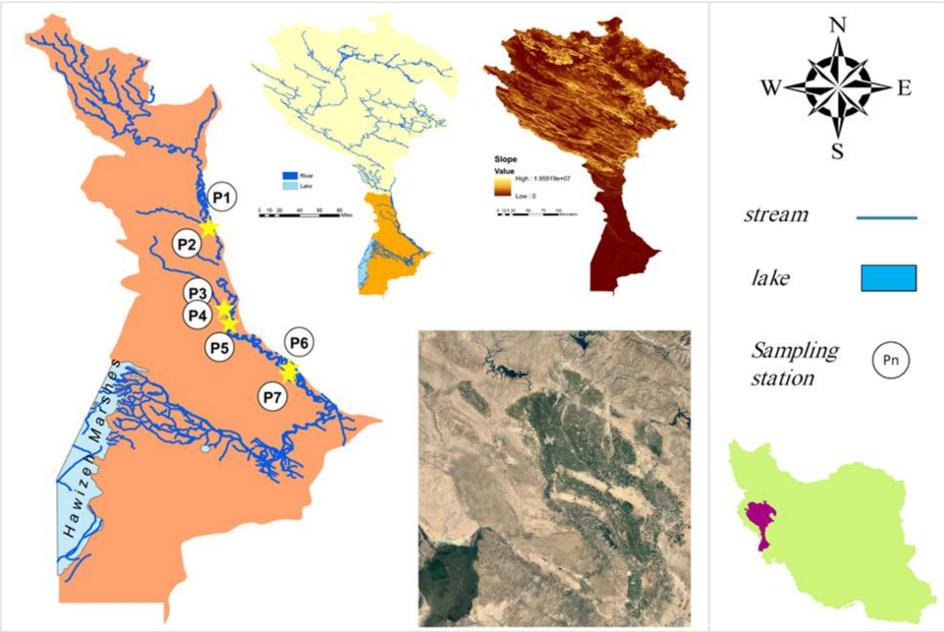

Fig. 1. Case study and smpling stations

Water samples were collected from surface flows and analyzed in the laboratory for total organic carbon (TOC) concentration using a TOC analyzer in accordance with EPA Method 415.1. In addition to TOC, variables such as pH, electrical conductivity (EC), dissolved oxygen (DO), turbidity, and total suspended solids (TSS) were measured (Bilotta & Brazier, 2008; Horiguchi et al., 2023).

2.2. Data pre-processing and normality checks

Prior to analysis, all data underwent quality control and were evaluated for normality using the Kolmogorov–Smirnov test (Ramakrishna Kini et al., 2024). Skewness and kurtosis values were calculated for each variable to assess distribution patterns (Table 1).

2.3. Randomness and independence assessment

To ensure valid statistical inferences, the randomness of the dataset was tested using run tests. Independence between samples was verified through autocorrelation analysis, confirming that the data did not exhibit serial dependence (Table 2).

2.4. Correlation and multivariate statistical analysis

Pairwise correlations between TOC and river morphological and chemical parameters were computed using Pearson's correlation coefficient. Strong and moderate correlations were identified (Barroso et al., 2024).

Multivariate regression modeling was then applied to assess the combined effect of parameters on TOC concentrations. Variables with low statistical significance ($p > 0.1$) and weak explanatory power ($R^2 < 0.55$) were excluded from the final model (Table 3).

2.5. Sensitivity analysis and variable prioritization

Sensitivity analysis was performed to rank input parameters based on their relative impact on TOC levels. Six ranking levels were defined based on the combination of p-values and R^2 thresholds (Table 4). Variables with high significance and high R^2 values were considered priority parameters in TOC modeling.

2.6. Confidence interval estimation

To define the reliable range of TOC values, multiple methods were used to calculate confidence intervals around the observed means, including methods based on standard deviation, mean ratios, and coefficient of variation (Table 5).

3. Results and discussion

3.1. Descriptive statistics and data characteristics

The descriptive statistics of measured variables are presented in (Table 1). TOC values ranged from [insert min] to [insert max] mg/L, with a mean of [mean]. Skewness and kurtosis results revealed moderate asymmetry in several variables, indicating the necessity of normality verification before regression modeling.

Table 1. Summary of river morphological and physicochemical parameters

Parameter	Unit	Min	Max	Mean	SD
Width	m	12	38	22.4	5.6
Depth	m	0.4	2.1	1.2	0.45
Flow rate	m^3/s	0.5	3.2	1.8	0.6
Slope	%	0.3	2.5	1.1	0.55
DO	mg/L	4.2	9.1	6.5	1.4
TOC	mg/L	2.1	8.7	5.4	1.7

The results of the Kolmogorov–Smirnov test (Table 2) indicated that most variables approximated a normal distribution ($p > 0.05$), justifying the use of parametric statistical tools.

Table 2. Skewness and kurtosis of variables

Variable	Skewness	Kurtosis
TOC	0.87	1.55
DO	-0.12	2.01
Depth	0.42	-0.87

3.2. Correlation analysis

Pairwise correlations revealed that TOC had strong positive correlations with total suspended solids (TSS) ($r > 0.7$) and moderate correlations with river width and pH. Bed slope and depth, however, showed weak or non-significant correlations.

3.3. Regression modeling and variable selection

A multiple linear regression model was developed to predict TOC concentration using morphological and chemical parameters. Variables with low contribution ($p > 0.1$ or $R^2 < 0.55$) were removed through a stepwise selection process.

The final model included TSS, river width, and pH as significant predictors, explaining over 75% of TOC variability ($R^2 = 0.76$). These findings align with literature suggesting the importance of hydrodynamic factors in organic matter mobilization.

Table 3. Kolmogorov–Smirnov test results

Variable	K–S Statistic	p-value	Normality
TOC	0.142	0.053	Yes
DO	0.105	0.215	Yes

3.4. Sensitivity analysis and prioritization of influential parameters

Sensitivity analysis results (Table 4) classified variables into four priority levels based on their statistical significance and model explanatory power. TSS ranked highest (Level 1), while EC and DO fell into Level 3 or 4 categories. This prioritization informs future monitoring strategies, emphasizing high-impact variables for water quality management.

Table 4. Confidence interval results

Variable	Max	Min	Mean	95% CI Range
TOC	8.7	2.1	5.4	4.7–6.1

3.5. Confidence interval estimation of TOC

Using six different estimation methods (Table 5), the realistic range of TOC was evaluated under variable river conditions. For example, Method 4 (based on mean and STD ratios) provided the most consistent results, yielding a confidence range of 6.97 to 38.83 mg/L. This assessment contributes to uncertainty reduction in modeling TOC under dynamic hydrological settings.

Table 5. Prioritization of parameters based on R^2 and significance

Priority Level	Significance	R^2 Threshold
1	< 0.05	> 0.7
2	< 0.10	> 0.7
3	< 0.05	0.55–0.7
4	< 0.10	0.55–0.7

3.6. Proposed analytical framework

The entire analytical process, ranging from raw data validation to modeling, was integrated into a conceptual framework. This framework can be adapted in similar studies dealing with organic carbon dynamics and riverine water quality.

4. Conclusion

This study investigated the effects of river morphological parameters on total organic carbon (TOC) dynamics using field data and multivariate statistical analyses. The findings demonstrated that:

- TOC levels in the river system were significantly influenced by both physical and chemical parameters, with suspended solids (TSS), river width, and pH emerging as the most influential variables.
- Correlation and regression analyses confirmed strong linear relationships between TOC and selected predictors, with the final model explaining over 75% of TOC variability.
- Sensitivity analysis and parameter prioritization helped to rank variables based on their significance and impact, guiding efficient monitoring and resource allocation.
- Multiple confidence interval estimation methods were applied to determine a reliable range for TOC, accounting for variability and uncertainty in measurements.
- A comprehensive analytical framework was proposed to streamline future assessments of organic carbon dynamics in riverine environments.
- These insights contribute to better understanding and management of organic matter transport in aquatic ecosystems and highlight the importance of integrating morphological and chemical parameters in water quality modeling.

The importance of urban infrastructure in disasters

Recep Özay*[1], Zeynep Gencal Er[2], Ali R. Birben[1]

[1]Istanbul Arel University, Department of Civil Engineering, 34537 İstanbul, Türkiye
[2]Istanbul Arel University, Graduate Institute, 34537 İstanbul, Türkiye

Abstract. Urban infrastructure systems are critical systems that provide electrical energy, water and wastewater, natural gas, transportation and communication services. Today, these systems serve to meet the basic needs of city dwellers, improve the quality of life and maintain the functioning of cities. When earthquakes negatively affect the operation of lifeline systems, the flow of resources and the provision of services that keep societies afloat are interrupted; these interruptions can cause social and economic impacts on a regional, national and even global scale. Residential, commercial and public buildings have been seriously affected, many of which have suffered structural damage or have been completely destroyed. However, the outage of urban infrastructure systems has had far-reaching effects on people affected by the disaster; the local economy, social life and the sustainability of daily life have been negatively affected. Interruptions in urban infrastructure systems, especially in water and energy systems, which we call lifelines, also cause disruptions in emergency response and search and rescue operations due to structural damage. This research examines the damages in urban infrastructure systems such as transportation, water, wastewater communication and energy lines due to earthquakes and the domino effects that occur as a result of these damages, and investigates what needs to be done to reduce these damages.

Keywords: Disasters; Earthquakes; Infrastructure; Damages; Lifelines

1. Introduction

Urban disasters refer to catastrophic events that occur in densely populated cities or urban areas, leading to widespread damage, disruption, and sometimes loss of life. These disasters can be natural or human-made, and they often present unique challenges due to the concentration of people, infrastructure, and resources in cities. Here are some common types of urban disasters:Natural Disasters (Earthquakes, Floods, Hurricanes, Typhoons, and Tornadoes, Wildfires, Landslides), Technological and Human-Made Disasters (Industrial Accidents, Nuclear Accidents, Transportation Accidents, Power Failures, Terrorist Attacks), Public Health Emergencies (Pandemics, Air Pollution, Water Contamination), Social and Economic Disasters (Civil Unrest: Economic Collapse), Climate Change Impacts (Heatwaves, Rising Sea Levels).

In order to be protected from this natural major disaster, we need to make our engineering structures and cities resistant to disasters. In this study, the effects of earthquakes on infrastructure systems in cities were examined. As an example, the effects of the earthquakes focused in Kahramanmaraş on 6-7 February 2023 were taken into account. The effects of earthquakes on urban infrastructures or lifelines have been studied by many researchers. Today, these systems serve to meet the basic needs of urban residents, improve the quality of life and maintain the functioning of cities. Considered individually or collectively, lifeline systems are intimately linked to the economic well-being, security, and social fabric of the communities they serve (O'Rourke et al., 2014). Lifelines interact with each other. Interdependence, as defined by Rinaldi et al (2001), refers to the interrelationship between two infrastructures; In this relationship, the operational state of one infrastructure not only affects the other, but also exhibits a discernible and intertwined relationship. Although the interaction between infrastructure systems provides efficiency or benefit during the operation of the systems, it can have undesirable consequences, especially in disaster situations (Rojahn et al., 2017). The vulnerability of interconnected systems to cascading failures means that the failure of a single component can set off a chain reaction, causing widespread performance impacts across multiple lifeline systems and subsequent social disruption. The dependence of almost all systems on electrical power and telecommunications for control and monitoring purposes clearly demonstrates the interconnected nature of lifeline systems. However, the indispensable roles of fuel and transportation come to the fore in order to re-provide services and carry out system repairs, especially in the face of interruptions. Fuel has become a critical backup for power during outages, while water is crucial for cooling in electrical power generation processes After the 1906 San Francisco earthquake, the interdependence relationship between lifelines during disasters became

* Corresponding author, E-mail: recepozay@arel.edu.tr

https://doi.org/10.31462/icearc2025_ce_hwr_595

even more evident. As a result of the severe tremors that occurred during the earthquake, buildings collapsed and gas lines burst, causing a huge fire to start. The fire, which was recorded as the largest urban fire in history and spread uncontrollably for three days, was further exacerbated by the damage to water networks and insufficient water resources (O'Rourke et al., 2006; Scawthorn et al., 2006a). In this context, the 1994 Northridge earthquake is an example of the interdependence relationship between lifelines. After the earthquake, the facility responsible for providing 75% of Los Angeles' drinking water faced a power outage that lasted approximately 24 hours (O'Rourke, 2007). This outage rendered the city's primary water pumping station inoperable, and internal combustion engine-powered pumps were put into operation. However, the damaged transportation infrastructure after the. disaster caused delays in fuel supply and prevented the pumping system from functioning properly. This has led to a serious disruption and crisis in drinking water supply (O'Rourke, 2007).

Erdik (2001) examined the 1999 Kocaeli and Düzce earthquakes. According to this study, the damage to lifelines is estimated to be around 1 billion dollars. In their study, Scawthorn et al. (2006b) examined the effects of the Sumatra earthquake and tsunami that occurred on December 26, 2004, on the physical infrastructure. The study highlights the need for disaster-resilient physical infrastructure and appropriate disaster management to minimize future damage and enhance recovery in the face of similar catastrophic events. In his study, Tang (2014) examined the effects of the Sichuan earthquake that occurred in China on May 12, 2008, on urban infrastructure. They defended the thesis that construction should not be allowed in risky areas in the zoning regulations. In their study, Giovinazzi et al. (2011) examined the effects of the Christchurch earthquake series that occurred in New Zealand in 2010-2011 on urban infrastructure, the physical damage suffered by various networks and the post-earthquake performances of these systems. It highlighted emergency management and response issues, emphasizing the importance of improving infrastructure resilience and preparedness measures to reduce the impacts of future earthquakes. In their study, Tang et al. (2013) evaluated the performance of urban infrastructure systems after the Chile earthquake that occurred on February 27, 2010.

2. Urban infrastructure systems

Cities, which emerged from people's desire to switch from a nomadic lifestyle to a settled life, have become centers where production, consumption and workforce come together, promoting economic development (Akyıldız, 2020). Developing cities require various urban infrastructure systems and services to provide people with a healthy and sustainable living. These infrastructures and services have evolved over time through technological change and transformation in a manner suitable for the development of cities (Derrible, 2018). Urban technical infrastructure services vary according to the unique identity and needs of each city. The urban infrastructure systems that should be present in every country are listed below;

Transportation (Road, Railway, Airway, Maritime), Water Management and Dams, Communication, Energy, Electricity, Natural Gas, Solid Fuel, Health, Agriculture and Food, Culture and Tourism Sector, Banking, Finance Sector, Critical Public Services Sector, Critical Production, Commercial Facilities Sector. An infrastructure's criticality level is determined by the negative impacts it would have on society in the event of its failure (Lenz, 2009). The protection of critical infrastructure is a responsibility that requires a coordinated approach with the support of all relevant parties such as the government, civil society, and the private sector, and it is a responsibility towards the whole society. The importance of this responsibility is also reflected in the definition of "critical infrastructure" by the Disaster and Emergency Management Authority (AFAD). According to AFAD's definition, critical infrastructure is defined as "a network, asset, system, and structure covering sectors such as transportation, communication, energy, water, finance, in which the sustainability of social order or the provision of public services will be adversely affected when their functions are partially or completely impaired" (AFAD, 2014). In this study, the urban infrastructures affected by the earthquake disaster are as follows; transportation, water supply and wastewater management, energy infrastructure, communication infrastructure.

3 Infrastructure damages caused by earthquakes

In order to show the effects of earthquakes on urban infrastructure systems, the studies carried out by expert scientists based on observations in the field after the severe earthquakes are given below.

3.1. Damage to transportation infrastructure

Damages in the transportation sector were examined under four main headings: Highways, Railways, Airports and Ports.

3.1.1. Highways

Highways, which are a ground structure, are greatly affected by severe earthquakes. The main effects of these effects are ground movements such as liquefaction, lateral spreading, settlement and slope failure that occur in the ground layers during earthquakes. These movements in the ground cause the stability of the highway superstructure to deteriorate. The simplest one starts with the cracking of the road superstructure, and as the intensity of the earthquake increases and depending on the characteristics of the ground, the damage increases until the highway is out of servis. Another type of damage seen on highways is damage to bridges, tunnels and culverts. The main studies on this subject in past earthquakes are (Chen et al., 2021), (Ledezma et al., 2012), (Panjamani et al., 2011), (Baral and Shahandashti, 2022), In Fig. 1, the effects of the earthquake on the Tarsus Adana Gaziantep road are shown.

Fig. 1. Damage on the Tarsus-Adana-Gaziantep highway. (A Haber, 2023)

As stated in Fig. 1, major damage occurred on the highway. As a result of the vertical and extreme displacements caused by earthquake waves (Low and Rayleigh) in the ground layers, the asphalt was broken, settlement and lateral formation occurred on the ground. During earthquakes, liquefaction and lateral spreading occur in water-saturated sandy soil layers. Large deformations occur in soft clay and similar soil layers. The break in the asphalt layer is due to the formation of secondary faults. The reason for the settlement seen in the figure is due to liquefaction in the ground layers under the road. To form a definitive opinion, undisturbed samples should be taken on-site, and laboratory examination should be performed. Fig. 2 shows the deformation on the Hatay Reyhanlı highway. The reason for this, at first glance, is due to liquefaction occurring in the ground layers. As can be seen from these pictures, the importance of local ground conditions in the damage caused to highways during severe earthquakes is understood. On the highways that were not damaged or slightly damaged by the earthquake, transportation disruptions occurred due to traffic congestion. In addition to the damage to the roads due to the earthquake, the mobility created by vehicles heading to the disaster area further increased the tension on the roads; Failure to effectively manage the increasing traffic flow led to traffic congestion and caused delays in response and relief efforts in the disaster area. This congestion not only prevented critical personnel and vehicles from reaching the region on time, but also prevented emergency services and aid delivery to those in need. As can be understood from here, post-earthquake traffic dispatch and management becomes very important in earthquake preparation studies. The damages described above occur as a result of loss of strength and excessive deformations caused by earthquakes in the soil layers on which the road superstructure sits on highways. Another effect that causes roads to become unusable is the damage to the structures we call road engineering structures (viaducts, bridges, culverts, support structures, overpasses, underpasses, etc.). These damages, which are within the field of expertise of structural and geotechnical engineering, are summarized below. Highway bridges located in areas affected by severe earthquakes are exposed to many earthquakes, including multiple main shocks or aftershocks, during their service life.

Fig. 2. Hatay- Reyhanlı highway damage (A Haber 2023)

3.1.2. Bridges and viaducs

Repeated seismic loads can lead to a decrease in the structural capacity of bridges or their collapse, causing disruption in the normal functioning of transportation networks (Ghosh et al., 2015). Bridges and viaducts have been described as the most sensitive components of the transportation system, as they are vulnerable to structural collapse in addition to seismic-induced damages, ground surface and geotechnical failures observed after severe earthquakes in the past (Stergiou and Kiremidjian, 2006). Since the bridge is an engineering structure, the cause of damage due to earthquake is related to the structure, materials and ground. Insufficient load transfer between the bridge deck, cap beam and side piers caused damage to bridge components during the earthquake. The absence of diaphragm elements placed between the beams in the head beam or supports to ensure lateral stability, and the insufficient number or insufficient size of earthquake wedges placed between the beams in the supports to transmit lateral loads contributed to the deterioration of the bridge components. Seismic activity caused displacement and dislocation of thick elastomeric pads. These damages observed in elastomeric cushions negatively affected the performance and safety of the bridge by causing the load distribution to change, the support system to deteriorate, and the bridge's vulnerability to structural damage and shaking to increase. Another damage that occurs in bridges is the conditions related to the ground on which the bridge piers sit. During the earthquake, liquefaction and lateral spreading occurred in the saturated sandy silty soils on which the bridge pier foundations sit. As a result of the total and differential settlements on the bridge foundations because of liquefaction, the bridges have become unusable. As a result of settling, especially in the approach embankments, a difference in elevation occurred in the bridge supports and dilations, and the superstructure became unusable. Damage to critical components on bridges due to earthquakes, displacement of bridge piers or supports, significantly reducing the load-carrying capacity, hindering the serviceability of bridges. Bridges are state-supervised engineering works, and their material strength is higher than buildings. Beams are mostly produced as pre-stressed and then assembled. Structural damages on bridges occur due to non-compliance with constructive principles rather than design. While damage to highways occurs due to ground properties, damage to highway bridges and their components results from both ground and structural features. We can summarize the damage to the bridges as follows. Damages occur on the side walls of bridges due to the dynamic forces created by earthquakes. These damages are primarily caused by intense ground movements and the intensification of seismic waves passing through the ground. Displacements occur as a result of repetitive stresses acting on the edge piers of bridges, which can lead to various forms of damage, including cracking, spalling and failure of structural elements. This damage is more common in areas with poor soil conditions and on bridges that lack adequate reinforcement or seismic design considerations. Unqualified design or detailing, such as inadequate reinforcement or lack of connections between bridge elements, increases the vulnerability of bridges to edge wall damage during seismic events. Additionally, interactions between the bridge structure and the underlying soil, such as liquefaction, settlement, and lateral spreading, can also contribute to the severity of damage. The aging or deterioration of bridges over time further increases their susceptibility to abutment wall damage during earthquakes. A full understanding of these reasons is of great importance in terms of assessing bridge sensitivity, taking appropriate design measures, performing maintenance practices and increasing bridge durability, reducing damage that may occur during earthquakes. Fig. 3 shows the wall damage caused by the bridge superstructure hammering the edge pier wall in the longitudinal direction (Avşar et al., 2023). Damages caused by exceeding the ground shear strength in the edge abutment approach fillings can be seen in Fig. 4.

Fig. 3. Bridge edge pier wall damage

Fig. 4. Bridge edge abutment approach embankment damage on the Asi River (Çetin et al., 2023)

Two bridges completely collapsed during the 6-7 Şubat Maraş earthquakes due to the displacement caused by the earthquake as a result of insufficient support widths. This issue can be seen in Fig. 5

Fig. 5. Bridge collapsed due to insufficient support width in Hatay

3.1.3. Tunnels

Tunnels are important components of the transportation system, providing essential connectivity and efficient routes for road and rail networks. These structures, which shorten travel distances by supporting regional harmony and provide safe passageways for people and commercial goods, carry the risk of serious damage during earthquakes. During earthquakes, tunnels are exposed to displacements in the surrounding soil and rocks due to ground movements. These displacements cause deformations and settlements as a result of dynamic forces applied to the tunnel structure, which endangers the stability and direction of the tunnels. Structural damage occurs in the form of cracks in walls, ceilings and floors, concrete spills and coatings breaking off, and negatively affects the integrity of the tunnel. This may pose a risk to the safety and functionality of vehicle and train traffic in the tunnel The consequences of tunnel damage caused by earthquakes are very important. Damages that require partial or complete closure of tunnels disrupt the transportation system, causing delays and route changes. Traffic congestion will have far-reaching consequences, affecting emergency responses, the local economy, and the well-being of individuals and communities, as alternative routes cannot handle the increased vehicle volume. To minimize these negative effects, it is critical to quickly evaluate, repair and reopen tunnels after an earthquake

3.1.4. Railways
The impact of the periods when railways are out of service after a major earthquake is of great importance. The disruption can affect the movement of goods, supply chains and trade, causing economic losses. The damages in these regions, where there were difficulties in meeting the high demand even before the earthquake, caused disruptions in export logistics. Manufacturers in the affected region considered road transport as an alternative option due to railway disruptions. However, the higher costs of road transport compared to railway and the fact that only a limited part of millions of tons of cargo can be transported by road have revealed that this alternative is an impractical option (UTİKAD, 2023). According to information received from the General Directorate of State Railways of the Republic of Turkey, there are 446 bridges, 6161 culverts, and 175 tunnels on the railway line affected by the earthquakes centered in Kahramanmaraş. The earthquake caused significant damage to railway engineering structures, including tunnels, viaducts, and bridges The damage to the steel railway bridges and railway tracks caused by the Kahramanmaraş earthquakes can be seen in Fig. 6 (NTV, 2023; Anadolu Agency 2023).

Fig. 6. Damages seen on railway bridges

Instability problems that occurred in the sloped sections of railway routes during earthquakes also caused the roads to be out of service. During the Kahramanmaraş earthquakes, the train route became unusable as a result of rocks rolling down from the mountainside onto the train tracks near the Fevzipaşa Train Station can be seen Fig. 7.

Fig. 7. Slope stability problems in railways during earthquakes (Hürriyet, 2023)

3.1.5. Airports
Another sector affected by earthquakes is airports. Damages to runways and terminal buildings at airports cause transportation to be disrupted or disabled. When the earthquake effects that occur especially on runways with a ground structure are examined, it is understood that this is mostly due to local soil properties. Following two successive earthquakes of magnitude 7.7 and 7.6, with the epicenter in Kahramanmaraş, significant damage occurred at some airports in the region. While some airports were closed to civilian flights, others continued their activities to ensure easy access of humanitarian aid and search and rescue teams to the region (AFAD, 2023). The

length of airport closures varied depending on the extent of damage and the time required for repairs and assessments While there was no situation that would disrupt transportation at Kahramanmaraş and Gaziantep airports, damage to the transportation roads and flight runway occurred at the airport in Hatay due to local ground conditions. The airport was out of service for about a week.

3.1.6. Maritime lines

Maraş earthquakes had negative effects on maritime transportation and ports in Turkey, causing significant damage. Especially Iskenderun Port was seriously affected, a fire broke out in the storage area where the containers were stacked, rendering the port inoperable and causing exports and imports to stop. It has been stated that the fire caused by materials containing chemicals such as PVC is difficult to extinguish and it takes three days to bring it under control. After the earthquake, cracks occurred on the pavements as a result of bearing capacity losses and settlement on the ground in the port.

3.2. Damage to water and wastewater systems

Damage to water supply and wastewater systems has led to a lack of access to clean drinking water in many areas, disruption of sewage delivery and treatment, leading to public health risks and environmental pollution. Mobile toilets and drinking water have been provided to affected areas to reduce the risk of disease. Damage to various components of the water and sewage infrastructure has had serious impacts. Damage occurred to varying degrees in the piping systems, with most of the damage resulting from loosening and breaking of joints. While most piping systems perform well, some older HDPE (High density polyethylene) pipes have experienced localized swelling. Although water treatment plants suffered moderate damage, they were able to maintain water supply after the earthquake. Citizens residing in high altitude areas of Kahramanmaraş were completely deprived of water service for three days following the incident, primarily due to the combined effects of damage to water transmission lines and power outages. This was because the pumping stations used to provide water flow to high altitude areas were rendered inoperable due to power outages. In the region, the water distribution network is mainly composed of ductile iron pipes, while prestressed concrete pipes, polyethylene and glass fiber pipes are also used. Damage observed in the water transmission pipe due to 4.5 m fault movement can be seen Fig. 8 (Çetin et al., 2023).

Fig. 8. Damage observed in the water transmission pipe due to 4.5 m fault movement

3.3. Damage to energy infrastructure systems

Power plants are the basic unit of the electrical energy system. If serious damage occurs in the earthquake, it not only causes direct economic loss, but also causes a series of chain hazards due to the loss of electricity generation function and power supply interruption, seriously supporting post-earthquake emergency rescue, people's survival and post-disaster reconstruction. While electrical energy is essential for maintaining the functionality of other lifelines such as communications, water supply and wastewater treatment, it also plays an important role in the economic vitality of society. Therefore, the stability and continued functionality of the power grid is necessary after disasters such as earthquakes (Omidvar et al., 2017).

Damages to energy systems in the earthquake zone are examined under the following headings: thermal power plants, hydroelectric power plants, electricity substations, electricity transmission and distribution overhead systems, natural gas transmission and distribution systems, LPG storage and distribution facilities, crude oil and fuel stations, wind turbines.

3.3.1.Thermal power plants

A hydrogen gas leak occurred at the Hunutlu Thermal Power Plant, 110 km away from the epicenter of the earthquake. After the earthquake, the location of this leak was found and isolated, ensuring uninterrupted operation of the system. Among the damages detected, small vertical cracks in the base columns of the concrete cooling tower, broken insulators, transformer failures, movements of pipes in the boiler building colliding with steel frames due to shaking and ground settlement were observed. (Çetin et al., 2023). Damage occurred to the unit of the Iskenderun Thermal Power Plant, which was in operation during the earthquake. It was observed that the transformers were displaced by approximately 10 cm by coming out of their sweat. As a result of ground settlement around the tribune building, repairable faults occurred in the installation.

3.3.2. Hydroelectric power plants

It seems that the general performance of hydroelectric power plants in the disaster-affected areas is quite successful. All units started operating again after power was supplied from the grid, and activation times varied between 3 and 6 days depending on the region. No significant cracks or deformations indicating the instability of the dam were observed in the regions, and it was determined that the damage was limited to small lateral spreads on the top of the dam and rocks falling from the adjacent slopes to the land and highways. Menzelet Dam, built between 1980 and 1989 on the Ceyhan River in Kahramanmaraş, is a body type rock fill and serves two purposes: irrigation and energy production. The clay core of the Menzelet Dam was not damaged, the roads leading to the dam could not be closed due to the rocks falling from the mountains after the earthquake, and the road equipment had to be cleaned. Some retaining walls to which the dam is a The Kilavuzlu dam, which was built later (1996-2001) on the Ceyhan River, is a body type earth fill. This dam survived the earthquake with minor damage. Small lateral spreads have occurred in the fill on the dam crest. Again, approximately 1 cm cracks occurred at 200 m intervals in the Concrete arch body type dam located on the Ceyha River. All of these damages are repairable and do not cause any interruption in energy production.ttached were also damaged due to rockfall (Çetin et al., 2023).

3.3.3. Electricity substations

Among the damages observed in substation buildings during earthquakes; These include wall fillings collapsing and falling on equipment, equipment that is not sufficiently fixed against the intensity of the earthquake falling over, rocks rolling down from the slopes surrounding the transformer building, and nearby structures collapsing onto the substation buildings. The structural design of the substation should take into account the potential impact of infill walls during earthquakes. When the walls of substation buildings collapse during an earthquake, they can cause serious damage to the equipment inside, resulting in interruptions in power supply, equipment failure, and extensive repair or replacement costs. After the earthquake, various cases were observed in which the walls of the substation buildings collapsed and the equipment inside was damaged. Another type of damage to transformer buildings is related to the area where the building is located. Slope slides and rock falls that occur due to the ground are the main ones. Another issue is that the building next to the transformer where it is located completely collapses, causing the transformer building to collapse as well.

3.3.4. Electricity transmission and distribution overhead systems

After electricity is produced in various sources such as power plants, it is transmitted through a network of electrical cables to reach its destination. This network consists of transmission and distribution lines that make up the electrical grid. Transmission involves moving generated electricity over long distances from generation facilities to substations near areas where demand is high. Transmission lines are characterized by larger, taller poles and towers that support multiple cables over long distances. Distribution represents the final step in delivering electrical energy from production to consumers. The power transferred over high-voltage transmission lines is subjected to voltage reduction using transformers in substations. It is then distributed through low voltage distribution lines. These lines, which can be seen along the streets, deliver electricity directly to homes, workplaces and other end users. The earthquake caused 11 poles connecting the 1,128 km long electricity transmission line to fall; It caused significant damage to the electricity distribution lines and substations in the region, especially Hatay, Gaziantep, Kahramanmaraş and Adıyaman (SBD, 2023). Distribution lines are either overhead or underground. There are more underground lines in urbanized areas. Outside the city, lines in rural areas go by air. While no major malfunctions were observed in the underground lines in the earthquake region, significant malfunctions occurred in the aboveground lines. Various types of damage have occurred in overhead lines and poles, such as the failure of the conductor, the collapse of concrete transformer poles and concrete network poles, especially due to the low voltage insulators breaking or flying off their pins during an earthquake. In rural areas, high voltage cables are connected to towers rising from the ground. As a result of mass movements on the ground during severe earthquakes, damage such as tipping, collapsing and tilting occurred in the towers. Electricity poles used in overhead power networks are installed using concrete or iron in city centers, and iron or wooden poles in rural areas. The primary reason for electric poles falling over in cities is that they are not properly fixed to the ground. The second and most important effect is that the debris created as a result of the collapse of the buildings also topples the poles on the street. Contact with the electrical conductor cables of collapsed buildings can cause various physical damage to the cables and even complete breakage of the cables. Following the devastating earthquake, the collapse of buildings towards roads and infrastructure areas caused the underground electricity network and field distribution boxes to be inaccessible. However, after the removal of the debris, it was determined that there was no damage, especially to the underground network, and in general, the cable section of the electrical network was not damaged.

3.3.5. Natural gas transmission and distribution systems

In today's industrialized society, a portion of energy is provided by natural gas. Energy outages resulting from damage to natural gas facilities during earthquakes cause major problems in the electricity supply. The length of the natural gas transmission line in the 11 provinces affected by the Kahramanmaraş earthquakes is 2,224 km and the length of the natural gas distribution line is 20,694 km (SBD, 2023). The earthquake caused explosions and failures at approximately 20 different points of the main natural gas transmission lines serving the affected regions, and damage occurred to natural gas distribution lines and facilities in the region (SBD, 2023). As a result of the damage, natural gas supply was interrupted in the cities of Gaziantep, Hatay, Kahramanmaraş and Adıyaman (SBD, 2023). Authorities reported that as of February 11, 2023, the repair of major damages, including steel pipelines, was completed and additional work was needed to return service to residents of the cities

3.3.6. LPG storage and distribution facilities, crude oil and fuel stations

LPG (liquefied petroleum gas) has a wide range of use in Türkiye and is widely used as a vehicle fuel, as well as an energy source in homes, kitchens, heating systems and the industrial sector. In the post-earthquake inspections, it was observed that LPG terminals generally performed well. Minor damage occurred to storage facilities and distribution lines due to local ground conditions. In the earthquake region, there were overturns in LPG storage facilities, but no leaks occurred. In order to prevent this, precautions should be taken to prevent gas cylinders in storage facilities from overturning.

3.3.7. Crude oil and fuel stations

There are 1,785 km of crude oil pipelines in the 11 affected provinces, corresponding to 56% of the length of crude oil pipelines in Turkey (SBD, 2023). As a result of the inspections, it was determined that there were small-scale damages in the crude oil pipelines and that the production areas were negatively affected by the earthquake (SBD, 2023). Following the earthquake, some gas stations and fuel storage facilities suffered damage, including the collapse of underground storage tanks and connection points. Gas stations generally consist of pump stations covered by a canopy structure and an adjacent single-story store building. While the canopy structures covering the pump stations were not damaged, the adjacent single-story store buildings were mostly severely damaged (Çetin et al., 2023).

3.3.8. Wind turbines

Earthquakes also affect green energy sources such as wind turbines, and in areas close to the earthquake, they damage turbine structures and transmission lines, causing power outages. Following the Kahramanmaraş Earthquakes, wind power plants in the affected region were assessed for damage and found to be undamaged. After the necessary repairs were made to the transmission network and the network was restored to its former state, the wind power plants continued to operate at full capacity. However, during the period when the network was down, the power plants had to temporarily stop their operations because the generated electricity could not be delivered to the distribution points (Anadolu Agency, 2023).

3.4. Communication infrastructure

The consequences of damage to communications infrastructure during an earthquake can go beyond disruptions to communications networks. The dependence of various sectors on communications can become a vital link affecting the functioning of infrastructures and services. For example, emergency services rely heavily on communications systems to coordinate their responses and efficiently allocate resources to affected areas. Without proper communications, response times can be extended, lives can be at risk, and the impact of the disaster can be exacerbated. The uninterrupted operation of critical public services such as electricity grids, water supply systems and gas pipelines largely depends on communication systems for monitoring and control; therefore, any disruption in communication can lead to disruption of restoration efforts or extended service outages. Public services, including government agencies and civil society organizations, also rely on communication for coordination and support; when communication is dysfunctional, it becomes difficult to provide basic services to affected communities. Serving as critical components of mobile communication networks, base stations can be installed in different locations to optimize network performance and increase communication capacity. While tower-type base stations are generally installed in rural areas to provide wider coverage, they are usually installed on rooftops in cities to meet high data traffic needs. Base stations need electrical power to provide communication services. The stations are supported by battery systems with an average operating time of 6 hours to continue operating during power outages. Communication disruptions during earthquakes can occur not only with damage to base stations, but also with power outages. In the examinations carried out in the region affected by the Kahramanmaraş earthquakes, it was determined that 2,451 of the 8,900 base stations were disabled (TÜRKONFED, 2023).

4. Conclusions

Today, urban infrastructure systems are closely related to the economic well-being, security and social fabric of the communities they serve. These systems, which include electricity, communication, natural gas, transportation, water and wastewater services and are often referred to as lifelines, serve as important channels that facilitate the production and distribution of needed goods and services. The sustainability of urban life depends on the functionality and reliability of these critical systems. Damage to urban infrastructure systems after an earthquake and the resulting service interruptions have important consequences for the execution of emergency activities and the ability to meet the basic needs required for the survival of society. In the worst cases, these interruptions can lead to social and economic impacts on a regional, national and even global scale. Urban infrastructure is a complex network of interconnected systems. Damage to any one component of the system can have a cascading effect, further exacerbating the overall impact of an earthquake. For example, in the event of a power outage, communications become critically challenged as landlines, mobile networks, and internet services cannot function without electricity, potentially hindering the dissemination of vital information and emergency response efforts. Without the power needed to operate pumps and filtration systems, water treatment operations that provide clean and safe drinking water come to a standstill, while wastewater treatment operations can also be disrupted, potentially posing environmental risks and public health concerns. Understanding the interdependencies and cascading effects between urban infrastructure systems is of great importance. In the century we live in, a large proportion of the population of countries lives in cities. Making cities resilient to disasters depends on the work to be done before the disaster. Post-disaster emergency efforts can also be successful by making preparations before the disaster. In this study, the effects of the recent major earthquakes on cities were examined in terms of transportation, water, wastewater, energy and communication. Just as it is important to make our structures durable and resistant to disasters, urban infrastructure must also be made resilient in order to reduce the damages that may occur. Local ground and structural damages, especially affecting transportation and communication systems, must be reduced. Since local ground conditions have an increasing effect on transportation systems, damage reduction studies should be carried out before the disaster.

Mathematical formulations of the temporal Intensity pattern of 6-hour design storm in central Tehran Metropolis

Sara Ghaznavinia[1], Seiyed M. Hosseini[*2]

[1] *B.S. Geography student, Faculty of Geography, University of Tehran, Tehran, Iran*
[2] *Associate professor, Physical Geography Department, University of Tehran, Tehran, Iran.*

Abstract. The identification of design storm temporal patterns in urban areas plays a crucial role in rainfall-runoff modeling, stormwater drainage design, and sediment retention structural design. In this study, we aimed to characterize and parameterize the 6-hour rainfall temporal pattern in the Tehran metropolis, the capital of Iran, which is considered the baseline for design storms in hydrologic and hydraulic engineering. Over 35 storm events with a duration of 6 hours and 28 storm events with a duration of 24 hours were collected, each with high-resolution one-minute time steps, to identify the temporal patterns of each duration. To address this issue, we derived the characteristics of 6-hour design storms, including depth, duration, intensity, and temporal pattern. The duration and intensity of the 6-hour rainfall events were then normalized with respect to the average characteristics of 24-hour events. Finally, a three-parameter exponential function was fitted to the normalized 6-hour patterns to represent their temporal distribution. The results indicated that formulating the rainfall pattern offers significant advantages in facilitating the comparison of its properties across different locations. Moreover, the derived design storm pattern enhances the accuracy and efficiency of hydrological modeling and computational implementations, which are essential for engineering applications such as urban drainage design, flood forecasting, and sediment control systems.

Keywords: Urban design storm; Temporal pattern of rainfall; Urban hydroclimatology; Modeling; Exponential function fitting

1. Introduction

Design storms or design hyetographs are precipitation patterns used as input for hydrologic models (Chow et al. 1988). The design rainstorm pattern plays a vital role in the planning and design of urban drainage pipe network, and is the basis for obtaining the rainwater runoff process line (Xiaoling Su et al., 2019). Different rainstorm profiles will lead to significant differences in the calculation results of rainfall runoff (Jiang, 2015). Short-duration precipitation models, such as the six-hour design storm, enhance urban drainage planning by accounting for peak rainfall intensities. A key consideration in the development of rainfall temporal patterns is the representation of characteristic intensity fluctuations during the peak phase of storm events (Bustami et al., 2012). By incorporating historical precipitation data, a 6-hour design storm model supports hydrological modeling, structural design, and sedimentation control. It shows the temporal distribution of rainfall within the design storm which is an important factor that affects the runoff volume, magnitude and timing of the peak discharge (Bustami et al., 2012). Understanding design storm temporal patterns in densely populated city is essential for improving hydrological modeling, urban drainage planning, and flood management.

A range of temporal rainfall disaggregation methods has been developed worldwide, though few have been evaluated for arid region conditions (Al-Wagdany, 2021). Often, rainfall intensity–duration relations developed for a specific location or a region are used to construct synthetic design storms by assuming a general shape of the hyetograph (Froehlich, 2009). In India, (Chowdhury et al., 2007) employed an empirical reduction formula, developed by the Indian Meteorological Department, to derive short-duration rainfall from daily precipitation data. Similarly, (Eastgate et al., 1979) applied the NRCS hydrograph procedure to generate 24-hour cumulative rainfall curves for western Queensland, Australia. (Pilgrim & Cordery, 1975) developed synthetic rainfall hyetographs that are based on ranking the time intervals in a storm according to their corresponding rainfall depths (Al-Wagdany, 2021).

In previous studies, temporal rainfall patterns were typically designed based on quantiles, such as quartiles and deciles. However, in our approach, we have quantified this process by introducing a mathematical formulation for

[*] Corresponding author, E-mail: smhosseini@ut.ac.ir

https://doi.org/10.31462/icearc2025_ce_hwr_634

fitting and approximation. This approach facilitates tasks such as coding, management and other computational and practical applications, making them more efficient and streamlined.

This study aims to quantify 6-hour precipitation events in a fully urbanized region of central Tehran. To achieve this, a centrally located synoptic meteorological station, offering high-resolution data at 1-minute intervals, was utilized Continued research in this field is essential for developing effective strategies to mitigate the impacts of changing rainfall patterns, ensuring the resilience of urban communities and ecosystems against hydrological and climatic uncertainties (Ghaznavinia & Hossini, 2024).

2. Materials and methods

The overall methodology adopted in this study is summarized in Figure 1. The process begins with the collection of high-resolution rainfall data (1-minute time step) from the Yousef Abad weather station. Storm events are then classified into 6-hour and 24-hour durations using the Pilgrim and Cordery method. Following a data adequacy check, 56 significant rainfall events are selected, and their main characteristics including depth, duration, intensity, and temporal patterns are extracted.

To allow for meaningful comparison, the depth and intensity of 6-hour storms are normalized with respect to 24-hour storms. An exponential model is then fitted to the normalized data to approximate the design storm pattern. The model is subsequently calibrated and verified, followed by a final analysis of the results.

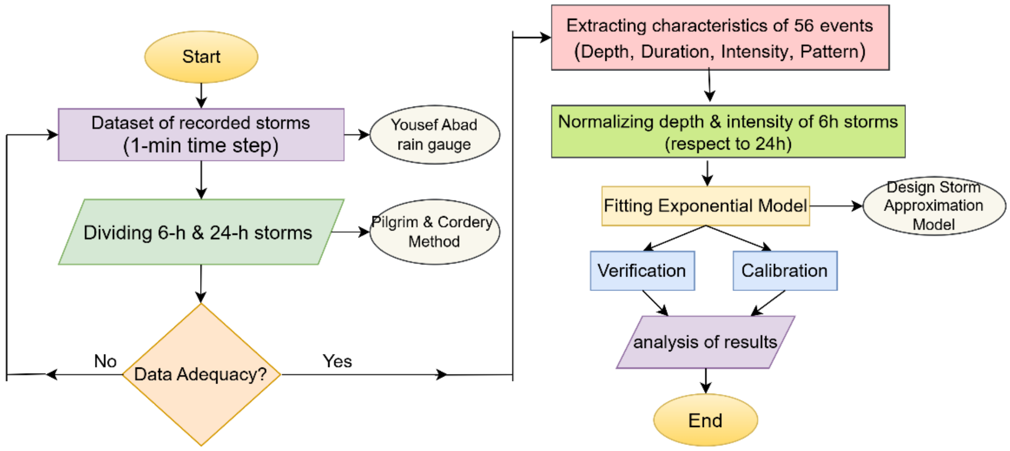

Fig.1. Location of Yousef Abad weather station in Tehran metropolis, Iran

2.1. Methods

In this study, prior to the analysis, the Chi-square hypothesis test was employed to assess the adequacy of the number of analyzed rainfall events. This test was applied to evaluate whether the selected sample size sufficiently represents the overall distribution of rainfall occurrences. By comparing the observed and expected frequencies, the Chi-square test ensured that the dataset was statistically robust for further analysis, thereby validating the reliability of the selected rainfall events. The Chi-square formula is presented as follows:

$$X^2 = \sum_{i=1}^{r}\sum_{j=1}^{c}\frac{\left(N_{ij}-\frac{N_i.N_j}{n}\right)^2}{\frac{N_i.N_j}{n}} \qquad \text{Eq.(1)}$$

Eq.(1) Where r = Number of rows, c = Number of columns, N_{ij} = Number of specific events (frequencies) in the i-th row and j-th column, N_i = Number of events (frequencies) in the i-th row, N_j = Number of events (frequencies) in the j-th column, n = Total number of events (frequencies) (Khaksefidi et al., 2010).

An expression for the time distribution of rainfall intensity in synthetic design storm hyetographs is then found as follows (Froehlich, 2009):

$$\hat{\imath}_{*(t)} = \left(i_{p^*} - i_{0^*}\right) exp\left[-\left(\frac{mt_d}{r}\right)\left(1-\frac{t}{t_d}\right)\right] + i_{0*} \qquad For\ 0 \le t/t_d \le r$$

$$\hat{\imath}_{*(t)} = \left(i_{p^*} - i_{0^*}\right) exp\left[-\left(\frac{mt_d}{1-r}\right)\left(\frac{t}{t_d}-r\right)\right] + i_{0*} \qquad For\ r \le t\ /\ t_d \le 1 \qquad \text{Eq.(2)}$$

where $i_{p*} = i_p/\bar{\imath}_{24}$, and $i_{0*} = i_0/\bar{\imath}_{24}$. Optimal values of the two parameters i_{0*}, and "m" found for Yousef Abad wather station events by fitting Eq.(2) to the normalized 6-hour rainfall data.

Ttime-to-peak intensity ratio $r = tp/td$,where tp = time to peak rainfall intensity, and td = storm duration, which is 6 hours. Distributing rainfall about the time of peak intensity proportioned by r, rainfall intensity given by Eq.(2) corresponding to time t occurs a time rt before the peak and a time $(1-r)\,t$ after the peak.

2.2. Study area

The study area of this research focuses on weather station in the central business district (CBD) of Tehran metropolis, the capital of Iran (figure.2), which is highly developed and characterized by dense infrastructure, impervious surfaces, and limited green spaces. This area experiences a semi-arid climate, with an average annual precipitation of about 230 mm and a mean annual temperature of approximately 18°C. Most rainfall occurs during the colder months, while summers are typically hot and dry. Rapid urbanization and topographic variations contribute to localized climatic differences, particularly in the central zones. Figure.1. shows that the Yousef Abad weather station which is located in the CBD of city 35° 44′ North latitude and 51° 24′ East longitude. This station can be considered as a representative for illustrating the temporal intensity pattern of rainfall in the city center.

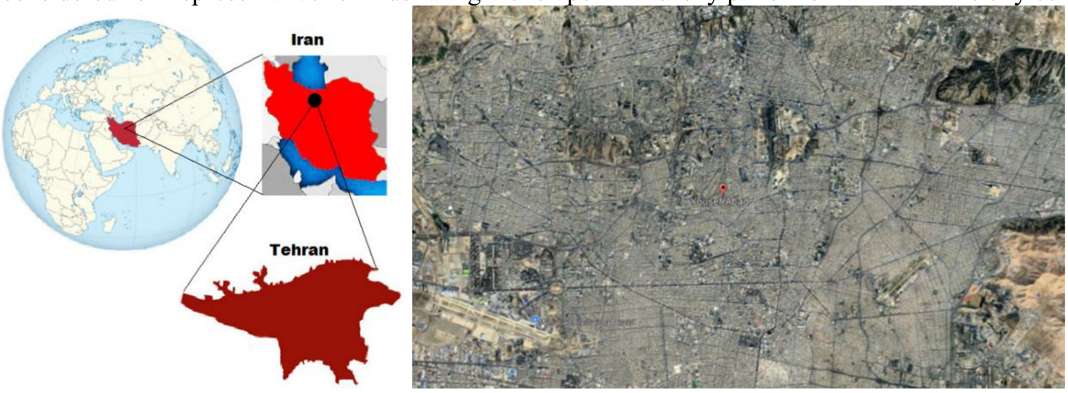

Fig. 2. Location of Yousef Abad weather station in Tehran metropolis, Iran

2.3. Data set

Precipitation events recorded over a 27-year period by the rain gauge at the weather station were analyzed, including 28 events lasting 24 hours and another 28 lasting 6 hours. The general characteristics of the dataset and the selected events are presented in Table 1.

Table 1. Characteristics of storm events (6 hr and 24 hr) used in the analysis.

3. Results and discussion

3.1 Data adequacy

Using the Chi-square test, the results indicate that the p-value is 0.2, and the number of observed events is sufficient at the 95% significance level. Therefore, the dataset passes the adequacy check, and the subsequent steps of the study such as fitting model and pattern extraction can be reliably performed.

3.2 Design pattern

Based on the events and information presented in Table 1, averaging was performed to obtain representative values for further analysis. Following the analysis of 28 rainfall events and the modeling of 6-hour rainstorms using Eq.(2), the individual and cumulative mean rainfall patterns were derived. The averaging process and development of hyetograph patterns were carried out using the Pilgrim & Cordery (1975) method, as illustrated in figure.3.

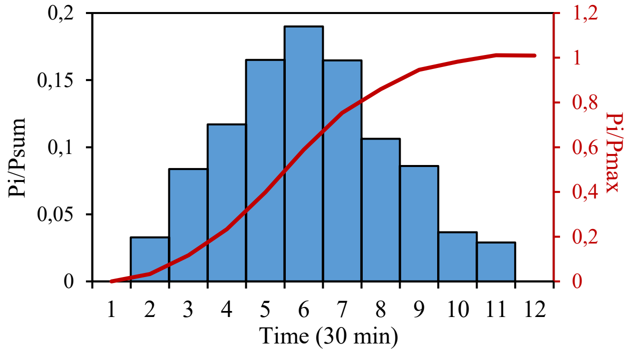

Fig.3. Average pattern of 6-h design hyetographs

3.3 Fitting exponential model

After normalizing the 6-hour rainfall data to 24-hour rainfall values, the exponential modeling formula was fitted to the data separately using the Solver tool in Microsoft Excel. The calibrated "m" values are presented in the dataset table1.

The four parameters, namely i_{o*}, m, r, and td, were optimized based on the derived information, including intensity, time duration, depth, peak, and i_{p*} of each event. The average values of these parameters were used in the analysis.

On average, the optimal parameters of the exponential rainfall intensity equation for 6-hour design storm approximations include a calibrated (m) of 9.73 h^{-1} with a standard deviation of 1.82 h^{-1}. The storms had an average duration of 6 hours, a total rainfall depth of 9.92 mm, and an average intensity of 1.65 mm/h. The peak of rainfall (r) associated with the model was 0.5.

Table 2. The input (t_d and r) and calibrated (m) parameters used for fitting the exponential model to the standardized temporal pattern of 6-h storms

Comparisons of the actual ranked dimensionless intensities and the approximation given by Eq.(2) using the optimized parameters are shown in Fig.4.

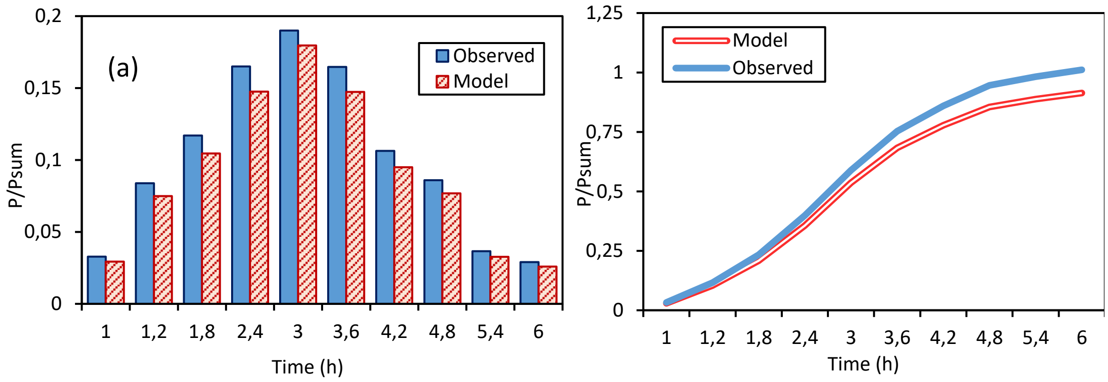

Fig.4. Histogram of Observed 6-h Rainfall Pattern and Fitted Model **(a)**, and cumulative curve of patterns **(b)**

4. Conclusions

An exponential function was fitted to the 6-hour storm temporal pattern and examined for a 28 events. The results indicated that the proposed formula accurately matched the 6-hour dataset. Quantifying rainfall intensity patterns can significantly contribute to hydrological design and urban drainage network planning. Moreover, due to its formulation-based approach instead of relying on quantiles, this method offers valuable applications in coding-related implementations as well.

Potential of machine learning algorithms for sediment transport in annulus

Serra E. Akyurt[1], Pelin İlker[1], Mehmet Sorgun[*1]

[1] İzmir Katip Çelebi Üniversitesi, Civil Engineering Department, Çiğli, 35620 İzmir, Türkiye
[a] Corresponding author, Prof. Dr.

Abstract. Understanding the hydraulic behavior of sediment-laden flows in annular geometries is crucial for the efficient design and operation of multiphase flow systems. The frictional pressure loss can be considered as an significant parameter affecting sediment transport in annulus. There exists a correlation between pressure loss and shear stress, whereby an increase in pressure loss leads to a corresponding rise in shear stress on the sediment particle. Therefore, accurate calculation of pressure loss is a important issue for hydraulic engineering. Friction factor is a key parameter in the determination of pressure losses in closed conduits. In this study, a dimensional analysis is performed by using Buckingham Pi Theorem to find the parameters affecting the friction factor. Experimental data are analyzed with machine learning techniques, employing a cross-validation method to categorize the data as training and test data. Log-Log Regression (LLR), Artificial Neural Network (ANN), Teaching-Learning Based Optimization (TLBO), Extreme Gradient Boosting (XGBOOST), Negative Binomial Regression (NBR), Gaussian Process Regression (GPR) models are trained. The machine learning algorithms are evaluated in terms of AAE (Average Absolute Error), AAPE (Average Absolute Percentage Error), RMSE (Root Mean Square Error) and the optimal model is found out. Results indicate that the LLR model showed slightly better performance than other machine learning algorithms (based on LLR=18.70%, ANN=19.00%, TLBO=19.18%, XGBOOST=20.67%, NBR=24.71%, GPR=48.53% AAPE values).

1. INTRODUCTION

Sediment transport in pipelines is an important issue for civil and hydraulic engineering. The efficiency of the system to be designed in areas requiring sediment transport is quite critical in terms of energy and resource management. The transport of solid particles with a certain fluid directly affects the performance of the pipeline and the energy used. For this reason, a correct and optimal system design is the most important factor in this case. Many researchers have been conducting studies in the subject of sediment transport for years by using experimental and numerical approaches.

With the domain of sediment transport, the estimation of various factors and parameters by artificial intelligence models and machine learning algorithms has become the subject of many scientific researches today. Altunkaynak (2009) conducted a estimation study on the discharge and sediment load data of the Mississippi River and used Genetic Algorithms (GA) and regression models for comparison. As a result of this comparison, it was seen that genetic algorithms gave better results compared to regression models. In the study conducted by Azamathulla et al. (2010), Support Vector Machines (SVM) and conventional methods were compared to estimating sediment load values in three rivers in Malaysia. In the study conducted by Melesse et al. (2011), suspended sediment load values of the Mississippi, Missouri and Rio Grande rivers were estimated by algorithms such as Artificial Neural Network (ANN), Multiple Linear Regression (MLR), and Multiple Nonlinear Regression (MNLR). Azamathulla et al. (2013); the suspended sediment load of the Muda, Langat and Kurau rivers in Malaysia was estimated using Gene Expression Programming (GEP) and the results were compared with ANFIS and regression models. According to Nourani and Andalib (2015), the use of wavelet together with the Least Square Support Vector Machines (LSSVM) algorithm in the suspended sediment load estimations of the Mississippi River improved the estimation results. In the study by Osgouei et al. (2015), friction pressure losses for multiphase flow in a horizontal annulus were investigated and Nearest Neighbor (NN), regression trees, MultiLayer Perceptron (MLP) and Support Vector Machines (SVM) algorithms were used for pressure loss estimations. In the study by Singh et al. (2018), different regression algorithms were developed to make pressure loss estimations of narrow aperture well channels. Kanin et al. (2018) used Random Forest, Gradient Boosting,

Support Vector Machine and Artificial Neural Network algorithms for estimating the flow pattern pressure gradient in the pipe. Yilmaz et al. (2019) conducted a study using Artificial Neural Network (ANN), Teaching-Learning Based Optimization (TLBO) and Artificial Bee Colony (ABC) algorithms to estimate the suspended sediment load in the Coruh River Basin. In the study by Rahmat and Wongwises (2020), an artificial neural network model was developed to estimate the pressure drop for two-phase flow in a pipe stream. Khamehchi and Bemani (2020) used Extreme Learning Machine (ELM) and Gradient Tree Boosting (GTB) machine learning algorithms to facilitate the calculation of bottom well pressure for two-phase flow. Kumar et al. (2020) investigated the performances of Bayesian Neural Network (BNN), Artificial Neural Network (ANN), Random Forest (RF) and Support Vector Machine (SVM) algorithms to estimate the pressure loss in the annulus for Herschel-Bulkley fluids. Sharafati et al. (2020) evaluated the performances of three different machine learning algorithms, namely Gradient Boost Regression, Random Forest Regression and AdaBoost Regression, to estimate the suspended sediment load of the Mississippi River. In the study by AlDahoul et al. (2021), an algorithm called Long Short Term Memory (LSTM) was developed to estimate the suspended sediment load. Darabi et al. (2021) used three different models, namely MultiLayer Perceptron (MLP), Adaptive Neuro-Fuzzy Inference System (ANFIS) and Radial Basis Function Neural Network (RBFNN), to estimate the suspended sediment load in rivers. Afterwards, they integrated these models with Sine-Cosine Algorithm (SCA), Particle Swarm Optimization (PSO), Firefly Algorithm (FFA) and Bat Algorithm (BA) algorithms for performance improvement. Wahid et al. (2021) conducted a study with 5 different machine learning algorithms, namely Support Vector Machine (SVM), Genetic Programming (GP), Random Forest (RF), Artificial Neural Network (ANN) and k-Nearest Neighbor (kNN), and hybrid versions of these algorithms were studied to estimate the pressure gradient in liquid-liquid flow in horizontal well lines. Jain et al. (2021) used Random Forest (RF) algorithm for flow behavior analysis in industrial pipelines and turbine machines. Wan et al. (2024) estimated the pressure drop in pipe flow and two-phase flow using Random Forest (RF), Back Propagation (BP) and Polynomial Regression (PR) machine learning algorithms.

2. Theory

2.1. Dimensional analysis

As can be seen in Figure 1, the experimental study conducted by Sorgun (2010), sediment transport in annular flow was investigated. The friction factor variable used in the study is expressed with other variables as follows:

$$f = func(v, \rho, \mu, D_h, \Omega, g, \theta, C_c) \tag{1}$$

where; v is the fluid velocity (L/T), ρ is the density of fluid (M/L^3), μ is the dynamic viscosity of fluid (M/LT), D_h is the hydraulic diameter (L) ($D_h = D_o - D_i$, D_o is the outer pipe diameter and D_i is the inner pipe diameter), Ω is the inner pipe rotation speed (1/T), g is the gravitational acceleration (L/T^2), θ is the hole inclination and C_c is the sediment concentration.

Dimensional analysis with Buckingham Pi Theorem was performed with the friction factor as the dependent variable and the other parameters given as independent variables. The relations created by dimensional analysis are;

$$\pi_1 = \frac{\rho v D}{\mu} \tag{2}$$

$$\pi_2 = \frac{v^2}{gD} \tag{3}$$

$$\pi_3 = C_c \tag{4}$$

$$\pi_4 = \theta \tag{5}$$

$$\pi_5 = \frac{\Omega D}{v} \tag{6}$$

2.2. Log-log regression (LLR)

In the log-log regression model, dependent and independent variables are processed by taking their logarithms. In other words, the log-log regression model works on the basis of transforming the data into terms that allow it to be expressed logarithmically. This model is quite successful in modeling scale-dependent relationships and effectively modeling linearized correlations and processing data. A study was conducted by Lemaire et al. (2024) to estimate hydraulic conductivity and the log-log regression model was used to relate some of the data in the study. In the study conducted by Nigate et al. (2024), the parameters of volcanic aquifer systems were estimated in order to provide groundwater analysis and management and it was concluded that log-log regression is a powerful tool in interpreting the data.

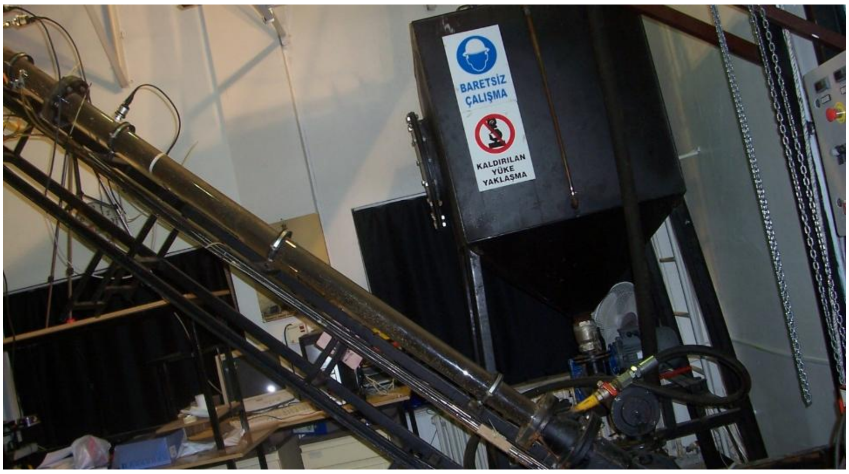

Figure 1: Experimental Test Setup (Sorgun, 2010).

2.3. Artificial neural network (ANN)

Artificial neural networks have a structure similar to the human brain in terms of working principle. This structure consists of nodes corresponding to neurons in the human brain and the connections between these nodes. These connections form the layers of the model: Input layer, internal layers and output layer. It is one of the algorithms that performs quite well in analyzing and modeling complex data. Williams and Ojuri (2021) conducted a prediction study on the hydraulic conductivity of soil types and as a result, it was revealed that the ANN model performed better in the context of estimating hydraulic conductivity than other models. According to Tawfik (2023), instead of using time-consuming traditional models to solve pipeline systems, an ANN was trained to predict the flow rate. The ANN model provided a successful correlation between real data and the prediction results.

2.4. Teaching-learning based optimization (TLBO)

TLBO is defined as a model that does not require any algorithm-specific parameters (Rao, 2016). As the name suggests, this algorithm is an algorithm that works on the principle of teacher and student. In the teaching process, information is transferred to the learning process and the solution space of the learning process is strengthened. In the learning process, each point receives information from each other and aims to provide more consistent and better solutions. In the study conducted by Sayari et al. (2019), other algorithms were used together with TLBO to estimate the critical flow rate for sediment transport in the pipeline. As a result of this study, it was determined that the TLBO algorithm improved the results of other models. Elshaboury et al. (2021) conducted a study on estimating the condition of pipes in water distribution lines in a region in Egypt and it was seen that much more accurate and successful results were obtained by strengthening the FFNN model with the TLBO algorithm.

2.5. Extreme gradient boosting (XGBoost)

The XGBoost model was developed from decision trees and is considered an important advance in the field of artificial intelligence techniques and machine learning (Niazkar et al, 2024). This model consists of a series of decision trees and works with the principle of gradient descent. In other words, each tree in its structure works to improve and optimize the errors in the previous tree. It is one of the algorithms frequently used in solving regression and classification problems thanks to its fast and accurate results even in large and complex data sets. Sun et al. (2024) optimized the genetic algorithm (GA) with the XGBoost algorithm to estimate the bottom cavity pressure in reservoirs and created a hybrid GA-XGBoost model. It was determined that this hybrid model gave better results compared to other models, made much more successful generalization especially with smaller data sets and produced consistent results.

2.6. Negative binomial regression (NBR)

The negative binomial distribution can be defined as the discrete distribution of the number of successes of Bernoulli trials that are independently and identically distributed before a certain number of errors are seen (Yang and Berdine, 2015). In fact, this model is similar to Poisson regression in terms of how it works, but since Poisson regression can only work when the variance and mean are equal, it does not work correctly when this equality is broken and leads to overdispersion. Negative binomial regression is preferred on data where the overdispersion problem is seen and uses numerical data as the dependent variable.

2.7. Gaussian process regression (GPR)

Gaussian process regression is a machine learning model based on Bayesian regression and is one of the algorithms that show strong performance in modeling uncertain sets. This regression model defines the relationship between points in a data set as a function. Gaussian process is defined in Gerschman and Blei (2012) as a nonparametric and discriminative approach that models the conditional distribution of output data after processing the input data. This model specifies a probability function to make predictions by considering that the function values come with the distribution. Gaussian process regression works much faster than other regression models and techniques used in the literature and saves the result functions (Schulz et al., 2018).

In this study, the estimation of the friction factor, which is important for sediment transport in the annulus, was estimated using machine learning algorithms such as Log-Log Regression (LLR), Artificial Neural Network (ANN), Teaching-Learning Based Optimization (TLBO), Extreme Gradient Boosting (XGBoost), Negative Binomial Regression (NBR) and Gaussian Process Regression (GPR), and the comparison of these estimation results with experimental data were discussed.

3. Results & discussion

Firstly, the parameters affecting the friction factor were determined and dimensional analysis was performed with Buckingham Pi Theorem. In continuation of the dimensional analysis, dimensionless parameters were created and the dataset was transferred to Python. The experimental data used in this study were taken from Sorgun (2010). A small representation of the parameters is given in Fig. 2. A new friction factor equation was proposed with the pi-terms formed as a result of the dimensional analysis. Then, the friction factor was estimated with machine learning algorithms in Python and compared with experimental friction factor data. The coding of the XGBoost algorithm can be seen as an example in Fig. 3. The graphical interpretation of these results can be seen in Fig. 4, Fig. 5, Fig. 6, Figure 7, Fig. 8 and Fig. 9, where the relevant data are presented. Additionally, the R^2 (R-Square), AAE (Average Absolute Error), AAPE (Average Absolute Percentage Error) and RMSE (Root Mean Square Error) values of the machine learning models used are presented in Table 1.

4. Conclusion

In this study, the friction factor was estimated by machine learning algorithms and compared with experimental data. Based on the estimation results and comparisons made;

- LLR performed slightly better than other machine learning models (based on LLR=18.70% AAPE value).
- Artificial Neural Network (ANN) follows LLR by a small margin (based on ANN=19.00% AAPE value).
- It has been observed that the performance of LLR, ANN, TLBO and XGBoost models are quite close to each other (based on LLR=18.70%, ANN=19.00%, TLBO=19.18% and XGBoost=20.67% AAPE values).
- GPR performed quite poorly compared to other models (based on GPR=48.53% AAPE value).

Determination of unit hydrographs for Karabuk Bulak stream in Türkiye using six different synthetic methods

Sayed Abdul Matin Hashemi[1], Hasan Törehan Babacan[2], Fatih Saka*[1]

[1] *Karabuk University, Department of Civil Engineering, 78000 Karabük, Türkiye*
[2] *Amasya University, Taşova Yüksel Akın Vocational School,Transportation Services Department , 05000 Amasya, Türkiye*

Abstract. In water resources planning, hydrographs that show the variation of flow over time are very important. The unit hydrograph, which can reveal the relationships between precipitation and flow that have the most effect on flow, is also very important for understanding the time of peak discharge. Synthetic unit hydrograph methods are useful for estimating runoff, especially in cases where rainfall data are missing or incomplete. Different synthetic methods may be suitable for different basins according to basin characteristics. In this study, the unit hydrographs of the Bulak basin in Karabük province were obtained and compared using six different synthetic unit hydrograph methods: Snyder, SCS, Mockus, DSİ, Nakayasu and Gamma methods. The peak discharge and the times to reach peak discharge were obtained as follows, using the Snyder, DSİ, Mockus, SCS, Nakayasu and Gamma methods, respectively: 1.029 ($m^3/s/mm$), 6.07 hours, 1.96 ($m^3/s/mm$), 3.15 hours, 1.847 ($m^3/s/mm$), 3.38 hours, 3.33 ($m^3/s/mm$), 1.91 hours, 2.88 ($m^3/s/mm$), 2.16 hours, and 3.426 ($m^3/s/mm$), 1.75 hours.

Keywords: Synthetic unit hydrograph; Snyder; SCS; DSİ Synthetic; Mockus; Nakayasu; Gamma

1. Introduction

Water plays a critical role in human life and ecosystems but also poses risks when excessive rainfall leads to floods (United Nations World Water Assessment Programme (WWAP), 2021). To preserve current water resources, address the rising demand from the country's rapidly growing population, and tackle potential future challenges, a comprehensive, well-structured long-term strategy is essential for sustainable water resource management. Effective planning and management of natural resources require a thorough understanding of the hydrological behavior of watersheds (N. Singh & Singh, 2017). Floods, often exacerbated by human land use practices, require careful management through hydrological analysis and protective infrastructure (Bedient et al., 2013). Understanding the rainfall-runoff relationship within watersheds is essential for designing effective flood control measures, with unit hydrograph analysis being a key tool (Ven Te Chow & David R. Maidment, 1988). A hydrograph illustrates the fluctuation of discharge over time, comprising a rising limb (flow increase), peak (maximum flow), and falling limb (flow decrease) (Dingman, 2015; Ven Te Chow & David R. Maidment, 1988). This was one of the first tools available to the hydrologic community for determining the complete shape of hydrographs, rather than just peak discharges, and is essential for understanding flood dynamics and watershed behavior (Bhunya, Panda, et al., 2021; Kalgonda Patil & Bhagwat, 2019).

The unit hydrograph, introduced by Sherman in 1932 (L.K. Sherman, 1932), represents direct runoff from 1 cm of effective rainfall over a specific duration. Its assumptions include uniform rainfall distribution and proportional hydrograph ordinates (Dingman, 2015; Ven Te Chow & David R. Maidment, 1988). While simplifying complex rainfall-runoff relationships, the theory is unsuitable for large basins or events involving snowmelt (Gupta, 2017; Maidment, 1993). Unit hydrographs can be derived from observed rainfall and runoff data, but in their absence, synthetic unit hydrographs (SUH), derived from watershed characteristics rather than rainfall-runoff records, are commonly used (Bhunya et al., 2007). Due to similarity in the shape of statistical distributions and a conventional unit hydrograph, several attempts have been made by different researches to derive the SUHs by using the probability distribution functions (pdfs) (Bhuyan et al., 2015). Synthetic unit hydrograph methods were originally classified into four primary categories: traditional methods, conceptual methods, probabilistic methods, and geomorphological methods (Kalgonda Patil & Bhagwat, 2019; Pedroso & Mannich, 2021).

This study focuses on deriving and evaluating synthetic unit hydrographs for the Bulak watershed in Karabük, Türkiye. Six synthetic methods (Snyder, SCS, Mockus, DSİ, Nakayasu and Gamma) were reviewed and applied.

2. Materials and methods

2.1. Characterization of the study area

The study area encompasses the Bulak Stream Basin located within the Karabük Province, situated in the Western Black Sea Region of Turkey. The province shares its borders with Bartın to the north, Kastamonu to the northeast and east, Çankırı to the southeast, Bolu to the southwest, and Zonguldak to the west (Karabuk Governorship, 2022). On the 1:25,000 topographic map, the basin is depicted on sheets F29-a3, F29-a4, F29-d1, and F29-d2 (General Command of Mapping, 2019). Furthermore, the Karabük Province is situated at an average elevation of approximately 270 meters above sea level, characterized by valleys and plateaus (Karabuk Governorship, 2022). The geographic location of Karabük Province within Türkiye and the specific location of the Bulak Basin within Karabük Province are illustrated in Fig. 1.

Karabük Province exhibits partial characteristics of the Black Sea climate (Türkeş, 2012). While the annual average air temperature in the Black Sea Region is 13.15°C (TSMS (Türkiye Meteoroloji Genel Müdürlüğü), 2021), it is approximately 13.2°C in Karabük Province (TSMS (Türkiye Meteoroloji Genel Müdürlüğü), 2022). During July, the warmest month of the year, the average air temperature in the Black Sea Region is 23.24°C (TSMS (Türkiye Meteoroloji Genel Müdürlüğü), 2021), while it hovers around 23.1°C in Karabük. January is the coldest month in Karabük, with an average air temperature of 2.6°C (TSMS (Türkiye Meteoroloji Genel Müdürlüğü), 2022). The highest recorded air temperature in the province is 43°C, whereas the lowest is -14.2°C (TSMS (Türkiye Meteoroloji Genel Müdürlüğü), 2021).

For the study area, rainfall is most abundant in late autumn and scarce in early spring, akin to the Eastern Black Sea Region (Bahadır & Özdemir, 2011). However, the precipitation amount is nearly half that of the Eastern Black Sea Region (TSMS (Türkiye Meteoroloji Genel Müdürlüğü), 2022). Karabük Province experiences precipitation throughout the year due to its Black Sea climate characteristics(Türkeş, 2012), yet it undergoes a dry period in July and August . The annual average precipitation in the province is 487.7 mm, with a prevailing wind direction from the southwest, and an annual average wind speed of 0.8 m/s (TSMS (Türkiye Meteoroloji Genel Müdürlüğü), 2022).

2.2. Synthetic unit hydrograph methods

Synthetic unit hydrographs are generally categorized into three groups in the literature (Maidment, 1993). Those that relate watershed characteristics to hydrograph characteristics (peak flow rate, base time, etc.), such as the Snyder (Snyder, 1938) and Gray methods (Bhunya, S.N. Panda, et al., 2021; Patil & Bhagwat, 2019). Those based on dimensionless unit hydrographs, such as the SCS method (US Soil Conservation Service (SCS), 1986). Those based on watershed storage models, such as the Clark method (Clark, 1945).

In this section, we briefly discuss several synthetic unit hydrograph methods that are commonly used, including Snyder, SCS, Mockus, DSİ, Nakayasu and Gamma synthetic methods.

2.2.1. Snyder synthetic unit hydrograph method

In 1938, Franklin F. Snyder proposed the concept that watershed characteristics, such as shape, topography, main channel slope, flow density, and channel storage, influence the shape of hydrographs (Snyder, 1938). Based on this idea, he introduced an empirical unit hydrograph formula called the synthetic unit hydrograph, which averages these characteristics with coefficients for watersheds of similar character (Linsley et al., 1982; Ponce, 1989; Snyder, 1938; Viessman, 2003)

The Snyder method (Snyder, 1938), the first unit hydrograph method applied in watersheds with no historical rainfall-flow measurements, remains one of the most widely used synthetic unit hydrograph methods today (Gupta, 2017; Maidment, 1993). In international literature, the Snyder method is noted for assuming that each watershed has a single unique unit hydrograph (V. P. Singh, 1988). Snyder conducted extensive research on watersheds in the Appalachian Mountains region of the United States, with watershed areas ranging from 26 to 26.000 km², resulting in a standardized unit hydrograph shape (Linsley et al., 1982; Snyder, 1938). The key formulas for calculating hydrograph parameters using the Snyder method are provided in various hydrology texts (Linsley et al., 1982; V. P. Singh, 1988; Snyder, 1938).

$$t_L = 0.75 \times C_t \times (L \times L_c)^{0,3} \tag{1}$$

$$t_r = \frac{t_L}{5.5} \tag{2}$$

$$t_p = \left(\frac{t_r}{2}\right) + t_L \tag{3}$$

$$Q_p = \alpha \frac{C_p \times A}{t_L} \tag{4}$$

Here, L represents the main channel length up to the watershed boundary (in km), L_c is the length from the watershed centroid to the watershed outlet (in km), C_t is a timing coefficient (typically between 1.8 and 2.2), t_L is the lag time of the unit hydrograph for the watershed (in hours), t_r is the effective rainfall duration (in hours), t_p is the time to peak (in hours), Q_p is the peak discharge (in m³/s/mm), α is a conversion constant (0.275 for SI units, 640 for CU units), and C_p is a peak coefficient (typically between 0.59 and 0.69, depending on soil type) and A is the drainage area of the watershed (in km²). Using the formula below, base time (T_b) can be calculated (McCuen, 2016).

$$T_b = 5 \times [\left(\frac{t_L}{11}\right) + t_L] \tag{5}$$

Additionally, following equations provide formulas for calculating the widths of the hydrograph at 50% (W_{50}) and 75% (W_{75}) of the peak discharge.

$$W_{50} = \alpha_{50} \times \left(\frac{Q_p}{A}\right)^{-1.075} \tag{6}$$

$$W_{75} = \alpha_{75} \times \left(\frac{Q_p}{A}\right)^{-1.075} \tag{7}$$

Here, α_{50} and α_{75} are constants, 0.18 for both, used in the formulas (V. P. Singh, 1988).

2.2.2. SCS synthetic unit hydrograph method

The Soil Conservation Service (now known as the Natural Resources Conservation Service or NRCS) developed the SCS Method (US Soil Conservation Service (SCS), 1986), which derives unit hydrographs with a simple triangular shape from numerous hydrographs obtained from different regions and watershed characteristics.

In the SCS method, the process begins with determining the time of concentration (T_c), which is also referred to as the concentration time.

$$T_c = 0.066 \times (\frac{L^2}{S_0})^{0.385} \ (hours) \tag{8}$$

Here, L is the main channel length of the watershed (in km), and S_0 represents channel slope (McCuen, 2016; US Soil Conservation Service (SCS), 1986). Next, the lag time (t_L) and effective rainfall duration (t_r) are calculated using the following equations:

$$t_L = 0.6 \times T_c \ (hours) \tag{9}$$

$$t_r = 0.133 \times T_c \ (hours) \tag{10}$$

The time to peak (t_p) is determined using following equation (McCuen, 2016):

$$t_p = \left(\frac{t_r}{2}\right) + t_L \tag{11}$$

The potential maximum retention capacity of the watershed is denoted as S and is related to the hydrological characteristics of the watershed, as well as factors such as vegetation cover. The formula for S is presented in the following equation:

$$S = \left(\frac{25400}{CN}\right) - 254 \ (mm) \tag{12}$$

Here, CN represents the curve number of the watershed, which takes values between 0 and 100. CN is a function of the watershed's soil classification and surface cover (McCuen, 2016; Mishra & Singh, 2003; Pedroso & Mannich, 2021). The peak discharge (Q_p) can be calculated using the formula:

$$Q_p = \frac{0.2083 \times A}{t_p} \left(\frac{\frac{m^3}{sn}}{mm}\right) \tag{13}$$

where A is the watershed area (in km²) and t_p is the time to peak (in hours) (McCuen, 2016).

The SCS triangular unit hydrograph does not include a base time, as it is a simple triangular shape without a flat base (McCuen, 2016). The SCS method is widely used due to its simplicity and is particularly useful when hydrograph data are not available for a specific watershed. However, it is important to note that it assumes a triangular unit hydrograph shape, which may not accurately represent the actual hydrograph characteristics of all watersheds (Mishra & Singh, 2003).

2.2.3. DSİ synthetic unit hydrograph method

This method is applied to watersheds up to 1000 km² in size. When applied to watersheds larger than 1000 km², the watershed area should be divided, and a separate unit hydrograph should be determined for each sub-area. Additionally, the unit hydrographs used in this method are obtained based on 2-hour rainfall values, so the time to peak of the unit hydrograph (T_p) should not be less than 2 hours (Demir & Ülke Keskin, 2022; Gevrek & İrvem, 2021; Tanrıverdi, 2021). The formulas used in the DSİ synthetic unit hydrograph method are the following:

$$E = \frac{L \times L_c}{\sqrt{S_h}} \tag{14}$$

$$q_p = \frac{414}{A^{0.225} \times E^{0.16}} \tag{15}$$

$$Q_p = q_p \times A \times 10^{-3} \tag{16}$$

$$V_b = A \times h_a \times 10^{3} \tag{17}$$

$$t_b = 3.65 \times \frac{V_b}{Q_p} \tag{18}$$

Where, E is a dimensionless coefficient dependent on the harmonic slope of the main channel, S_h represents the harmonic slope of the main channel (%), q_p is the unit discharge (lt/sec/km^2/mm), Q_p denotes the peak discharge of the hydrograph (m³/sec/mm), V_b represents the total water volume of the hydrograph (m³), t_b signifies the base volume of the hydrograph, A is the watershed area (km²), L is the main channel length (km), L_c is the distance from the centroid to the outlet (km), and ha is the effective rainfall depth (mm) (Tanrıverdi, 2021).

In the DSİ Synthetic Unit Hydrograph method, the time to peak (t_p) is theoretically determined by summing the lag time (t_L) and 80% of the effective rainfall duration (t_r), as given by the equation $t_p = t_L + 0.8 \times t_r$. However, in practical applications where detailed rainfall-runoff data are limited, t_p is commonly approximated as one-fifth of the base time (t_b), i.e., $t_p \approx t_b / 5$. This practical approach allows for a simplified estimation of the hydrograph shape and timing, and has been commonly adopted in DSİ engineering studies (Ekemen Keskin et al., 2018).

2.2.4. Mockus synthetic unit hydrograph method

The Mockus method is another synthetic unit hydrograph method commonly used for obtaining unit hydrographs in watersheds where rainfall-runoff data is not available. The simplicity of calculation and the triangular shape of the resulting hydrograph make this method widely used (McCuen, 2016; Mishra & Singh, 2003; US Soil Conservation Service (SCS), 1986). According to the literature, some sources suggest that the method can be applied in watersheds smaller than 1000 km² (Linsley et al., 1982; Mishra & Singh, 2003), while others indicate it is more suitable for watersheds smaller than 10 km² (Linsley et al., 1982; McCuen, 2016). Additionally, it is emphasized that the time of concentration should be less than 30 hours for the Mockus method to be applicable (Linsley et al., 1982; McCuen, 2016; Mishra & Singh, 2003; Ponce, 1989; V. P. Singh, 1988; Viessman, 2003).

In the Mockus method, like in the Snyder method, certain watershed coefficients are required for calculation. One of these coefficients is the climate parameter (K), and the other is H_c. H_c depends on the climate parameter K and ranges from 1 to 2. K, on the other hand, can be determined based on a known unit hydrograph from a watershed with similar climatic characteristics. However, if there is no watershed with similar characteristics, the K coefficient can be considered as 0.208 (Mishra & Singh, 2003; Ponce, 1989). The formulas required for the Mockus synthetic unit hydrograph method are:

$$t_c = 0.00032 \times \left(\frac{L^{0.77}}{So^{0.385}}\right) \tag{19}$$

$$t_r = 2 \times t_c^{\frac{1}{2}} \tag{20}$$

$$t_p = 0.5 \times t_r + 0.6 \times t_c \tag{21}$$

$$t_f = H_c \times t_p \tag{22}$$

$$Q_p = K \times A \times \frac{h_a}{t_p} \tag{23}$$

Where tc is the concentration time of the hydrograph (hours), t_r is the effective rainfall duration (hours), t_p is the time to reach the peak (hours), t_f is the recession time of the hydrograph, and Q_p is the peak discharge of the hydrograph (m³/sec/mm). L is the length of the main channel of the watershed (km), S_0 represents the slope of the main channel (m/m), and A is the watershed area (km²). L is the length of the main channel of the watershed (km), S_0 represents the slope of the main channel (m/m), and A is the watershed area (km²). The rainfall height h_a is taken as 1 mm in the peak discharge formula.

2.2.5. Gamma synthetic unit hydrograph method

The Gamma synthetic unit hydrograph method requires more watershed and river characteristics compared to other synthetic methods to determine the unit hydrograph for the desired watershed (Mishra & Singh, 2003; US Soil Conservation Service (SCS), 1986). Before calculating parameters such as peak discharge and time to peak for the hydrograph, factors such as Source Factor (SF), Source Frequency (SN), Joint Number (JN), Drainage Network Density (D), Width Factor (WF), Symmetry Factor (SIM) and Relative Upstream Area (RUA) of the watershed must be determined (Rodríguez-Iturbe & Valdés, 1979). Formulas to obtain these parameters are:

$$SF = \frac{\text{Total length of 1st order streams}}{\text{Total length of the stream network}} \quad (24)$$

$$SN = \frac{\text{Total number of 1st order streams}}{\text{Total number of the stream network}} \quad (25)$$

$$JN = (\text{Total number of 1st order streams}) - 1 \quad (26)$$

$$D = \frac{\text{Total length of the stream network}}{\text{Watershed area}} \quad (27)$$

$$WF = \frac{\text{Width of the watershed at 75\% distance from the outlet}}{\text{Width of the watershed at 25\% distance from the outlet}} \quad (28)$$

$$RUA = \frac{\text{Area at the headwaters of the watershed}}{\text{Watershed area}} \quad (29)$$

$$SIM = WF \times RUA \quad (30)$$

Once these watershed parameters are obtained, the hydrograph's time to peak (t_p), peak discharge (Q_p), and baseflow time (t_b) are calculated using the following formulas.

$$t_p = 0.43(\frac{L}{100 \times SF})^3 + 1.0665 \times SIM + 1.2775 \quad (31)$$

$$q_p = 0.1836 \times A^{0.5886} \times t_p{}^{-0.4008} \times JN^{0.2381} \quad (32)$$

$$t_b = 27.4132 \times t_p{}^{0.145} \times s_0{}^{-0.0986} \times SN^{0.7344} \times RUA^{0.2574} \quad (33)$$

2.2.6. Nakayasu synthetic unit hydrograph method

The Nakayasu synthetic unit hydrograph method was developed based on studies conducted on numerous rivers in Japan in the 1940s by Dr. Nakayasu (H. M. Raghunath, 2006; V. P. Singh, 1992). Unlike other synthetic unit hydrograph methods, calculations in this method do not require coefficients specific to the watershed. Instead, readily available watershed characteristics like area and length are used for calculations, simplifying the process. However, it's worth noting that this method is rarely used in Turkey and European countries, despite its popularity in East Asian countries (Bhunya, S.N. Panda, et al., 2021; US Soil Conservation Service (SCS), 1986).

To apply this method, some coefficients need to be determined, including α and the rainfall coefficient C. The α coefficient ranges from 1.5 to 3, while C is typically considered as 1 in the literature (Kamila et al., 2019; Limantara* et al., 2019). The delay time of the hydrograph, t_L, is calculated using different formulas depending on the length of the main channel. If the length of the main channel of the watershed is greater than 15 km:

$$t_L = 0.4 + 0.058 \times L \quad (34)$$

If the length of the main channel of the watershed is less than 15 km:

$$t_L = 0.8 + 0.048 \times L \quad (35)$$

After determining the delay time of the hydrograph, other parameters required for hydrograph construction are calculated using the following formulas:

$$t_r = 0.75 \times t_L \quad (36)$$

$$t_p = t_L + 0.8 \times t_r \quad (37)$$

$$t_{0.3} = \alpha \times t_L \quad (38)$$

$$Q_p = \frac{C \times A \times h_a}{3.6 \times (0.3 \times t_p + t_{0.3})} \quad (39)$$

In these formulas. tr represents the effective rainfall duration (hours). t_p is the time to reach the peak (hours). $t_{0.3}$ is the time required for the hydrograph to decrease to 30% of its peak. and Q_p is the peak discharge of the hydrograph (m^3/sec/mm) (Kamila et al., 2019; Limantara* et al., 2019).

3. Results and discussion

3.1 Basin characteristics

The basin's area, slope, elevations, and other characteristics were obtained using the Global Mapper extension. The maximum. minimum. and average elevations for the Bulak Basin were determined to be 1583.81 m. 280.16 m. and 651.82 m. respectively.

The main watercourse of the basin has a length of 16.508 km. The centroid of the basin is situated at an elevation of 664 m above sea level. and the distance to the basin's outlet is determined to be 6.851 km. The basin parameters for the study area. the Karabük Bulak Stream Basin. are presented in Table 1.

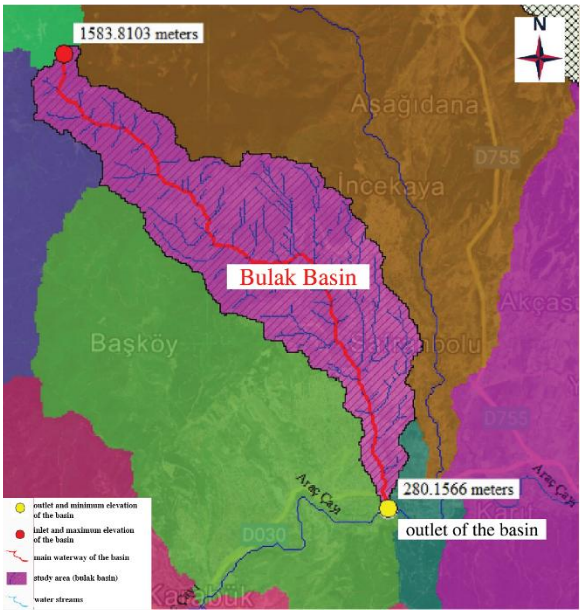

Fig. 2. Minimum and Maximum Elevation Values of the Basin

Table 1. Quantitative parameters identified for the Karabuk Bulak Stream Basin.

No	Parameters	Symbol	Value	Unit
1	Basin Area	A	30.485354	km²
2	Main Channel Length	L	16.389	km
3	Distance from Centroid to Outlet	L_c	6.851	km
4	Maximum Elevation of the Basin	-	1583.81	m
5	Minimum Elevation of the Basin	-	280.16	m
6	Harmonic Slope of the Main Channel	So	1.501863	%
7	Total Length of Stream Network	-	88.327	km
8	1st Order Stream Networks	-	121	count
9	Total Length of 1st Order Stream Networks	-	47.575	km
10	Total Stream Network Count	-	190	count
11	Basin Width at 25% Distance from Outlet	-	1.609	km
12	Basin Width at 75% Distance from Outlet	-	1.624	km

3.2 Unit hydrograph calculation for the Karabük Bulak Stream Basin using synthetic methods

Unit hydrograph calculations for the Karabük Bulak Stream Basin were performed using the Snyder. DSİ. SCS. Mockus. Nakayasu. and Gamma methods. In the calculations, the slope of the main channel was computed harmonically to prevent it from being influenced by extreme values (elevations of the highest-ranked channel). This harmonic slope was considered for all six methods used. The dimensionless unit hydrograph corresponding to the SUH methods was constructed based on standard dimensionless relationships and graphically presented. The validation of the hydrograph was performed by comparing the area under the hydrograph curve with the direct runoff volume corresponding to unit precipitation. The dimensionless unit hydrograph coordinates were developed, and their validation involved comparing the area under the hydrograph curve with the direct runoff volume corresponding to unit precipitation.

3.2.1. Unit hydrograph calculation using the Snyder synthetic method

To apply the Snyder method, it is necessary to determine the coefficients C_t and C_p. In this study. C_t and C_p coefficients were adjusted based on the total water volume of the basin. with $C_p = 0.683$ and $C_t = 1.8$. The required basin parameters for the application of this method are as follows: A = 30.485354 km². L = 16.389 km. $L_c = 6.851$ km. and ha = 1 mm.

Since a 1-hour unit hydrograph is desired for the basin. and the effective rainfall duration (t_r) is close to 1 hour. it was considered $t_R = t_r$. $q_{pR} = q_P$ and $t_{LR} = t_L$ for further calculations.

Using the Snyder method. the derivation of the unit hydrograph for the Karabük Bulak Stream Basin yielded several key hydrographic parameters. The time lag (t_L) was calculated as 5.564 hours. while the effective rainfall duration (t_r) was 1.012 hours. The time to peak (t_p) was determined to be 6.07 hours. The unit peak discharge (Q_p) was found to be 1.029 m³/s/mm. The hydrograph width at 50% of the peak discharge (w_{50}) was 6.876 hours. and at 75% of the peak (w_{75}). it was 3.82 hours.

The base time of the hydrograph (T_b) was calculated to be 30.352 hours. These results yielded the development of the unit hydrograph for the basin using the Snyder method. as illustrated in the Fig. 3.

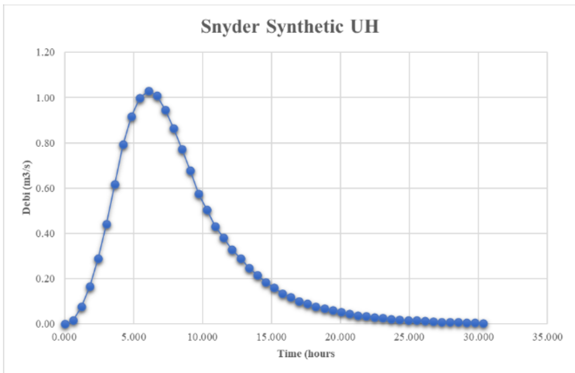

Fig. 3. Snyder unit hydrograph for the study area

3.2.2. Computation of basin unit hydrograph using DSİ synthetic method

The slope of the basin, like other basin parameters was obtained using the Global Mapper program. Additionally, harmonic slope calculation was used to prevent misleading results due to extreme values in channel slopes. The DSİ Synthetic method initiated the hydrograph solution by calculating the dimensionless coefficient E dependent on the harmonic slope to be used in the unit discharge resulting in 916.20 using formula (2.13).

Subsequently, the unit discharge (q_p) (lt/sec/km^2/mm) and peak discharge (Q_p) (m^3/sec/mm) values were calculated as 64.44 lt/sec/km^2/mm, and 1.96 m³/s/mm, respectively. The unit volume (V_b, m^3), base time (T_b), and time to peak (t_p) of the hydrograph were found as 30485 m^3, 15.73 and 3.15 hours, respectively. The unit hydrograph of the Karabük Bulak stream basin was drawn in Fig 4.

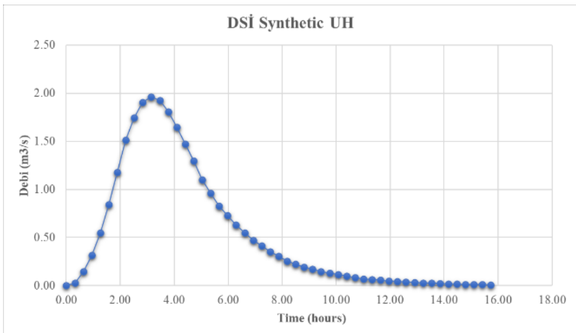

Fig. 4. Unit hydrograph obtained with the DSİ synthetic method for the Bulak basin

3.2.3. Computation of basin unit hydrograph using Mockus synthetic method

For the Mockus synthetic unit hydrograph method, the basin-specific coefficients K and H_c were adopted as 0.205 and 1.67, respectively. In cases where the K coefficient cannot be determined based on watershed characteristics, a default value of 0.208 is typically assumed to facilitate hydrograph derivation. In this study, however, the K value was slightly adjusted to ensure that the total volume under the unit hydrograph accurately reflects the effective rainfall-runoff volume. The concentration time (tc, hours) for the Mockus method was calculated as 2.836 hours. Subsequently, the effective rainfall duration (t_r, hours), time to peak (t_p, hours), and recession time (t_f, hours), as well as the desired discharge value, were calculated as 3.367, 3.384, 5.6506 hours and 1.847 m^3/sec/mm, respectively. The unit hydrograph of the Karabük Bulak stream basin was drawn using the Mockus synthetic method and shown in Fig. 5.

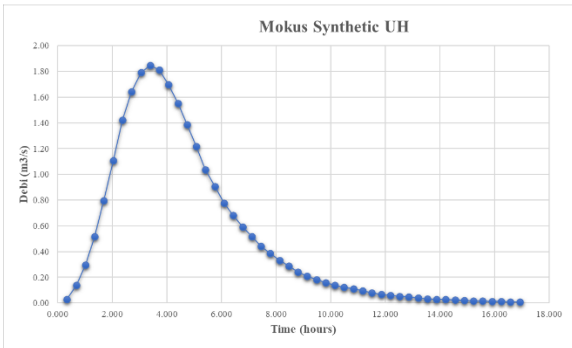

Fig. 5. Unit hydrograph obtained with the Mockus synthetic method for the Bulak basin

3.2.4. Computation of basin unit hydrograph using Nakayasu synthetic method

In the Nakayasu synthetic unit hydrograph method, the α coefficient, essential for hydrograph computation, generally ranges between 1.5 and 3 (Kamila et al., 2019). The rainfall coefficient, denoted as C, is typically taken as 1 (Limantara* et al., 2019). In this study, the α value was adjusted to 1.70 to ensure that the total volume under the hydrograph accurately represents the effective runoff. The computation of the hydrograph's lag time (t_L, hours) commenced by determining the time at which the hydrograph peaks. The lag time (t_L) for a basin with a main channel length greater than 15 km is calculated as 1.35 hours.

Subsequently, the effective rainfall duration (t_r) and time to peak (t_p) were calculated as 1.01 hours and 2.16 hours, respectively. To determine the time interval ($t_{0.3}$) required for the hydrograph to decrease by 30% of its peak discharge (Q_p), $t_{0.3}$ and Q_p were calculated as 2.30 hours and 2.88 m^3/sec/mm, respectively. With the peak discharge (Q_p) in hand, we proceeded to calculate the rising limb of the hydrograph's discharge (Q_a) and subsequently the base time (t_b) as 0.45 and 7.90 hours, respectively. Using the above calculated values of t_p, t_L, Q_p, t_r and t_b, the unit hydrograph of the Karabük Bulak Stream Basin using the Nakayasu synthetic method can be drawn as illustrated in Fig. 6.

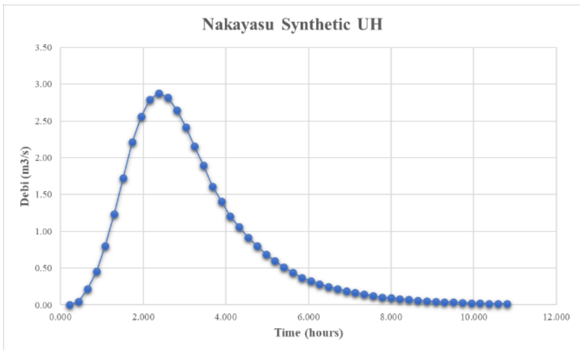

Fig. 6. Unit hydrograph obtained with the Nakayasu synthetic method for the Bulak basin

3.2.5. Computation of basin unit hydrograph using SCS synthetic method

The application of the SCS synthetic unit hydrograph method requires the determination of the Curve Number (CN). CN is a function of the basin's soil classification and land use, ranging between 0 and 100 (Mishra & Singh, 2003). For this study, the CN value was taken as 74, considering the region's soil type and land use. The necessary basin parameters for the application of this method are presented in Table 1. Potential Maximum Retention (S) value was calculated as 89.24 mm.

Subsequently, Concentration Time (t_c), Effective Rainfall Duration (t_r), Lag Time (t_L), Time to Peak (t_p), and Peak Discharge (Q_p) were calculated as 2.86, 0.38, 1.72, 1.91 hours and 3.33 m^3/sec/mm, respectively. With the calculated values of t_p, t_L, Q_p, t_c and t_r, the unit hydrograph of the Karabük Bulak Stream Basin using the SCS method is drawn in Fig. 7.

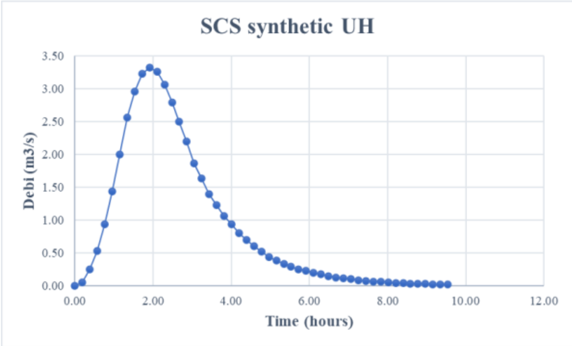

Fig. 7. Unit hydrograph obtained with the SCS synthetic method for the Bulak basin

3.2.6. Computation of basin unit hydrograph using Gamma synthetic method

The Gamma synthetic unit hydrograph method demands more extensive knowledge of basin and river characteristics compared to other methods. To calculate the time to peak (tp), peak discharge (Qp), and base time (tb) using the Gamma synthetic unit hydrograph method, it is first necessary to determine the relevant Gamma factors. These include the Source Factor (SF), Source Frequency (SN), Joint Number (JN), Drainage Network Density (D), Width Factor (WF), and Symmetry Factor (SIM), so these values were calculated as 0.5386, 0.6368, 120, 2.897 km/km^2, 1.009, 0.43 and 0.434, respectively. Based on the above calculated values, time to peak (t_p), peak discharge (q_p), and base time (t_b) were calculated as 7.75 hours, 3.426 m^3/sec and 10.52 hours, respectively. The unit hydrograph for the basin using the Gamma synthetic unit hydrograph was shown in Fig. 8.

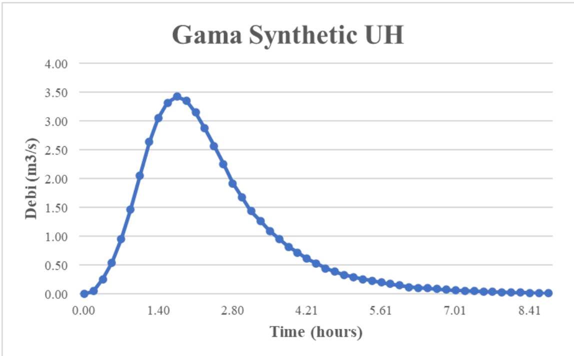

Fig. 8. Unit hydrograph obtained with the Gamma synthetic method for the Bulak basin

4. Conclusions

The dimensionless unit hydrograph coordinate values required for transferring peak flow and time to peak from synthetic hydrographs to the observed hydrograph were controlled to ensure that they match the water volume entering the basin. In the literature, the availability or development of these coordinate values for all synthetic methods is important for obtaining more accurate results in future studies.

Effective rainfall duration was obtained without losses such as infiltration, considering only the recorded rainfall for hydrograph estimation. Especially in larger basins, future studies can take into account such effects to conduct different investigations.

According to the Snyder method, the unit hydrograph peak discharge is higher by 0.93 $m^3/s/mm$ for DSİ, 0.82 $m^3/s/mm$ for Mockus, 2.30 $m^3/s/mm$ for SCS, 1.82 $m^3/s/mm$ for Nakayasu, and 2.40 $m^3/s/mm$ for Gamma, demonstrating how the peak discharge can be obtained from the lowest to the highest, respectively. The time to peak of unit hydrographs directly affects the durations of hydrographs that will be obtained with rainfall. Therefore, it is recommended to update unit hydrograph models by observing these values in real basins.

According to the Gamma method, the unit hydrograph time to peak discharge is higher by 4.32 seconds for Snyder, 1.4 seconds for DSİ, 1.634 seconds for Mockus, 0.16 seconds for SCS, and 0.41 seconds for Nakayasu, demonstrating how the time to peak discharge can be obtained in ascending order from the lowest to the highest, respectively. Since the times to reach peak discharge also vary with basin characteristics, these values need to be compared with real basin data.

Prediction of flood discharge with Jaya algorithm for Trabzon Province

Arife Günay*[1], Ömer Yüksek[1], Tuğçe Anılan[1]

[1]Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. Floods are the natural disasters that cause the highest life and property loss worldwide after earthquakes. Therefore, accurate prediction of flood discharges has a critical role in the design of hydraulic structures for economic and safe structure design. By employing developing technology, different algorithms are frequently used for modelling of flood flow prediction. In these modelling studies, a number of variables; including the areas, elevations, record lengths, latitude, and longitude of the stations are used as variable parameters. These studies are carried out for regions with a high probability of flooding. In this study, Trabzon Province of the Eastern Black Sea Basin (EBSB), one of the basins of Türkiye with a high probability of being exposed to flood disasters, was selected as the application basin. Various models were developed to estimate the flood discharges using the area and elevation data of 16 Stream Gauge Stations (SGS) located in the Trabzon province in the EBSB. The observation durations of SGS's were between 9 to 42 years. Multiple linear regression, classical regression (CRA), and Jaya algorithms that optimize hyperbolic and exponential regression functions were used for maximum flood flow estimations. As a result of the study, the Jaya optimization algorithm to model the maximum flood discharges, with low error values, has been found very successful.

Keywords: Prediction of flood discharge, Jaya algorithm, Regression analysis, Trabzon Province

1. Introduction

Floods are natural disasters that interrupt vital activities by causing loss of life, property, and land by exceeding the cross-section because of a rapid increase in the discharge in a riverbed (Demir and Keskin, 2022). Reliable estimation of flood discharges is important in the planning, design, and management of hydraulic structures to be built on the river (Anılan et al., 2016). The methods used for this can be divided into two main groups as deterministic and statistical methods. While it can be made deterministically by unit hydrograph method, it can also be made by statistical methods that use distributions such as Log-Normal III, Gumbel, and Log-Pearson Type III (Zhang et al., 2024). The study of predicting flood discharge at various return periods with the help of available discharge observations using these distributions is defined as flood frequency analysis. Some of the methods used in this analysis are listed by Anılan (2014) as follows: Method of moments, maximum likelihood method, least squares method, probability weighted method of moments, and L-moment method. In addition, developing computer technologies and optimization techniques have enabled better estimation of flood discharges by employing the existing data.

Thanks to technological developments, flood discharge prediction has become a subject that is frequently tried to be predicted with different optimization algorithms. For example, Shu and Burn (2004) and Dawson et al. (2006) showed that artificial neural networks (ANNs) can make more accurate flood discharge predictions compared to multiple regression models and empirical methods. Similarly, Shu and Ouarda (2007), Besaw et al. (2010), Seçkin et al. (2010), Aziz et al. (2013), Rezaeianzadeh et al. (2013), Anılan et al., (2016) and Anılan et al., (2020) showed that ANNs give good results in their studies. In addition to this success of ANN, the success of artificial bee colony and teaching-learning based optimization algorithms in flood discharge prediction has been demonstrated by Anılan et al. (2016) and Günay et al. (2024). In this study, the flood discharge prediction of Trabzon province located in the Eastern Black Sea Basin (ESBS) was made with the Jaya algorithm and classical regression analysis (CRA).

2. Materials and methods

2.1. Study area

The study area was selected as Trabzon province, which is in ESBS and is one of the provinces most exposed to floods. The reason for choosing a province from ESBS is that it receives high rainfall, has a mountainous and rugged topography, deforestation in the province, improper land use and stream beds opened to development (Yüksek et al., 2022). A location map of ESBS and Trabzon province, is given in Fig. 1.

In this study, data from 16 SGS's, located in Trabzon province with annual flow observations, which have 9 to 42 years observation durations, were used in the analyses. Drainage area and elevation data belonging to SGS's were used. Annual maximum discharges were taken from each station. These discharges were used in the analyses by taking their natural logarithms. The parameter values of these data used are shown in Table 1. The maximum and minimum values used for normalization of the data in the study methods are given in Table 2. These values were used in the proposed models to anomalyize the normalized results.

Table 1. Information about 16 stations located in Trabzon province

Station No	Drainage area (km^2)	Elevation (m)	Duration of observation (year)
2228	191.4	17	35
22-57	242.6	650	27
2202	635.7	78	42

D22A086	728.4	160	28

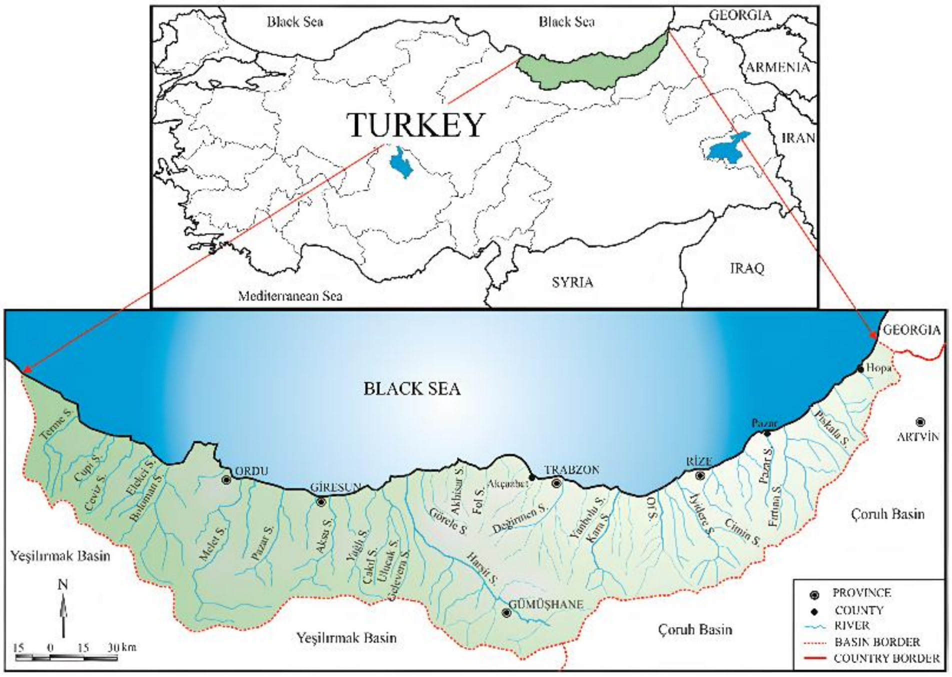

Fig. 1. Location map of EBSB and view of Trabzon Province (Anılan et al., 2016)

Table 2. Minimum and maximum values of input and output data

Parameters	Training Data		Testing Data	
	Min.	Max.	Min.	Max.
Drainage Area (DA), km^2	74.500	746.600	74.500	746.600
Elevation (E), m	17.000	1114.000	17.000	1114.000
ln(Q), m^3/s	2.272	5.565	2.342	5.497

2.2. Methods

Jaya optimization algorithm can solve complex engineering problems effectively (Rao, 2019; Uzlu and Dede, 2020; Houssein et al., 2021). In this study, CRA and Jaya algorithms were used to predict the probable maximum flood discharge. In these methods, the data taken from the stations and presented in Table 1 were divided into two groups as training (318 data) and test (80 data) sets. The separation process as training and test sets was carried out by considering the chronological order and ensuring that there was data from all levels in the training and test sets. Multiple linear, hyperbolic, and exponential regression functions were optimized in these algorithms. Drainage area and elevation information were used as input in these functions, and flood discharge was calculated as output. A normalization process was applied to the data for the swarm-based algorithms used. The normalization process was performed as in Eq. 1.

$$X_i = 0.8 \times \frac{(X - X_{min})}{(X_{max} - X_{min})} + 0.1 \quad (1)$$

where X_i is the normalized value of a particular parameter, X is the observed value for this parameter, X_{min} and X_{max} are the minimum and maximum values in the database for this parameter, respectively.

The results of the analyses performed in this study were used in the mean absolute error (MAE), root mean square error (RMSE) and relative error (RE) statistics, calculated from the following equations.

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(Yi_{observed} - Yi_{calculated})^2} \quad (2)$$

$$MAE = \frac{1}{N}\sum_{i=1}^{N}|Yi_{observed} - Yi_{calculated}| \quad (3)$$

$$RE = \frac{1}{N}\sum_{i=1}^{N}\left|\frac{Yi_{observed} - Yi_{calculated}}{Yi_{observed}}\right| * 100 \quad (4)$$

where, N is the number of data, and Yi is the maximum discharge.

The Jaya algorithm for optimizing multiple linear, hyperbolic, and exponential regression functions is described in Section 2.2.1.

2.2.1. Jaya algorithm

Jaya algorithm, which is faster than other algorithms and named after the word meaning victory in Sanskrit language, is an algorithm developed by Rao (2016) (Pradhan and Bhende 2019; da Silva et al., 2023). This optimization algorithm requires the ordinary control parameters to move toward the best solution, avoiding the worst (Mishra and Ray 2016; da Silva et al., 2023). This algorithm has two control parameters: Population size and maximum number of iterations. Jaya is an algorithm based on creating new individuals from the interaction of the best and worst individuals in a population. The purpose of this algorithm is for individuals in the population to move closer to the most successful individual and away from the worst individual. The flowchart of the algorithm is shown in Fig. 2.

According to this flowhart, a random initial population is generated. Then, the best and worst individuals in the population are determined using the objective function of the problem. The renewal of individuals is done in the general logic of the algorithm. Then, it is decided whether to keep the old state of the individual or to continue with the new state. In this way, iterations are continued by renewing all individuals until the stopping criterion is met (Uzlu, 2016; da Silva et al., 2023).

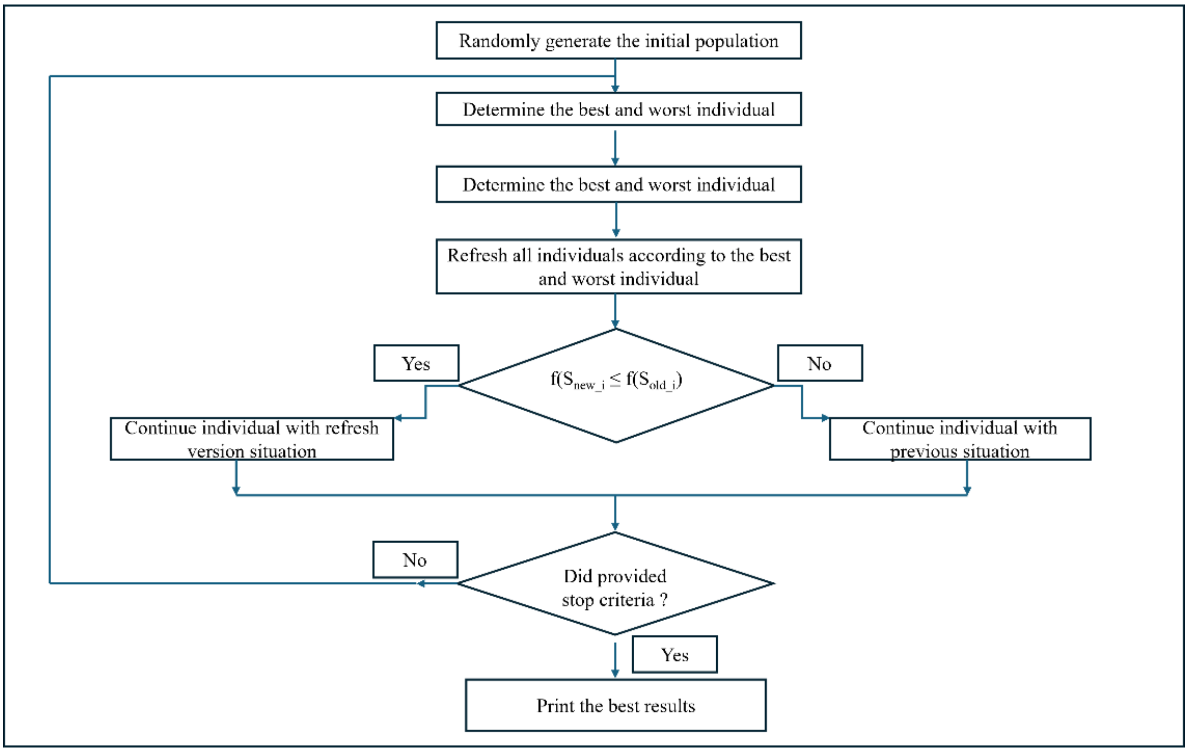

Fig. 2. Flowchart of Jaya algorithm

3. Findings and discussion

Table 3 shows the coefficients of the models developed using the analyses. Tables 4 and 5 show the results obtained from the training and testing set data. The bold values in Tables 4 and 5 show the most successful values in the analyses.

Table 3. Obtained coefficients

	Coefficients			
	w_0	w_1	w_2	w_4
CRA	3.550	0.002	−0.001	
Jaya	0.375	0.340	−0.146	
$y_{\ linear} = w_0 + (x_1)w_1 + (x_2)w_2$				
CRA	2.087	0.156	−0.045	
Jaya	0.521	0.287	−0.190	
$y_{\ hyperbolic} = w_0 (x_1)^{w1} (x_2)^{w2}$				
CRA	−6.648	2.324	0.0001	−6.271e-5
Jaya	−0.661	0.096	0.255	−0.220
$y_{\ exponential} = w_0 + exp(w_1 + (x_1)w_2 + (x_2)w_2)$				

*x_1: Drainage area, km^2; x_2: Elevation, m; y: Ln(*Q*), m^3/s

Table 4. Training data set results

Functions	MAE		RMSE		RE(%)	
	CRA	Jaya	CRA	Jaya	CRA	Jaya
Linear	0.383	**0.382**	**0.503**	**0.503**	10.457	**10.285**
Hyperbolic	0.391	**0.385**	0.515	**0.506**	10.841	**10.566**
Exponential	0.383	**0.383**	**0.503**	0.505	10.471	**10.407**

Table 5. Testing data set results

Functions	MAE		RMSE		RE(%)	
	CRA	Jaya	CRA	Jaya	CRA	Jaya
Linear	0.546	**0.554**	0.679	**0.706**	13.871	**13.915**
Hyperbolic	**0.512**	0.514	0.666	**0.654**	13.447	**13.415**
Exponential	0.536	**0.536**	0.669	**0.669**	13.788	**13.769**

According to the training set results given in Table 4, all regression functions optimized with the Jaya algorithm gave better results than CRA for all of the three examination criteria. Only the exponential function CRA gave better results according to the Jaya in RMSE criteria. According to the results of the testing set given in Table 5, Jaya algorithm gave the lowest MAE, RMSE, and RH values in hyperbolic function optimization. Only in the hyperbolic function did CRA give better results in MAE value according to the Jaya algorithm. Considering these evaluations and giving priority to the test set and RE values, the hyperbolic function model of the Jaya algorithm was the recommended model for flood flow modeling in the Trabzon province. The reason for considering the testing set is its success in data that it has never seen before. The reason for considering the RE value is that it is a criterion that plays a critical role in understanding how much the prediction results of the model deviate from the observed values.

The proposed flood discharge prediction model is given in Eq. 5. The result obtained with this equation is the normalised discharge value. To use the obtained result, it should be abnormalised with the min. and max. values given in Table 3. The comparison of the results obtained by training the hyperbolic regression function through Jaya with the training set and test data and the observed results are given in Figs. 3 and 4, respectively.

$$ln(Q) = 0.521 \times DA^{0.287} \times E^{-0.19} \quad (5)$$

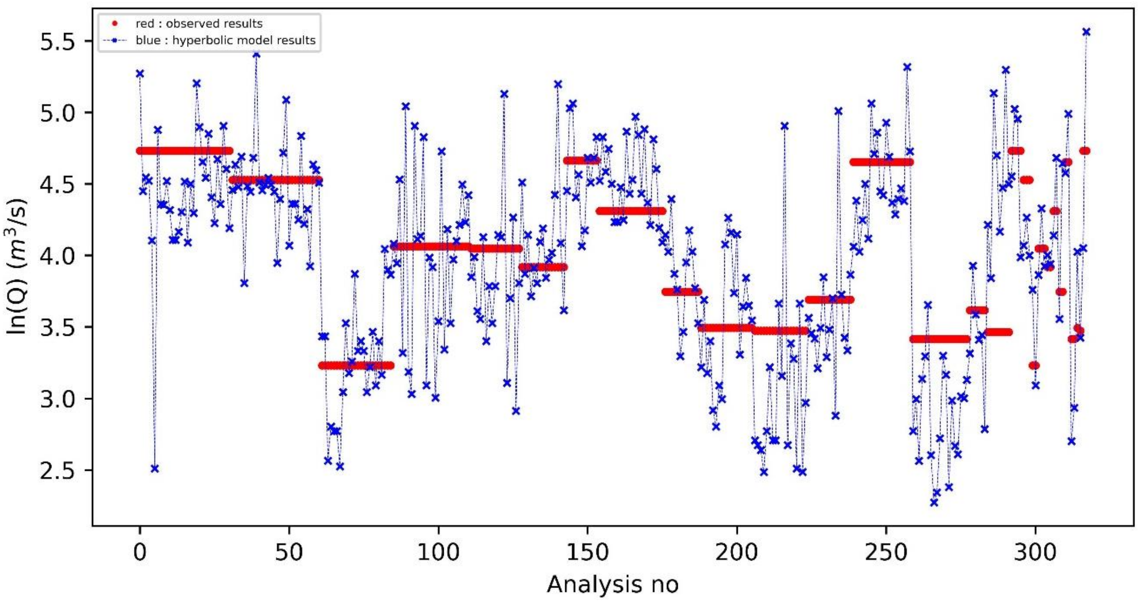

Fig. 3. Comparison of the observed results with the results obtained by training the hyperbolic regression function with the training set via Jaya

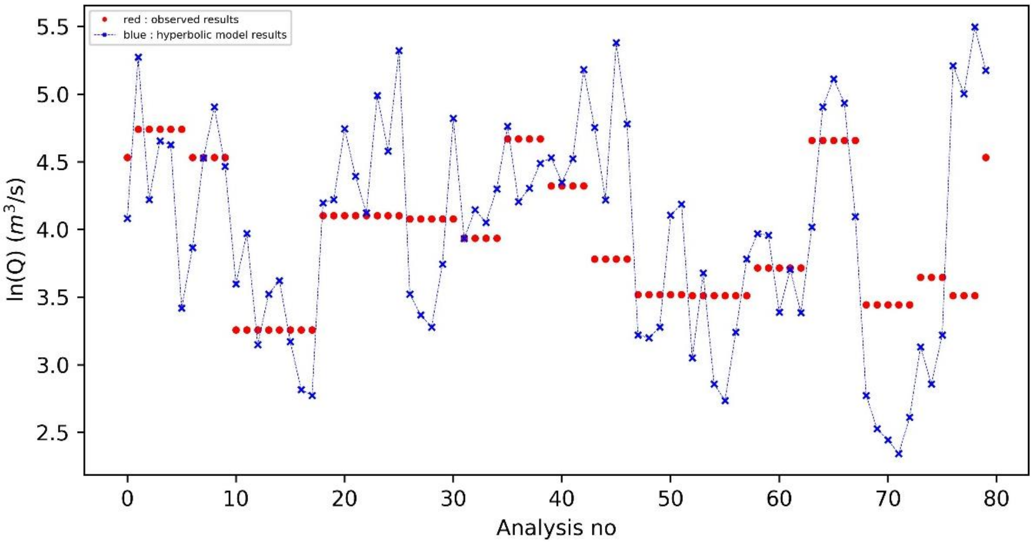

Fig. 4. Comparison of the observed results with the results obtained by training the hyperbolic regression function with the testing set via Jaya

4. Conclusions

In this study, classical regression analyses (CRA) and Jaya optimisation algorithms were applied to flood discharge estimation for Trabzon province in the Eastern Black Sea Basin (ESBS). Utilizing these algorithms, the relationship between the annual maximum discharge values of the flow observation stations in the Trabzon province and the elevation and drainage area of each station was modeled. For this modeling study, 16 flow observation stations in the Trabzon province with flow observation years ranging from 9 to 42 years were used. A total of 398 data were taken, 318 of which were used in the training set and 80 in the test set. In this modeling study, using different statistical criteria, the hyperbolic regression function optimised with Jaya was more successful. This study has concluded the success of the Jaya algorithm, which is not widely used in flood flow modeling. This algorithm can be used in flood risk management models in the future by enabling more accurate and reliable predictions in different regions and climatic conditions. In addition, the approach used in this study may enable the development of new algorithms or the improvement of existing methods.

Abstract. Water quality assessment is critical for environmental sustainability and public health, yet traditional Water Quality Indices (WQIs) often rely on static, expert-defined weights, limiting their adaptability to diverse conditions. This study introduces an AI-based Water Quality Index (AI-WQI) that leverages machine learning to dynamically evaluate water quality and prioritize chemical contaminants. Using a Random Forest classifier, we analyzed 7,996 samples from the U.S. Geological Survey, covering 20 physicochemical parameters (e.g., aluminium, perchlorate, cadmium) and a binary safety indicator. The model achieved 96% accuracy and a 0.974 ROC AUC, reliably classifying water safety. Feature importance analysis identified aluminium (20.24%), perchlorate (10.36%), and cadmium (10.13%) as key contaminants influencing water quality. The AI-WQI, constructed using normalized parameter values weighted by Random Forest feature importance, showed strong agreement with a conventional WQI (mean difference: -0.42, 95% LoA: -4.02 to 3.17), demonstrating its potential as an adaptive alternative for reflecting real-world water quality trends. This approach supports real-time monitoring, contaminant prioritization, and optimized treatment strategies, offering a scalable, interpretable tool for environmental management. Despite challenges like dataset imbalance affecting safe water predictions, the AI-WQI advances water quality assessment by integrating machine learning's flexibility with traditional indexing's clarity, providing a framework for sustainable monitoring in civil, chemical, and water engineering.

Keywords: Water quality; AI-WQI; Feature importance; Environmental monitoring; Chemical contaminants

1. Introduction

1.1. Background and motivation

Water quality assessment is vital for safeguarding public health, preserving ecosystems, and supporting sustainable development. Poor water quality, driven by pollutants such as heavy metals, nitrates, and microbial contaminants, poses significant risks to human health, including waterborne diseases and long-term exposure to toxic substances (UNEP, 2011). It also threatens aquatic ecosystems and economic activities like agriculture and fisheries, making effective monitoring essential (Makarigakis & Jimenez-Cisneros, 2019). Traditional Water Quality Indices (WQIs), such as the National Sanitation Foundation WQI (NSF WQI) and the Canadian Council of Ministers of the Environment WQI (CCME WQI), aggregate multiple parameters into a single value to simplify water quality evaluation. However, these indices often rely on fixed weights or guideline thresholds set by expert judgment, which may not adapt to local conditions, emerging contaminants, or temporal variations (Chidiac et al., 2023; Davies, 2006).

Machine learning (ML) offers a data-driven alternative, capable of modeling complex relationships in large datasets. Random Forest (RF), an ensemble ML method, excels in water quality assessment due to its robustness and ability to rank parameter importance through feature importance metrics (Tyralis et al., 2019). By leveraging ML, we can develop adaptive tools that overcome the rigidity of traditional WQIs, enhancing environmental monitoring and management.

1.2. Objectives and contributions

This study aims to advance water quality assessment through the following objectives:

1. *Develop an AI-based Water Quality Index (AI-WQI)* using RF feature importance to dynamically assign weights to parameters based on their impact on water safety predictions.

* Corresponding author, E-mail: jparsa78@gmail.com

https://doi.org/10.31462/icearc2025_ce_hwr_788

2. *Identify key chemical contaminants* influencing water quality, such as aluminium and perchlorate, using RF-derived feature importance.
3. *Compare AI-WQI with a conventional WQI* to demonstrate improved accuracy and adaptability in reflecting real-world water quality trends.

These objectives contribute a novel, interpretable, and data-driven WQI that integrates ML with traditional indexing, offering a tool for policymakers, engineers, and researchers to prioritize contaminants and optimize water treatment strategies.

1.3. Paper organization

The paper is structured as follows: Section 2 reviews traditional WQIs and ML applications in water quality assessment, identifying research gaps. Section 3 describes the dataset, preprocessing, RF model, and AI-WQI formulation. Section 4 presents model performance, key contaminants, and AI-WQI comparisons. Section 5 discusses findings, limitations, and future directions. Section 6 concludes with key contributions and their implications for water quality management.

2. Literature review

2.1. Traditional water quality indices

Water Quality Indices (WQIs) are widely used tools that aggregate multiple water quality parameters into a single numerical value, simplifying the assessment and communication of water quality status for environmental management and public health. Two prominent examples are the National Sanitation Foundation Water Quality Index (NSF WQI) and the Canadian Council of Ministers of the Environment Water Quality Index (CCME WQI), both of which rely on predefined parameters and expert judgment (Uddin et al., 2021; Uddin et al., 2022).

The NSF WQI, developed in 1970, integrates nine physicochemical and biological parameters: dissolved oxygen (DO), fecal coliform, pH, biochemical oxygen demand (BOD), temperature change, total phosphate, nitrates, turbidity, and total solids (TS). Each parameter is assigned a fixed weight based on a Delphi survey of water quality experts, with DO having the highest weight (0.17) and TS the lowest (0.07). Measurements are converted to sub-index values (Q-values) using standardized curves, ranging from 0 (worst) to 100 (best), and the final WQI is computed as a weighted sum:

$$NSF\ WQI = \sum_{i=1}^{9}(Q_i . w_i) \tag{1}$$

where (Q_i) is the sub-index value for parameter (i), and (w_i) is its corresponding weight. The resulting index classifies water quality from excellent (90–100) to very poor (0–25) . This approach, while standardized, assumes static parameter importance, which may not reflect local conditions or temporal changes (Effendi & Wardiatno, 2015).

The CCME WQI, introduced in 2001, offers a more flexible framework applicable to various water bodies and parameters. It evaluates water quality based on three factors: scope (F1), frequency (F2), and amplitude (F3) of guideline exceedances. These are calculated as follows:

Scope (F1): Percentage of parameters failing guidelines at least once:

$$F1 = \left(\frac{Number\ of\ failed\ parameters}{Total\ number\ of\ parameters}\right) \times 100 \tag{2}$$

Frequency (F2): Percentage of tests failing guidelines:

$$F2 = \left(\frac{Number\ of\ failed\ tests}{Total\ number\ of\ tests}\right) \times 100 \tag{3}$$

Amplitude (F3): Magnitude of guideline exceedances, calculated in three steps:

$$excrusion_i = \begin{cases} \frac{Failed\ Test\ Value_i}{Objective_j} - 1 & if\ value\ exceeds\ objective \\ \frac{Objective_j}{Failed\ Test\ Value_i} - 1 & if\ value\ below\ objective \end{cases}$$

$$nse = \frac{\sum_{i=1}^{n} excrusion_i}{Number\ of\ Tests}$$

$$F3 = \frac{nse}{0.01 + 0.01.nse} \tag{4}$$

The CCME WQI is computed as:

$$CCME\ WQI = 100 - \sqrt{\frac{(F1^2 + F2^2 + F3^2)}{1.732}} \tag{5}$$

This yields a score from 0 (poor) to 100 (excellent), categorized as excellent (95–100), good (80–94), fair (65–79), marginal (45–64), or poor (0–44) (WATER, 2001). The CCME WQI's flexibility allows it to incorporate any parameter with established guidelines, but these guidelines are still expert-defined, limiting adaptability to data-driven insights.

Both indices depend on static, expert-driven frameworks, limiting their adaptability to diverse or changing environmental conditions. Studies have noted that such rigidity can lead to inconsistent assessments across different water bodies (Noori et al., 2019).

2.2. Machine learning in water quality assessment

Machine learning (ML) has emerged as a powerful tool for water quality assessment, offering the ability to model complex, nonlinear relationships in large datasets. Random Forest (RF), an ensemble learning method, is particularly popular due to its robustness, accuracy, and interpretability through feature importance metrics.

RF has been applied in both regression and classification tasks for water quality. For regression, studies like Jena et al. (2023) used RF to predict parameters such as total dissolved solids (TDS), pH, and iron in the Kulik River, India, achieving high accuracy (R^2 up to 0.908) (Jena et al., 2023). For classification, Hurley et al. (2012) employed RF to predict indicator bacteria levels at swimming beaches, demonstrating its efficacy in binary classification tasks (Hurley et al., 2012). Similarly, Tesoriero et al. (2017) used RF to classify groundwater contaminant concentrations, identifying key predictors of redox-sensitive pollutants (Tesoriero et al., 2017).

A key advantage of RF is its ability to compute feature importance, which ranks parameters based on their contribution to model predictions. For instance, Jena et al. (2023) identified calcium and magnesium as critical predictors for TDS, using correlation-based feature importance. This capability allows researchers to prioritize contaminants for monitoring and treatment, aligning with environmental management goals. A review by Tyralis et al. (2019) highlights RF's extensive use in water resources, noting its application in water chemistry and quality assessment alongside streamflow modeling (Tyralis et al., 2019).

Other ML models, such as Support Vector Machines (SVM) and Artificial Neural Networks (ANN), have also been explored. For example, Ahmed et al. (2021) compared RF, SVM, and ANN for water quality prediction at Rawal Dam, Pakistan, finding RF to be highly effective due to its interpretability (Ahmed et al., 2021).

2.3. Gaps and research need

Traditional WQIs, while effective for standardized assessments, face limitations due to their reliance on fixed weights or guideline thresholds. The NSF WQI's weights, established in the 1970s, may not reflect current environmental conditions or local variations, potentially leading to biased assessments (Ariza Restrepo et al., 2023). The CCME WQI, though more flexible, still depends on predefined guidelines, which may not adapt to emerging contaminants or data-driven insights.

ML-based approaches address some of these limitations by leveraging data to uncover patterns and prioritize parameters. However, challenges remain, particularly with interpretability. While RF provides feature importance, other models like deep neural networks can act as "black boxes," making it difficult to explain predictions to stakeholders (Wang et al., 2017). Additionally, many ML studies focus on prediction rather than integrating their findings into practical indices, limiting their applicability in regulatory frameworks.

There is a critical need to bridge traditional WQIs and ML approaches to develop adaptive, data-driven indices that combine the interpretability of conventional methods with the flexibility of ML. Recent studies advocate for such integration, noting that ML can enhance WQI predictions by dynamically adjusting weights based on data (Ahmed et al., 2021; Uddin et al., 2021; Uddin et al., 2022). Our study addresses this gap by proposing an AI-based Water Quality Index (AI-WQI) that uses RF-derived feature importance to assign dynamic weights, offering a novel, interpretable, and data-driven approach to water quality assessment.

3. Materials and methods

This section provides a detailed exposition of the dataset utilized, the preprocessing steps undertaken, the development of the machine learning model, the analysis of feature importance, and the formulation of both an AI-based Water Quality Index (AI-WQI) and a conventional Water Quality Index (WQI). The methodology seamlessly integrates advanced data-driven techniques with established traditional approaches to deliver a robust and comprehensive framework for assessing water quality across diverse environmental settings.

3.1. Dataset description

3.1.1. Chemical measurements dataset

The study utilizes the Kaggle dataset, comprising 7,996 water samples, each characterized by 20 physicochemical features and a binary target variable, is_safe. The physicochemical features include aluminium, perchlorate, cadmium, arsenic, ammonia, barium, chloramine, chromium, copper, fluoride, bacteria, viruses, lead, nitrates, nitrites, mercury, radium, selenium, silver, and uranium. These parameters represent key contaminants and properties influencing water safety. The target variable, is_safe, denotes whether the water is safe for consumption (1) or not (0), based on predefined safety thresholds.

The dataset was obtained from the U.S. Geological Survey (USGS) National Water Information System, providing a robust foundation for analyzing water quality across diverse environmental contexts. This comprehensive dataset supports the development of predictive models and quality indices applicable to real-world scenarios.

3.2. Data preprocessing

To ensure the dataset was suitable for machine learning analysis, preprocessing steps addressed missing values and feature scaling.

3.2.1. Handling missing values

Coercion of non-numeric values: Non-numeric entries in the dataset were converted to NaN to maintain data consistency and enable numerical processing.

Median imputation: Missing values in the feature columns were imputed using the median value of each feature. This method, implemented via the SimpleImputer from the sklearn library, minimizes bias while preserving the dataset's central tendency.

Removal of invalid target rows: Rows lacking a value for the is_safe target were excluded, reducing the dataset from an initial size of approximately 8,000 to 7,996 samples. This ensured all samples had valid labels for model training and evaluation.

3.2.2. Normalization

The 20 physicochemical features were normalized to a [0, 1] range using the MinMaxScaler from sklearn. This scaling standardizes the magnitude of features, preventing those with larger ranges from disproportionately influencing the model. The normalized value (x'_{ij}) for feature (j) in sample (i) is given by:

$$x'_{ij} = \frac{x_{ij} - \min(x_j)}{\max(x_j) - \min(x_j)} \tag{6}$$

where (x'_{ij}) is the original value, and $\min(x_j)$ and $\max(x_j)$ are the minimum and maximum values of feature (j), respectively.

3.3. Model development

3.3.1. Random forest classifier

A Random Forest Classifier was employed to predict the is_safe target and derive feature importance scores. Implemented using RandomForestClassifier from sklearn with 100 trees (n_estimators=100), this ensemble method leverages multiple decision trees to enhance prediction accuracy and robustness. The model's ability to handle high-dimensional data and provide interpretable feature importance makes it well-suited for this study. The trained classifier predicts water safety and quantifies the influence of each physicochemical feature on the outcome.

3.3.2. Train/test split

The dataset was divided into training and testing sets with a 70:30 ratio, using train_test_split from sklearn (test_size=0.3, stratify=y). Stratification ensured that the proportion of safe (1) and unsafe (0) samples remained balanced in both sets, yielding 5,597 training samples and 2,399 testing samples. This approach supports reliable model evaluation by maintaining a representative distribution of the target variable.

3.4. Feature importance analysis

3.4.1. Tree-based feature importance

Feature importance scores were extracted from the Random Forest model using the feature_importances_ attribute. These scores, based on the mean decrease in impurity across all trees, rank the 20 physicochemical features by their contribution to predicting is_safe. Preliminary results identified aluminium, perchlorate, and cadmium as top-ranking contaminants, indicating their significant impact on water quality.

To explore potential relationships between the 20 physicochemical features in the dataset, a feature correlation heatmap was constructed using Pearson correlation (equal to 0.697) coefficients (Fig. 1). The heatmap revealed minimal correlations between most features, suggesting that the physicochemical parameters are largely independent in their influence on water safety. For instance, aluminium and cadmium exhibited a weak positive correlation (approximately 0.15), potentially indicating shared environmental sources such as industrial discharges or soil leaching. Similarly, mercury, selenium and flouride showed near-zero correlations with most other features, consistent with its unique sources. This analysis supports the Random Forest model's feature importance rankings (Section 4.2), as the low inter-feature correlations imply that the model's prioritization of aluminium, perchlorate, and cadmium is driven by their individual predictive power rather than multicollinearity. Understanding these relationships can guide future studies in identifying contaminant interactions for targeted treatment strategies.

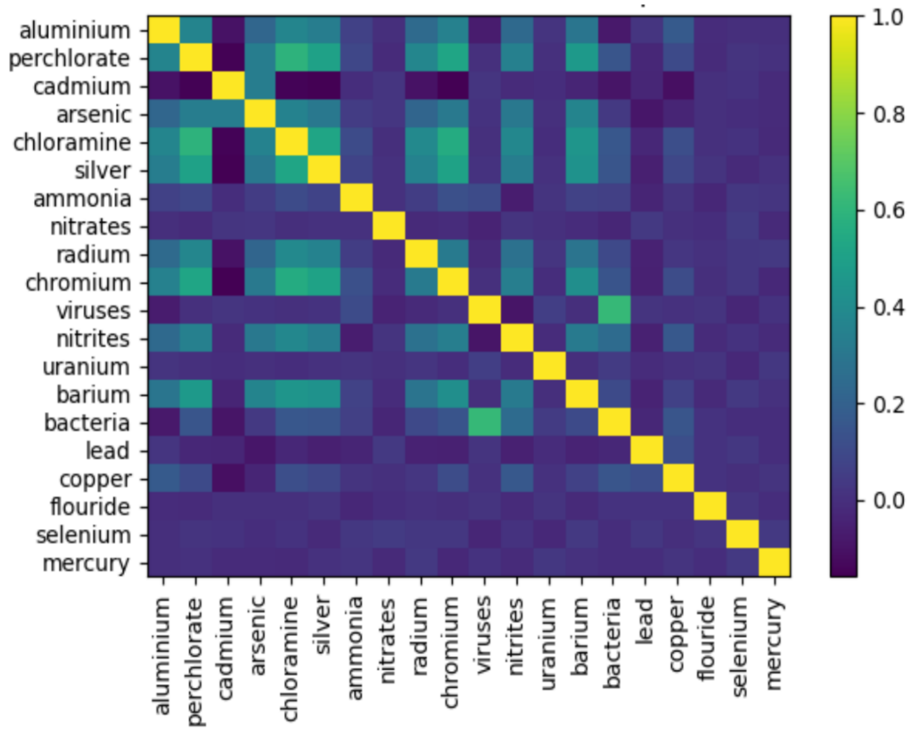

Fig. 1. Feature correlation heatmap

3.4.2. Validation of importance

The robustness of the importance scores was assessed by examining their consistency across multiple train-test splits. The rankings, particularly for high-impact features like aluminium and perchlorate, remained stable, reinforcing their reliability. While permutation importance was not implemented here, it could enhance validation in future studies by evaluating the effect of feature shuffling on model performance.

3.5. AI-WQI formulation

3.5.1. Definition

The AI-WQI was developed as a weighted sum of the normalized features, with weights derived from the Random Forest feature importance scores. This data-driven index reflects the relative influence of each parameter on water safety. For each sample (i), the AI-WQI is calculated as:

$$AI - WQI_i = \frac{\sum_{j=1}^{n}(x'_{ij}.w_j)}{\sum_{j=1}^{n} w_j} \tag{7}$$

where x'_{ij} is the normalized value of feature (j) for sample (i), (w_j) is the feature importance score for feature (j), (n) is the number of features (20). This denominator normalizes the index, ensuring comparability across samples.

3.5.2. Computation

The AI-WQI was implemented in Python using matrix operations for efficiency. The normalized feature matrix was multiplied element-wise by the feature importance vector, and the resulting sums were divided by the total sum of weights. This approach scales effectively for large datasets and provides a standardized water quality metric.

3.6. Conventional WQI computation

3.6.1. Methodology

A conventional WQI was computed as a baseline, using standard weights based on guidelines from the World Health Organization (WHO) and Environmental Protection Agency (EPA) (Organization, 2017). Sub-indices (Q_j) for each parameter (j) were calculated by comparing measured concentrations to guideline thresholds:

$$Q_j = \frac{C_j}{S_j} \times 100 \quad (8)$$

where (C_j) is the measured concentration, and (S_j) is the guideline standard for parameter (j).

3.6.2. Implementation

The conventional WQI was then derived as a weighted arithmetic mean (Table 1):

Table 1. Weights, reflecting health and environmental significance

Substance	Value
Aluminium	0.1
Perchlorate	0.15
Cadmium	0.20
Arsenic	0.08
Other 16 Parameters	0.47

Weights for remaining parameters were similarly assigned based on WHO/EPA standards. This conventional WQI provides a standardized reference to compare against the AI-WQI, highlighting the advantages of the data-driven approach.

4. Results

This section presents the outcomes of the machine learning analysis, feature importance rankings, and the comparison between the AI-based Water Quality Index (AI-WQI) and a conventional WQI. The results underscore the efficacy of the Random Forest (RF) model, highlight key chemical contaminants affecting water safety, and demonstrate the advantages of the AI-WQI's data-driven approach. Visualizations, including performance metrics, feature importance rankings, and index comparisons, enhance the interpretability of the findings.

4.1. Model performance

The Random Forest classifier was evaluated on a test set of 2,399 samples (30% of the 7,996-sample dataset) to assess its ability to predict the binary is_safe target (0 = unsafe, 1 = safe). The model achieved an overall accuracy of 96%, indicating that it correctly classified 96% of the test samples. Detailed classification metrics, including precision, recall, and F1-score, are summarized in Table 2 for both classes.

Table 2. Classification performance metrics

Class	Precision	Recall	F1-Score	Support
Unsafe (0)	0.96	0.99	0.98	2,125
Safe (1)	0.94	0.69	0.80	274
Weighted Avg	0.96	0.96	0.96	2,399

Precision: For the unsafe class (0), 96% of samples predicted as unsafe were correctly classified, while for the safe class (1), 94% of predicted safe samples were accurate.

Recall: The model identified 99% of actual unsafe samples but only 69% of actual safe samples, indicating a lower detection rate for safe water.

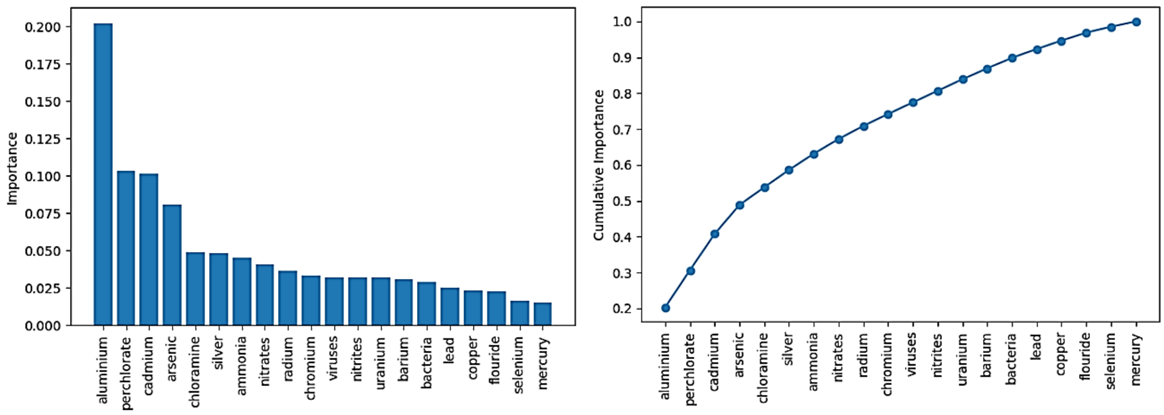
F1-Score: The harmonic mean of precision and recall was 0.98 for unsafe and 0.80 for safe, reflecting strong performance for the majority class but reduced effectiveness for the minority class.

Support: The test set contained 2,125 unsafe samples (88.5%) and 274 safe samples (11.5%), highlighting a significant class imbalance.

Aluminium's dominance (Fig. 2) aligns with its role in industrial pollution and coagulant use in water treatment. Perchlorate (a rocket fuel component) and cadmium (toxic heavy metal) are critical due to their persistence and health risks.

The full ranking is visualized in Fig. 2a, a bar plot illustrating the relative importance of all 20 features. Aluminium's leading role underscores its prevalence in industrial and natural water sources, where it can leach from soils or result from anthropogenic activities like mining or manufacturing (WHO, 2017). Perchlorate, often associated with industrial discharges and rocket fuel, poses risks due to its chemical stability and bioaccumulation potential (EPA, 2020). Cadmium and arsenic, both heavy metals, are critical due to their toxicity, persistence, and ability to contaminate groundwater and surface water, aligning with global water quality concerns (UNEP, 2016).

These contaminants' high importance scores indicate their strong influence on the is_safe classification, suggesting that monitoring and treatment efforts should prioritize these parameters. The environmental prevalence of aluminium and the acute toxicity of cadmium and arsenic justify their prominence, consistent with regulatory priorities outlined by WHO and EPA guidelines.



(a) (b)

Fig. 2. Random forest feature importances

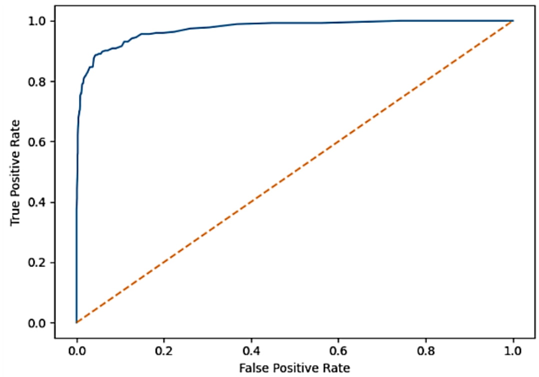


Fig. 3. Receiver Operating Characteristic (ROC) curve (AUC = 0.974)

The ROC curve (Fig. 3) plots the true positive rate against the false positive rate across various classification thresholds, assessing the model's ability to distinguish between safe and unsafe water samples. An AUC of 0.974 indicates excellent discriminatory power, confirming the model's reliability in separating the two classes, even with imbalanced data. The high AUC (0.974) confirms strong discriminatory power, though the class imbalance (88.5% unsafe vs. 11.5% safe) affects safe water identification, as evidenced by the lower recall for the safe class (69%). The steep curve reflects high true positive rates even at low false positive thresholds. Oversampling or weighted loss functions could mitigate this in future work.

4.2. Key contaminants

Feature importance analysis, derived from the Random Forest model's feature_importances_ attribute, identified the most influential physicochemical parameters affecting water safety. The top-ranked features, with their respective importance scores, are:

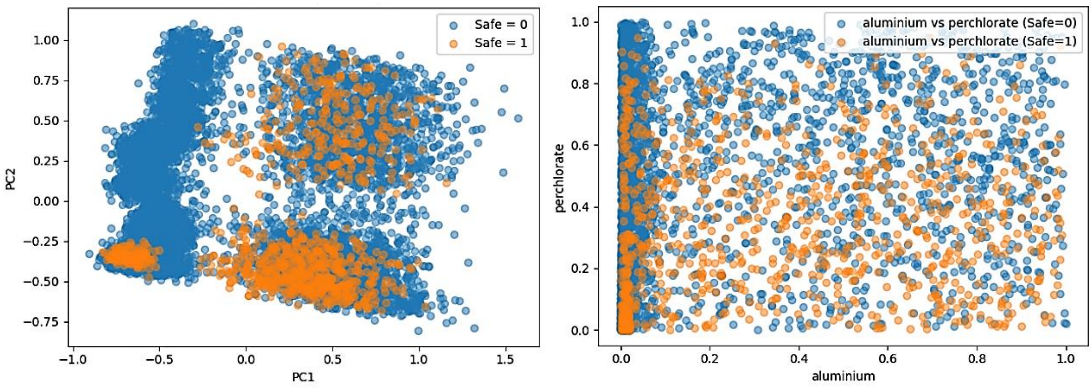
Aluminium (20.24%): The dominant contributor, reflecting its widespread environmental presence and toxicity.

Perchlorate (10.36%): A persistent chemical with health implications, particularly for thyroid function.

Cadmium (10.13%): A highly toxic heavy metal linked to severe health effects.

Arsenic (8.07%): A known carcinogen with significant environmental and health concerns.

The box plot reveals that unsafe samples have significantly higher concentrations of aluminium and perchlorate compared to safe samples, which aligns with their top feature importance. Fig. 4a depicts the distribution of cadmium concentrations alongside aluminium. Cadmium levels are notably higher in unsafe samples, supporting its high feature importance and highlighting its environmental and health significance. To further explore these contaminants, their distributions in safe and unsafe samples were examined. Fig. 4b shows the distribution of aluminium concentrations in comparison to perchlorate.



(a) (b)

Fig. 4. Comparison of two principal components (Aluminium, and a-Cadmium and b-Perchlorate)

4.3. AI-WQI indices vs.conventional water quality

The AI-WQI was computed for each sample as a weighted sum of normalized feature values, with weights derived from Random Forest feature importance. Sample AI-WQI values for the first five samples ranged from 0.284 to 0.470, as shown in Table 3. In contrast, the Traditional WQI, calculated using WHO/EPA guideline-based weights, was computed for the same samples to provide a baseline for comparison. Table 4 presents the Traditional WQI values for the first five samples, showing a range from 62.1 to 71.8 on a 0–100 scale, where higher values indicate better water quality.

Table 3. Sample AI-WQI values

Sample	AI-WQI
0	0.682
1	0.635
2	0.74
3	0.667
4	0.689

In here, higher AI-WQI values indicate poorer water quality, as they reflect greater contributions from influential contaminants like aluminium and perchlorate. The distribution of AI-WQI values across all samples is visualized in Fig 5, a histogram showing a right-skewed distribution with most values between 0.4 and 0.7, indicating variability in water quality.

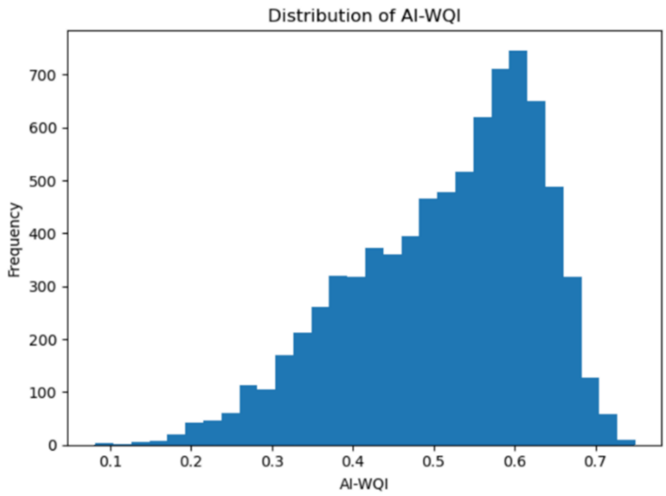


Fig. 5. Distribution of AI-WQI

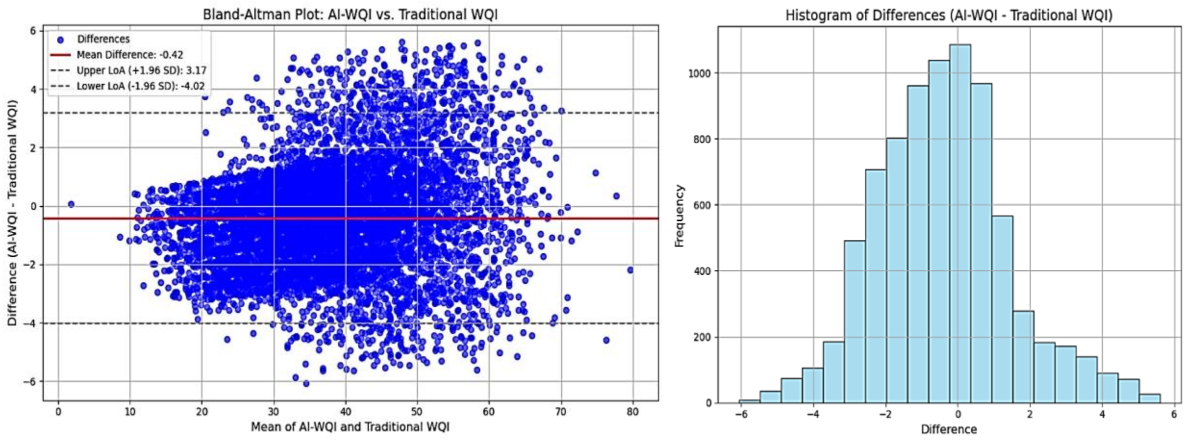
Table 4. Sample traditional WQI values

Sample	Traditional WQI
0	0.68
1	0.62
2	0.72
3	0.65
4	0.69

The distribution of AI-WQI values across all samples is visualized in Fig. 5, a histogram showing a skewed distribution with most values between 0.4 and 0.7, indicating variability in water quality. To evaluate the agreement between the AI-WQI and the Traditional WQI, a Bland-Altman plot was constructed after rescaling the AI-WQI to a 0-to-100 range to match the Traditional WQI scale (Fig. 6a). The mean difference was -0.42, indicating that the AI-WQI systematically underestimates the Traditional WQI by an average of 0.42 units. The 96% limits of agreement ranged from -4.02 to 3.17, reflecting low variability in the differences between the two indices. The scatter of points showed no significant trend, suggesting the absence of proportional bias across the range of mean values. A histogram of the differences confirmed approximate normality, supporting the validity of the limits of agreement (Fig. 6b). Most differences fell within the limits of agreement, indicating strong agreement between the two methods. The slight systematic underestimation by AI-WQI may reflect its greater sensitivity to key contaminants like aluminium and cadmium, as identified by the Random Forest feature importance analysis (Section 4.2). This is particularly relevant given that higher AI-WQI values indicate poorer water quality, while higher Traditional WQI values indicate better quality, suggesting that AI-WQI may be more conservative in its assessment of water safety.



(a) (b)

Fig. 6. Bland-Altman plot to evaluate the agreement between the AI-WQI and Traditional WQI

5. Discussion

This study introduces an AI-based Water Quality Index (AI-WQI) that leverages Random Forest (RF) feature importance to dynamically assess water quality and prioritize chemical contaminants. The following subsections interpret the findings, highlight the advantages of AI-WQI, discuss implications for stakeholders, and outline limitations with directions for future research.

5.1. Interpretation of findings

The identification of aluminium (20.24%), perchlorate (10.36%), and cadmium (10.13%) as the top contaminants influencing water safety aligns with established chemical and environmental engineering principles. Aluminium's dominance reflects its prevalence in natural and industrial contexts, often introduced through soil leaching or as a coagulant in water treatment processes (WHO, 2017). Its high feature importance underscores its role in impacting water safety, particularly in regions with industrial activity, where elevated concentrations can pose risks to aquatic ecosystems and human health. Perchlorate, a persistent chemical linked to rocket fuel and industrial discharges, affects thyroid function and is a known concern in groundwater contamination (EPA, 2020). Cadmium, a toxic heavy metal, is associated with severe health effects, including kidney damage and cancer, and its prominence in the RF model highlights its environmental significance (UNEP, 2016). These findings are consistent with global water quality priorities, where heavy metals and persistent pollutants are often targeted for monitoring and regulation due to their toxicity and bioaccumulation potential.

From a chemical engineering perspective, the high importance of these contaminants suggests complex interactions with water matrices, such as pH-dependent solubility for aluminium or redox conditions affecting cadmium mobility. In environmental engineering, these results emphasize the need for source control measures, such as reducing industrial discharges, and advanced treatment technologies to mitigate these contaminants' impact. The AI-WQI's ability to identify these key parameters through data-driven analysis enhances our understanding of water quality dynamics, providing a foundation for targeted interventions.

5.2. Advantages of AI-WQI

The AI-WQI offers distinct advantages over traditional WQIs like the NSF WQI and CCME WQI, primarily through its data-driven weighting approach. Unlike conventional indices that rely on fixed, expert-defined weights—often established decades ago (e.g., NSF WQI weights from 1970)—the AI-WQI uses RF feature importance to assign weights dynamically based on their predictive contribution to water safety. This adaptability ensures that the index reflects current environmental conditions and contaminant priorities, addressing the rigidity of traditional methods noted in prior studies (Noori et al., 2019). For instance, the high weight assigned to aluminium in this study reflects its prevalence in the USGS dataset, which may differ across regions or datasets, making AI-WQI more contextually relevant.

Additionally, the AI-WQI is well-suited for real-time monitoring and treatment optimization. Its reliance on machine learning enables rapid computation of water quality scores as new data is collected, facilitating continuous assessment in dynamic environments like industrial discharge zones or urban water systems. The Bland-Altman analysis in Section 4.3 revealed strong agreement between AI-WQI and Traditional WQI (mean difference: -0.42, 96% LoA: -4.02 to 3.17), suggesting that AI-WQI can serve as a reliable alternative while offering greater flexibility. Engineers can use AI-WQI scores to optimize treatment processes, such as adjusting coagulant doses to target aluminium or enhancing filtration systems for cadmium removal, improving efficiency and cost-effectiveness in water management.

5.3. Implications for stakeholders

The AI-WQI has significant implications for diverse stakeholders in water quality management. For policymakers, the prioritization of contaminants like aluminium, perchlorate, and cadmium informs regulatory frameworks. These contaminants' high importance scores suggest they should be focal points for updated water quality standards, particularly in regions with similar environmental profiles to the USGS dataset. For example, stricter discharge limits for perchlorate could mitigate its impact on groundwater, aligning with EPA recommendations (EPA, 2020).

For environmental and chemical engineers, AI-WQI facilitates the design of targeted treatment systems. The model's identification of key contaminants enables engineers to focus on specific removal technologies, such as ion exchange for cadmium or advanced oxidation for perchlorate, optimizing resource allocation. Furthermore, the index's adaptability supports the development of modular treatment systems that can be adjusted based on real-time AI-WQI scores, enhancing resilience to changing water quality conditions.

For chemists, the AI-WQI provides insights into contaminant interactions. The prominence of aluminium and cadmium suggests potential synergistic effects, such as co-precipitation under certain pH conditions, which could influence their removal efficiency. Future studies could leverage these findings to explore chemical interactions in greater detail, informing both treatment strategies and environmental modeling.

5.4. Limitations and future work

Despite its strengths, this study has several limitations that warrant further investigation. The dataset's class imbalance (88.5% unsafe vs. 11.5% safe samples) impacted the RF model's recall for the safe class (69%), potentially limiting its ability to identify safe water sources accurately. Future work could employ techniques like SMOTE or class-weighted loss functions to address this imbalance, improving model performance for minority classes.

The reliance on a single USGS dataset also limits the generalizability of findings. Incorporating additional datasets, such as Kaggle dataset, which includes parameters like turbidity and organic carbon, could enhance the AI-WQI's robustness by capturing a broader range of water quality factors. Additionally, while RF feature importance provided interpretable weights, exploring other explainability methods, such as permutation importance, could validate the rankings and offer deeper insights into feature contributions.

Finally, the AI-WQI was validated on a dataset primarily representing groundwater and surface water from the U.S. Applying the model to diverse water sources, such as rivers, lakes, or wastewater, would test its adaptability and ensure its applicability across different environmental contexts. Future research should focus on these validations to strengthen the AI-WQI's utility as a global tool for water quality assessment.

6. Conclusions

This study developed an AI-based Water Quality Index (AI-WQI) using Random Forest (RF) feature importance to enhance water quality assessment, achieving significant advancements over traditional methods. The RF model demonstrated high performance, with 96% accuracy and a 0.974 ROC AUC, effectively classifying water safety across 7,996 samples from the USGS dataset. Feature importance analysis identified aluminium (20.24%), perchlorate (10.36%), and cadmium (10.13%) as the primary contaminants influencing water safety, aligning with their environmental prevalence and toxicity. Comparative analysis via a Bland-Altman plot revealed strong agreement between AI-WQI and Traditional WQI (mean difference: -0.42, 95% LoA: -4.02 to 3.17), with AI-WQI showing slight underestimation due to its sensitivity to key contaminants, highlighting its superiority in capturing data-driven trends over static, expert-defined weights.

The AI-WQI contributes to civil, chemical, and water engineering by offering an adaptive, interpretable tool for water quality monitoring. Civil engineers can leverage it for real-time infrastructure management, chemical engineers can optimize treatment processes targeting key contaminants, and water engineers can prioritize resource allocation for contaminant mitigation. We recommend adopting AI-WQI for adaptive monitoring systems to improve water management flexibility. However, addressing the dataset's imbalance (88.5% unsafe vs. 11.5% safe samples) through techniques like SMOTE is essential to enhance safe water predictions. Expanding the model to additional datasets, such as Kaggle dataset, will further validate its applicability across diverse water sources, ensuring broader environmental impact.

Optimization of well flow rate's pumping cost with various metaheuristic algorithms

Nurcan Öztürk*[1]

[1] *Karadeniz Technical University, Faculty of Technology, Department of Civil Engineering, 61830 Trabzon, Türkiye*

Abstract. The study's aim is to determine the optimum well coordinates and flow rate values in a well problem, encountered optimization problem in the management of water resources, with minimum pumping cost through the application of ten metaheuristic optimization algorithms - Particle Swarm Optimization (PSO), Harmony Search (HS), Cuckoo Search (CS), Symbiotic Organisms Search (SOS), Teaching Learning Based Optimization (TLBO), Light Spectrum Optimizer (LSO), Electric Eel Foraging Optimization (EEFO), Geyser Inspired Algorithm (GEA), Newton-Raphson-Based Optimizer (NRBO), and Puma Optimizer (PO). For this purpose, a problem suite was developed consisting of two different problems with four existing, two, and three new wells. In this problem, the objective function is the pumping cost, while the design variables are the coordinates of the two new wells added for the case with six wells, the coordinates of the three wells added for the case with seven wells, and the flow rate values in all wells. The optimum solution, which determines the well locations and flow rate values that minimize the pumping cost of a certain total well flow rate value from an infinite aquifer with two zones of different transmissivities, was sought by means of these algorithms in this problem. The solutions obtained from independent simulations conducted on this problem suite were statistically assessed. The performances of the algorithms were evaluated with Friedman which is a non-parametric statistical test and Wilcoxon paired comparison test. According to the findings, it was seen that the LSO algorithm had the highest performance among the ten algorithms examined.

Keywords: Metaheuristics; Optimization; Flow rate; Cost; Water management

1. Introduction

Water demand is rising daily due to industrial, agricultural, and urban usage as the world's population increases at an accelerated rate. Since surface water resources in critical areas with high human density have become significantly polluted and largely unusable, groundwater resources have assumed greater importance in meeting water needs. The management of groundwater resources to address the growing global water demands is a challenging task due to the depletion of water resources. However, excessive consumption of groundwater resources leads to issues that are difficult for people to overcome, like ground settlements, ecological damage, salt water intrusion into groundwater, and failure to manage the aquifer storage-depletion trajectory.

For many years, optimization techniques have been employed to deal with groundwater management issues and create the water budget required for appropriate resource management. Researchers are developing increasingly sophisticated and precise groundwater optimization methods because of advancements in computer technology. There are two main types of optimization methodologies applied in water resources management: mathematical methods and evolutionary and metaheuristic algorithms (Jahandideh-Tehrani et al., 2020).

The usage of metaheuristic algorithms has been increasing in recent years, and they have been successfully applied to solve various groundwater quantity and quality problems. Although numerous metaheuristic algorithms exist in the literature, both commonly used in groundwater management problems and novel algorithms developed were employed in this paper: Particle Swarm Optimization (PSO), Harmony Search (HS), Cuckoo Search (CS), Symbiotic Organisms Search (SOS), Teaching Learning Based Optimization (TLBO), Light Spectrum Optimizer (LSO), Electric Eel Foraging Optimization (EEFO), Geyser Inspired Algorithm (GEA), Newton-Raphson-Based Optimizer (NRBO), and Puma Optimizer (PO).

Some previous studies that have been applied to groundwater management problems with the metaheuristics employed in this paper are summarized below. PSO was applied to solve two groundwater hydraulic management problems: (1) maximum pumping from an aquifer, (2) minimum cost to develop the new pumping well system

* Corresponding author, E-mail: nurcan@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_hwr_982

and was found to be efficient in identifying the optimal location and discharge of the pumping wells (Gaur et al., 2011). HS was also employed for the optimal management of groundwater resources. The optimal management included the maximization of total pumping from an aquifer, and minimization of the total pumping cost to satisfy the given demand (Ayvaz, 2009).

Reviews of the literature show most of the groundwater management studies have used PSO and HS for optimization of the pumping cost. Furthermore, for the purpose of this study, CS, SOS, TLBO, LSO, EEFO, GEA, NRBO, and PO have been applied for the first time in the literature. The motivation to use the metaheuristic techniques in the present study is largely due to the need for obtaining optimal solutions for problems.

This study introduces two different problems with four existing, two, and three new wells based on rather common aspects of water resources management problems, namely groundwater pumping cost. In this study, the optimal solutions of the problems are calculated and then the performance of metaheuristic algorithms on these solutions is evaluated.

2.Method

2.1. Design variables, parameters, constraints, and objective function

Minimize the cost of pumping a given total well flow rate Q_T from an "infinite" aquifer with two zones of different transmissivities T_1 and T_2 (Fig. 1). The problem suite with four current wells, two and three new wells will be used for this task. As shown in Fig.1 , the existing wells (W_1 to W_4) are located at the vertices of a square while the new ones should be constructed inside the square area, shown with broken line. The interface between the two aquifer zones is illustrated by the solid lines in Figure1, which lie on the x-axis and coincide with the y-axis. The coordinates of the current wells, W_1 to W_4, are (−150, 450), (150, 450), (150, 750), and (−150, 750), respectively, to standardize the problem. The new wells have a range of 0 to 1,200 for y and −600 to 600 for x (Karpouzos & Katsifarakis, 2013).

While the required total flowrate Q_T=200 L/s, T_1=0.002 m^2/s and T_2=0.001 m^2/s are the aquifer's features. The radius r_o of each well is 0.25 m, and the radius of influence of the system of wells R is 2,000 m; these values are used in subsequent equations, with R being larger than the maximum possible distance between wells.

The objective function of the optimization problem is the cost function (Eq.1) that should be minimized.

$$f(x) = A \sum_{i=1}^{N} Q_i \, s_i \tag{1}$$

where N represents the total number of wells, Q_i denotes the flow rate of well i and A is a constant depending on the energy cost and the duration of pumping. The hydraulic head level drawdown at well i, caused by pumping, is denoted by s_i. While A is conveniently set to 1,000, Qi and s_i are expressed in m^3/s and m, respectively, in Eq. 1. Its distance from the wells, the wells' flow rates, and the aquifer's properties and boundaries all affect s. The method of images, which introduces imaginary wells symmetrical to the real ones with respect to the zone interface to fulfill the boundary condition there (Bear J, 2012) and the superposition principle, can be used to calculate the corresponding s_i analytically given the set of Qi and the well coordinates.

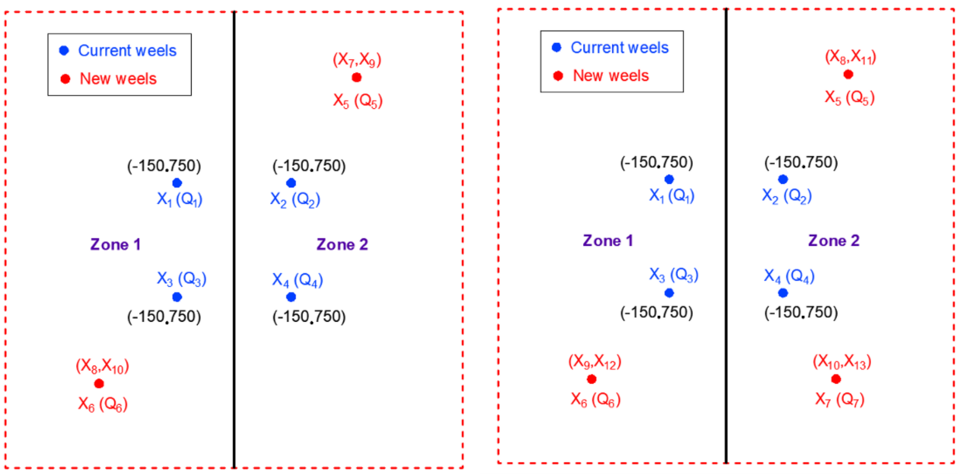

Fig. 1. The two-zone aquifer problems with six and seven wells

Suppose that wells 1 to K are located in zone 1, and the remaining wells (K+1 to N) are located in zone 2. Then, s_i for wells 1 to K is provided as follows:

$$s_i = -\frac{1}{2\pi T_1}\sum_{J=1}^{K} Q_J \ln\frac{r_{iJ}}{R} - \frac{T_1 - T_2}{2\pi T_1(T_1+T_2)}\sum_{J=1}^{K} Q_J \ln\frac{r_{ij}}{R} - \frac{1}{\pi(T_1+T_2)}\sum_{J=K+1}^{N} Q_J \ln\frac{r_{iJ}}{R} \tag{2}$$

while for zone 2 wells K+1 to N, s_i is provided as:

$$s_i = -\frac{1}{2\pi T_2}\sum_{J=K+1}^{N} Q_J \ln\frac{r_{iJ}}{R} - \frac{T_2 - T_1}{2\pi T_2(T_1+T_2)}\sum_{J=K+1}^{N} Q_J \ln\frac{r_{ij}}{R} - \frac{1}{\pi(T_1+T_2)}\sum_{J=1}^{K} Q_J \ln\frac{r_{iJ}}{R} \tag{3}$$

The capital letters in Eqs. 2 and 3 represent the real wells, whereas the lowercase letters represent their images. In addition, R represents the system of wells' radius of effect, r_{iJ} is the distance between wells i and J (r_{iJ}=r_{Ji}), and r_{ij} is the distance between well i and the imaginary well j (r_{ji}). The value of r_{ii}, specifically, is represented by r_0 for every i and is taken to be equal to the radius of well i. It should be mentioned that only Q is summed. The following expression for the cost function (f(x)) is generated by using Eqs. 2 and 3 to express s_i in Eq. 1 (Karpouzos & Katsifarakis, 2013).

$$\begin{aligned} f(x) = &-A\sum_{i=1}^{K} Q_i\left(\frac{1}{2\pi T_1}\sum_{J=1}^{K} Q_J \ln\frac{r_{iJ}}{R} + \frac{T_1 - T_2}{2\pi T_1(T_1+T_2)}\sum_{J=1}^{K} Q_J \ln\frac{r_{ij}}{R} + \frac{1}{\pi(T_1+T_2)}\sum_{J=K+1}^{N} Q_J \ln\frac{r_{iJ}}{R}\right) \\ &- A\sum_{i=K+1}^{N} Q_i\left(\frac{1}{2\pi T_2}\sum_{J=K+1}^{N} Q_J \ln\frac{r_{iJ}}{R} + \frac{T_2 - T_1}{2\pi T_2(T_1+T_2)}\sum_{J=K+1}^{N} Q_J \ln\frac{r_{ij}}{R} \right.\\ &\left. + \frac{1}{\pi(T_1+T_2)}\sum_{J=1}^{K} Q_J \ln\frac{r_{iJ}}{R}\right) \end{aligned} \tag{4}$$

Thus, the objective functions, Eq.4, of the optimization problems with six and seven wells include ten and thirteen variables of two different kinds, namely six well flow rates and four coordinates for the problem with six wells and thirteen variables (seven well flow rates and six coordinates) for the problem with seven wells.

For the problems in this study, the well flow rate is the constraint to be respected and is expressed by Eq. 5.

$$g(x) = \left| Q_T - \sum_{i=1}^{N} Q_i \right| \tag{5}$$

2.2. Simulation environment and algorithm settings

To provide a fair comparison, the same equipment was utilized in each experiment. Table 1 provides a summary of the simulation environment's features. CS, EEFO, GEA, HS, LSO, NRBO, PO, PSO, SOS, and TLBO algorithms were tested in this study. The reference works of the algorithms and the settings recommended in the reference works are presented in Table 2. The maximum number of objective function evaluations (maxFEs) was used as the stopping criterion of the algorithms. This value was taken as 10000 times the number of design variables for all algorithms.

Table 1. The characteristics of the simulation environment

	Component	Description
Hardware	CPU and Frequency	Intel(R) Core(TM) i7-4600U CPU @ 2.10GHz
	RAM	8,00 GB
	Hard Drive	250 GB solid state drive
Software	Operating System	Windows 10 Pro 64 bit
	Language	MATLAB R2023b

Table 2. Settings of the tested algorithms

Algorithm	Reference	Parameters
CS	(Yang & Deb, 2009)	Number of Host Nests =25,pa=0.25
EEFO	(Zhao et al., 2024)	Population Size=100
GEA	(Ghasemi et al., 2024)	Population Size=60, Nc=40
HS	(Geem et al., 2001)	Harmony Memory Size = 50, Harmony Memory Consideration Rate = 0.93, Pitch Adjustment Rate = 0.18
LSO	(Abdel-Basset et al., 2022)	Population size = 20, Ps=0.05, Pe=0.6, Ph=0.4, β=0.05
NRBO	(Sowmya et al., 2024)	Population Size=30, Deciding Factor (DF)=0.6
PO	(Abdollahzadeh et al., 2024)	Population Size=30, PF1=0.5, PF2=0.5, PF3=0.3, U=0.2
PSO	(Eberhart & Kennedy, 1995)	Swarm size=30, cognitive constant=2, social constant=2, inertia weight linearly decreases from 0.9 to 0.4
SOS	(Cheng & Prayogo, 2014)	Ecosystem size = 50
TLBO	(Rao et al., 2012)	Population size=50

3. Results of optimization studies

This chapter is organized in two subsections. In the first subsection, the best solution of the well problems obtained by 10 different metaheuristic search algorithms is presented and the optimum solution findings are discussed. In the second subsection, the performances of the 10 metaheuristic search algorithms used in the optimal design are evaluated by analyzing their statistical data, Friedman scores and Wilcoxon pairwise comparison test results. Among the metaheuristic algorithms analyzed, the one with the highest performance is identified and proposed for solving similar problems.

3.1. Optimum design variables

Optimum designs were searched with 10 different metaheuristic algorithms whose settings are given in Table 2. Details of the least-cost solutions for the 6 and 7-well problems obtained from 21 independent simulations with each of them are presented in Table 3.

Table 3. Optimal design parameters

	Problem with 6 wells		Problem with 7 wells	
Design variables	Definition		Definition	
X_1	Flow rate of the 1st current well (Q1)	0.0285 $m^3 s^{-1}$	Flow rate of the 1st current well (Q1)	0.0232 $m^3 s^{-1}$
X_2	Flow rate of the 2nd current well (Q2)	0.0292 $m^3 s^{-1}$	Flow rate of the 2nd current well (Q2)	0.0224 $m^3 s^{-1}$
X_3	Flow rate of the 3rd current well (Q3)	0.0285 $m^3 s^{-1}$	Flow rate of the 3rd current well (Q3)	0.0232 $m^3 s^{-1}$
X_4	Flow rate of the 4th current well (Q4)	0.0292 $m^3 s^{-1}$	Flow rate of the 4th current well (Q4)	0.0248 $m^3 s^{-1}$
X_5	Flow rate of the 5th new well (Q5)	0.0423 $m^3 s^{-1}$	Flow rate of the 5th new well (Q5)	0.0359 $m^3 s^{-1}$
X_6	Flow rate of the 6th new well (Q6)	0.0423 $m^3 s^{-1}$	Flow rate of the 6th new well (Q6)	0.0359 $m^3 s^{-1}$
X_7	x coordinate of the 5th new well	-600 m	Flow rate of the 7th new well (Q7)	0.0345 $m^3 s^{-1}$
X_8	x coordinate of the 6th new well	600 m	x coordinate of the 5th new well	-600 m
X_9	y coordinate of the 5th new well	0	x coordinate of the 6th new well	600 m
X_{10}	y coordinate of the 6th new well	1200 m	x coordinate of the 7th new well	600 m
X_{11}	-	-	y coordinate of the 5th new well	0
X_{12}	-	-	y coordinate of the 6th new well	1200 m
X_{13}	-	-	y coordinate of the 7th new well	0
Cost		10315.444		9056.127

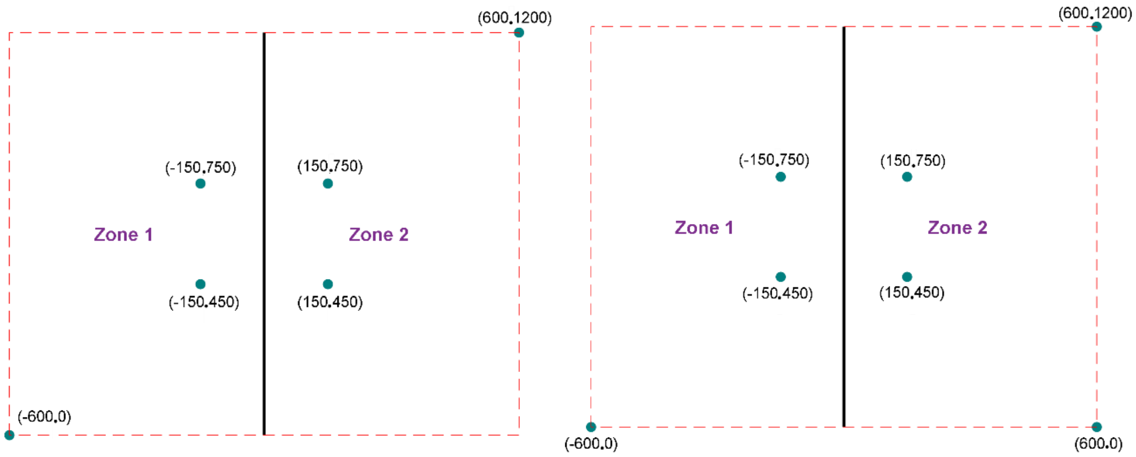

Fig. 2. Optimal coordinates of problems with 6 and 7 wells

The complexity of the objective function can be increased, by increasing the number of existing wells. It is safe to add them along the line y=600 or y=0, in order not to affect the optimal location of the new wells. It should be mentioned that the difference between the cost values depends on the ratio T_1/T_2.

In these optimization problems, the coordinates of the new wells are not known in advance. However, principles from groundwater hydraulics provide some guidance: (a) For a given well discharge Q_i, the resulting drawdown s_i at well i is smaller when the well is located in the region with higher transmissivity and generally decreases as the distance from the transmissivity interface increases. (b) For a given distribution of flow rates Q_i, the drawdowns s_i tend to decrease as the distances between wells increase. Based on these considerations, the most favorable positions for the new wells are likely to be near the corners of zone 1 (Fig. 2), as this zone has a higher transmissivity value (i.e., $T_1>T_2$) (Karpouzos & Katsifarakis, 2013).

If the new wells is located at (−600,0) and at (600,1200) in the problem with 6 wells and at (−600,0), (600,1200), and (600,0) in the problem with 7 wells (Fig. 2), the optimal flow rate distributions, shown in Table 3, result in minimum cost values of 10315.444 and 9056.127 respectively.

3.2. Comparison of algorithms performances

In this subsection, the performance evaluation of 10 metaheuristic algorithms used in the optimum designs is carried out. For this purpose, three different analyses were performed. In the first analysis, the average costs obtained from independent simulations and their standard deviations were assessed. In addition, the evaluation was also conducted with box plots using the same data.

When Table 4 is analyzed, it is seen that the algorithm with the lowest average cost among the 10 rival metaheuristic algorithms is the LSO algorithm. In addition, it is seen that the lowest standard deviation is also obtained by the LSO algorithm. This simple statistical evaluation shows that the LSO algorithm is more efficient and stable than the other rival algorithms. Nevertheless, it is found that the CS and EEFO algorithms rank second and third when evaluating the average cost and standard deviation.

Table 4. Mean and standard deviation of the algorithms

Problem with 6 wells			Problem with 7 wells		
	Mean	Std. Dev		Mean	Std. Dev
LSO	10315.45	0.004	LSO	9057.57	3.356
CS	10320.60	4.692	CS	9122.87	41.433
EEFO	11330.70	263.846	EEFO	9916.93	335.884
NRBO	11968.34	6027.551	NRBO	10288.64	2439.545
SOS	12972.56	1835.855	TLBO	11970.95	889.492
TLBO	13901.40	1627.601	SOS	12875.66	2970.444
GEA	18782.32	7086.682	GEA	17028.09	6378.369
HS	1.43E+12	3.59E+12	HS	20987.18	7433.758
PO	2.38E+12	1.09E+13	PO	2.86E+12	1.31E+13
PSO	4.38E+16	5.45E+16	PSO	9.52E+16	6.75E+16

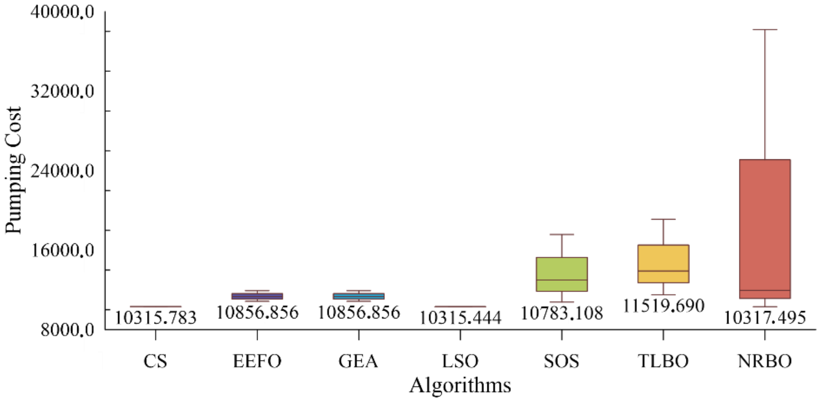

Fig. 3. Box plot of used algorithms for the problem with 6 wells

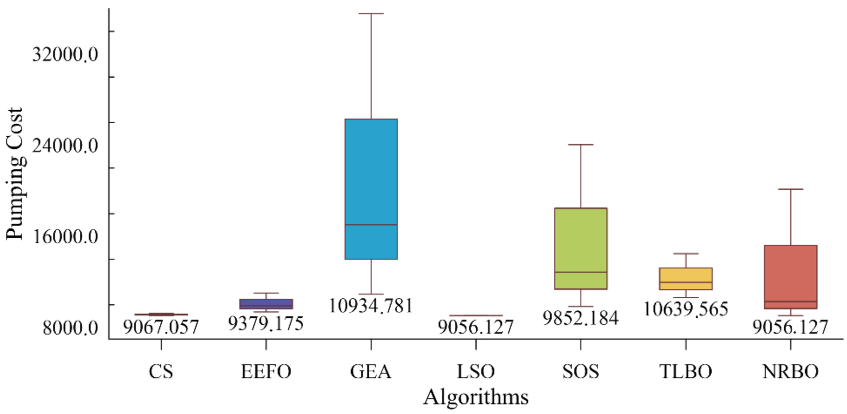

Fig. 4. Box plot of used algorithms for the problem with 7 wells

It is evident from the analysis of the box plots presented in Figures 4 and 5 that the LSO and CS algorithms are capable of achieving the lowest average cost values for both well problems. The small distance between the upper and lower bounds of the box-plot indicates that the standard deviation is also low. When a similar evaluation is made for the standard deviations by means of box-plot, it is seen that the standard deviations of LSO and CS algorithms are much lower than the others.

Since the rankings of the algorithms could not be determined very clearly in the first evaluation, the Friedman test, which is widely preferred in the literature for ranking the performance of metaheuristic search algorithms, was used (Friedman, 1940). The performance rankings of the 10 competing algorithms for both problems are presented in Table 5. In the last column of Table 5, the average Friedman scores obtained for both problems are presented to provide a general evaluation for all problems. In the table, the algorithm names are listed according to the scores.

Table 5. Friedman scores of the algorithms for the well problems

Friedman Scores and Rankings					
Problem with 6 wells		Problem with 7 wells		Mean Score	
LSO	1.00	LSO	1.29	LSO	1.14
CS	2.19	CS	2.43	CS	2.31
NRBO	3.71	NRBO	3.19	NRBO	3.45
EEFO	4.38	EEFO	3.86	EEFO	4.12
SOS	5.62	TLBO	5.95	SOS	5.90
PO	6.00	SOS	6.19	PO	6.17
TLBO	6.57	PO	6.33	TLBO	6.26
GEA	7.81	GEA	7.76	GEA	7.79
HS	8.43	HS	8.67	HS	8.55
PSO	9.29	PSO	9.33	PSO	9.31

Table 6. Wilcoxon test results of the algorithms for the well problems

LSO vs.	Problem with 6 wells	Problem with 6 wells
CS	0 / 0 / 1	0 / 0 / 1
EEFO	0 / 0 / 1	0 / 0 / 1
GEA	0 / 0 / 1	0 / 0 / 1
HS	0 / 0 / 1	0 / 0 / 1
NRBO	0 / 0 / 1	0 / 0 / 1
PO	0 / 0 / 1	0 / 0 / 1
PSO	0 / 0 / 1	0 / 0 / 1
SOS	0 / 0 / 1	0 / 0 / 1
TLBO	0 / 0 / 1	0 / 0 / 1

When the Friedman scores presented in Table 5 for both problems are evaluated, it is seen that the LSO algorithm ranks first for the six-well and 7-well problems. The average scores of the problems also indicate that the LSO algorithm performs better than its rivals in such problems. However, it is understood that the second and third ranked algorithms for the well problems are CS and NRBO algorithms, respectively.

The third evaluation involves pairwise comparisons with the LSO algorithm, which was determined to be the winner in the Friedman test. In order to perform these comparisons, a Wilcoxon pairwise comparison test (Wilcoxon, 1945) was applied to the LSO algorithm with each of the other 9 rival algorithms. The results are given in Table 6.

In Table 6, the three points assigned to each cell indicate that the rival algorithm performs better, similar or worse than the LSO algorithm, respectively. For example, 1/0/0 indicates that the LSO algorithm is the loser, 0/1/0 indicates that the LSO algorithm and the rival algorithm are tied, and 0/0/1 indicates that the LSO algorithm is the winner. The results of the Wilcoxon test presented in Table 6 show the superiority of the LSO algorithm over the other rival algorithms in both problems.

In summary, statistical evaluations reveal that the LSO algorithm significantly outperforms the other 9 rival metaheuristic search algorithms considered in this study in minimum cost well planning problems.

4. Conclusions

In this study, the performance of ten metaheuristic algorithms was evaluated for groundwater well placement and flow rate optimization with the objective of minimizing pumping costs in heterogeneous aquifer systems. Two distinct optimization problems involving six and seven wells were considered, with various configurations of existing and new wells. The results clearly demonstrate that among the tested algorithms, the Light Spectrum

Optimizer (LSO) consistently achieved the best performance in terms of both the lowest average cost and the smallest standard deviation, indicating high efficiency and robustness.

The comparative analysis based on average cost, standard deviation, and box plot visualization reinforced the superiority of the LSO algorithm. Furthermore, statistical tests-specifically the Friedman ranking and Wilcoxon signed-rank test-confirmed that LSO significantly outperforms the other nine algorithms across both optimization scenarios. The Cuckoo Search (CS) and Newton-Raphson-Based Optimizer (NRBO) algorithms were identified as the second and third best-performing techniques, respectively.

These findings suggest that LSO is a highly effective algorithm for solving complex groundwater optimization problems characterized by nonlinear objective functions. It can be recommended as a reliable tool for practical groundwater management tasks that require cost-effective planning under hydrogeological constraints. Future studies could extend the present work by incorporating multi-objective criteria such as water quality, environmental impact, and sustainability indicators to develop more comprehensive groundwater management problems.

Comparison of Reynolds shear stress and drag coefficient in a meander with submerged flexible and rigid vegetation

Mercede Alizadeh[1], Hossein Afzalimehr[*1], Saeid Okhravi[2]

[1] *Department of Civil Engineering, Iran University of Science and Technology, Tehran, Iran*
[2] *Department of Civil Engineering, Slovak Acadmy of Science, Bratislava, Slovakia*

Abstract. Natural channels and rivers rarely follow a straight path, often exhibiting meandering shapes. Due to the natural meanders that shape the river channels, understanding the flow characteristics is essential. Additionally, the presence of vegetation in the bed and banks of rivers and its interaction with the bends has a significant impact on the ecosystem and flow structure, as it alters the flow pattern and the distribution of hydraulic parameters. Moreover, the flow passing through open meandering channels, due to secondary and rotational flows, changes the water surface and flow pattern compared to straight channels, affecting flow characteristics such as velocity distribution and turbulence components, and influencing downstream flow as well. This research was conducted in the Hydraulic Laboratory at the Iran University of Science and Technology, in a curved channel with a concrete bed, 8 meters long, covered with sandy bed and a median particle diameter of 15.1, and varying aspect ratios (width-to-depth ratios). The aim of this study is to analyze the impact of submerged flexible and rigid reeds vegetation on the external walls of a reconstructed natural meandering channel with a sandy bed and fixed slope on, Reynolds stress, and drag coefficient. To investigate the effect of vegetation on the flow in the bend, submerged flexible and rigid plastic reeds, 4 cm in height, were used over the sandy bed with a 2% slope. To examine turbulent flow structures, three-dimensional Acoustic Doppler Velocimeter (ADV) velocity data were employed. The experiments consisted of two series: one series with flexible and oneother series with rigid vegetation, with a flow depth of 13 cm. Parameters such as, Reynolds shear stress, and drag coefficient were measured, calculated, and analyzed. The results obtained from the experimental data indicate that the Reynolds stress distribution is nonlinear. In the second section, where the flow interacts with the vegetated area, the Reynolds stress values show a significant decrease compared to the initial sections before the vegetation. This reduction highlights the effective role of vegetation in suppressing vertical mixing within the flow. The drag coefficient was calculated as an indicator of flow resistance, and the results showed that in the initial section, before the flow enters the vegetated zone, the drag coefficient for flexible vegetation is higher than that of rigid vegetation. However, after entering the vegetated area, the drag coefficient for flexible vegetation decreases by 40%, while for rigid vegetation it increases by 93% compared to the values before the vegetated zone.

Keywords: Submerged flexible and rigid reed vegetation; Meandering channel; Sandy bed; Reynolds stress; Drag coefficient

1. Introduction

The interaction between flow and sediment transport plays a pivotal role in the morphodynamic evolution of riverbeds, leading to aggradation and degradation processes that are highly relevant in river management engineering. Sediment transport at the bed level is one of the most essential characteristics of alluvial channels, directly influencing channel stability and morphology. Most natural rivers exhibit sinuous planforms (Langbein & Leopold, 1966), resulting from the complex interplay between flow dynamics, such as longitudinal flow and secondary circulation, and processes of erosion and deposition along the river bed and banks (Seminara, 2006). Channel curvature generates secondary flows in the cross-sectional plane due to the imbalance between centrifugal forces and barotropic pressure gradients (Thomson, 1877). These secondary circulations, as described analytically by Rozovskii (1957) and later by Kalkwijk and Booij (1986), have been widely observed in both riverine and estuarine bends (Buijsman & Ridderinkhof, 2008). This lateral circulation is critical to sediment redistribution, contributing to outer bank erosion, inner bank deposition, meander migration, and the formation of point bars. However, in estuarine systems, salinity-induced stratification can suppress or even reverse these secondary flows

golden light publishing

due to baroclinic pressure gradients, potentially explaining the absence of point bars in some tidal meanders (Kranenburg et al., 2019).

In river systems, aquatic vegetation has traditionally been regarded primarily as a source of flow resistance, and as such, it has often been removed to mitigate flood risks (Kouwen, 1992). However, aquatic vegetation also provides vital ecological services, making it an essential component of river ecosystems (Luhar et al., 2008). Understanding the influence of vegetation on flow is thus crucial for effective river restoration. Accurately estimating flow retardation in vegetated channels is particularly important for designing restoration projects (Järvelä, 2005). Despite its importance, the specific interaction between vegetation along channel banks and accelerating flow in gravel-bed rivers has yet to be thoroughly investigated or documented in existing literature.

Afzalimehr and Anctil (2000), has demonstrated that the maximum Reynolds shear stress typically occurs near the bed and decreases toward the free surface with a concave profile. The findings of the present study corroborate this general trend along the flume centerline. However, the presence of vegetation along the banks introduced significant deviations from the classic concave distribution, as reported in the aforementioned studies.

The drag coefficient C_D is commonly used as a quantitative parameter to represent the resistance exerted by aquatic vegetation. The estimation of this drag assumes that energy losses occur due to the distributed drag forces associated with characteristic vegetation (Marjoribanks et al., 2014). This approach is not limited to calculating vegetative drag using bed stress formulae from previous studies (Thompson and Roberson, 1976).

2. Material and method

The experiments were conducted in a meandering channel with natural geometry and a concrete bed. The channel width from the upstream end to the start of the final bend is 0.9 meters, and the total length of the channel is 8 meters. The wavelength of the channel bend is 3.2 meters, and its sinuosity is 1.05. The external bend angle at the end of the channel is 136 degrees, and the internal bend angle is 76 degrees. The channel bed has a gentle slope, consistent with the river slope, equal to 0.0002. Additionally, the channel is equipped with a recirculating flow system, where water flow is pumped from the downstream end and returned to the upstream end.

During the data collection, the flow depth was set and stabilized at a constant value of 13 cm. The data collection related to flow velocity and turbulence was performed using an Acoustic Doppler Velocimeter (ADV). On average, each velocity profile included 18 measurement points. For the channel bed coverage, natural sand was used with a median particle diameter (d_{50}) of 0.158 mm. Data were collected at two different sections: before the start of the bend and at a position with a 45-degree angle from the bend. To ensure high data quality and accurate recording of velocity fluctuations, the distance of the ADV from the outer bend wall was approximately 20 cm. This distance was selected so that the ADV device could record velocity values with a high correlation coefficient, and the spikes were removed using WINADV software.

In this study, to simulate the bed vegetation, flexible and rigid cylindrical plastic reeds with a diameter of 5 mm, which most closely resemble natural samples, were used. The vegetation employed in this experiment consists of reeds with a height of 4 cm above the bed surface, arranged in a submerged manner at the final 90-degree bend of the channel in the downstream section, with 5 cm spacing between them. These reeds are placed on a 2 cm thick plate in a regular arrangement. The reed density with different materials per unit area is 360 reeds.

Fig. 1. General layout of the channel at different bend angles

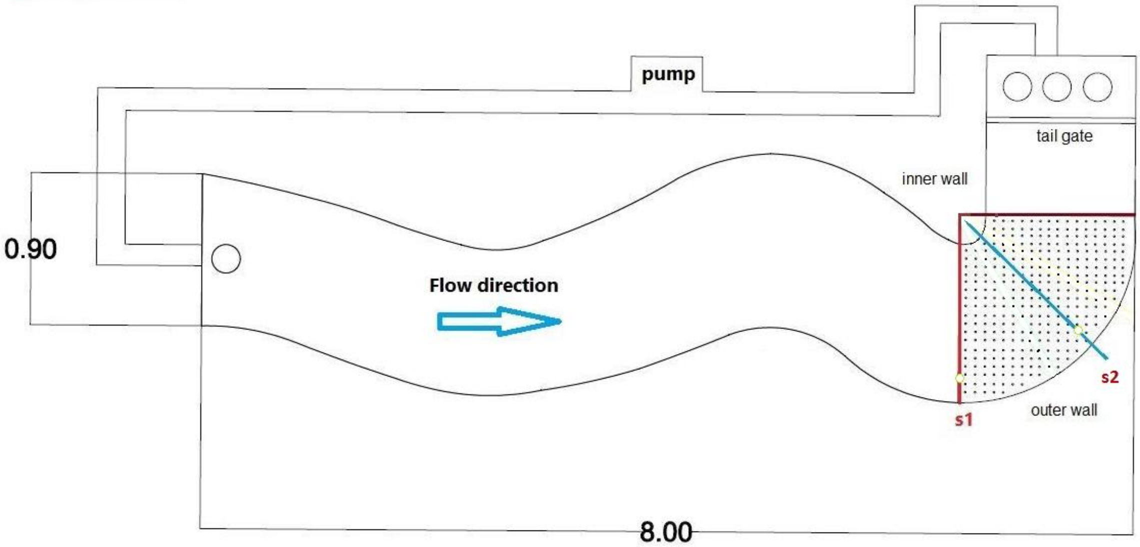

Fig. 2. Data acquisition locations in different cross-sections and the channel plan.

2.1. Reynolds shear stress
The vertical Reynolds stress ($u'w'$) induces longitudinal and vertical momentum exchange as well as vertical mixing (Velasco et al., 2003). Investigations show that the Reynolds stress distribution in all channel flows is nonlinear. The linearity occurs only for low depths above the peak as stress decays from its maximum near the boundary (bed or top of vegetation) to the free surface (Huai et al., 2009).

2.2. Estimation of flow resistance
In this study, flow resistance in the presence of vegetated banks was estimated using Equation (1), as follows:

$$C_D = 2u_*^2/U^2 \tag{1}$$

Where U is the mean cross-sectional velocity, u_* is the shear velocity, CD is the drag coefficient.

$$U = \frac{1}{h}\int_0^h u_i\, d_z \tag{2}$$

where u_i is the velocity at height z, and h is the total flow depth. This formula gives the average velocity over the water column. In practice, U is numerically computed using the measured velocity data along the depth.

2.3. Shear velocity estimation methods
In this study, the shear velocity for each cross section was estimated using the approache of the Boundary Layer Characteristics Method**.**

2.3.1. Boundary layer characteristics method
This method, proposed by Azalimehr and Anctil (2000), utilizes all measured point velocities within each vertical profile to estimate the shear velocity (u_*). The calculation is based on the velocity distribution observed within the boundary layer.

$$u_* = \frac{(\delta_* - \theta)u_{max}}{4.4\delta_*} \tag{3}$$

In this method, u_{max} represents the maximum velocity in each vertical profile. The displacement thickness (δ_*) and the momentum thickness (θ) of the boundary layer are calculated using Equations (4) and (5), respectively.

$$\delta_* = \int_0^h \left(1 - \frac{u}{u_{max}}\right) dz \tag{4}$$

$$\theta = \int_0^h \frac{u}{u_{max}}\left(1 - \frac{u}{u_{max}}\right) dz \tag{5}$$

Where h is the flow depth along the selected axis, u is the local (point) velocity, and U_{max} is the maximum velocity within the velocity profile.

4. Result

4.1 Reynolds shear stress

According to the S1 diagram, the values of ($u'w'/u_*^2$) are significantly higher than those in section S2, even reaching over 20. In the first section, both cases show a wavy and oscillatory structure, indicating turbulence due to the transition into the vegetation-covered region and local flow instabilities. This behavior suggests that the vegetation exerts its hydrodynamic effects even upstream.

In the S2 diagram, the Reynolds shear stress decreases dramatically, with most values falling below 1 and even becoming negative in some regions. This reduction indicates a weakening of vertical mixing due to the presence of plants, which is entirely expected as the vegetation's resistance reduces vertical velocity fluctuations.

In this diagram, it is observed that the maximum shear stress does not occur near the bed but is found at a middle height (around ($0.4 < z/H < 0.5$)). The nonlinear pattern and the shift in the location of the maximum shear stress clearly indicate the effects of plant resistance and secondary flows, which cause deviations from classic shear stress patterns.

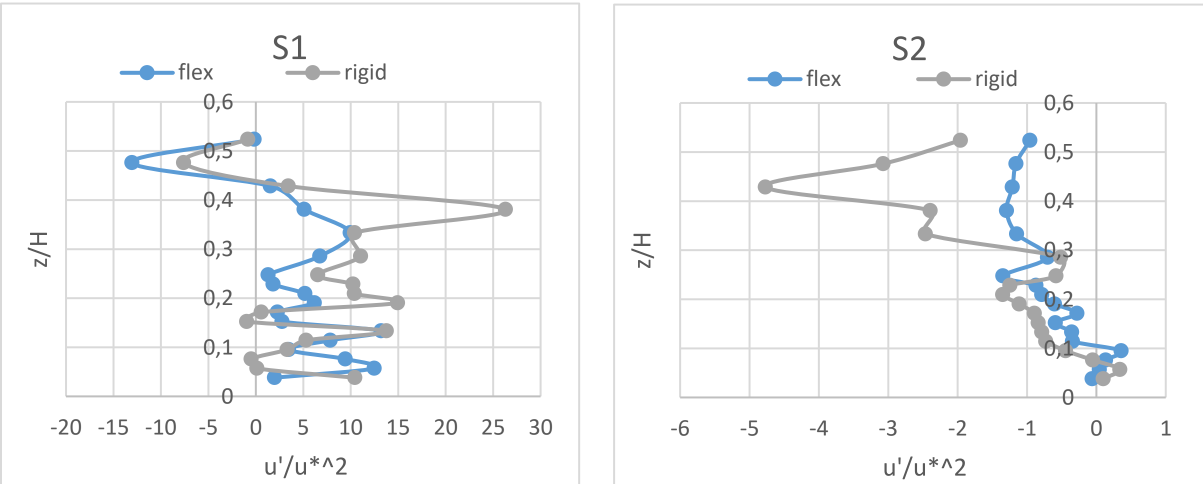

Fig. 3. Shear stress distributions

4.2. Shear velocity

As described in Section 2.3, the boundary layer characteristics method was used to calculate shear velocity in this study. The values of shear velocity and shear stress, calculated using the equation $\tau = \rho u{*}2$, are presented for the studied reach in Table 1. The results show that in cross section S1, the presence of flexible vegetation, compared to rigid vegetation, led to a significant increase in flow velocity, shear velocity, and consequently, shear stress. This increase indicates higher turbulence production and more effective momentum transfer to the bed in the presence of flexible vegetation. A similar pattern is observed in cross section S2 as well, where flexible vegetation also results in increased flow velocity, shear velocity, and shear stress, although the magnitude of this increase is smaller compared to that observed in S1.

Table 1. velocity, shear velocity and shear stress calculated from boundary layer

section	U (m/s)	Shear velocity (m/s)	Shear stress (N/m^2)
S1 flex	2.52	0.011	0.126
S1 rigid	1.38	0.004	0.022
S2 flex	3.38	0.012	0.134
S2 rigid	1.74	0.008	0.067

4.3. Estimation of flow resistance

In this study, the drag coefficient was used as an indicator of flow resistance. Following the calculation of the mean velocity and shear velocity for each cross section, the drag coefficient was determined based on Equation (1).

In this study, variations in the drag coefficient across different flow sections were investigated. The first section, which is located before the flow enters the vegetated area and bend, represents the effects of the flow structure without vegetation. In this section, the drag coefficient for flexible vegetation (0.50) is higher than that for rigid vegetation (0.29). This difference may be attributed to the increased turbulence and fluctuations in the flow caused by the flexible vegetation, which results in higher resistance to flow movement.

In the second section, where the flow is in the presence of vegetation and at a 45-degree angle relative to the bend, it is observed that the drag coefficient for rigid vegetation (0.56) is higher than that for flexible vegetation (0.30). This change indicates the influence of vegetation on the flow structure in this region. Flexible vegetation, with lower resistance to flow, leads to a reduction in the drag coefficient, while rigid vegetation, due to its more rigid structure, increases the resistance and consequently raises the drag coefficient.

Table 2. Drag coefficient of flexible and rigid vegetation

Section name	C_D flex	C_D rigid
Section 1	0.50	0.29
Section 2	0.30	0.56

5. Conclusions

In this study, flow resistance was evaluated for a meandering reach with a vegetated bed, conducted in the laboratory at Iran University of Science and Technology.

The results show that flexible vegetation increases turbulence and momentum transfer, leading to higher shear stress in the upstream section. In contrast, downstream shear stress decreases and even becomes negative, indicating weakened vertical mixing due to plant resistance. Additionally, the shift of maximum shear stress to mid-depth highlights the influence of vegetation resistance and secondary flows in altering the classic shear stress pattern.

Findings reveal that flexible vegetation, especially in upstream sections, enhances flow turbulence, shear velocity, and shear stress more effectively than rigid vegetation. Although this effect persists downstream, its intensity diminishes. Overall, flexible vegetation significantly alters flow dynamics by enhancing momentum transfer.

It was also observed that near the outer bend of the meander, flexible vegetation imposes less resistance to the flow compared to rigid vegetation. In general, flexible vegetation increases turbulence and reduces the drag coefficient, whereas rigid vegetation, due to its stiffer structure, creates greater resistance against the flow.

Investigation of temporal change of Van Lake surface area with climatic parameters

Osman T. BAKİ*[1],

[1] Karadeniz Technical University, Department of Civil Engineering, 61830 Trabzon, Türkiye

Abstract. Sustainable management of water resources is becoming increasingly important today. Closed basins, in particular, are of critical importance for the control of water resources. The Van Lake Basin is one of the largest closed basins in Türkiye and the efficient and sustainable management of its water resources is of great importance both environmentally and economically. Therefore, monitoring changes in the surface area of Van Lake plays an important role in developing strategies for managing water resources in this region. In this study, it was aimed to determine the changes in the surface area of Van Lake between 2016 and 2020. For this purpose, satellite images were used and Landsat 8 images were employed. The selection criterion was defined as a minimum cloudiness requirement of less than 10% cloud cover. This parameter, as well as, was deemed essential for the precise identification of surface water from satellite images taken in August, a period coinciding with the annual peak in temperature and annual nadir in precipitation. The month of August is widely accepted as the period during which the annual minimum rainfall is observed, and thus the minimum water level is recorded. This is particularly important in the context of monitoring changes in the lake's surface area. The Normalized Difference Water Index (NDWI) was used to delineate water surface. NDWI is a spectral index used to delineate water surfaces, and it has the ability to clearly distinguish the differences between water and land. With this method, the water surface boundaries of Van Lake were delineated and the changes in the surface area between 2016 and 2020 were analyzed. The extent to which changes in surface area are related to precipitation, temperature and snowfall height data has been determined, and the effect of environmental factors on water levels in the lake over the years has been expressed.

Keywords: Climate change; Landsat 8; NDWI; Türkiye; Van Lake

1. Introduction

Water resources are of significant importance for the continuity of life. Hence, sustainable management of water resources necessitates proper planning with ecological approaches, long-term monitoring and subsequent observation and monitoring studies of changes in the ecosystem. The assessment of water resources, both in terms of quantity and quality, is a topic that researchers frequently investigate.

Water resources, encompassing the ocean, rivers, lakes, streams and reservoirs, play a pivotal role in the preservation and regulation of diverse living resources within and surrounding ecosystems. The rapid process of urbanisation is expediting environmental transformation and compromising existing water resources. To ensure the conservation and utilisation of these resources, there is a necessity for continuous monitoring and appropriate surveys to be conducted for the purpose of acquiring data regarding water surface. While manual surveys offer dependable information, they are a costly and time-consuming process in terms of manpower. In recent years, advances in remote sensing have rendered it feasible to utilise timely information recorded by different sensors on the satellite. This factual information is widely utilised in various applications, including the extraction of information about water surface (Tambe et al., 2021).

Nowadays, satellite images are processed and widely used in land use and land cover changes, disaster observation, forest and vegetation changes, forest health, area suitability analysis and hydrology observations (Cihan et al., 2022; Demirağ Turan et al., 2021; Genc et al., 2005; Karaman et al., 2018). The utilisation of remotely sensed imagery, spatial technologies and computer processing is becoming increasingly advantageous in the monitoring of environmental changes and trends (Baban, 1999). Generally, object-based classifications and band ratios are preferred in land use and land cover assessment studies using satellite images. Different band proportioning studies have been carried out to more clearly separate water surface in the field from other land objects (Gülci et al., 2019).

It is imperative to acknowledge the significance of lake basins in the context of water resources management, ecosystem health, and environmental monitoring. These bodies of water exert a direct influence on the hydrological equilibrium of the surroundifng regions, thereby playing a pivotal role in diverse fields, including agriculture, industry, and drinking water supply. The alterations in the surface areas of lakes can be influenced by numerous factors, such as climate change, variations in precipitation patterns, escalating evaporation rates, and anthropogenic activities.

The quantity of water in lakes exerts a direct influence on a variety of physical, biological, and chemical processes, which in turn have significant ramifications for the health of ecosystems and the quality of life. A decrease or increase in the water level can disrupt the equilibrium of aquatic ecosystems by affecting the temperature, oxygen level, and distribution of nutrients in the water. While low water levels can pose a threat to the survival of fish and other aquatic creatures by reducing the oxygen content of the water, excessive water levels can lead to problems such as water pollution and erosion. Furthermore, fluctuations in the chemical composition of water have the capacity to modify biodiversity, given their impact on nutrient cycling and the proliferation of aquatic flora. These alterations may also exert an influence on human quality of life, given the pivotal role that lakes play in economic activities such as water supply, agriculture, tourism and fishing. Imbalances in the quantity of water in lakes have the potential to compromise the sustainability of these activities and to diminish the living standards of the local population (Sobek, 2011).

The quantity of water contained within a lake reservoir is principally determined by the harmonious interplay between inflow, which encompasses direct precipitation, inflowing river discharge, discharge from riparian communities and industries, and groundwater inflow and outflow, comprising direct evaporation, withdrawal, reservoir outflow, and groundwater infiltration (Duan & Bastiaanssen, 2013).

In the contemporary era, there is mounting pressure on water resources, particularly in arid and semi-arid regions, due to climatic changes, increasing water demand and human activities. As a consequence of climate change, irregularities in precipitation patterns and increases in evaporation rates result in substantial reductions in the water levels of lakes and other water surface. This phenomenon leads to the drying up of lakes, the shrinkage of their surface area or even their complete disappearance. The consequences of climate change extend beyond drought and water loss, as they can also result in an increase in periods of extreme rainfall. During such times, sudden increases in rainfall can lead to a significant rise in lake surface areas. Uncontrolled rises in lake levels, particularly in areas prone to frequent flooding, can have detrimental environmental and socio-economic impacts. Increased rainfall can lead to an increase in the flow of water in rivers and streams flowing into lakes, causing the lake volume to expand significantly in a short period of time. This phenomenon can have deleterious effects on settlements, agricultural lands and natural ecosystems in the vicinity of the lake. Consequently, the accurate monitoring of lake surface areas and the meticulous analysis of these fluctuations are paramount for the formulation of efficacious water management strategies, both during periods of drought and in the context of wetter climatic conditions. The repercussions of these processes extend beyond the jeopardy of regional ecosystems, as they also complicate the sustainable management of water resources.

Accurate monitoring and analysis of these changes is therefore critical in order to develop sustainable water management and environmental protection strategies. The objective of water surface extraction for remote sensing images is to differentiate between water surface and other non- water surfaces. This includes satellite images, man-made structures, forestry, snow, barren lands, and so forth. The process is inherently more complex, incorporating additional information such as data, which complicates the extraction of water surface. Consequently, conventional methods based on water surface indices are employed.

The utilisation of field measurements in the field of river sciences frequently engenders cost and time constraints that impede the capacity to amass the exhaustive records necessary to comprehend large and dynamic river systems. Consequently, river managers have increasingly resorted to Earth Observation (EO) science and remote sensing techniques. A significant number of studies have utilised historical water surface masks derived from pre-processed EO datasets, including the Global River Width from Landsat (GRWL, (Allen & Pavelsky, 2018)) and the Surface Water and Ocean Topography mission River Database (SWORD, (Altenau et al., 2021)).These datasets are typically static in time and assumed to be centred around the mean river width (Allen & Pavelsky, 2015).

Traditional water surface masking methods employ the Normalised Difference Water Index (NDWI). NDWI utilises green and near-infrared wavelengths, rendering it compatible with data from the majority of satellite Earth observation missions. The extraction of water surface masks based on NDWI involves the implementation of histogram thresholding methods, which exhibit minimal computational demand. However, this technique is contingent on the selection of specific threshold values that vary by region. (Frazier & Hemingway, 2021; McFeeters, 1996). Xu (Xu, 2006), developed NDWI through the use of shortwave infrared radiation, subsequently renaming the index as modified NDWI (MNDWI). Ouma and Tateishi (Ouma & Tateishi, 2006) proposed a water index (WI) for determining the coastal boundary by integrating the Tasseled Cap Wetness (TCW) index and NDWI. The utilisation of Landsat TM/ETM+ (Thematic Mapper/Advanced Thematic Mapper Plus) (Lu et al., 2008; Zhang et al., 2011), MODIS (Moderate Resolution Imaging Spectroradiometer) (Rogers & Kearney, 2004;

Xiao et al., 2005) and SPOT (Système Pour l'Observation de la Terre) (Bastawesy et al., 2008), ASTER (Advanced Spaceborne Thermal Emission and Reflection Radiometer) (Sivanpillai & Miller, 2010) and HJ-1A/B (Lu et al., 2011) satellite images, have been extensively employed to delineate water surface features.

The advent of satellite imaging technologies has enabled the more precise and effective determination and monitoring of lake surface areas. Satellite data has become a valuable research tool due to its ability to cover large areas and provide consistent data over time series. The high resolution and frequent repetition intervals of satellite imagery make it possible to monitor dynamic changes in the surface area of lakes. The use of these technologies offers great advantages in terms of both time and cost compared to manual measurements. Examining water level and surface area changes and their causes and predicting the changes in the coming years are important and necessary data for the design of coastal structures to be built on the shores of lakes. Although Van Lake cannot be used as drinking and irrigation water due to its soda structure, it serves as a very important water source for the region.

Precipitation and evaporation represent a pair of factors which form the basis of the hydrological cycle (Tanny et al., 2008). The investigation presented herein examined the change in Van Lake water volume with the effects of precipitation and temperature.The study aims to ascertain the alterations in the surface area of Van Lake by means of satellite imagery. To this end, the surface area will be determined using the NDWI index, and the effect of meteorological parameters on the changes in the lake surface area will be examined. Furthermore, by comparing the surface area and water level data obtained by remote sensing, the effect of meteorological data on these changes will be evaluated. The overarching objective of this study is to establish a scientific basis for the sustainable management of water resources and the advancement of environmental protection studies.

2. Study area and data

The Van Lake, the largest lake in Türkiye, also holds the distinction of being the fourth largest salt and soda lake in the world. The Van Lake is considered to be one of the ten largest endorheic (closed basin) saline lakes in the world. It is located in the southern part of the Eastern Anatolia region within the borders of Türkiye (Aydin & Karakuş, 2016; Batur et al., 2009).

The Van Lake is classified as a closed basin, and, according to topographic water divisions, the total surface area of the basin is 17,694 km^2, including both open water surface and land area (Fig 1). The geographical context of Van Lake is defined by its location between the eastern city of Van and the western city of Bitlis. The lake's hydrology is influenced by the streams and rainfall that originate in the surrounding region. According to the mass balance equation, the water budget components of Van Lake consist of precipitation, surface runoff, and groundwater discharge as inflows, and evaporation loss as an outflow. The location of Van Lake within a depression basin on an active fault system contributes to the occurrence of volcanism, hydrothermal activity, and earthquakes (Cukur et al., 2015). The main drainage network in the closed basin of Van Lake consists of permanent streams such as the Zilan, Deliçay, Bendimahi, Karasu, Çaybağı, Engil, Gevas, Kotum, and Yeniköprü (Fig 2).

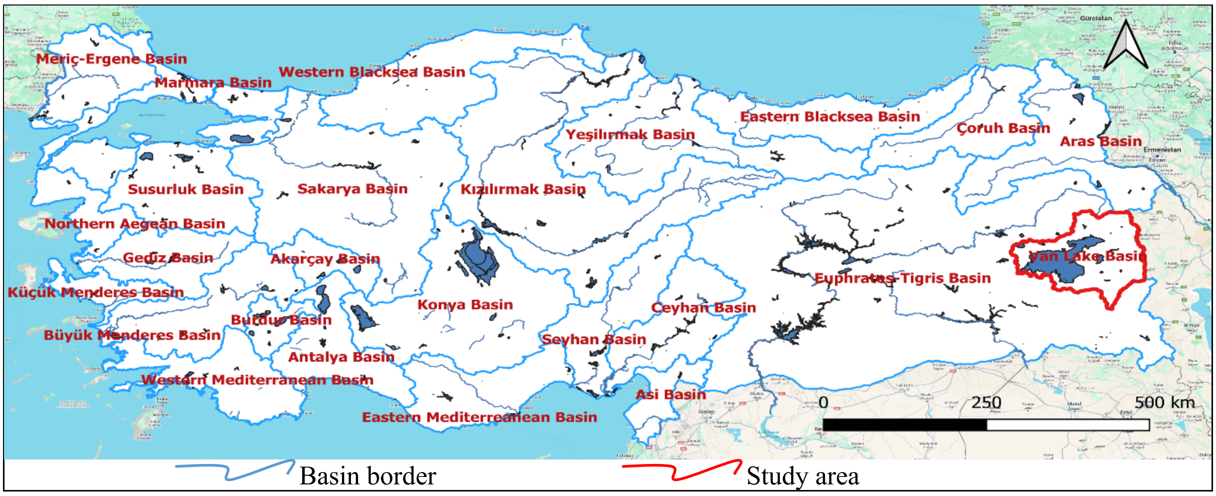

Fig. 1. Water basins of Türkiye

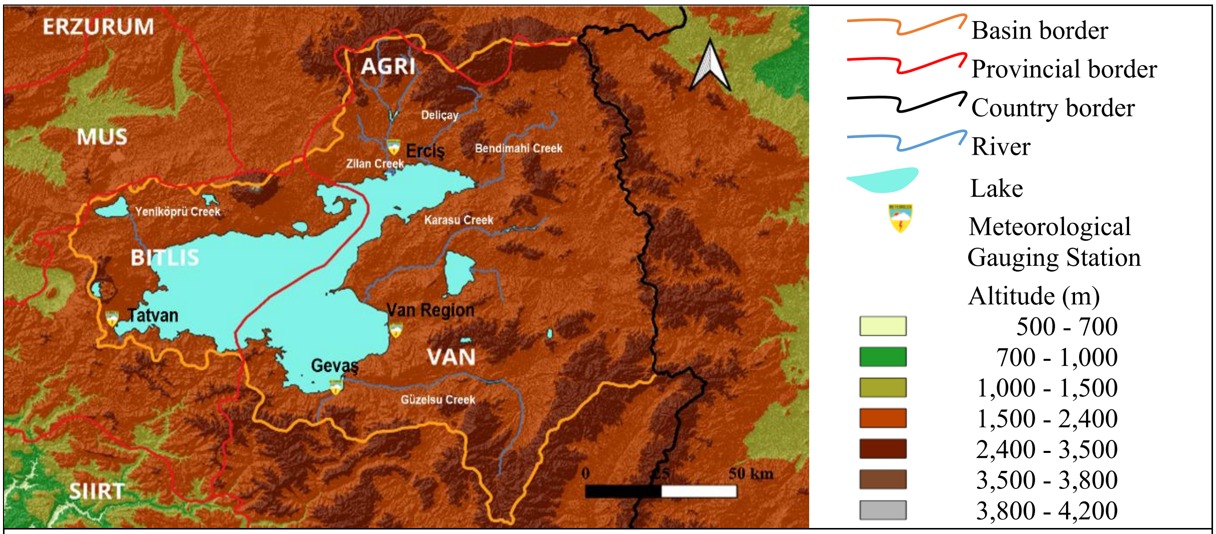
The Van Lake Basin, at an altitude of about 2,185 m, is located in an area far from the sea and surrounded by mountains. The deepest point of the lake is 450 m. The basin covers the provinces of Ağrı, Bitlis, Muş, and Van. In terms of geometric altitude, its lowest elevation starts from 1,648 m and reaches 4,054 m asl at its highest points (Aydin & Karakuş, 2016; Osman, 1993). Although the continental climate type seems to dominate throughout the basin, the areas near the lake have a more temperate climate. Meteorological data for the years 2016-2020, obtained from the Turkish State Meteorological Service (MGM) meteorological gauging stations representing the basin and shown in Fig 2, are presented in Table 1.



Station no	Gauging station	Coordinates	
		Latitude	Longitude
17172	Van Regional Directorate (R. D.)	38.475012	43.355045
17205	Tatvan	38.515670	42.274648
17784	Erciş	39.050682	43.340941
17852	Gevaş	38.390140	43.188428

Fig. 2. Van Lake Basin

Table 1. Meteorological statistics for the study area for the years 2016 to 2020

	Average Temp. (°C)				Average Prep. (mm)			
Year	Van R. D.	Tatvan	Erciş	Gevaş	Van R. D.	Tatvan	Erciş	Gevaş
2016	10.37	9.73	8.90	9.43	39.07	74.76	32.95	45.17
2017	10.59	9.79	9.40	9.47	26.08	60.93	24.17	40.33
2018	12.18	11.62	11.17	11.03	31.06	69.98	32.65	42.55
2019	11.05	10.51	9.63	10.02	19.28	59.33	39.75	27.82
2020	10.77	10.43	9.74	9.87	28.61	49.13	27.05	38.92

According to the average temperature values of the whole basin, the hottest station of the basin was recorded in the Van R.D., while the coldest station was the Erciş gauging station. While the rainiest station was Tatvan, the lowest rainfall values were recorded at the Van R.D. gauging station. The time series of monthly changes in temperature and precipitation values over the years are presented in Fig 3.

The months of July and August are distinguished by a marked scarcity of rainfall within the basin. With the exception of summer, precipitation is observed in almost every other season. Fig 3 demonstrates that April is typically the month with the highest rainfall, while August is usually the month with the lowest. The monthly average temperatures are also of interest. It is evident from these data that the lowest temperatures are recorded in January, while the highest are recorded in August. Furthermore, it is notable that evaporation is at its peak in August.

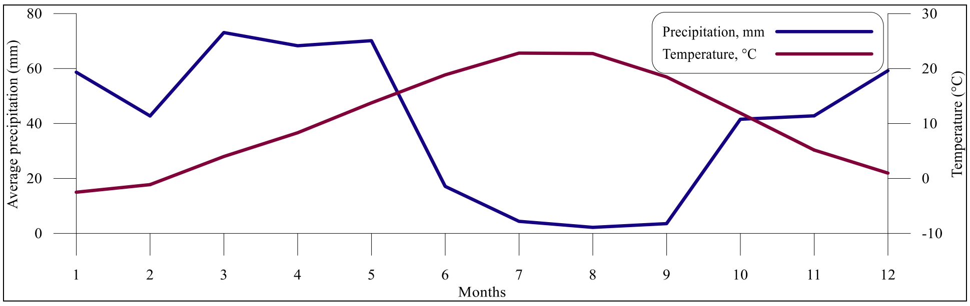


Fig. 3. Monthly average time series of precipitation and temperature

The water level in Van Lake is regulated by the entry of water into the basin and the evaporation process. The surface of the lake fluctuates at regular intervals over long periods of time depending on the dynamics of these natural processes. This phenomenon has a significant impact on lakeside settlements. As the lake's waters expand to cover the low-lying areas on the coast, the inhabitants of these areas are forced to move to higher ground either inland or higher elevations.

The minimum and maximum water levels of Van Lake ranged from 1,646.49 to 1,650.47 m, with an average 1,648.33 m at sea level (EİE, 2007). In the long term, it is understood that lake surface area and volume vary between 3,547.7 and 3,621.0 km^2 (3,581.6 km^2 on average) and 561.6 to 575.8 km^3 (568.2 km^3 on average) at minimum and maximum water levels, respectively (Aydin & Karakuş, 2016).

In accordance with the mass balance equation, the water budget components of Van Lake comprise precipitation, surface runoff, and groundwater discharge as inflows, and evaporation loss as an flow (Aydin & Karakuş, 2016).

2.1. Data sources and methods

The present study employed the method with a view to achieving the objectives and accomplishing the goals of the study, and to determine the surface area of the water of Van Lake. The water surface area of Van Lake was determined by means of the NDWI and Landsat 8 Enhanced Thematic Mapper (ETM+) images. Subsequently, an examination was conducted of the relationship between the precipitation and temperature data obtained from the meteorological observation stations within the basin and the change in eye surface area. Furthermore, an evaluation was made of the effect of meteorological data on the water surface area.

2.1.1. Normalised difference water index (NDWI)

NDWI was first proposed by McFeeters in 1996 for the detection of surface water in wetland environments and measurement of surface water extent (McFeeters, 1996). Notwithstanding the fact that the index was created for use with Landsat Multispectral Scanner (MSS) image data, it has been employed with success in conjunction with other sensor systems in applications where measurement of the extent of open water is required (McFeeters, 2013). The NDWI is derived using the following equation:

$$NDWI = \frac{(Band3 - Band5)}{(Band3 + Band5)} \quad (1)$$

where Band 3 is the top-of-atmosphere (TOA) green light reflection and Band 5 is the TOA near-infrared (NIR) reflection. McFeeters (McFeeters, 1996) proposed that NDWI values greater than zero are indicative of water surfaces, while values less than or equal to zero are assumed to be non-water surfaces. The process was executed utilising the raster calculator tool within the QGIS 3.40.1 open source programme.

2.1.2. Landsat 8

Landsat 8 is a satellite mission that was launched on 11 February 2013 by the United States' space agency National Aeronautics and Space Administration (NASA) and the United States Geological Survey Geological Survey (USGS). It is part of the Landsat series of satellites and is used to image the land surface on Earth with high resolution. This satellite provides critical data for a range of applications, including the monitoring of changes on the planet's surface, agriculture, forestry, water management, urban growth, environmental change and disaster management. Landsat 8 monitors an area 185 km wide and offers a resolution of 15 m, allowing detailed analysis of land use from satellite images. Landsat 8 collects data in 11 different spectral bands (including visible light, infrared, and thermal bands). This capacity enables users to analyse diverse environmental features (e.g. vegetation, water resources, soil moisture) with greater precision. Landsat 8's monitoring frequency is 16 days apart for each region, ensuring the provision of updated data at regular intervals. The data from Landsat 8 is utilised by scientists, researchers, governments and the private sector in numerous domains, including environmental monitoring, disaster management and agricultural monitoring. The data is predominantly made available at no cost and is supportive of open-sourcing initiatives (U.S. Geological Survey, 2025).

2.1.3. HydroWeb project

The HydroWeb project provides a time series of water levels from Van Lake, representing a platform developed by Laboratoire d'Etudes en Géphysique et Océanographie Spatiales (LEGOS). This open source system collects and shares data on the ocean, sea level and ocean currents with users, facilitating enhanced understanding of ocean dynamics through online observation and sea level data. The HydroWeb project utilises satellite data and diverse observation tools to monitor sea level changes, ocean temperatures and sea currents, facilitating the regular monitoring of variations in lake water levels. This time series has been derived from multialtimetry satellites (i.e., TOPEX/Poseidon, ENVISAT, Jason-2 and Jason-3, SARAL, Sentinel-3A, and Sentinel-6A) and has been processed, validated and distributed by the HydroWeb portal, which is part of the THEIA pole of earth observations (Sylvestre et al., 2024).

2.2. Calculation of NDWI

Landsat 8 satellite images were obtained from the USGS. Satellite images from August, the month with the lowest precipitation and the highest temperature, were selected for analysis. To mitigate the impact of cloudiness on satellite images, those with cloudiness below 10% were filtered. Then, the satellite images were cropped within the boundaries of the study basin and the NDWI was calculated using the equation (1) outlined above. Subsequently, the image classified between (-1, 1) was reclassified in the range of (0, 1), and the classification was completed in such a way that non-water places were not taken into account. The determined water surfaces were calculated separately for each year, and the water surface change was determined.

3. Results and discussion

In order to detect surface area changes of the Van Lake in period 2016-2020, the water surface of lake in temporal image was extracted NDWI. Water bodies enhanced by the NDWI in the study area are shown in Fig 4. NDWI has been demonstrated to be an effective method of distinguishing between water bodies, with the suppression of background objects being a notable feature. The alteration in surface areas of water bodies was calculated and is presented in Fig. 4.

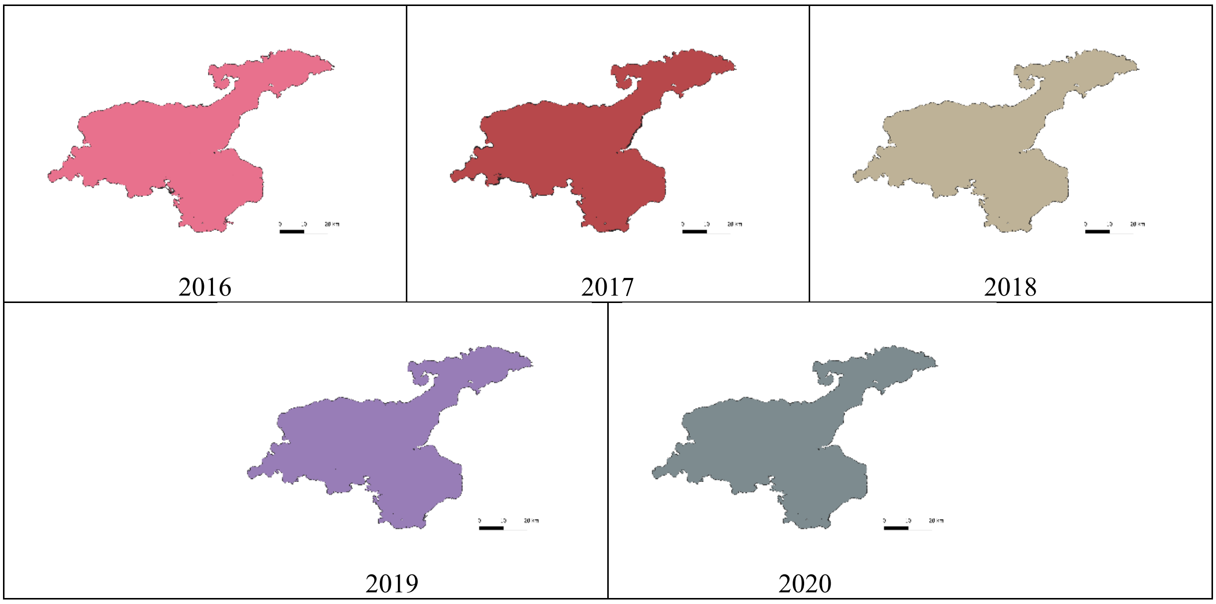

Fig. 4. Spatial change in Van Lake by NDWI method according to years

According to the NDWI findings, the water surface in the lake covered an area of 3,594.39 km^2, 3,593.89 km^2, 3,592.24 km^2, 3,591.98 km^2, and 3,591.65 km^2 in 2016, 2017, 2018, 2019, and 2020, respectively. It was determined that the surface area of the lake tended to decrease over time. Alterations in water surfaces in closed basin lakes, such as Van Lake, are entirely attributable to meteorological effects. Consequently, this variation in the water surface was elucidated by means of average precipitation and temperature data procured from meteorological data for the same period. For this purpose, meteorological data for the period in question are presented in Table 2. In order to make definitive comments on the effects of precipitation data on the basin, the previous month's precipitation heights and annual total precipitation heights were taken into account, taking into account the lag times. During the winter months, snow on the ground surface allows water to be stored. When snowmelt occurs in the summer months due to rising temperatures, this water enters the basin, thereby creating a significant water source. Accumulated waters can serve as a source for the lake during periods of rising temperatures. The data concerning the surface area of the lake and the associated meteorological information delineated in Table 2 encompass the values pertinent to the temporal segments of the investigation conducted within the study region.

Precipitation was selected for further analysis based on a comparison of data sets focusing on precipitation that falls within the lake basin and has the potential to rapidly impact the lake area. When significance could not be determined from these data, temperature data were used. However, if significance could not be determined despite the application of temperature data, lake surface area changes were examined using the annual average snowfall height.

Table 2. Statistical meteorological values between 2016-2020

Date	Surface Area (km^2)	Prec_Aug. (mm)	Prec_July (mm)	Prec_Ann. (mm)	Temp_Aug. (°C)	Temp_Ann. (°C)	Snow._Ann. (mm)
Aug. 2016	3,594.39	3.00	3.37	47.98	23.05	9.60	8.08
Aug. 2017	3,593.89	3.50	1.35	37.87	23.37	9.81	5.20
Aug. 2018	3,592.24	0.47	1.07	44.05	23.17	11.49	2.35
Aug. 2019	3,591.98	3.15	0.60	36.54	22.95	10.30	2.60
Aug. 2020	3,591.65	10.87	15.52	35.92	21.12	10.20	13.88

* Prec., Aug., Snow., Temp., and Ann. represents precipitation, August, snowfall, temperature, and annual, respectively.

In 2017, the surface area of the lake decreased by approximately 0.5 km² compared to 2016. A relative increase in precipitation data was observed in August compared to 2016, while data for July showed a decrease and annual average precipitation levels decreased. While temperature data for August increased compared to 2016, there was also an increase in annual average temperatures. The observed decrease in the lake surface area is believed to be a consequence of the annual average temperature increase, the low precipitation levels recorded in July, and the absence of snowfall during the winter months.

In 2018, the surface area of the lake decreased by approximately 1.5 km² compared to 2017. A significant decrease in August precipitation data was observed compared to 2017, as well as a decrease in July data and an increase in annual average precipitation levels. While the temperature data for August decreased compared to 2017, there was also an increase in annual average temperatures. The observed decrease in the lake surface area is believed to be a consequence of the annual average temperature increase, the low precipitation levels recorded in July and August, and the lack of snowfall during the winter months.

In 2019, the surface area of the lake decreased by approximately 0.3 km² compared to 2018. An increase in August precipitation data was observed compared to 2018, while July data exhibited a decrease and annual average precipitation heights showed a decline. While August temperature data decreased compared to 2018, a decrease in annual average temperatures was also noted. It was determined that there was a relative increase in annual average snowfall heights. Concurrent with the decline in average annual precipitation, a decrease in the surface area of the lake has been documented. While a decrease in temperature and increased snowfall during the winter months have been recorded, these factors, in conjunction with the decline in precipitation, have contributed to the observed decrease in lake surface area.

In 2020, the surface area of the lake decreased by approximately 0.3 km² compared to 2019. An increase in August precipitation data was observed compared to 2019, as well as an increase in July data. No significant change was detected in annual average precipitation heights. While the temperature data for August decreased compared to 2019, a relative decrease in annual average temperatures was also noted. An increase in annual average snowfall heights was determined. Notwithstanding the rise in average annual precipitation, the decline in temperature values, and the heightened snowfall in winter, a decrease in the lake surface area has been documented. The decrease in lake surface area observed in 2020 cannot be attributed to meteorological factors alone. Following a thorough examination, it was ascertained that the meteorological data did not result in a reduction of the lake surface area. It is hypothesized that the lake surface area may have diminished as a consequence of basin activities.

Lake surface altimetry data obtained from HydroWeb was utilized to ascertain the consistency of the alterations detected in the lake surface area. The lake surface area and altimetry data are presented comparatively in Table 3.

Table 3. Lake surface area and altimetry

Date	Surface area (km^2)	Altimetry* (m)
Aug. 2016	3,594.39	1,647.63
Aug. 2017	3,593.89	1,647.61
Aug. 2018	3,592.24	1,647.41
Aug. 2019	3,591.98	1,647.34
Aug. 2020	3,591.65	1,647.32

*Altimetry data retrieved from HydroWeb

As illustrated by the altimeter data presented in Table 3, it has been determined that the water surface elevation of Van Lake exhibited a continuous decrease between 2016 and 2020. Concurrently, a parallel change was observed in the lake area. During the period of maximum water surface level change, which corresponded to an approximate change of 0.2 m, a decrease of approximately 1.5 km^2 in lake area was observed. It was determined that the change factors were also the water level, and it was established that the changes occurring in the lake area are also visible at the lake level. Despite the absence of a direct correlation between fluctuations in water level and changes in lake area, the direction of change exhibits a high degree of similarity. It has been observed that minor alterations in water level can result in substantial changes in lake area.

4. Conclusion

In view of the adverse effects of global climate change on water resources, it is essential to monitor all water resources, including those with large and small flow rates. Monitoring and modelling of water resources with remote sensing methods has been a widely utilised approach since time immemorial. A comparison of Landsat satellite images with meteorological data provides a significant foundation for the evaluation of the impact of climate data on water resources. The employment of open-source data and software in water resources management has led to a progressive reduction in research costs. It has been ascertained that the surface area and water level of Van Lake underwent a gradual decline between 2016 and 2020. The hydrology of the Van Lake basin, being closed and dependent on precipitation, has been found to be a key factor in this change. The analysis of annual temperature and precipitation data, as well as snowfall heights, has revealed that these factors significantly influence the change in lake surface area. However, it has been determined that not all of the observed changes can be attributed to meteorological data, with some cases being too complex to be fully explained by meteorological factors alone. In light of these findings, it is recommended that human factors be taken into consideration in future studies, as they have been delineated as a potentially significant influence on the dynamics of Van Lake. Consequently, a study should be conducted to examine the relationship between decreasing lake area and water levels, and changes in land use.

Experimental study on restoration of sandbar using traditional Japanese river works *“Hijiri-ushi”*

Reita Hayashimoto[1], Yasunori Muto*[1], Kazunari Takano[1], Takao Tamura[1]

[1] *Yachiyo Engineering Co., Ltd., CS Tower, 5-20-8 Asakusabashi, Taito-ku, Tokyo, Japan 111-8648, Japan*

Abstract. In recent years, the amount of sediment flowing down river channels in Japan has been decreasing due to the construction of dams and the progress of landslide control. This causes both flood control and environmental problems due to fixation of river channel topography, dugging waterway deeper and narrower, and increasing the sandbar height with possible vegetation intrusion. This study utilizes a traditional Japanese river works, a permeable groyne “*Hijiri-ushi*”, as one of the possible measures to solve the fixed topography of sandbars. As a first step in seeking the best condition for the placement of groynes that cause the destruction of fixed sandbar topography and the activation of sediment transport, the flow patterns in the downstream of the groynes were investigated. The number of groynes in one row, the angle of each groyne, and the row angle were varied, and the velocity distributions in the downstream were measured in detail. As a result of the experiments, a condition for the arrangement of the groynes which newly forms a high-speed region as well as induces meandering of the flow was found. The former expects to promote the destruction of sandbars, and the latter dose to introduce a new meandering mode onto the original sandbar formation. We are further continuing to study the conditions which strengthen the new meander mode by using multiple rows of groynes. In addition, movable bed experiments under the best condition of the placement of groynes derived from the fixed bed experiments are planned.

Keywords: Sandbar; Restoration; Experiment; Traditional Japanese river works; Meander flow

1. Interoduction

In recent years, the reduction in sediment supply due to dam construction and other factors has become a significant issue in Japan. As a result, the degradation of low-flow channels and the development of sandbar height have progressed, leading to the polarization of river channels, the fixation of sandbar topography, and deep riverbed erosion under prolonged low-flow conditions. These changes have contributed to the deterioration of river environments (Tsujimoto, 1999).

In the Kizu River, part of the Yodo River system, the fixation of sandbar topography has become particularly pronounced in the downstream reaches. This fixation induces eccentric flow, increasing the risk of levee failure. Additionally, the natural dynamics of the river, such as disturbances and flow variations, have been lost. To address these issues, river improvement projects utilizing “*Hijiri-ushi*” a traditional river engineering technique—are being carried out under the leadership of the MLIT of Japan, Kinki Regional Development Bureau, Yodogawa River Office. Specifically, experimental studies are being conducted to install “*Hijiri-ushi*” on fixed sandbars to promote erosion and deposition processes, thereby inducing riverbed variations (Takemon, 2021).

This study focuses not on the primary functions of “*Hijiri-ushi*”, such as flow velocity reduction and flow direction control, but rather on its effectiveness in managing sediment dynamics around the structure. The objective is to clarify the installation conditions of “*Hijiri-ushi*” that can promote sediment transport in fixed sandbar topographies.

2. Study on flow velocity measurement by changing the arrangement conditions of “*Hijiri-ushi*” under fixed bed conditions

2.1 Experimental method

Layout of the experimental channel is shown in Figure 1. The experimental channel was 15.5 m long and 0.65 m wide, with a channel slope of 1/200 and a rectangular cross-sectional shape. To ensure uniform flow conditions, a

*Corresponding author, Professor, E-mail: muto_yas@ce.tokushima-u.ac.jp

https://doi.org/10.31462/icearc2025_ce_hyd_244

weir was installed at the downstream end of the channel, while an aluminum flow straightener was placed at the upstream end to suppress turbulence and vortex formation.

A steady flow with a discharge of $Q = 35$ l/s was introduced into the channel. The water depth (h) was adjusted to 5 cm at the groyne installation section by controlling the downstream weir, and the experiment was conducted under overflow conditions. For velocity measurements, a three-axis electromagnetic current meter (ACM3-RS manufactured by JFE Advantech Co., Ltd.) was used. The groyne model used in the experiment had a length of 7 cm, a height of 4 cm, and a width of 4.7 cm, representing a 1/120 scale model (Tominaga A et al, 2005). Table 1 summarizes the hydraulic conditions.

Velocity measurements were conducted in the horizontal plane (x-y plane), with the upstream end of the groyne group (x = 0 cm) and the right bank (y = 0 cm) used as reference points. The measurement cross-sections in the flow direction for groyne group were taken at x = -40 cm and the downstream end of the groyne group at 4 cm intervals up to x = 36 cm, and then at 8 cm intervals up to x = 60 cm, covering a total of 15 sections. This is summarized in Figure 2. Additionally, measurements in the cross-sectional direction were conducted at 12 sections, with a 5 cm pitch. The measurement depth was set at half the water depth (2.5 cm), and velocity data were recorded at a sampling frequency of 10 Hz for one minute, with the average velocity used for analysis.

2.2 Results and Discussion

2.2.1. An experiment with a row arrangement

To enhance sediment transport in stabilized sandbar topography, a certain range of high flow velocities are required to promote surface erosion of the sandbar. Additionally, meandering flow plays a crucial role in generating localized cycles of erosion and deposition, leading to morphological changes in the sandbar. Therefore, it is essential to establish extensive high-velocity zones in the wake region of the groyne system while also inducing distinct meandering flows.

First, summarize the experimental cases of the groyne arranged in a row in Table 2. With the installation angle of each groyne fixed at α =45°, the installation interval b and group angle θ are varied, and the contour of the downstream velocity u for the cases (Case 2, 6, and 7) is shown in Figure 2.

In order to define "high–velocity region" the approach flow's mean velocity was used as a reference then. The proportion of measurement points within the wake region that exhibit higher flow than the reference flow was determined, as shown in Figure 3. Here, the wake region was defined as the area downstream of the groyne system's terminal point in the streamwise direction and extending laterally to the outermost groyne on the left bank.

A comparison across Case 1 to 7 revealed that Case 7 exhibited the most extensive high-velocity zone. This is thought to be because the installation angle θ and the installation spacing b of the groyne group are large, resulting in a larger permeable cross-section of the groyne group, which reduces resistance to the flow and suppresses the flow velocity reduction effect. Consequently, case 7 is expected to have a significant potential for improving stabilized sandbar topography.

Next, the contour of the transverse velocity v is shown in Figure 4. Regarding the transverse velocity, in Case 2 and Case 7, a strong flow toward the left bank was observed near the groyne installation, followed by a strong flow toward the right bank near the opposite side of the river. This indicates that a distinct meandering flow was formed in both cases. Furthermore, according to the velocity measurement results of a single groyne in the study by Hayshiamoto (2023), it was confirmed that when the groyne head was tilted at an angle of 45°, the water deflection effect, which induces flow deviation, was maximized. Based on this finding, the installation angle α of each groyne in this study was set to 45°. As a result, this water deflection effect became prominent, contributing to the formation of the meandering flow.

Based on the above results, it was clarified that in order to enhance sediment transport in a stabilized sandbar topography, it is essential to form a wide high-velocity region in the downstream area of the groyne and to establish distinct meandering flow conditions, as observed in Case 7.

Table 2. Summary of the experimental cases of the groynes arranged in a row

No	Case	Number of Installed Groynes n	Installetion Interval of Groynes b (cm)	Installation Angle of Groyne Groups Θ	Installation Angle of Each Groyne α
1	SN-30-0	5	1	30°	0°
2	SN-30-45	5	1	30°	45°
3	SW-15-0	5	4	15°	0°
4	SW-15-45	5	4	15°	45°
5	SW-30-0	5	4	30°	0°
6	SW-30-45	5	4	30°	45°
7	SW-5-45	5	4	45°	45°

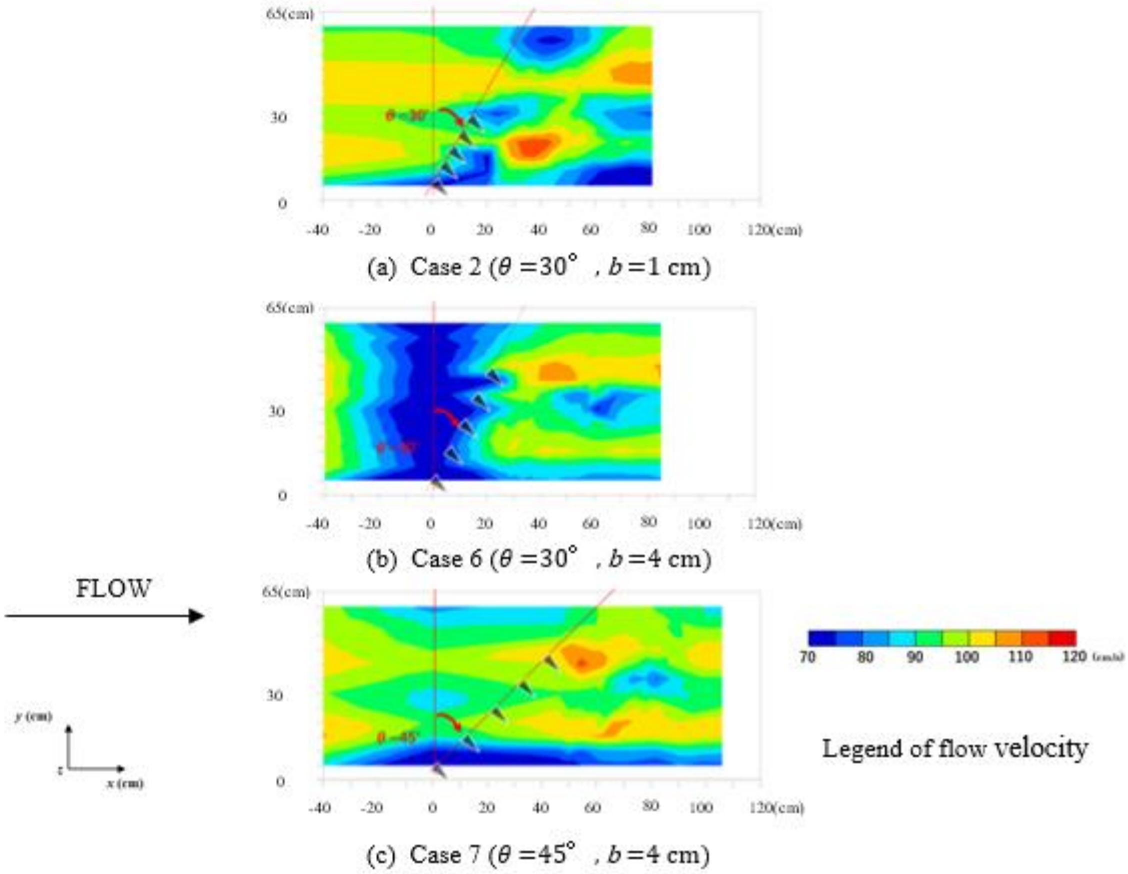

Fig 2. Contour plot of flow velocity u in the downstream direction

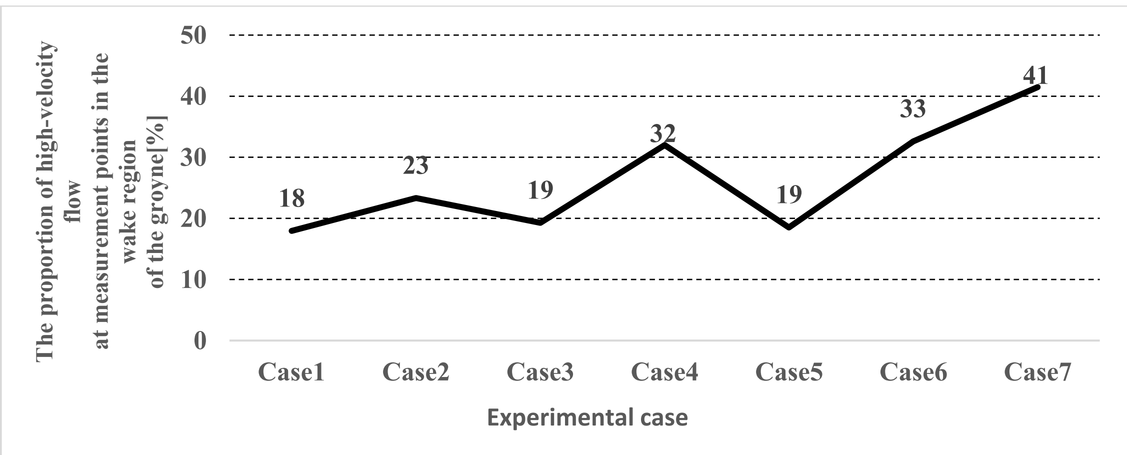

Fig 3. Percentage of high-speed flow region at the downstream in each case

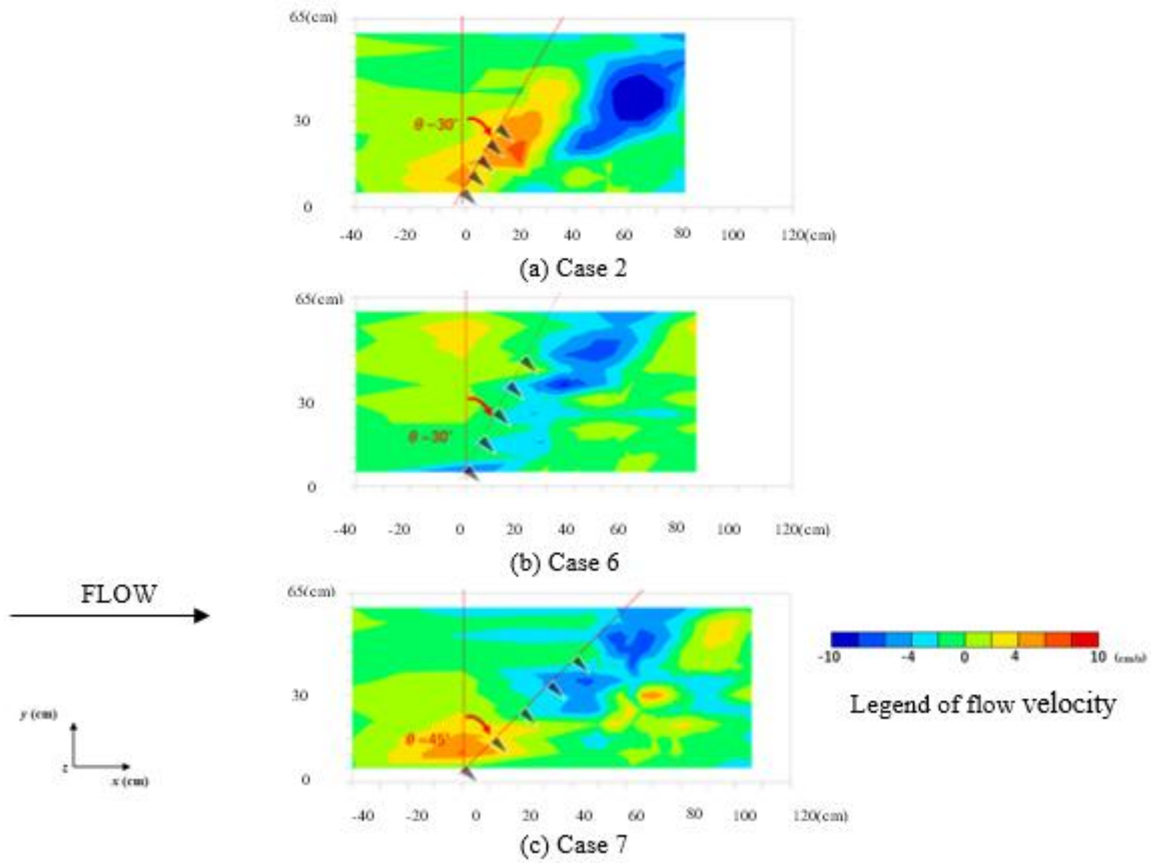

Fig 4. The contour of the transverse flow velocity v for each experimental case

2.2.2. An experiment with a three-row arrangement

Furthermore, analysis of the transverse velocity v in case 7 revealed that the leftward flow generated near the groyne installation site was also observed at x =80cm. This suggests that the distance from x = 0 to 80 cm can correspond to one wavelength of the meandering flow. Based on this wavelength λ =80 cm, five experimental cases (cases8-12)were conducted with distance between groynes groups l set at 40, 80, 90, 100, and 120cm, respectively. The experimental cases conducted are shown in Table 3. The experimental cases conducted are shown in Table 3, with the contours of transverse velocity v for these cases shown in Figure 5.

To determine the optimal configuration for reinforcing periodic meandering flow within the influenced zone by the groynes. Correlation coefficients using phase-aligned velocity data were calculated among the three wake regions. The averaged correlation coefficients across different cases are shown in Table 4.

As shown in Table 4, the highest correlation coefficient was observed in case11, where the groyne groups were spaced at l=100 cm, corresponding to 1.25 times the meandering wavelength of 80 cm identified in case 7. In cases 8-10, where group distance l was 90 cm or less, the correlation coefficient tended to decrease as the distance decreased. Conversely, in cases 11 and 12, where the spacing was 100 cm or more, sufficient distance was maintained to allow for stable formation of periodic meandering flows. These results indicate that there exists an optimal group distance for forming periodic meandering flow, with a minimum required spacing of at least 100 cm.

Table 4. Correlation coefficient of each experimental case

Case	First group and Second group	First group and Second group	First group and Second group	Average
8	0.74	0.31	0.31	0.45
9	0.66	0.50	0.64	0.6
10	0.68	0.43	0.73	0.61
11	0.80	0.73	0.91	0.81
12	0.70	0.68	0.87	0.75

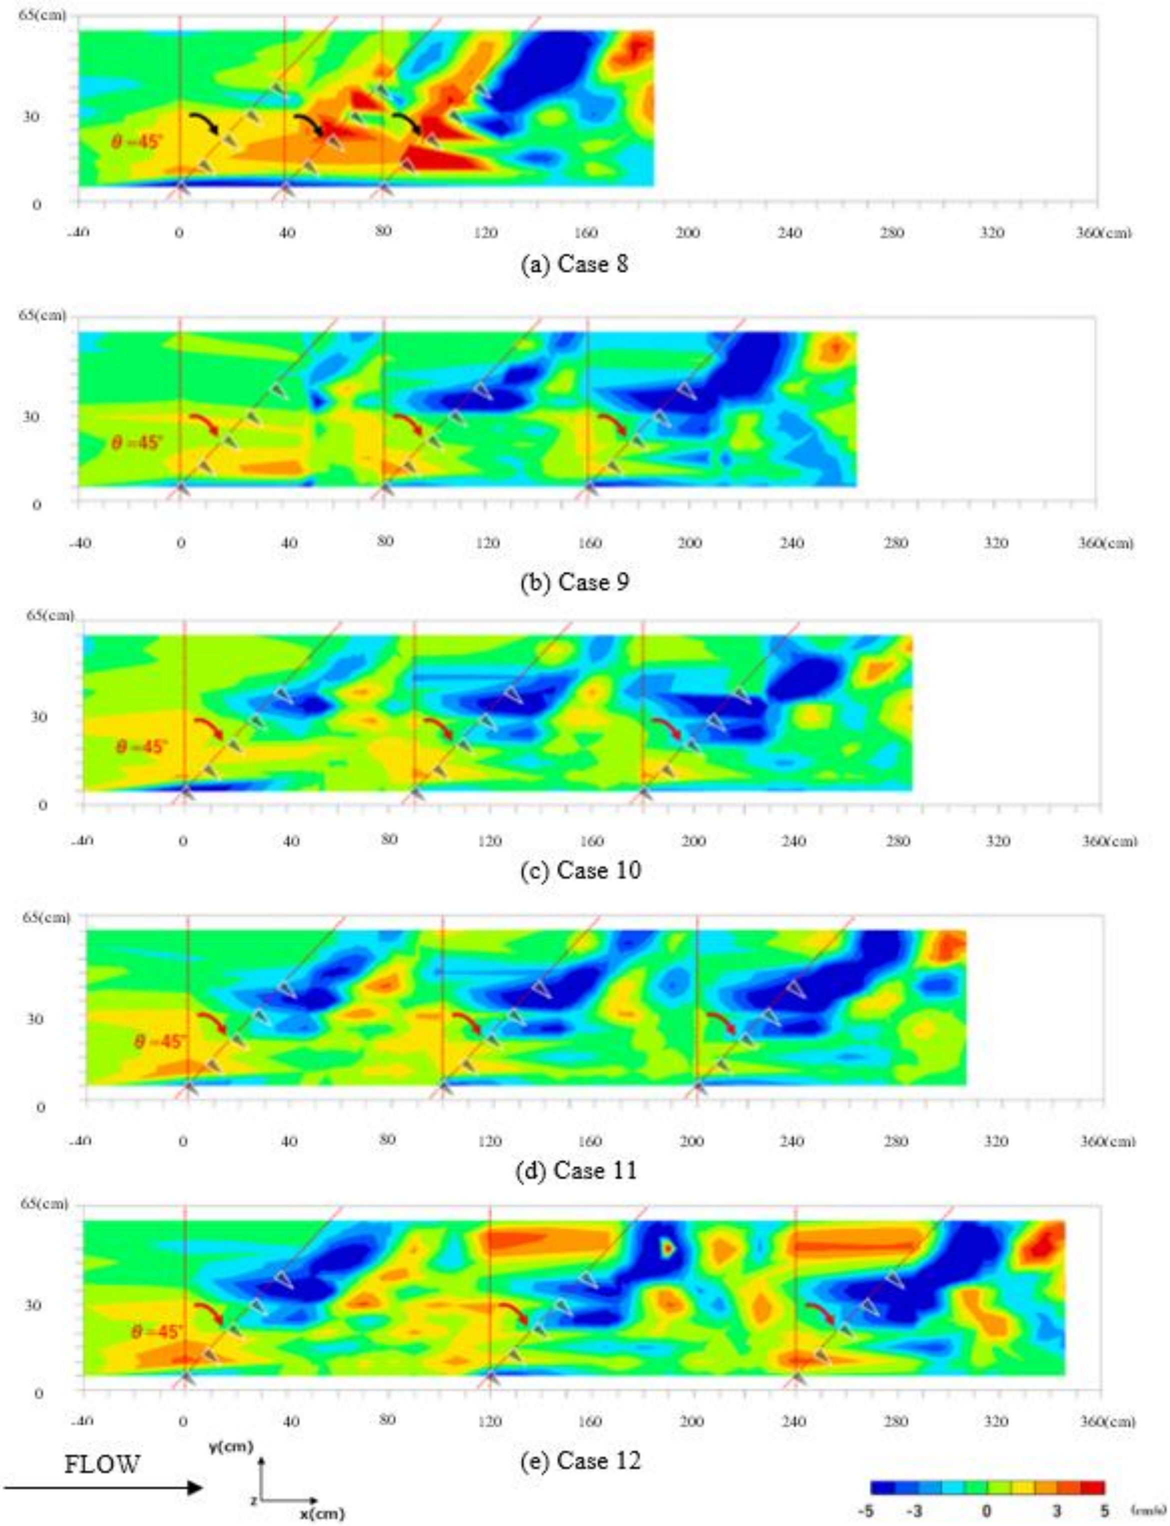

Fig 5. The contour of the transverse flow velocity v for each experimental

3. Bed variation caused by "*Hijiri-ushi*" installation

3.1 Experimental Method

Based on the results of chapter 2, in which attention was given to the widespread high-velocity flow and the periodic meandering flow within the groyne area, it was determined that the optimal arrangement condition is Case

11, with θ = 45° and α = 45°. The arrangement of these groynes was applied to mobile bed experiments to examine whether the high-velocity flow and meandering flow wavelengths observed in fixed bed experiments were reproduced under conditions with bed deformation.

In this experiment, the mobile bed section was set from the upstream end of the flume to 11.5m towards the downstream direction. Silica sand No. 3, with an average grain diameter of 0.9 mm, was spread evenly to a thickness of 10 cm, forming a flat riverbed as amn initial condition. The experiment was conducted with a discharge of 11.7 *l*/s, and observations continued until the riverbed reached an equilibrium state. In the preliminary experiment, a discharge of 11.7 *l*/s was supplied for 5 hours under conditions without groynes to form alternate bars. This discharge is approximately 5.5 times the dimensionless critical shear stress calculated based on the dimensionless shear stress and the Iwagaki equation (Japan Society of Civil Engineers [JSCE], 1999). After the formation of alternate bars, a series of groynes was installed, and the water discharge was continued for an additional hour. Subsequently, a comparative analysis of the riverbed topography before and after groyne installation was conducted to investigate the sediment transport characteristics in the vicinity of the groynes. The hydraulic conditions of this experiment are presented in Table 5.

Table 5. The hydraulic conditions

Discharge Q [l/s]	Water Depth h [cm]	Froude Number Fr	Reynolds Number Re	Friction Velocity u_*	Dimensionless Tractive Force τ_*	Dimensionless Critical Tractive Force τ_{*c}	τ_*/τ_{*c}
11.7	5.5	0.448	18113	0.519	0.119	0.037	5.506

3.2 Results and discussion

The bed topography contours before and after the installation of the groynes are shown in Figure 6. First, from the bed contour before groyne setup, a meandering thalweg can be observed in the downstream region beyond x = 300 cm. Additionally, a sandbar has formed in the downstream region around x = 500–700 cm.

Next, after groyne setup, meandering thalweg slightly shifts towards the left bank. This phenomenon suggests that, in addition to the origined meandering flow present before the installation of the groyne group, a new meandering flow pattern with a different wavelength was introduced due to the installation, leading to the development of transverse flow. This resulted in a more complex flow structure, which further promoted local erosion and subsequent bed deformation. This shift could also have been caused by the meandering flow and high-velocity regions observed in the wake of the groyne group during the fixed-bed experiments.

The analysis of bed variations in the vicinity of the groyne group revealed that, particularly between the first set of groynes, a sand ribbon was observed extending in the transverse direction along the flow. This phenomenon suggests that the installation of the groyne group serves to suppress the formation of depositional landforms while mitigating excessive local scouring that would otherwise occur with impermeable groyne.

Additionally, Endo (2023) reported that the installation of permeable groynes, such as "*Hishi-ushi*", resulted in the formation of numerous sandbars with reduced height and wavelength, indicating similar tendencies in riverbed disturbances to those observed in the present study. However, regarding the flow between groyne groups, while distinct meandering was observed in the fixed-bed experiment, no significant bed variations attributable to meandering flows were confirmed in this experiment.

Based on these findings, the groyne arrangement of Case 11 demonstrated to be effective in maintaining riverbed topography, as it facilitated the formation of a wide range of high-velocity flows, which suppressed localized scouring while maintaining an appropriate level of sediment transport. However, due to the limited number of comparative cases, further detailed analysis is required for a more quantitative evaluation.

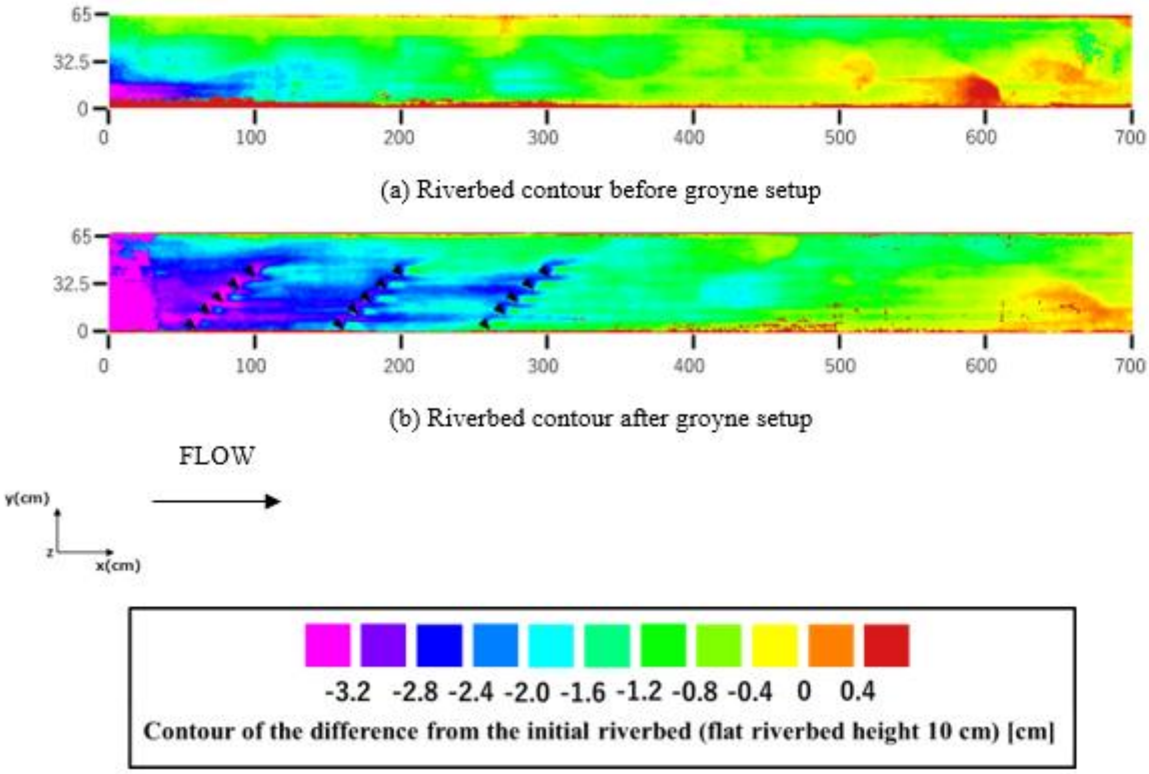

Fig 6. Riverbed contour before and after groyne installatio

4. Conclusions

As a result of this study, the following findings were obtained.

- Even for highly permeable “*Hijiri-ushi*” structures, when the installation intervals are small, the inflow into the groyne field becomes restricted, leading to the occurrence of localized high-velocity flow due to overflow. While this high-velocity flow is effective in suppressing stabilized sandbar topography.
- When a group of “*Hijiri-ushi*” structures is installed in a downstream-facing orientation, flow deflection occurs, causing a meandering current that reflects upon reaching the opposite bank and subsequently returns to the original side.
- In Case 2 and Case 7, the strongest transverse flow was observed in the vicinity of the groynes, followed by the formation of a distinct meandering current in the downstream region. This is due to consistent with the velocity measurement results of an individual “*Hijiri-ushi*” structure, installation angle α of 45°, as the water deflection effect becomes most pronounced under the condition.
- When three consecutive groups of “Hijiri-ushi” structures were installed, an optimal spacing for generating periodic meandering flow was 100 cm, equivalent to 1.25 times the wavelength (80 cm) of the meandering flow observed under the one group.
- The results of a mobile bed experiment revealed that the formation of periodic meandering flow and high-velocity zones induced sand ribbons, particularly between the first set of groynes, with additional scouring observed along the meandering flow in the downstream region. These phenomena suggest the potential for enhanced sediment transport in stabilized sandbar topography.

This study has provided insights into the optimal configuration conditions for utilizing "Hijiri-ushi" structures, a traditional engineering technique, to improve stabilized sandbar topography. However, river discharge and channel morphology are highly diverse, and these factors were not fully considered in this study. Additionally, the investigation of riverbed variations was limited to specific installation conditions, necessitating further examination based on the conditions set in the fixed-bed experiments. These will provide a more accurate representation of real river environments.. Furthermore, combining laboratory experiments with numerical simulations will enable more precise quantitative assessments based on experimental findings. By clarifying physical phenomena that are difficult to reproduce through current numerical analysis and utilizing them to enhance the accuracy of numerical simulations, this approach is expected to contribute valuable insights into actual river channel managements.

Abstract. In recent years, the progress of dam construction projects and landslide prevention projects in Japan have caused changes in the amount of sediment production, outflow, and sediment drift within watersheds, resulting in a decrease in the supply of sediment reaching downstream. This has resulted in a deterioration of flood control safety, especially in the downstream areas, due to the immobilization of sandbars and the overgrowth of trees caused by a decrease in the frequency of flooding of high water beds. In addition, the coarsening of sediment grain size is affecting the river environment. This study investigated the use of "Hijiri-ushi," a permeable groyne, which is a traditional Japanese river training method, as a countermeasure to mitigate the fixation of sandbar topography. The analysis utilized Nays2DHver4, a two-dimensional horizontal reverbed deformation solver available within iRIC, a numerical simulation platform for hydraulic engineering that is freely available in Japan. Since the standard model treated as vegetation lacks functionality to represent the fluid drag characteristics of the Hijiri-ushi, a customized Hijiri-ushi model was developed by modifying and enhancing the source code to incorporate a drag term that can account for the projected area of its complex structural components depending on the depth of the water. The modified model successfully reproduced the intricate flow conditions and localized scour around the groyne, which the standard model could not reproduce. Furthermore, the model validity was confirmed through comparison with riverbed evolution and velocity data obtained from hydraulic flume experiments where the Hijiri-ushi was installed.

Keywords: Sandbar; groyne; riverbed evolution; numerical simulation; Japanese river works

1. Introduction

In recent years, Japan has experienced more frequent and severe floods, such as Typhoon No. 15 and Typhoon No. 19, and the torrential rains in July 2020, and the scale of damage has also been more enormous. In addition, it is predicted that precipitation will continue to increase in the future due to climate change, and there is concern about the occurrence of torrential rains and associated linear precipitation bands in the future.

Under such circumstances, many rivers in Japan have been dammed upstream and landslide prevention countermeasures have also been implemented, resulting in changes in the amount of sediment production within the river basin and a decrease in the sediment supply to the downstream areas. As a result, there is concern about a bipolarization problem in the downstream area as the water channel becomes fixed due to the deepening of the channel, while the sandbar becomes fixed and forested.

In response to these issues, the river channel administrators have carried out hardware improvement measures such as revetment construction and excavation of sandbars to prevent the progression of riverbank erosion; however, the high cost of construction required for improvement, the time required for improvement and maintenance, and the large burden on the river environment have prevented progress in implementing these measures.

To address these problems, this study investigated whether the use of Hijiri-ushi, a traditional Japanese groyne, could promote bed evolution in the river channel and solve the bipolarization problem.

2. Hijiri-ushi, a traditional Japanese groyne

Groyne techniques have developed since 1750, and various types of materials have been used, including stone, wood, and bamboo for gabions, fence outings, random piles, stone outings, kayabutai, and rock crib.

*Corresponding author, E-mail: c612341001@tokushima-u.ac.jp

https://doi.org/10.31462/icearc2025_ce_hyd_271

Fig. 1. Hijiri-ushi maintained on the Kizu River

By 1870, the Kelep groyne system had been introduced from the Netherlands as a flood control technology. By 1930, conventional groyne structures had been improved, and the wide range of materials were used from natural materials to concrete, iron, and polymeric materials. Among them, the Hijiri-ushi, which has existed since ancient times, has a structure made of logs and gabions combined into a triangular pyramid shape, and is classified as a permeable type. In recent years, three units have been installed in Kizu River in Japan, as shown in Fig. 1, and their effects have also been organized in papers (Takemon, 2021; Tazumi et al., 2019). Since the materials used for the Higiri-ushi are of natural origin, they are environmentally friendly and can be produced and maintained by local residents. However, because of the lack of scientific knowledge on the effects of Hijiri-ushi, its function has not been adequately evaluated.

3. Fluid drag model based on the characteristics of Hijiri-ushi

The Hijiri-ushi units are installed in a model river channel for numerical experiments, and the effects of bed evolution are checked by numerical simulations using a planar two-dimensional model. The analysis software used is iRIC, a free software from Japan. The analysis solver was Nays2DHver4 (Shimizu & Nelson, 2007).

The basic concept is based on a fluid drag model for vegetation and pile water control. However, Nays2DHver4 does not have the capability to reflect the fluid drag characteristics of Hijiri-ushi. The only fluid drag characteristic given is the degree of vegetation density.

In the past, there have been cases where analysis was conducted using the Hijiri-ushi as vegetation, but verification of validity remains an issue (Takano et al., 2024). Although it is appropriate to treat the spatial density of vegetation and pile water control by the number of vegetation per area or projected area per volume, in the case of the Hijiri-ushi, the number of installed units is the basic unit, and it is not appropriate to consider them in terms of spatial density; hence, it will be appropriate to treat them by actual projected area. Therefore, the source code of Nays2DHver4 was modified and improved. Specifically, by considering a drag term in the momentum equation that can reflect the projected area of the components of the Hijiri-ushi according to the mesh resolution, the model can represent a different flow structure than the drag term of a single pile group such as vegetation or pile water control.

The continuity equation incorporating the Hijiri-ushi is as follows

$$\frac{\partial h}{\partial t}+\frac{\partial (hu)}{\partial x}+\frac{\partial (hv)}{\partial y}=0 \tag{1}$$

The continuity equation is as follows

$$\frac{\partial (uh)}{\partial t}+\frac{\partial (hu^2)}{\partial x}+\frac{\partial (huv)}{\partial y}=-gh\frac{\partial H}{\partial x}-\frac{\tau_x}{\rho}+D_x-\frac{F_x}{\rho} \tag{2}$$

$$\frac{\partial (vh)}{\partial t}+\frac{\partial (huv)}{\partial x}+\frac{\partial (hv^2)}{\partial y}=-gh\frac{\partial H}{\partial y}-\frac{\tau_y}{\rho}+D_y-\frac{F_y}{\rho} \tag{3}$$

provided that

$$\frac{\tau_x}{\rho}=\frac{gn^2}{h^{\frac{1}{3}}}u\sqrt{u^2+v^2} \tag{4}$$

$$\frac{\tau_y}{\rho} = \frac{gn^2}{h^{\frac{1}{3}}} v\sqrt{u^2 + v^2} \tag{5}$$

$$\frac{F_x}{\rho} = \frac{1}{2} C_D a_s h_v u\sqrt{u^2 + v^2} + \frac{1}{2} C'_D \beta u\sqrt{u^2 + v^2} \tag{6}$$

$$\frac{F_y}{\rho} = \frac{1}{2} C_D a_s h_v v\sqrt{u^2 + v^2} + \frac{1}{2} C'_D \beta v\sqrt{u^2 + v^2} \tag{7}$$

$$a_s = \frac{n_s D_s}{S_s^2} \tag{8}$$

$$\beta = \frac{\Sigma A_s}{DX \cdot DY} \tag{9}$$

where h is Depth of water; t is Time; u, v are Depth-averaged fluid velocity in the x,y directions; g is Acceleration of gravity; H is Water level; τ_x, τ_y are Riverbed shear stress in the x,y directions; n is Manning's Roughness Coefficient; D_x, D_y are Reynolds stress term in the x,y directions; F_x, F_y are Fluid drag per unit area due to vegetation and Hijiri-ushi in the x,y directions; C_D is Drag coefficient of vegetation; a_s is Area of vegetation interception per unit area (density) ; h_v is the effective depth, that is either vegetation height or water depth whichever the smalle; n_s is Number of vegetation; D_s is Average trunk diameter of vegetation; S_s is Sampling grid width; C'_D is Drag coefficient of Hijiri-ushi member; β is Intercepted area of Hijiri-ushi member in calculated mesh area; ΣA_s is Accumulated shielding area by depth of water in the Hijiri-ushi component; DX, DY are Length of calculated mesh in the x,y directions

The second term on the right-hand side of the momentum equation applies the Manning equation with the bottom friction term.

The fourth term on the right side is the drag term due to fluid drag, and in addition to the drag due to vegetation density, the drag term due to Hijiri-ushi was considered.

For β, the projected area was calculated cumulatively with height in order to account for the interception area depending on the water depth.

The fluid drag coefficient C_D shall be 1.0 of the cylinder standard value, which is a common value (Aoki et al., 2009).

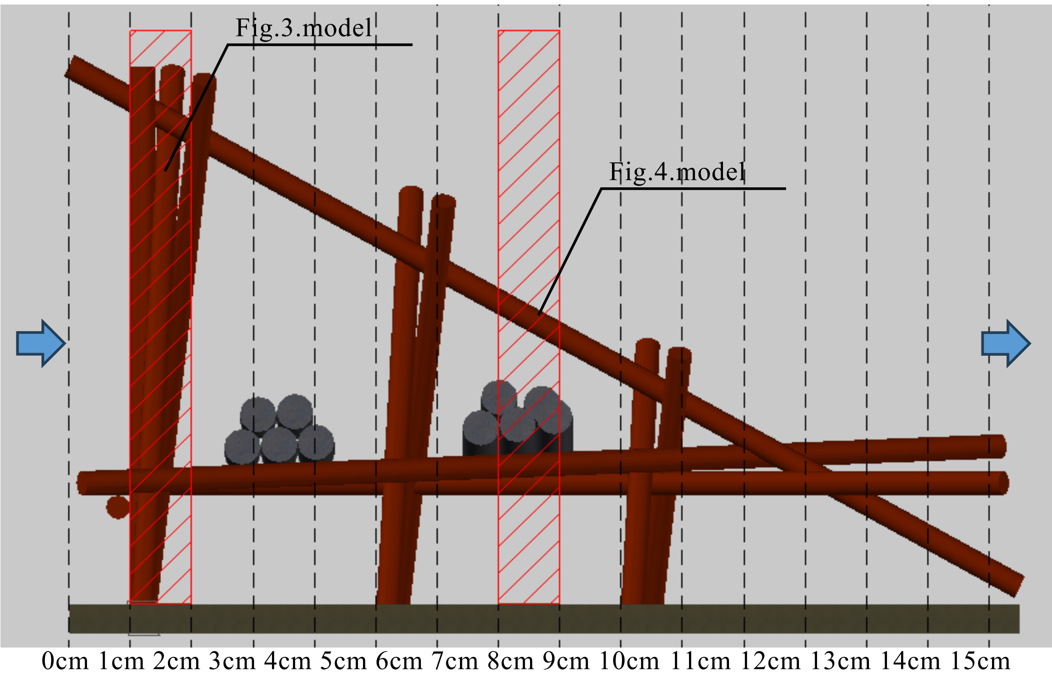

Fig. 2. Lateral model diagram of a Hijiri-ushi and mesh spacing in the flow direction

Fig. 2 shows a side view of Hijiri-ushi, with the upstream side on the left and the downstream side on the right. Because fluid drag varies with the location between structures (0 cm to 15 cm), it was divided at 1 cm intervals, the same as the mesh size for the analysis. Fig. 3 shows a cross-sectional view of Hijiri-ushi projected from upstream to downstream at a point between 1 cm and 2 cm. The area to be blocked is calculated cumulatively from the bottom to the top, so that it can be reflected in ΣA_s in Equation (9). Fig. 4 shows a cross-sectional projection of the area between 1 cm and 2 cm. The area to be blocked is calculated by accumulating the area from the bottom to the top, so that it can be reflected in ΣA_s in Equation (9).

Fig. 5 Model drawing of a Hijiri-ushi

In addition, the model of the Hijiri-ushi is set as an isosceles triangle with a base of 8.0 cm, a height of 5.6 cm, and a length of 15.5 cm in the upstream and downstream directions, as shown in Fig. 5.Table 1 also shows the hydraulic conditions.

4.2 Characteristics of flow field and bed evolution when one Hijiri-ushi unit is installed
Fig. 6 shows the bed evolution after water flow in CASE 1, where one Hijiri-ushi unit is installed on the right bank. Scouring develops on the main channel side behind the Hijiri-ushi, and the scouring area extends downstream on the left bank side. On the other hand, in front and near the gabion, a localized sedimentation pattern tended to be observed. The flow velocity tended to be high behind the Hijiri-ushi and decreased toward the front. At site A, the riverbed degraded by -0.004 m and the flow velocity was 0.24 m/s. At site B, the riverbed rose by 0.009 m and the flow velocity was 0.19 m/s. This is thought to be due to the shielding effect of the forward-placed gabion. The riverbed degraded the most at C, where it degraded by 0.009 m. Figure 7 (caseP) shows the results of an experiment conducted at Kumamoto University, in which a Hijiri-ushi was placed on the contour of the river channel and bed after water flow. Similar to the results of the analysis conducted in this study, it can be seen that scouring is more likely to occur behind the hijiri stones, while sedimentation occurs on the left bank in front of the hijiri stones (Miyake et al., 2024).

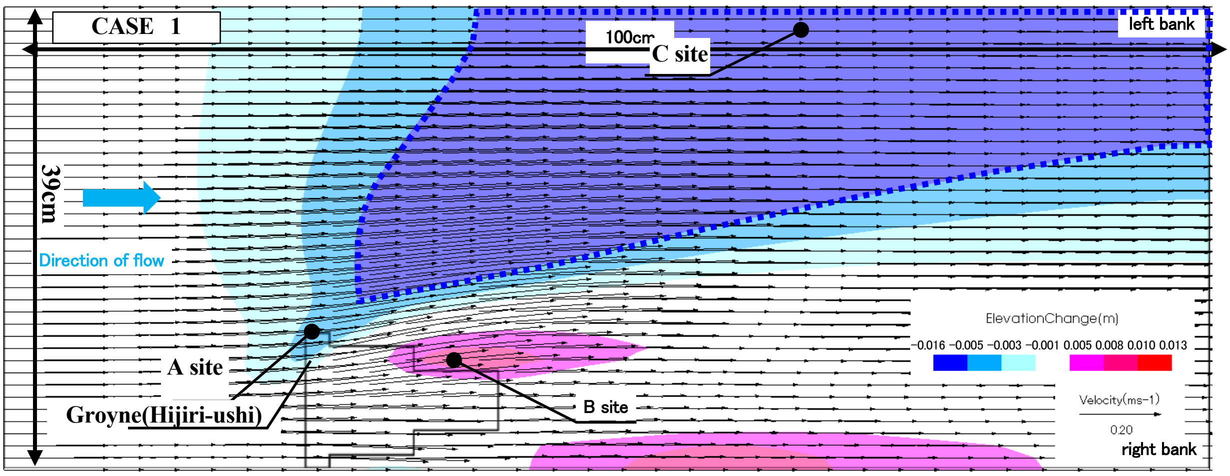

Fig. 6. Fluctuation of the riverbed after water flow with one Hijiri-ushi unit installed

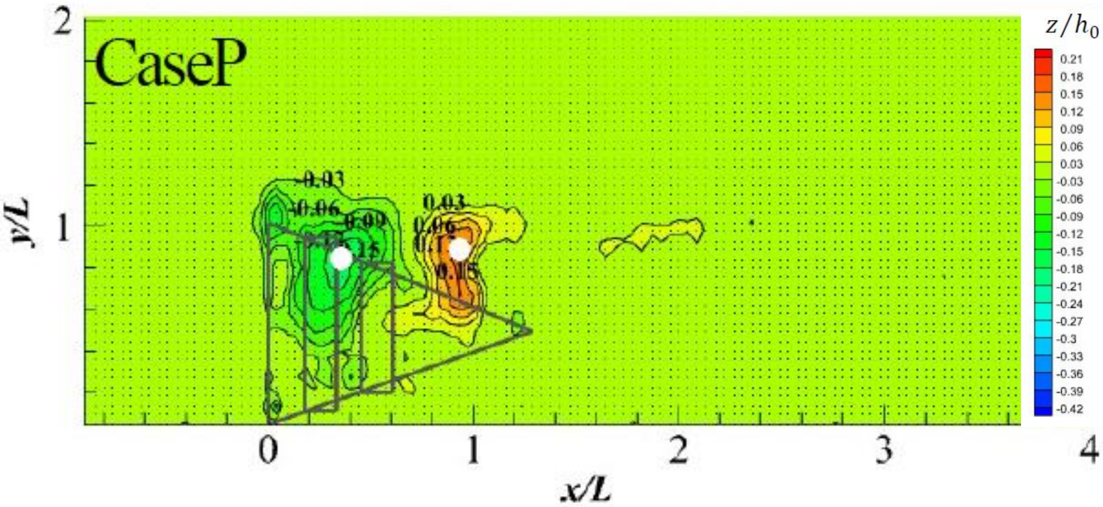

Fig. 7. Map of bed evolution derived from experimental data

4.3 Characteristics of flow field and bed evolution when two Hijiri-ushi units are installed
Following on from Section 4.2, as CASE 2, analyses were performed when multiple units were installed, similar to the installation example in the Kizu River. The second unit is also modeled by the same Hijiri-ushi model as the first unit. Figure 8 shows the reverbed fluctuation after water flow. At site A, the riverbed degraded by -0.006 m and the flow velocity was 0.24m/s, which can be confirmed similarly in the main channel side. On the other hand, at site B, the riverbed rose by 0.002 m and the flow velocity was 0.18 m/s. The riverbed rose the most at site D, with a rise of 0.008 m.

There was no difference in the depth of scour compared to the case with only one unit, but the scoured area below -0.005 m has expanded. The riverbed was degraded the most at Site E, with a degradation of 0.014 m.

4.4 Characteristics of flow field and bed evolution due to changes in fluid drag coefficient
The verification has been conducted with the drag coefficient as 1.0, which is a standard value for cylindrical shapes until now; however, in the past, the validity of the drag coefficient has been studied through experiments and quasi-three-dimensional analysis, concluding that a drag coefficient of 5.0 is appropriate regardless of the extension, spacing, and accuracy of the Hijiri-ushi (Kawaguchi et al., 2002). Therefore, in CASE 3, one Hijiri-ushi unit was installed on the right bank side, and in CASE 4, two Hijiri-ushi units were installed on the right bank side, and the drag coefficient was set to 5.0 for both cases. Other analysis condisions were the same as those of Case 1. The analysis results of CASE 3 are shown in Fig. 9. Compared to Fig. 6, the scoured area extended downstream of the main channel, with the riverbed degradation by -0.009 m and the flow velocity of 0.24 m/s at site A. The riverbed degraded the most at site F, with a degradation of 0.024 m. The riverbed rose at site G, with a rise of 0.016m.

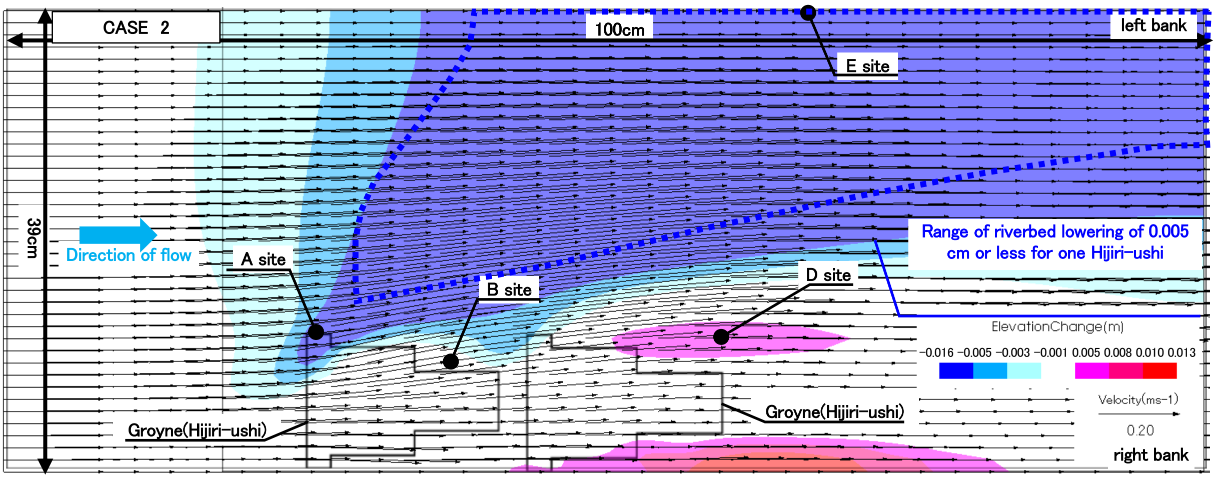

Fig. 8. Fluctuation of the riverbed after water flow with two Hijiri-ushi units installed

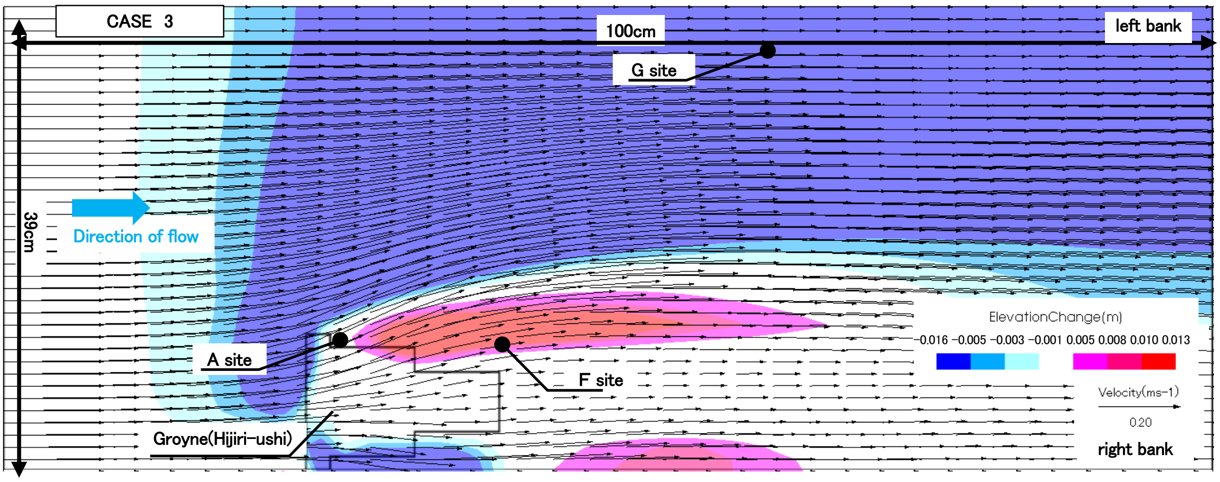

Fig. 9. Fluctuation of the river bed after water flow with one Hijiri-ushi unit installed

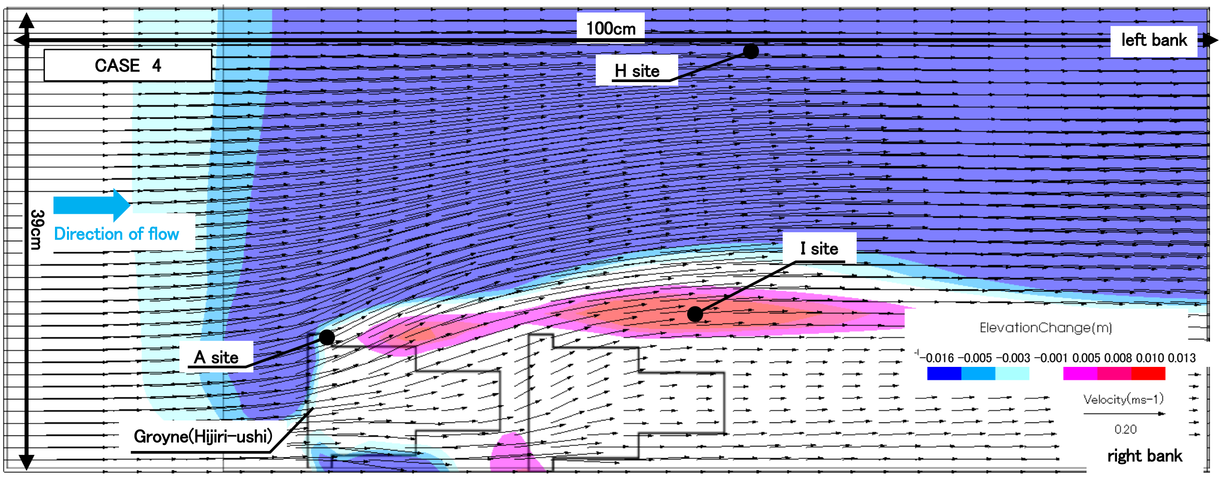

Fig. 10. Fluctuation of the river bed after water flow with two Hijiri-ushi units installed

Table 2. Comparion of the amount of bed evolution and flow velocity for each case

CASE	Riverbed degradation at Site A (m)	Flow Velocity at Site A (m/s)	Maximum riverbed degradation (m)	Maximum riverbed rise (m)
CASE1	0.004	0.240	0.009 (Site C)	0.009 (Site B)
CASE2	0.006	0.240	0.014 (Site E)	0.008 (Site D)
CASE3	0.009	0.240	0.024 (Site F)	0.016 (Site G)
CASE4	0.009	0.240	0.035 (Site H)	0.014 (Site I)

The analysis results for CASE 4 are shown in Fig. 10. Compared to Fig. 8, the scoured area extended downstream of the main channel, with the riverbed degradation by -0.009 m and the flow velocity of 0.24 m/s at site A. The riverbed degraded the most at site H, with a degradation of 0.035 m. The riverbed rose at Site I, with a rise of 0.014 m.

5. Conclusions

By installing the Hijiri-ushi in the water channel, we confirmed the characteristics of bed evolution around the Hijiri-ushi and at places slightly away from it. In addition, in order to confirm the validity of the numerical simulation results, the bed evolution characteristics were compared with those of the experimental results. The results of the numerical simulation showed that the bed evolution around the Hijiri-ushi units was similar to that of the experimental results, with scouring developing in the back and sedimentation promoted in the front. On the other hand, the numerical simulation showed that the effect of the scoured area was more widespread than that of the experimental results. Therefore, it can be concluded that for complex structures such as the Hijiri-ushi, it is more appropriate to adopt a flow structure that reflects the projected area according to the mesh resolution, rather than considering it in terms of spatial density.

Regarding the characteristics of bed evolution depending on the number of Hijiri-ushi units, it was confirmed that although the scoured area changed, there was no significant difference, and it was possible to disturb the riverbed even with one Hijiri-ushi unit. In addition, the installation of the Hijiri-ushi can create a diverse environment because it leads to the creation of a small-scale and tranquil environment in the vicinity of the Hijiri-ushi, by promoting sedimentation in front of the unit.

As for the numerical simulation results with different drag coefficients, it was confirmed that the bed evolution characteristics with a drag coefficient of 1.0 after water flow were more similar compared to those of the experimental results.

In the future, we will confirm the superiority of Hijiri-ushi by verifying characteristics of the flow field and bed evolution when the Hijiri-ushi is installed in a real river model.

Essentials of manifold flow hydraulics-I: Hydraulic (HGL) and energy gradient (EGL) lines

Gürol Yıldırım*[1]

[1] Giresun University, Engineering Faculty, Civil Engineering Dept., 28100, Giresun, Türkiye.

Abstract. Manifold pipelines can be used to distribute and collect fluids and have applications in various engineering fields, especially in the water supply system. Analysis of the hydraulic design of manifold pipelines is very important concern for the proper hydraulic performance of water supply distribution systems. The hydraulic (HGL) and energy (EGL) gradient lines are useful tools to clearly analyse the shape of hydraulic profiles, i.e., pressure head and outflow distributions along the manifold line.

Keywords: Manifolds; Steady-state analysis; Fluid mechanics; Fluid flow; Hydraulic gradient

1. Theoretical background

In this paper an analytical procedure taking into account the nonuniform outflow profile for hydraulic analysis and design of multiple outlets pipelines, is presented. Energy relations are improved based on the average friction drop approach with a simple exponential function, to express the nonuniform outflow concept (Sadeghi et al., 2016; Singh & Mahar, 2003). To determine friction head losses, the Darcy-Weisbach formula is used here; and the kinetic head change is considered whereas minor head losses are neglected. Several mathematical relationships are also derived for computing extreme pressure heads and their locations of occurrence along the pipeline (Sadeghi & Peters, 2011; Singh et al., 2000). The presented method also provides specific lengths of the segments in which the different flow regimes occur along its length.

2. Methodology

2.1. Flow rate and velocity head

The energy-gradient line (EGL) in a manifold line as manifold will not be a straight line but a curve of the exponential type. Fig. 1 sketches a horizontal multi-outlet submain line with a single inlet (single line size system) and shapes of hydraulic (piezometric) (HGL) and energy-gradient (EGL) curves along its length (Yıldırım, 2023a,b; Yıldırım, 2010a,b; Yıldırım & Singh, 2013a,b). Flow in manifold is considered to be steady, spatially varied flow with decreasing discharge along the direction of flow (from upstream inlet to dowmnstream closed end). Flow in a submain line is usually turbulent ($3{,}000<R<10^5$; R: Reynolds number). Sometimes fully turbulent flow ($10^5<R<10^7$) exists at the upstream end, and flow becomes laminar ($R<2{,}000$) at the downstream reach where the flow velocity decreases to zero. The transition flow approximately occurs in the interval $2{,}000<R\leq 3{,}000$, and the flow characteristics are indeterminate for the transition zone (Yıldırım, 2012a,b; Yıldırım, 2014a,b; Yıldırım, 2009).

Typically, the discharge through each outlet is governed by the following relationship:

$$q = kH^x \tag{1}$$

in which q = discharge through the outlet; H = operating pressure head of the outlet; k and x = coefficient and exponent of the outlet discharge, respectively.

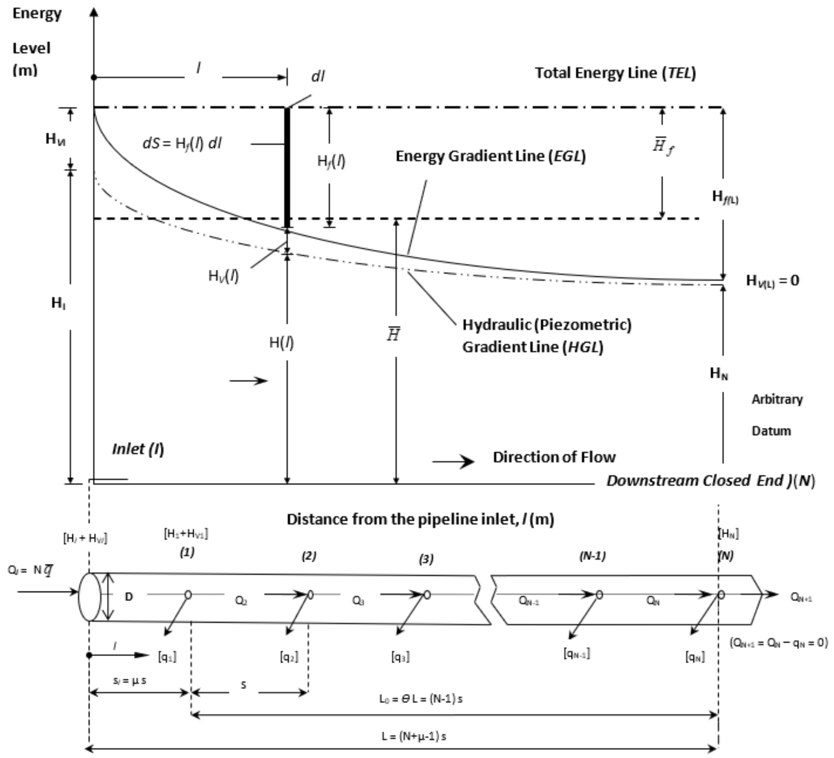

Fig. 1. Shapes of hydraulic (piezometric) gradientl line (HGL), and energy gradient line (EGL) along horizontal submain line with multiple outlets (Yıldırım, 2008)

Assuming that outlets along the pipeline have uniform outflow , then the total flow rate that passes through the pipe section located at any distance l from the pipeline inlet Q(l) is commonly given as (Scaloppi & Allen, 1993)

$$Q(l) = \left(N - \frac{l}{s}\right)\overline{q} = Q_I(1-i) \tag{2}$$

where Q(l) = the discharge at a section of length l measured from the pipeline inlet; $Q_I = N\overline{q}$ = total inflow rate for the entire length of the pipeline; N = total number of equally spaced operating outlets for the entire pipeline; s = outlet spacing; and i = dimensionless variable of distance i = l/L, which is the percentage of the length to the total length.

According to Eq. (2) the average flow velocity also varies linearly along the pipeline and, the velocity head gradient can be written as follows

$$S_V(l) = \frac{2H_{VI}}{L}(i-1) \tag{3}$$

where $S_V(l)$ = velocity head gradient at any distance l; and $H_{VI} = 8(N\overline{q})^2/\pi^2 gD^4$ = velocity head at the inlet of the pipe; and D and L = internal diameter and length of the pipe.

Integrating the gradient of the velocity head given by Eq. (3) between the limits 0 and l and then, the velocity head at any distance l is obtained as

$$H_V(l) = H_{VI}(1-i)^2 \tag{4}$$

where $H_V(l)$ = velocity head for the pipe section located at any distance l.

2.2. Friction head loss

To compute total friction drop at the closed end of the multiple outlets pipeline requires calculating the friction head loss for each pipe segment between consecutive outlets, in a stepwise manner. This procedure is characterized by a stepwise correction factor, FSW computed for finite number of outlets as given by

$$F_{SW} = \frac{1}{N^{m+1}} \sum_{K=1}^{K=N} K^m \tag{5}$$

where K = an integer represents the consecutive order of outlets; and m = velocity (or flow rate) exponent for the particular friction head loss formula used.

For the traditional approach, the friction correction factor takes the form

$$F = \frac{1}{(m+1)} \tag{6}$$

Eq. (6) represents the friction loss correction factor that takes into account the continuous and uniform outflow along the pipeline. This correction factor is essentially equivalent to that proposed by Christiansen (1942), provided the number of outlets is infinity.

The correction factor FC proposed by Christiansen (1942) for the case in which the first outlet is located in a full outlet spacing from the pipeline inlet, is of the form

$$F_C = \frac{1}{(m+1)} + \frac{1}{2N} + \frac{\sqrt{m-1}}{6N^2} \tag{7a}$$

If the first outlet is half outlet spacing from the pipeline inlet, FC is given by (Cuenca 1989)

$$F_C = \frac{2N}{(2N-1)}\left(\frac{1}{m+1} + \frac{\sqrt{m-1}}{6N^2}\right) \tag{7b}$$

Christiansen's (1942) approach given by Eq. (7) is based on uniform and discrete outflow from a finite number of operating outlets. Therefore, significant differences between the two correction factors given by Eq. (6) and Eq. (7) are expected especially, when the number of outlets in the pipeline is small (Scaloppi & Allen, 1993). In order to do a systematic comparison, three correction factors (F_{SW}, F and F_C) are computed for the value of the velocity exponent m = 1.75 (Darcy-Weisbach formula and turbulent flow in a smooth pipe), full outlet spacing from the pipe inlet (s_l = s), and for various number of operating outlets (presented in the logarithmic scale), then the results were plotted in Fig. (2). In this figure, the secondary axis of y (dotted line) represents the percentage differences between three correction factors F_{SW}, F and F_C.

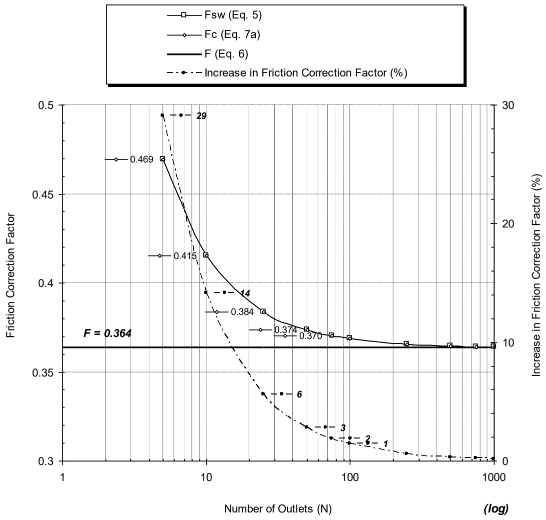

Fig. 2. Variation of the friction correction factors (F, F_{SW} and F_C) and percentage differences between these factors (Dotted Line) for the Darcy-Weisbach formula (m = 1.75) and full outlet spacing from the inlet, with respect to the various number of operating outlets

As shown in Fig. (2), the traditional factor F [Eq. (6)] yields the constant value as 0.3636 that is independent of the number of outlets N. The factor F_C [Eq. (7a)] yields almost the same values with the stepwise correction factor F_{SW} [Eq. (5)] for various number of outlets. The comparison test shows that the Christiansen's factor F_C accurately predicts the friction head loss since F_C is an accurate approximation of the stepwise correction factor F_{SW}. The traditional factor F tended to give underpredicted values systematically with respect to the factors F_C and F_{SW}, particularly, as the number of outlets decreases, the difference from these factors (F_C and F_{SW}) being more significant. For instance, for a large value of N = 100, the difference 1.4%, and for a value of N = 10, the difference 14% whereas for an extreme small value of N = 5, the difference 29%.

The general form of the Darcy-Weisbach formula which proved to be the most accurate and reliable (von Bernuth and Wilson 1989, von Bernuth 1990, Watters and Keller 1978) can be approximated by the following expression:

$$S_f(l) = \frac{dH_f(l)}{dl} = \frac{f}{D} H_V(l) = \frac{C}{D^n} Q^m(l) \tag{8a}$$

$$f = c_1 \left[R_I\right]^{m-2} \tag{8b}$$

$$C = \frac{8c_1(\nu/4)^{2-m}}{g\pi^m} \tag{8c}$$

where $S_f(l)$ = friction slope or the slope of the energy grade line at any distance l from the pipe inlet expressed as the energy loss per unit length of the pipeline, and per unit weight of fluid; $H_f(l)$ = friction head loss per unit weight of fluid at any distance l; f and C = friction coefficient and combined friction coefficient for the Darcy-Weisbach formula assuming to be constant along the pipe; c_1 = constant for the particular friction coefficient formula used; $R_I = (4N\overline{q}/\pi D\nu)$ = Reynolds number at the inlet of the pipe; m and n = velocity and diameter exponents, respectively. Generally n is approximately equal to m+3 (Scaloppi & Allen, 1993); ν = kinematic viscosity of water; and g = acceleration due to gravity.

For laminar flow regime (R < 2,000; R = Reynolds number for pipe flow), m = 1.0, n = 4.0, c_1 = 64 and C = 4.195 10^{-6}; for turbulent flow regime in a smooth pipe (3,000 < R $\leq 10^5$), m = 1.75, n = 4.75, c_1 = 0.316 (Blasius equation) and C = 7.792 10^{-4}, and finally for fully turbulent flow regime (10^5 < R < 10^7), m = 1.828, n = 4.828, c_1 = 0.130 (Watters and Keller 1978) and C = 9.589 10^{-4}, are taken.

Note that, the combined friction coefficient C is appropriate for plastic pipes (PVC or PE). For aluminum pipes, the friction coefficient f is given by the well-known Churchill equation (Churchill 1977)

$$f = 8\left[(8/R)^{12} + 1/(A+B)^{3/2}\right]^{1/12} \tag{9a}$$

where A and B = empirical parameters for computing Darcy-Weisbach friction coefficient. A and B are calculated by

$$A = \left\{2.457 \ln\left[1/\left((7/R)^{0.9} + 0.27(\varepsilon/D)\right)\right]\right\}^{16}\ ;\ B = (37{,}530/R)^{16} \tag{9b}$$

where ε = equivalent roughness height of the internal pipe surface.

Integrating Eq. (8a) with Eq. (2) between the limits 0 and l yields (Wu and Gitlin 1975, Anyoji and Wu 1987)

$$H_f(l) = H_{f(L)}\left[1-(1-i)^{m+1}\right] \tag{10a}$$

$$H_{f(L)} = FH_{f0} = \frac{1}{(m+1)} H_{f0} \tag{10b}$$

$$H_{f0} = f\frac{L}{D}H_{VI} = C\frac{Q_I^{\,m}}{D^n}L \tag{10c}$$

where $H_f(L)$ = total friction drop at the closed end of the pipeline; and H_f0 = total friction drop in a similar pipeline without outlets conveying the total flow rate along its entire length. It should be noted, the second multiplying term in the bracket in the right-hand side of Eq. (10a) can be described as the friction drop ratio, $R_i = H_f(l)/H_{f(L)}$.

An alternate version for the total friction drop $H_f(L)$ may be obtained by replacing in Eq. (10b) the traditional correction factor F by the Christiansen's correction factor F_C given by Eq. (7) (Scaloppi & Allen, 1993)

$$H_{f(L)} = F_C H_{f0} \tag{10d}$$

3. Determination of energy-grade line (EGL): Analytical approach

In the following section, the improved energy-grade line of a multiple outlets pipe is determined based on the average friction drop approach with a simple exponential function, to express the nonuniform outflow concept. In the first stage of the analytical development the preliminary energy relations for the uniform outflow profile will be presented here (Yıldırım & Singh, 2010; Yıldırım, 2008; Yıldırım & Kose, 2016a; Yıldırım, 2015a, Yıldırım, 2016b).

3.1 Uniform outflow

Let H(l) be the pressure head at a given length l from the pipe inlet, H_I be the pressure head at the pipe inlet, and S_0 be the uniform slope of the pipeline [Fig. (1)]. Assuming the average pressure head for the entire pipeline is located in the middle of the length of the pipeline, and applying conservation of energy principle between the pipe segments l = 0 and l = l, then pressure head distribution along the pipeline is expressed by

$$H(l) = H_I + H_{VI}\left[1-(1-i)^2\right] - H_{f(L)}\left[1-(1-i)^{m+1}\right] - pi\Delta S\,;\ \Delta S = S_0 L \tag{11}$$

in which ΔS = total head loss or gain due to elevation at the closed end of the pipeline. Note that in this analysis, the slope of a downhill pipeline is negative (p = -1), and the slope of an uphill pipeline is positive (p = 1).

Let $\overline{H}$ be the average pressure head along the pipeline can be written

$$\overline{H} = H_I - (\overline{H}_f + p\overline{\Delta S})\,;\ \overline{\Delta S} = \frac{\Delta S}{2} \tag{12}$$

in which $\overline{H}_f$ = average head loss due to friction along the pipeline; and $\overline{\Delta S}$ = average head loss or gain due to elevation.

To find out the average head loss due to friction along the pipeline $\overline{H}_f$, a strip of length dl is considered at any length from the pipeline inlet as shown in Fig. (1). Let dS be the area of the strip, then the average head loss due to friction along the pipeline $\overline{H}_f$ is expressed as

$$\overline{H}_f = \frac{1}{L}\int_{l=0}^{l=L} dS = \frac{1}{L}\int_{l=0}^{l=L} H_f(l)dl = \left(\frac{m+1}{m+2}\right)H_{f(L)} \tag{13}$$

Eq. (13) yields for m = 1.75, the average head loss due to friction along the pipeline is about 73% of the total friction drop at the downstream closed end of the pipeline, when the Darcy-Weisbach formula is used.

Substituting the expression for $\overline{H}_f$ from Eq. (13) into Eq. (12) then, subtracting from Eq. (11), finally one can obtain the following expression for the pressure head distribution

$$H(l) = \overline{H} + H_{VI}\left[1-(1-i)^2\right] + H_{f(L)}\left[(1-i)^{m+1} - \frac{1}{(m+2)}\right] - p\Delta S\left(i - \frac{1}{2}\right) \tag{14}$$

3.2. Nonuniform outflow

To this point the preliminary analytical derivations presented above are similar to the referred paper (Anyoji and Wu 1987). In the following analytical derivation, the energy-grade line will be improved for the nonuniform outflow profile.

Instead of the traditional Eq. (2), to describe variation of flow rate along the pipeline Q(l), a simple but sufficiently accurate exponential function (Scaloppi & Allen, 1993; Valiantzas, 1998, 2002; Yıldırım & Kose, 2016a) is given by

$$Q(l) = Q_I(1-i)^{\beta} \tag{15}$$

where β = nonuniform outflow exponent; then the outflow from the each multiple outlet will not be uniform along the pipeline. It should be noted that, a similar form of Eq. (15) was presented in the recent papers (Valiantzas, 1998, 2002) on the basis of the average outlet flow approximation (Eq. 23 of Valiantzas, 2002) $\left\{\overline{q} = (k/Ns)\left[\int_{l_0}^{l_{Q_I}} H^x(l)dl\right] \cong (k/Ns)\left[\int_{l_0}^{l_{Q_I}} H(l)dl\right]^x\right\}$ which directly referred to the paper of Anyoji and Wu (1987).

However, according to the opinion of Wu (personal communication 2002) this approximation used is not possible in the mathematical consideration (the power of function x must be inside of the integration), except for a special case of the value of the emitter discharge exponent, x = 1.0. Further analysis and discussion for this approximation was presented in the recent papers (Yıldırım & Singh, 2013a,b).

If Eq. (15) is evaluated for the upper half segment of the pipeline (i = 0.5), then arranged with the expression for the flow rate entering over the upper half segment of the pipeline, $Q_{0.5} = (kN/2)\overline{H}^x{}_{0.5}$, finally the β can be evaluated from

$$\beta = 1 - 3.322x\log\left(\frac{\overline{H}_{0.5}}{\overline{H}}\right) \tag{16}$$

where $\overline{H}_{0.5}$ = average pressure head along the upper half segment of the pipeline.

Assuming the average pressure head for the upper half segment of the pipeline $\overline{H}_{0.5}$ is located in the middle of the length of the upper half segment of the pipeline, and applying the conservation of energy principle between the pipe segments l = L/4 and l = L, then the $\overline{H}_{0.5}$ can be expressed as

$$\overline{H}_{0.5} = H_N + H_{f(L)} + (p\overline{\Delta S}_{0.5} - \overline{H}_{f0.5})\,; \quad \overline{\Delta S}_{0.5} = \frac{3}{4}\Delta S \tag{17}$$

where H_N = downstream pressure head at the first outlet from the closed end of the pipeline; $\overline{H}_{f0.5}$ = average head loss due to friction along the upper half segment of the pipeline; and $\overline{\Delta S}_{0.5}$ = average head loss or gain due to elevation at the end of the upper-quarter segment of the pipeline.

Downstream closed end pressure head H_N can be obtained for i = 1 using the expression of pressure head distribution given by Eq. (14) as follows

$$H_N = \overline{H} + H_{VI} - \left(\frac{1}{m+2}\right)H_{f(L)} - \frac{p\Delta S}{2} \tag{18}$$

Average head loss due to friction between the pipe segments l = 0 and l = L/2 for the upper half segment of the pipeline $\overline{H}_{f0.5}$ can be expressed as

$$\overline{H}_{f0.5} = \frac{2}{L}\int_{l=0}^{l=L/2} dS = \frac{2}{L}\int_{l=0}^{l=L/2} H_f(l)dl = \left(\frac{m+0.5^{m+1}}{m+2}\right)H_{f(L)} \tag{19}$$

Eq. (19) yields for m = 1.75, the average head loss due to friction along the upper half segment of the pipeline is about 51% of the total friction drop at the downstream closed end of the pipeline, when the Darcy-Weisbach formula is used.

Combining the expression for $\overline{\Delta S}_{0.5}$ from Eq. (17) with Eq. (18) and Eq. (19) into Eq. (17), and dividing by $\overline{H}$ then, substituting into Eq. (16), finally the β can be computed from:

$$\beta = 1 - 3.322x\log\left[1 + \frac{H_{VI}}{\overline{H}} + \lambda\frac{H_{f(L)}}{\overline{H}} + \frac{1}{4\overline{H}}(p\Delta S)\right];\ \lambda = \left(\frac{1-0.5^{m+1}}{m+2}\right) \tag{20}$$

From this point of the analysis, the energy grade line for nonuniform outflow distribution can be determined by the following Eq. (21) instead of Eq. (14), in which the velocity exponent m should be replaced by its improved value as $m_\beta = \beta$ m:

$$H(l) = \overline{H} + H_{VI}\left[1-(1-i)^2\right] + H_{f(L)}\left[(1-i)^{m_\beta+1} - \frac{1}{(m_\beta+2)}\right] - p\Delta S\left(i - \frac{1}{2}\right) \tag{21}$$

3.3. Inlet and extreme pressure heads

Consider a pipeline with all multiple outlets being equally spaced then, the inlet spacing s_I, from the pipeline inlet to the first outlet is expressed as the some fraction, μ ($0 \le \mu \le 1.0$) of the common outlet spacing s, s_I = μs, and it usually taken as 0.5 or 1.0 for multiple outlets pipelines.

Inlet pressure head H_I can be evaluated from Eq. (21) for the value of variable of distance, i = 0. Substituting the expression for i_{max} (i_{max} = μ s/L) into Eq. (21), then the maximum pressure head H_{max} for uphill and zero slope, can be obtained as

$$H_{\max} = \overline{H} + H_{VI}(1-\theta^2) + H_{f(L)}\left[\theta^{m_\beta+1} - \frac{1}{(m_\beta+2)}\right] + p\Delta S\left(\theta - \frac{1}{2}\right) \tag{22}$$

where θ = L_0/L, length ratio which is the percentage of the distance between the first and last outlets to the total length of the pipeline; L_0 = (N-1) s = length of the distance between the first and last outlets except for the inlet spacing, s_I; L = (N+ μ-1) s = total length of the pipeline.

Similarly, the minimum pressure head Hmin for uphill and zero slope cases, is obtained from Eq. (21) for i_{min} = 1.0, which is essentially equivalent to the downstream end pressure head H_N given by Eq. (18).

For downhill slope case, the location of the maximum pressure head is found either to the first outlet near the pipeline inlet (i_{max} = μ s/L) or at the first outlet from the downstream closed end point (i_{min} = 1.0).

The location of the minimum pressure head for downhill line is determined where the first derivative of the pressure head distribution given by Eq. (21) is equal to zero. For simplification of this derivative procedure, the velocity head term can be omitted in Eq. (21), then the location i_{min} where the minimum pressure head occurs, can be approximated by

$$i_{\min} = \frac{l_{\min}}{L} = 1 - \left[\frac{(-p\Delta S)}{(m_\beta + 1)H_{f(L)}}\right]^{1/m_\beta} \quad (23)$$

Substituting Eq. (23) for i_{min} into Eq. (21), then the H_{min} for downhill slope case, can be easily found.

4. Types of pressure head or energy profiles along manifold line with uniform slope

When a submain line with multiple outlets is designed using a single inlet system and laid on a uniform slope (S_0), the pressure head profile along the line resulting from the total energy drop by friction, $h_{f(L)}$ [$h_{f(L)} = S_f \times L$; S_f: the slope of the energy-gradient line or the friction slope] and the total potential energy gain (or loss) by a uniform downslope (or upslope) at the end of the line, ΔS ($\Delta S = S_0 \times L$), can be classified into three general types (Type-I, Type-II and Type-III). The classification can be based on a dimensionless energy gradient ratio, K_S ($K_S = S_0/S_f$). There are five typical pressure head profiles (Type-I, Type-II.a, Type-II.b, Type-II.c and Type-III) (Barragan & Wu, 2005) under three general types, and can be expressed in what follows:

4.1. Zero and uphill slope situation

4.1.1. Pressure profile type I (minimum pressure at the downstream closed end of the line)

The pressure head decreases with respect to the submain length. This type occurs when the submain line is laid on zero or uphill slopes. In this condition, the dimensionless energy-gradient ratio is $K_S = S_0 / S_f \le 0$. The total energy is lost by both elevation change due to uniform upslope and by friction. The maximum pressure head, H_{max} is at the inlet of the line and is equal to the operating inlet pressure, H_{0I} ($H_{0I} = H_{max}$); the minimum pressure head, H_{min}, is at the closed end of the line, and is equal to the downstream pressure head ($H_d = H_{min}$).

4.2. Downhill slope situation

4.2.1. Pressure profile type II (minimum pressure along the line):

The pressure head decreases from the upstream end with respect to the pipeline length, reaches a minimum point (i_{min}) , and then increases with respect to the submain line. The minimum pressure head is located somewhere along the line ($0 < i_{min} = l_{min}/L < 1$), depending on the large interval of K_S, $0 < K_S = S_0/S_f < 2.75$.

4.2.1.1. Pressure profile type II-a

This type of pressure profile occurs under the friction and slope situation, where $0<K_S = S_0/S_f<1.0$. In this type, the total energy gain by uniform downslope at the end of the line is smaller than the total energy drop by friction; so the downstream end pressure head (H_d) is still less than the operating inlet pressure (H_{0I}). The maximum pressure head is at the inlet ($H_{max} = H_{0I}$); and the minimum pressure head is located somewhere along the line.

4.2.1.2. Pressure profile type II-b (optimal pressure profile)

This is under the friction slope situation where the dimensionless energy-gradient ratio is $K_S = S_0/S_f = 1.0$. This profile is similar to Profile II-a, but the profile is such that the downstream closed end pressure head is equal to the operating inlet pressure head ($H_{0I} = H_d$). The maximum pressure is at the inlet ($H_{max} = H_{0I}$) as well as at the closed end of the line ($H_{max} = H_d$). The minimum pressure is located somewhere near the middle section of the line.

4.2.1.3. Pressure profile type II-c

This is under the friction and slope situation where the dimensionless energy-gradient ratio is $1.0<K_S<2.75$ for the Darcy-Weisbach (DW) or $1.0<K_S<2.852$ for the Hazen-Williams (HW) equation. This occurs when the line slope is even steeper, so the pressure at the end of line is higher than the operating inlet pressure. In this condition, the maximum pressure is at the downstream closed end of the line ($H_{max} = H_d$), and the minimum pressure is located somewhere along the upstream segment of the line.

4.2.1.4 Pressure profile type III (minimum pressure at the upstream inlet of the line)

This occurs when the submain line is on a steep downslope where the total energy gain by the uniform downslope is larger than the total energy drop by friction for all sections along the line. The pressure head increases with respect to the line length. This is caused by a steep downslope situation where the dimensionless energy-gradient ratio is $K_S \ge 2.75$ for the DW equation, or $K_S \ge 2.852$ for the HW equation. In this condition the maximum pressure is at the downstream closed end of the line ($H_{max} = H_d$), and the minimum pressure head is at the pipe inlet and equal to the operating pressure head ($H_{min} = H_{0I}$). Among all types of pressure profiles, the Type-II profile is considered as the optimal (or ideal) pressure profile which can produce the minimum pressure head difference for a given pipe length as discussed earlier (Yıldırım, 2015b). This profile occurs when the total energy loss by friction is just balanced by the total energy gain due to uniform downslope (Profile II-b).

4. Conclusions

Determination of the proper operating inlet pressure head is important for hydraulic design of multi-outlet pipelines in submain lines. This paper presents an analytical energy-gradient ratio (EGR) approach which offers simple, direct but sufficiently accurate relationships to determine the operating inlet pressure head and the the required pressure parameters, incorporating different uniformity patterns for water application. For this purpose, some mathematical expressions are initially deduced to relate water application uniformity parameters; such as Christiansen uniformity coefficient, lower-quarter distribution uniformity, coefficient of variation of outlet discharge, emission uniformity and allowable pressure head variation. Hence, the operating inlet pressure head is reformulated by incorporating different uniformity patterns, and setting a multiplication factor, α, and the required average outlet pressure head, and β^*, for the change in potential energy head due to the uniform line slope. The present formulations can be efficiently used for a wide range of water application uniformity, and for different types of pressure profiles in different line slope situations, without requiring any additional hydraulic variables.

Hydraulic Analysis of Multi-outlets Submains-I: Software Development

Gürol Yıldırım*[1]

[1] Giresun University, Engineering Faculty, Civil Engineering Dept., 28100, Giresun, Türkiye

Abstract. This paper aims to present an efficient computer program in Visual Basic 6.0, named "Multi-flowCAD" based stepwise computation algorithm for determining the hydraulic design variables (pipe size, pipe length and operating inlet pressure head), and the hydraulic flow characteristics (outflow-pressure head distribution, discharge and total friction losses) along the energy-grade line. The stepwise algorithm takes into account the velocity head change and variation of the Reynolds number, which affects the selection of the proper friction coefficient formula to be applied along the different reaches of the pipeline, while some additional minor local losses due to emitter connections are neglected.

Keywords: Smooth pipe-flow; Steady-state analysis; Software; Computer-aided design (CAD)

1. Theoretical Background

In the past, numerous researchers have worked on the hydraulic analysis of submain unit pipeline networks. The increasing progress in computer technology has led to the development of analytical (Wu and Gitlin 1974, 1975; Anyoji and Wu 1987; Wu and Yue 1993; Wu 1992, 1997; Warrick and Yitayew 1988; Valiantzas 1998, 2002a,b; Yıldırım and Ağıralioğlu 2002, 2004a,b; Yıldırım 2006a,b, 2007a,b), and numerical, semi-theoretical or computer-aided stepwise methods (Yitayew and Warrick 1988; Scaloppi and Allen 1993; Hathoot et al. 1993, 2000; Kang and Nishiyama 1996a,b; Vallesquino and Luque-Escamilla 2001, 2002; Juana et al. 2004; Yıldırım 2008, 2009, 2010). As a matter of fact, a significant amount of these hydraulic analysis are based on the conventional design procedure in which the pipe size and length are known a priori; then the remaining design variables such as operating inlet pressure head, water application uniformity and total energy loss are determined depending on these known pipe geometric characteristics.

2. Methodology

2.1. Classification on Design Problems

Design of a manifold pipeline includes the determination of pipe geometric characteristics (pipe size and length), as well as operating inlet pressure head and total friction head losses along the line. Design engineers are often faced with three types of problems in most lateral hydraulic computations. In the first type of problem (energy grade-line determination) (Yıldırım and Singh 2013a,b, Yıldırım 2007a, 2008) for the given design values of uniform pipe slope (S0) and average outlet pressure head (Hav), the required hydraulic variables concerning the pressure head profile [the operating inlet pressure head (H0I = Hin), downstream closed end pressure head (HN), extreme pressure heads (Hmax and Hmin) with their locations along the line (imax, imin; i: percentage of length, l is a length from the inlet in m, and L is the total length of the lateral line in m), and the total energy drop due to friction Hf(L), can be determined ensuring the desired level of water application uniformity as well as the allowable pressure head variation along the line (Yıldırım 2007a). With the help of the present computer-aided design technique, knowledge of hydraulic properties for any type of pressure profile under consideration enables the design engineer to clearly evaluate the overall energy distributions with the required pressure parameters through the line sections between successive outlets, in a simple way.

Variation of the outflows along the pipeline within certain limited values which defined as the uniformity coefficients for water application is also very important concern. In the second type of problem (water application uniformity evaluation) (Yıldırım 2007a,b, 2009), when H0I is given as an input parameter together with the required average emitter pressure head (Hav) and for a given design slope (S0), proper values of the required water application uniformity coefficients can be directly approximated. The design procedure which based on the

* Corresponding author, E-mail: gurol.yildirim@giresun.edu.tr

https://doi.org/10.31462/icearc2025_ce_hyd_305

uniformity coefficients depending on the acceptable level of outflow variation can be accepted or refused. In fact, the real value of these coefficients, should be just obtained with taking into account all the emitter outflows along the pipeline by implementing computer-aided stepwise procedure.

Designers are often faced with the problem of selecting the pipe size and length for a given desired uniformity level and given design slope range, in order to keep the design operating inlet pressure head and the allowed limit of total energy loss along the pipeline. In the third type of design problem (direct sizing procedure) (Hathoot et al. 2000; Kang and Nishiyama 1996a,b; Valiantzas 2002, Yıldırım 2006a, 2009), the required parameters are the pipe inside diameter (D) or length (L) for a given design slope (S0), the desired level of water application uniformity (UC and DULQ), and the required average outflow and pressure head (qav , Hav), with the previously known design variables.

3. Fundamental principles of manifold flow hydraulics: governing equations

Hydraulically, flow insubmain unit pipeline is considered to be a steady, spatially varied flow with decreasing outlet outflow in the downstream direction. With decreasing discharge along the line, the energy gradient line decreases. Generally, outlets are usually identical, and installed at an equal spacing on the line. The flow characteristics of the outlets are typically described by a function of the form (Howell and Hiler, 1974; Keller and Karmeli, 1974).

$$q_i = cH_i^{\ y} \tag{1}$$

in which qi is the outflow from an individual outlet; Hi is the pressure head in the pipe at the outlet under consideration; c is the outlet coefficient that accounts for areal and discharge effects and makes the units correct.

Considering the H1 is the initial inlet pressure head, Q1 the initial lateral discharge upstream from the first outlet, and q1 the outflow of the first outlet, which may be written as

$$q_1 = c\, H_1 \tag{2}$$

Assuming that the outflow varies continuously in space along the pipeline (the number of outlets is sufficiently large), the outflow per unit length (q) can then be described by

$$q = \left(\frac{c}{s}\right) H_i^{\ y} \tag{3}$$

If continuity is preserved along lateral, the conservation of mass is written in the general following form

$$\frac{dQ}{dx} + \frac{dA}{dt} = -q \tag{4}$$

where Q is the pipeline inlet discharge; x and t are space and time coordinates. For steady flow condition $(dA/dt = 0)$ in irrigation laterals, the continuity equation, Eq.(4), may be rewritten as follows

$$A\frac{dv}{dx} = -q \tag{5}$$

where v is the velocity of flow in the pipe.

Using the continuity equation, Eq.(5), the inlet discharge, Qi+1, at the pipe reach between successive outlets (i) and (i+1), can be obtained from

$$Q_{i+1} = Q_i - q_i \tag{6}$$

The discharge between the first and second outletsQ_2 can be evaluated from Eq. (6) in the special form :

$$Q_2 = Q_1 - q_1 = (N\, q_{av}) - (c\, H_1^{\ y}) \tag{7}$$

The momentum effect resulting from decreasing the discharge in downstream direction, the conservation of momentum equation is given by the following form (Streeter and Wylie 1979)

$$\sum F = \rho\left(Q_{i+1}V_{i+1} - Q_iV_i\right) \tag{8}$$

where is the change of pressure force; is the density of irrigation water; Vi and Vi+1 are the flow velocity between successive emitters (i-1)~(i) and (i)~(i+1), respectively.

Using the conservation of momentum equation, Eq.(8), the change of pressure head, □Hi+1, due to change of momentum between successive emitters (i) and (i+1) resulting from decreasing the discharge from Qi to Qi+1, may be written as follows

$$\Delta H_{i+1} = \frac{\left(Q_{i+1}^{\ 2} - Q_i^{\ 2}\right)}{gA^2} \tag{9}$$

where g is the acceleration due to gravity.

Watters and Keller (1978) have shown that for small diameter smooth pipes, the Darcy-Weisbach friction formula can give accurate predictions for frictional losses based on conservation of energy. Therefore the following expression can be written

$$H_{fi+1} = f_{i+1}\frac{s}{D}\frac{Q_{i+1}^{\ 2}}{2gA^2} \tag{10}$$

where H_{fi+1} is the friction head loss between successive outlets (i) and (i+1); f_{n+1} is the Darcy-Weisbach friction coefficient for the pipe reach between successive outlets (i) and (i+1); D is the internal diameter of the pipe.

Eq. (10) may be rewritten simplifying

$$H_{fi+1} = \frac{8s}{\pi^2 gD^5} f_{i+1} Q_{i+1}^{\ 2} \tag{11}$$

If the pipe has a uniform slope S_0 , the difference in levels of points (i) and (i+1) may be given by

$$(z_i - z_{i+1}) \ = \ \pm \ s\, S_0 \tag{12}$$

The positive sign is for the sloping downward and the negative for upward slopes, z_i and z_{i+1} are elevations of successive outlets (i) and (i+1) respectively, above an arbitrary datum.

Using conservation of the energy principle with Eq.(9) and Eq.(11), between successive outlets (i) and (i+1), the following form can be obtained

$$H_i + \frac{V_i^{\ 2}}{2g} + z_i = H_{i+1} + \frac{V_{i+1}^{\ 2}}{2g} + z_{i+1} + H_{fi+1} + \Delta H_{i+1} \tag{13}$$

where H_i and H_{i+1} are pressure head for the successive outlets (i) and (i+1); $\frac{Q_i^{\ 2}}{2gA^2}$ and $\frac{Q_{i+1}^{\ 2}}{2gA^2}$ are velocity head under consideration.

Solving Eq.(13) for the pressure head at the outlet (i+1), H_{i+1} is related to H_i by the following equation

$$H_{i+1} = H_i + \left(\frac{Q_i^{\ 2}}{2gA^2}\right) - \left(\frac{Q_{i+1}^{\ 2}}{2gA^2}\right) + (z_i - z_{i+1}) - h_{i+1} - \Delta H_{i+1} \tag{14}$$

Combining conservation of mass and momentum principles Eq.(6) and Eq.(9) with Eq.(11) and Eq.(12), into conservation of energy principle, Eq.(14), and simplifying

$$H_{i+1} \ = \ H_i + \frac{3}{2gA^2}\ [\,Q_i^2 - (Q_i - q_i)^2] - f_{i+1}\frac{8s}{\pi^2 gD^5}(Q_i - q_i)^2 \pm \ s\, S_0 \tag{15}$$

For convenience, Eq.(15) is put in the form

$$H_{i+1} = H_i + B\,[Q_i^2 - (Q_i - q_i)^2] - E\, f_{i+1}\,(Q_i - q_i)^2 \pm \ s\, S_0 \tag{16}$$

in which

$$B = \frac{3}{2gA^2} \tag{17}$$

$$E = \frac{8s}{\pi^2 gD^5} \tag{18}$$

As presented from the above hydraulic analysis given in Table 1, there are four basic equations in the submain unit hydraulics. These equations are: 1. the outlet discharge-pressure head relationship as Eq. (1), 2. the continuity equation as Eq. (5), 3. the Darcy-Weisbach friction formula as Eq. (10), 4. the conservation of energy equation coupled with the conservation of momentum equation as Eq. (13). On the other hand, there are four unknown hydraulic variables (Q_{i+1}, q_{i+1}, H_{i+1} and H_{fi+1}) at any location of pipeline (i+1), with the known previous values (Q_i, q_i, and H_i), and the other parameters (z_i, z_{i+1}, f_{i+1}, D, s, c and y). These unknown variables can be estimated using some of the user-friendly computation method.

Table 1. Fundemental principles & governing formulations on hydraulic computation for fluid flow along submain manifold

Description of Basic Equation	Formulation
• Pressure head - outflow (discharge) relationship	$q_n = cH_n^{\ y}$ $q = \left(\frac{c}{s}\right)H_n^{\ y}$
• Conservation of mass law & principle: Continuity equation	$\frac{dQ}{dx} + \frac{dA}{dt} = -q$ $Q_{n+1} = Q_n - q_n$

• Conservation of momentum law & principle: Impuls-momentum equation	$\Delta F=\rho(Q_{n+1}V_{n+1}-Q_nV_n)$ $\Delta H_{n+1}=\frac{\Delta p}{\gamma}=\frac{\Delta F}{A\gamma}=\frac{\rho(Q_{n+1}V_{n+1}-Q_nV_n)}{A\gamma}$ $\Delta H_{n+1}=\frac{\rho}{A\rho g}\left(\frac{Q^2{}_{n+1}-Q^2{}_n}{A}\right)=\frac{(Q^2{}_{n+1}-Q^2{}_n)}{gA^2}$
• Continuous head (energy) losses due to friction: Darcy-Weisbach equation	$H_{fn+1}=f_{n+1}\frac{s}{D}\frac{Q_{n+1}{}^2}{2gA^2}$
• Local or minor head losses due to individual outlet barb connection: Borda-Carnot & Belanger equation	$h_k'=h_c+h_e=\frac{(V_c-V_r)^2}{2g}+\frac{(V_r-V_{n+1})^2}{2g}=\left(\frac{1}{C_cr}-1\right)^2\frac{V_{n+1}{}^2}{2g}=K\frac{V_{n+1}{}^2}{2g}$
• Conservation of energy law & principle: Bernoulli's equation	$H_n+\frac{V_n{}^2}{2g}+z_n+h_{kn}{}'=H_{n+1}+\frac{V_{n+1}{}^2}{2g}+z_{n+1}+H_{fn+1}+\Delta H_{n+1}+h_{kn+1}{}'$

4. Water application uniformity

One of the main tasks of the submain unit hydraulic computation is to provide a sensitive balance between the inlet pressure head, the water application uniformity, and the total frictional losses along lateral. The Christiansen's uniformity coefficient and the lower-quarter distribution uniformity are used here to express uniformity of outlet discharge throughout the system (please see, Table 2).

Table 2. Uniformity Criteria & Uniformity Coefficients for Water Application

Computation Method	Christiansen's Uniformity Coefficient (UC)	Lower-Quarter Distribution Uniform Coeff. (DU_{LQ})
(1) Forward-Step Method (*FSM*)	Keller and Karmelli (1974): $UC=1-\left(1/(Nq_{av})\right)\sum_{n=1}^{n=N}\lvert q_n-q_{av}\rvert$	$DU_{LQ}=4\left(\sum_{n=3n/4}^{n=N}q_n\right)/(Nq_{av})$
(2) Differential Method (*DM*)	Yitayew and Warrick (1988): $UC=1-\left(\frac{1}{Lq_{av}}\right)\int_0^L\lvert q-q_{av}\rvert dx$ $=1-\left(\frac{2}{X_0}\right)\left(X_0-X_{div}-X_0V_{div}\right)$	$DU_{LQ}=4\times V_{LQ}$
(3) *Runge- Kutta* Numerical Method (*RKM*)	Miller (1981): $UC=\frac{(K_1+K_3X_0+K_5X_0{}^2)}{(1+K_2X_0+K_4X_0{}^3+K_6X_0{}^4)}$	Warrick (1983): DU_{LQ} = 1 / 0.67 (UC – 0.33) (for uniform outflow distribution) DU_{LQ} = 1 / 0.63 (UC – 0.37) (for normal outflow distribution)
(4) Constant-Discharge Method (*CDM*)	Valiantzas (1998): $UC=1-0.798\frac{y}{H_s}\left(\frac{H_{f0}{}^2}{(2m+3)(m+2)^2}+\frac{(s_0L)^2}{12}-\frac{H_{f0}s_0L}{(m+2)(m+3)}\right)^{0.5}$	
(5) Variable Discharge Method (*VDM*)	Valiantzas (1998): $[M=m_\alpha=\alpha\times m]$ $UC=1-0.798\frac{y}{H_s}\left(\frac{H_{f0}{}^2}{(2M+3)(M+2)^2}+\frac{(s_0L)^2}{12}-\frac{H_{f0}s_0L}{(M+2)(M+3)}\right)^{0.5}$	

5. Coefficient of friction (f)

Flow in a submain unit pipeline is generally turbulent: 3000<R≤105 (R = Reynolds number), sometimes fully turbulent flow : 105<R< 107, exists at the upstream end of the pipeline and flow becomes laminar at the downstream reach where the velocity decreases to zero (please see, Table 3.)

Table 3. Friction Coefficient Formulations Regarding Flow Regimes in Different Hydraulic Computations

	Friction Coefficient Formula (fn)		
Computation Method	Laminar Flow: ($R_n < 2000$)	Turbulent Flow: ($3000 < R_n \le 10^5$)	Fully-Turbulent Flow**:** ($10^5 < R_n < 10^7$)
(1) Forward-Step Method (**FSM**)		Blasius Formula	Watters and Keller (1978):
(2) Differential Method **(DM)**	$f_n = \dfrac{64}{R_n}$	$f_n = 0.316\ R_n^{-0.25}$	
(3) Runge-Kutta Numerical Method (**RKM**)			$f_n = 0.130\ R_n^{-0.172}$
(4) Simplified Analytical Approach (**SAA**)	$f_0 = 64\left(\dfrac{\nu}{D}\right)$	$f_0 = 0.316\left(\dfrac{\nu}{D}\right)^{0.25}$	$f_0 = 0.130\left(\dfrac{\nu}{D}\right)^{0.172}$
(5) Constant Discharge Method (**CDM**) (6) Variable Discharge Method (**VDM**)	[m = 1.0]	[m = 1.75]	[m = 1.828]
(7)Successive Approximations Method (SAM)	$f_n = \dfrac{64}{R_n}$	Colebrook-White equation: [Zigrang and Sylvester, 1982] $\dfrac{1}{f_n} = -2\log_{10}\left(\dfrac{\varepsilon/D}{3.7} + \dfrac{2.51}{R_n\sqrt{f_n}}\right)$	

6. Software development

As a notable reference, the algorithm was first programmed in FORTRAN IV (Kreitzberg and Schneiderman 1975), then a useful flowchart was presented by Hathoot et. al. (1993). Herein, the steps of the present algorithm was improved in the following section “Implementation of the Design Criteria” based on the initial and boundary conditions of the algorithm, and reprogrammed in Visual Basic 6.0 (Smyth 2013), incorporating variable flow conditions through the pipe segments, in a stepwise manner. Calculation steps of the proposed computer program (Multi-flowCAD) is also provided. In practice the average outlet discharge qav, the corresponding pressure head Hav, the flow exponent y, total number of outlets N, the spacing between outlets S, and the uniform line slope S0 and the inside diameter of the pipe D are assigned in advance, for a certain design.

7. Computational steps of algorithm

The following computational steps should be taken into consideration in the present algorithm:

1. The initial pressure head Hmax is first assumed by adding a reasonable head increment □0 to the average head Hav (initial condition).
2. The outflow of each successive individual outlet qi is evaluated in a stepwise manner, starting from the first outlet at the upstream pipeline inlet; and in each step the corresponding pipe discharge Qi is evaluated.
3. At each step, the Reynolds number valid for the pipe segment between successive outlets is calculated, then the proper friction coefficient formula is selectively used to evaluate the head loss due to friction, hence the new pressure head at the head of outlet, is determined by applying Eq. (16).
4. If Eq. (16) yields negative values of H at any outlet , this would indicate that the assumed Hmax should be increased by □d (Boundary condition).
5. As negative values of H disappear, other conditions should be continued.
6. The velocity at any reach of the pipeline should be positive (boundary condition); otherwise, this would indicate that the sum of outlet outflows is greater than the total initial pipe inlet discharge Qmax, which means that Hmax should be decreased by □d (□d, being divided periodically by 10 on increasing or decreasing Hmax).
7. The discharge in the pipe segment from the last outlet toward the downstream lateral closed end should be zero, which forms an important boundary condition. Practically, this condition is satisfied if the relative velocity at that part becomes less than a sufficiently small quantity, □ .
8. As the proper value of Hmax is sensitively reached, outflow, pressure head for each outlet, the discharge and flow velocity at the corresponding reach of the pipe can be determined. Finally, water application uniformity of the submain unit system can be evaluated by computing the uniformity coefficients (UC and DULQ) as given by Eq. (19) and Eq. (20), respectively.

8. Conclusions

In this study, the algorithm for the submain unit pipeline hydraulic design based on the forward-step computation procedure was presented, and a user-friendly computer program in Visual Basic 6.0 language was developed for general engineering applications. In the present design methodology, the design of a subunit pipe with equally spaced individual outlets and uniform line slope was examined so that hydraulic design principles and the uniformity coefficients were more convenient for better evaluation. In designing of a manifold by the present algorithm, for a given design length and inside diameter, firstly, the proper value of operating inlet pressure head was sensitively appointed within the design interval based on the initial and boundary conditions, then the total friction drop along the pipeline and level of water application uniformity of the system were finally determined.

Evaluation of flood propagation dynamics through diffusion wave-based two-dimensional modeling

Hasan O. Marangoz*[1], Tuğçe Anılan[2]

[1]Recep Tayyip Erdogan University, Department of Civil Engineering, 53100 Rize, Türkiye
[2]Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. This study investigates the failure and flood wave propagation analyses of the Atasu Dam located in Trabzon. The dam failure model and flood wave propagation were evaluated using a two-dimensional modeling approach based on the diffusion wave method. The analyses focused on examining hydrographs generated under different reservoir water levels and detailing the flood wave propagation along the downstream region. Modeling results obtained through the diffusion wave approach evaluated the movement and velocity distributions of the flood wave along the downstream area. The findings demonstrated that the diffusion wave method effectively represents flow velocities and enables the analysis of flood depths in critical regions. This study provides valuable data for flood risk management and emergency response planning.

Keywords: Diffusion wave modeling, Two-dimensional flood analysis, Dam failure, Flood propagation

1. Introduction

Floods resulting from dam failures are among the most catastrophic hydrological disasters, posing significant threats to human life, infrastructure, and the environment. With increasing urbanization and climate variability, the accurate prediction and simulation of flood propagation dynamics have become essential for effective risk management and emergency planning. Numerical modeling tools offer a powerful means to simulate such extreme events, allowing for the assessment of flood extents, depths, and flow velocities under different failure scenarios.

The St. Venant equations govern unsteady open-channel flow and are frequently simplified into various wave models for computational efficiency. Among these, the diffusion wave model is particularly useful in large-scale flood simulations where inertial effects are relatively small compared to gravitational and frictional forces. This model neglects acceleration terms and thus provides a computationally efficient framework for simulating flood wave movements over complex terrains.

Using the St. Venant equations on dam-break cases is now very up-to-date to use (Gaudio et. Al, 2024; Marangoz et. Al., 2022; Adityawan et. Al. , 2023; Dharmawan et. Al., 2024). Dam break events represent some of the most severe and sudden hydrological disasters, capable of releasing vast volumes of water within minutes and causing extensive downstream flooding. Physical factors stem from forces and situations imposed on dams by natural events of floods and earthquakes. (Adamo, 2021). Numerical modeling plays a crucial role in analyzing such scenarios, with two-dimensional shallow water models offering detailed spatial and temporal insights into flood wave dynamics (Jafarzadegan, 2023). As urban areas increasingly encroach upon flood-prone regions, the importance of reliable dam break simulations has grown in flood risk management and emergency preparedness efforts.

In this study, the flood wave propagation resulting from a hypothetical failure of the Atasu Dam, located on the Galyan Stream in Trabzon, Türkiye, is analyzed using a two-dimensional diffusion wave-based hydrodynamic model. The modeling aims to capture the spatial and temporal characteristics of the flood wave as it travels downstream, with a particular focus on critical areas such as urban settlements and industrial zones. The analysis evaluates variations in flow depth and velocity, the effects of topography and river confluences, and the potential risks posed to the city of Trabzon. The results provide a scientific basis for the development of flood mitigation strategies and contribute to improved disaster preparedness.

2. Material and methods

The non-conservative momentum equation of the one-dimensional St. Venant equations is expressed in Equation (1).

* Corresponding author, E-mail: hasanogulcan@gmail.com

https://doi.org/10.31462/icearc2025_ce_hyd_317

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+g\frac{\partial \zeta}{\partial x}+g(S_f-S)=0 \quad (1)$$

This equation consists of five terms, namely: the local acceleration term, convective acceleration term, pressure force term, friction force term, and gravity force term, respectively.

Another derived form of the St. Venant equations is known as the diffusion wave model. In this model, the effects of the inertial terms (i.e., local and convective acceleration) are considered negligible due to their relatively small magnitude compared to the pressure, friction, and gravitational forces. Therefore, the diffusion wave is also referred to as an "inertia-less wave" (Vreugdenhil, 1986). As a result, the St. Venant equations are simplified and expressed in the form of Equation (2), representing the flow characteristics.

$$g\frac{\partial \zeta}{\partial x}+g(S_f-S)=0 \quad (2)$$

The kinematic wave model is another derived form of the St. Venant equations. In this approach, it is assumed that the flow is uniform and that the channel bed is nearly parallel to the free water surface. Due to this assumption, the pressure force term is neglected from the general equation. The kinematic wave model is applicable in cases where the changes in wave height and velocity over distance and time are negligible, typically under steep bed slopes (Vreugdenhil, 1986). A representative example of this situation is the flow of a shallow stream over a highly sloped terrain (Novak et al., 2010).

3. Results

The maximum flood depths reached up to 30 meters in the main channel and 18 meters in the floodplain of the Galyan Stream, where the dam is located. At the confluence with the Değirmendere Stream, the maximum recorded water depth was approximately 17 meters. A negative wave effect was also observed upstream of the confluence point between the Galyan and Değirmendere Streams. The flood wave was seen to move upstream over a distance of approximately 1,400 meters (Fig. 1). During this period, the maximum water depth in the main channel rose to about 16 meters, while in the floodplain it reached approximately 11 meters.

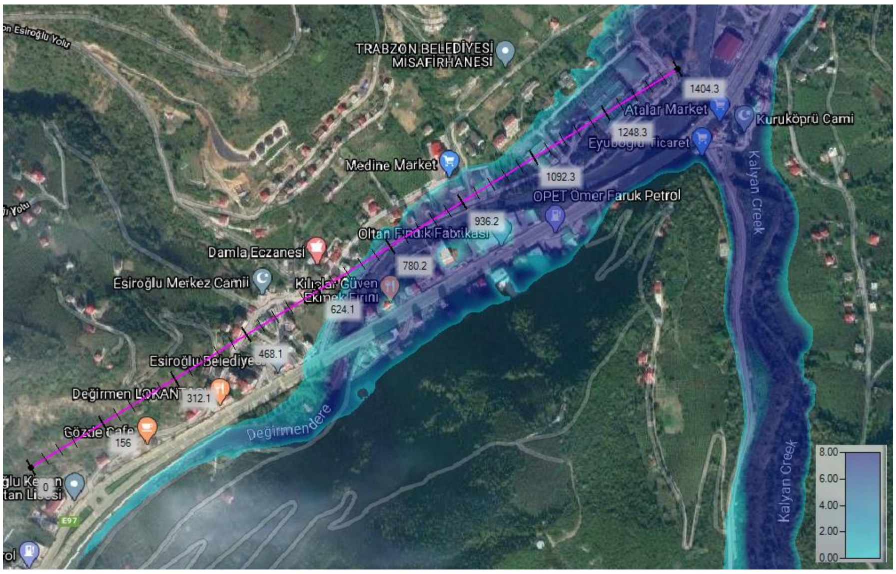

Fig. 1. Negative wave effect at the confluence of Galyan Stream and Değirmendere Stream

During the downstream propagation of the flood wave, the flood depth values along the river centerline were illustrated in Fig. 2. On the horizontal axis, the starting point of the river centerline represents the location closest to the dam axis, while the endpoint corresponds to the section located within the sea.

An analysis of flood elevations along the river centerline shows that the maximum flow occurred in areas closest to the dam axis throughout the simulation. In this region, the flood wave exhibited rapid surges and recessions. From meter 2573, the flow direction shifted toward the Değirmendere Stream. Along this section, the flood wave gradually decreased in height up to a height of 8413. Following this, the wave height began to increase again along the Değirmendere Stream, reaching a maximum flood elevation of 25.4 meters at meter 11968. In the urban center, the maximum observed flood height was 14 meters.

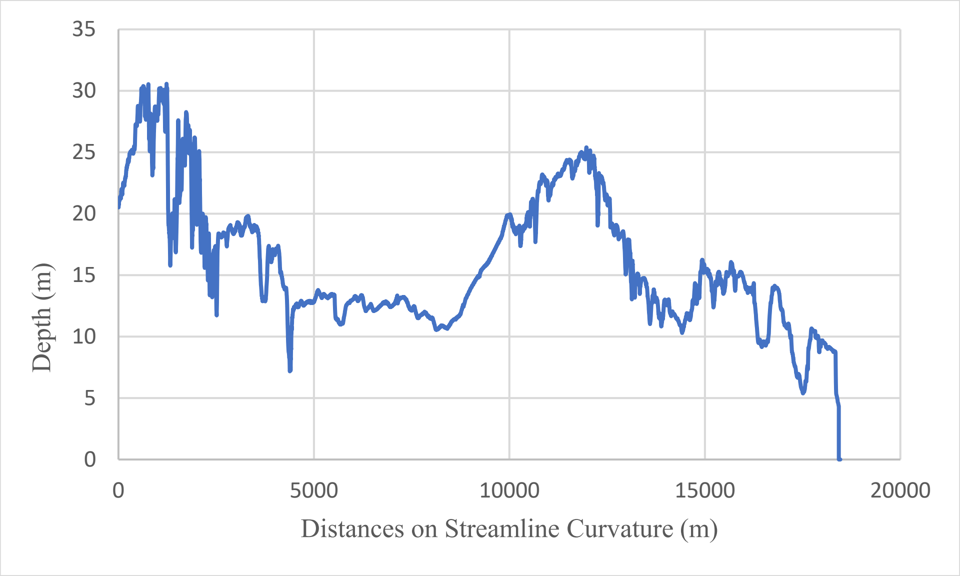

Fig. 2. Maximum flood wave depths along the river centerline

The maximum flood velocities along this centerline were recorded at 24 m/s. At the time of the dam failure, flow velocities along the Galyan Stream ranged between 17–23 m/s. In the confluence area of Galyan Stream and Değirmendere Stream, the flood propagation velocity was recorded as 5.63 m/s. Between 1000 and 2872 meters along the river centerline, the flood wave velocities varied between 3 and 13 m/s. In the city center, the maximum velocity along the main channel was observed to be 12.7 m/s, with an average velocity of 7.45 m/s.

Given the high population density and the presence of numerous industrial and commercial structures, capturing flood behavior within the urban center is of critical importance. The area designated as the city center, extending from meter 16,256 of the river centerline to the sea, includes 11 observation points randomly distributed. Real-time flood depth values were obtained at these locations.

The first flood wave reached the city center at the 28th minute, with a depth of 12.39 meters. By the 31st minute, the wave, now at 3.5 meters deep, had reached the sea for the first time. The maximum lateral spread of the flood wave in the city center was calculated as 1.93 kilometers. Fig. 3 presents the maximum flood extent in the urban area using a water depth color map. The flood propagation map obtained for the city center is presented in Fig. 3.

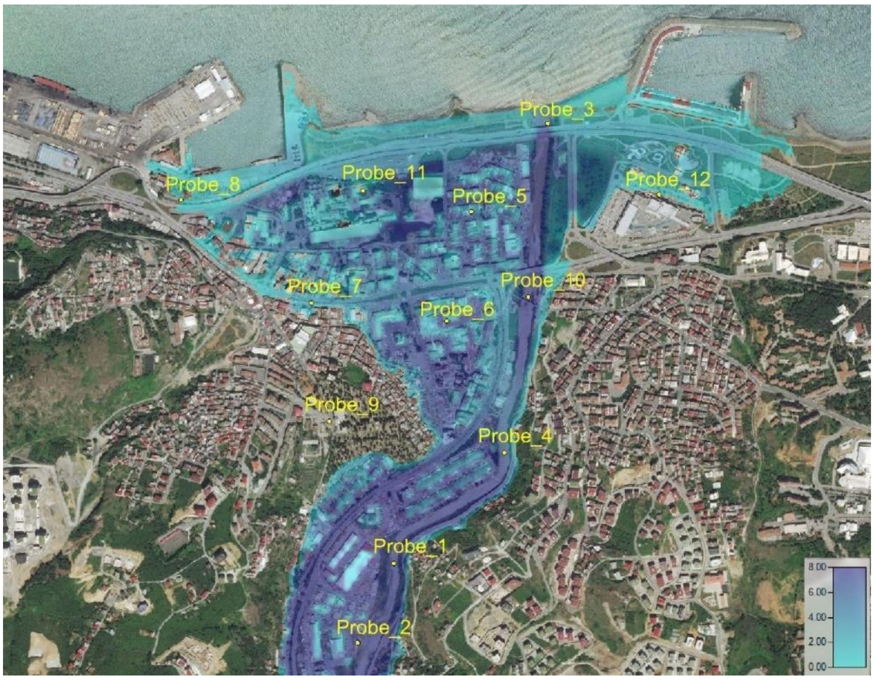

Fig. 3. Probe points placed in the city center and flood propagation extent

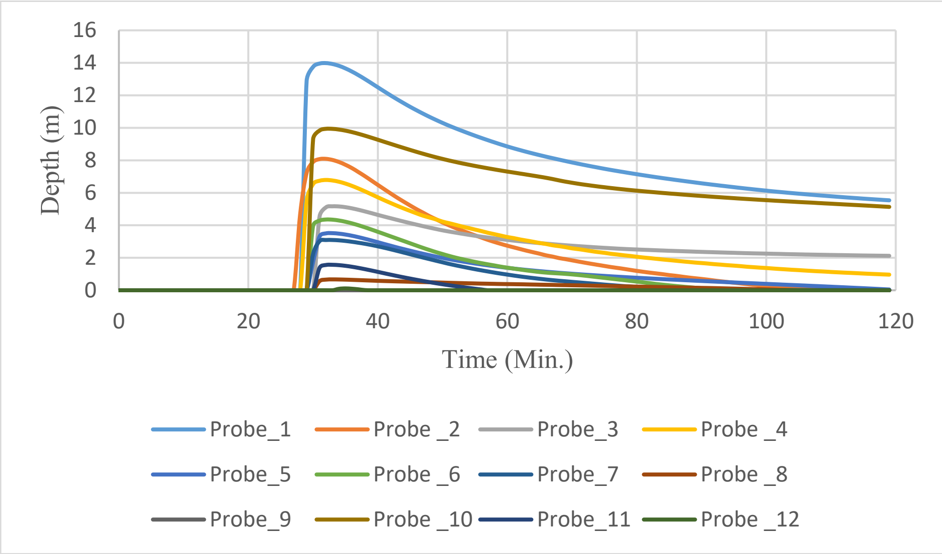

Fig. 4. Flood depth values at probe points located in the city center

As a result of routing the dam-break hydrograph at the dam axis downstream using the diffusion wave method, the flood water depths obtained at 12 observation points (probes) in the city center are illustrated in Fig. 4.

An analysis of the flood water levels recorded at the observation points in the city center revealed that the maximum value was observed at Probe_1, reaching 13.9 meters at the 32nd minute. Probe_9 recorded the lowest depths, indicating almost no noticeable flow at that location. Additionally, the flood depths at Probe_12 (0.11 m), Probe_8 (0.67 m), and Probe_11 (1.57 m) were considered negligible. At Probe_3, located near the point where the flood wave met the sea, the maximum wave height was 5.17 meters, recorded at the 33rd minute. To assess the lateral spread of the flood wave toward the west, Probe_8 was placed, where the recorded wave height was limited to 0.67 meters, suggesting a significant decrease in flood propagation in that direction. Probe_5, Probe_6, and Probe_7, located in densely built-up zones, recorded maximum water depths of 3.52 m, 4.36 m, and 3.1 m, respectively. The peak arrival times for these points were observed within 2 to 3 minutes of the initial flow contact.

The time-dependent advancement of the flood wave in the city center, along with its maximum velocity distribution, is shown in Fig. 5. Following the dam failure, the flood wave reached the city by the 27th minute, with a maximum velocity of 16.34 m/s along the main channel and up to 24 m/s in the floodplain. Because the water in the floodplain moved faster than in the main channel, it was observed to be 121 meters ahead of the main channel flood wave at that time. By the 28th minute, the wave had reached meter 16,775 of the river centerline and began to slow down upon encountering buildings. Consequently, the wave, with a maximum velocity of 14.14 m/s in the main channel, split into two branches in the floodplain, continuing at 13.17 m/s and 14 m/s. At minute 29, the wave rapidly spread into the city between buildings, with its front completely separating from the main channel. In the westernmost branch, the velocity reached 14.30 m/s, while in other branches (from left to right), the recorded maximum velocities were 21.45 m/s and 15.53 m/s, respectively.

At the 30th minute, the flood wave experienced its fastest expansion, covering most of the city center. The analysis showed that buildings in the city center created a corridor-like environment that channeled and accelerated the flow into multiple directions. The maximum distance between the main channel flood front and the urban flood front exceeded 90 meters. At that moment, the maximum velocity of the flood front in the main channel was 8.11 m/s, while the velocities in the side branches, though highly irregular, reached up to 14 m/s. By the 31st minute, the boundaries of the flood wave within the urban area were fully formed.

By the 41st minute, the flood wave had advanced westward as far as the Toprak Mahsulleri Office building, where the maximum velocity in the area was recorded at 6.1 m/s. As the wave reached the Trabzon Port, the flow velocities were observed to be negligible. On the eastern side, the flood extent reached as far as the fishing harbor and slipway area, located 440 meters west of Ahmet Suat Özyazıcı Stadium. In this region, the maximum velocity was approximately 9 m/s over an area of around 5 square meters. Consequently, in the shopping mall courtyard, which is one of the most frequently populated areas in the city center, the flood velocities remained negligible. After the 31st minute, both the velocity and depth of the flood wave in the city center showed a general decreasing trend until the end of the analysis period.

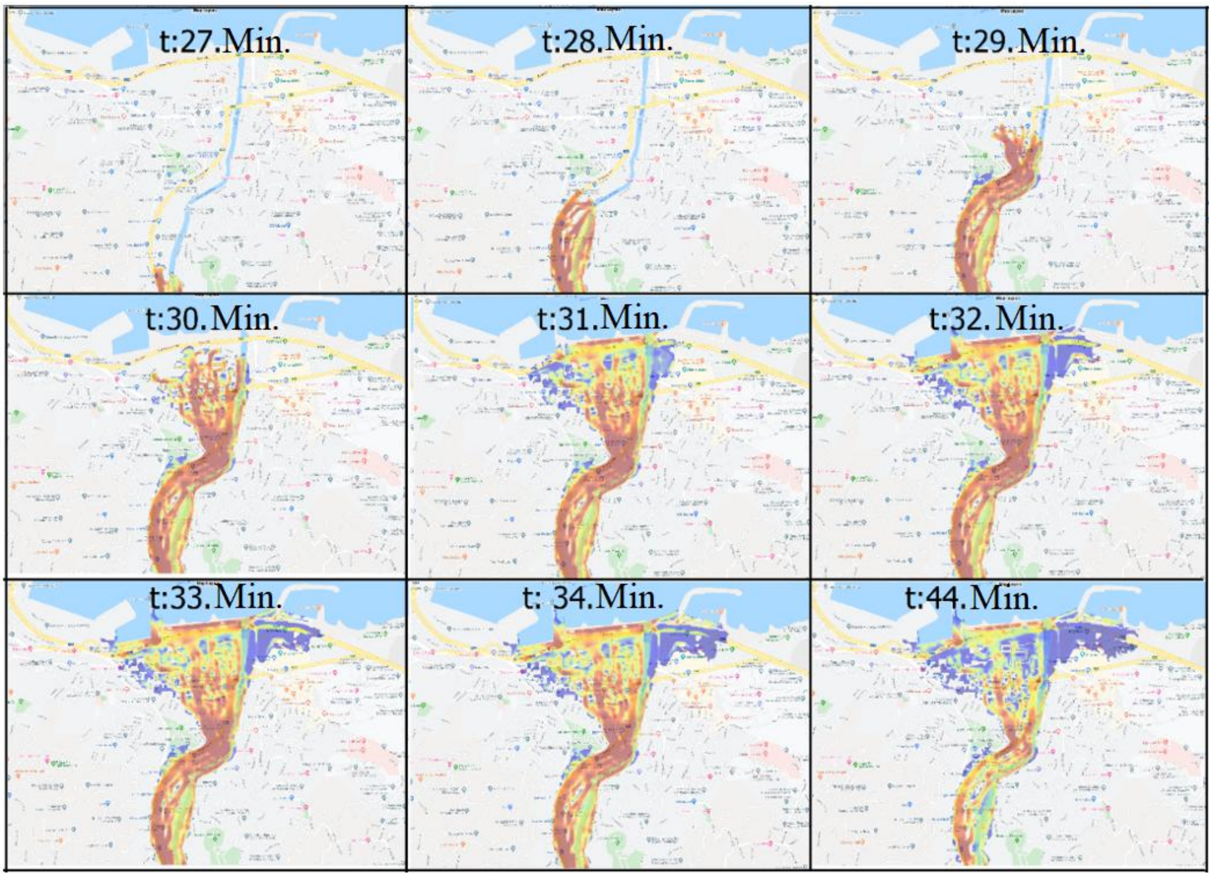

Fig. 5. Flood extents and flow velocities in the city center

4. Conclusions

In this study, a potential dam-break scenario for the Atasu Dam was simulated using a two-dimensional diffusion wave-based hydrodynamic model. The results revealed that the flood wave reached a maximum depth of 30 meters in the main channel and 18 meters in the floodplain along the Galyan Stream. At the junction with the Değirmendere Stream, a negative wave effect was observed, extending up to 1,400 meters upstream.

The model indicated that in the urban center of Trabzon, the initial flood wave arrived at the 28th minute with a depth of 12.39 meters, reaching its maximum depth of 13.9 meters at Probe_1 by the 32nd minute. The flood wave exhibited a maximum lateral spread of 1.93 kilometers, with flow velocities peaking at 24 m/s in the floodplain and averaging 7.45 m/s in the city center. These values underscore the destructive potential of such an event, particularly in densely built-up and populated areas. Moreover, the flood front reached the port area with negligible velocities, while on the eastern side, it extended close to the Ahmet Suat Özyazıcı Stadium with local velocities around 9 m/s. The model also demonstrated how urban structures act as corridors, accelerating and redirecting the flood wave into multiple branches, increasing both spatial spread and hazard complexity.

Overall, the diffusion wave model effectively captured the spatial-temporal dynamics of the flood event and identified critical locations requiring priority in emergency response planning. These results can support authorities in developing more robust flood mitigation strategies and urban resilience frameworks against dam failure scenarios.

Experimental and numerical study of the influence of bridge pier skew angle on dam break flood flow and impact force

Kutsi S. Erduran [1], Olusola O. Adekoya*[1], Uğur Ünal[1]

[1] Niğde Ömer Halisdemir University, Department of Civil Engineering, 51240 Niğde, Türkiye

Abstract. This study aims to investigate the influence of bridge pier skew angle and varying reservoir water depth on dam-break-induced flood flow and the resulting impact forces on bridge pier through experimental and numerical methods. Experiments were conducted in a 10 x 0.309 x 0.45 m horizontal rectangular channel of the Civil Engineering Department of Niğde Ömer Halisdemir University. Square bridge pier with blockage ratios of 0.129, 0.159, 0.177 and 0.183 corresponding to 0^0, 15^0, 30^0 and 45^0 skew angles was positioned 1.24 m downstream of the dam site (gate). Flow depth and the impact force time variations were measured using Image Processing Technique and a 6-Axis USA ATI Mark GAMMA model SI-32-2.5 load cell respectively. Numerical simulations, using Flow 3D, replicated experimental conditions and comparative analysis were conducted. The results reveal that the time to peak flow depth decreased with increase in reservoir depth. A maximum drop of 31 % was recorded between 15 and 25 cm for 15^0 skew angle. Higher skew angles also produced slightly lower times to peak depth, the maximum in this case was 10 % drop between 0^0 and 30^0 at 20 cm reservoir depth. Increase in force intensity generally ranged between 26.9 and 22.3 % and a maximum of 14 % increase in maximum impact force resulted from increasing skew angle. This study provides an understanding of the relationship between skew angle, flow dynamics, and force distribution, offering valuable insight for the design of bridge piers in dam-break-prone areas.

Keywords: Dam-break; Skew angle; Impact force; Bridge pier

1. Introduction

The sequence of dam failure occurrences recorded in very recent times and their damaging consequences on communities, buildings and infrastructures, highlight the need for potential damage evaluation towards improved design of resilient infrastructures. Dam break induced flow resulting from sudden removal of a dam (gate) idealises this critical hazard since real case data are difficult to obtain (Ozmen-Cagatay & Kocaman, 2011; Hu et al., 2018; Erduran et al., 2024). More so, dam break induced flow waves have been used as analogue for tsunami bore in several studies due to the similarities in their hydrodynamic characteristics and impact mechanisms (Nouri et al., 2010; Chen et al., 2020; Elsheikh et al., 2022; Gaudio et al., 2022; Yang et al., 2022; Mu et al., 2023; Zhou et al., 2024). Accurately predicting the characteristics and the flow-structure interaction of this flow is therefore essential for designing resilient hydraulic and coastal structures.

A lot of theoretical, experimental, and numerical research effort has gone into the study of the dynamics of dam break flow over the years. Analytical solutions based on shallow water equations (Ritter, 1892; Dressler, 1952; Hogg & Pritchard, 2004; Chanson, 2005 and 2009), provide data on wave front velocity and evolution of water profile. Nevertheless, these solutions generally does not cover impact forces on structures. This gap was addressed by the application of the momentum-based force estimation techniques like the zero-gravity similarity model (Cumberbatch, 1960), the hydrodynamic and hydrostatic force decomposition approach (Cross, 1967) as well as the momentum flux conservation method (Raju et al., 1983), but these models have been shown to overestimate impact forces when compared to experimental data (Kihara et al., 2015).

Experimental studies have, however, provided valuable insights into the dynamics of dam-break induced flow (Lauber and Hager, 1998a; 1998b; Leal et al., 2006). The effect of channel downstream geometry (Frazão & Zech, 2002; Chen et al., 2019; Zhang et al., 2022), and the effect of reservoir geometry (Feizi Khankandi et al., 2012; Hooshyaripor & Tahershamsi, 2015) on flow characteristics have been extensively studied. So also, is the influence of the presence of various types of obstacles (Soares-Frazão & Zech, 2007; Ozmen-Cagatay & Kocaman, 2011; Feizi, 2018; Saghi & Lakzian, 2019; Chumchan & Rattanadecho, 2020; Kocaman et al., 2020; Ansari et al., 2021; Gaudio et al., 2022; Maghsoodi et al., 2022; Vosoughi et al., 2022). Measurements of flow depth time history, free

https://doi.org/10.31462/icearc2025_ce_hyd_408

surface profile, velocity fields and impact pressures were provided by these studies. Recent developments in computational fluid dynamics have facilitated reliable modelling of dam-break flow, hence all the studies on the effect of various types of obstacles were numerically simulated and validated with experimental data using Eulerian; Reynolds-averaged Navier–Stokes (RANS) (Kocaman et al., 2020) and/or Lagrangian; Smoothed Particle Hydrodynamics (SPH) approaches (Ansari et al., 2021).

Understanding the fluid-structure interaction is crucial for assessing possible direct damage to structures and developing efficient design techniques, in addition to precisely forecasting flow evolution (Aureli et al., 2015). To this end, Aureli et al. (2015) conducted an experimental study on the impact of dam break wave against a rigid squat structure, measuring the impact force directly by using a load cell. Three numerical models were then validated by the experimental data. The influence of cylinder cross-section on dam break impact force was investigated by Kamra et al. (2019). They analysed the pressure signal on the cylinder as well as the vertical wall downstream of the cylinder (closed end of the channel). The impact of the obstacle (cylinder) on the impact pressure was evaluated by comparing the pressure induced on the wall with and without the obstacle in place. The square cylinder was found to obstruct the flow momentum in the x-direction more than the circular cylinder. This experimental work was used to validate the numerical model developed by Mu et al. (2023). They extended the study to numerically simulate the effect of impacting angle in a enclosed channel. The study concluded that the total force on the square cylinder was almost 2 times that of circular cylinder. The instantaneous surge height and dynamic pressure of a dam break surge on a vertical wall with different reservoir depths was experimentally investigated by Liu et al. (2022). They result indicated that the dynamic pressures at the instant of impact were roughly 3 times the equivalent static pressure in the bed and the highest surge run up heights on the wall were between 2.1 and 2.3 times the equivalent initial reservoir water depths. The effect of vertical wall inclination on the impact load of dam break induced surge was also studied by Li and Liu (2024) and they found that the breaking wave loads on non-vertical walls were underestimated by the calculation approach being used for design of induced maximum horizontal force. While these studies provide detailed force distributions, their application has been majorly restricted to perpendicular flow-structure interactions. Studies on the effect of the obstructing structure orientation on impact force which are possible scenarios involving dam break waves striking bridge pier or tsunami waves hitting coastal structures at oblique angles are limited.

Even though there are a good number of studies on dam-break flow impacts, the effect of obstacle impact angle on wave impact force is not well established. Most of the studies assumed perpendicular impact angle without considering the effect of impacting angle, refers to as skew angle in this study. This is possible in reality with possible alteration to flow separation, impact pressure and force coefficients. Understanding these effects is essential towards an enhanced engineering design.

This study, therefore, investigates the effect of bridge pier skew angle and varying initial reservoir water depth on the hydrodynamic loading induced by dam break flow wave on a square bridge pier. Numerical model was used to simulate the experimental setup, and the resulting numerical data were validated using the result of the experimental study. The study aims to provide an understanding of the relationship between skew angle, flow dynamics, and force distribution, offering valuable insight for the design of bridge piers in dam-break-prone areas.

2. Material and method

2.1. Experimental setup

The rectangular cross-sectional channel of the Civil Engineering Department Hydraulics Laboratory, Niğde Ömer Halisdemir University measuring 100 x 30.9 x 45 cm was used for this study (Fig. 1). The channel was divided into two sections using a 1.1 cm thick plexiglass gate as illustrated on Fig. 2. The upstream section was the reservoir with the gate positioned 44.05 cm away from the channel inlet. The gate is vertically movable with the aid of a 10 kg load connected to the gate through a pulley system that was fixed to the ceiling directly above the channel at the position of the gate.

The bridge pier was positioned 124 cm downstream of the gate and this distance was maintained for all cases regardless of the skew angle. This position was chosen after conducting several experimental and numerical tests to ensure that the shock wave was fully developed before impacting the bridge piers. Both the experimental and numerical models indicated that the shock wave was fully developed as at 70 cm away from the gate. The size and positioning of the bridge pier model is as indicated in Fig. 3. 0^0, 15^0, 30^0 and 45^0 skew angles with 0.129, 0.159, 0.177 and 0.183 blockage ratios were studied.

A camera with a video recording speed of 30 frames per second (FPS) was positioned such that it captured the flow propagation from the gate to the bridge pier and extended few metres beyond the pier (Fig. 2) This was possible because the channel walls are transparent. Table 1 outlines the experimental runs, and the experimental ID adopted in this study.

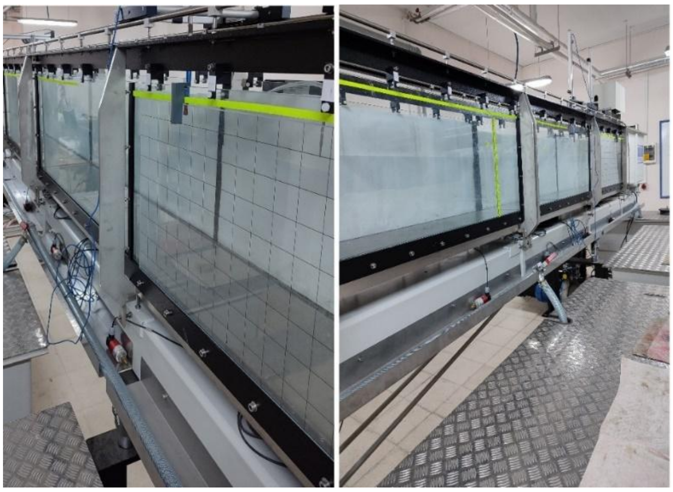

Fig. 1. The experimental channel

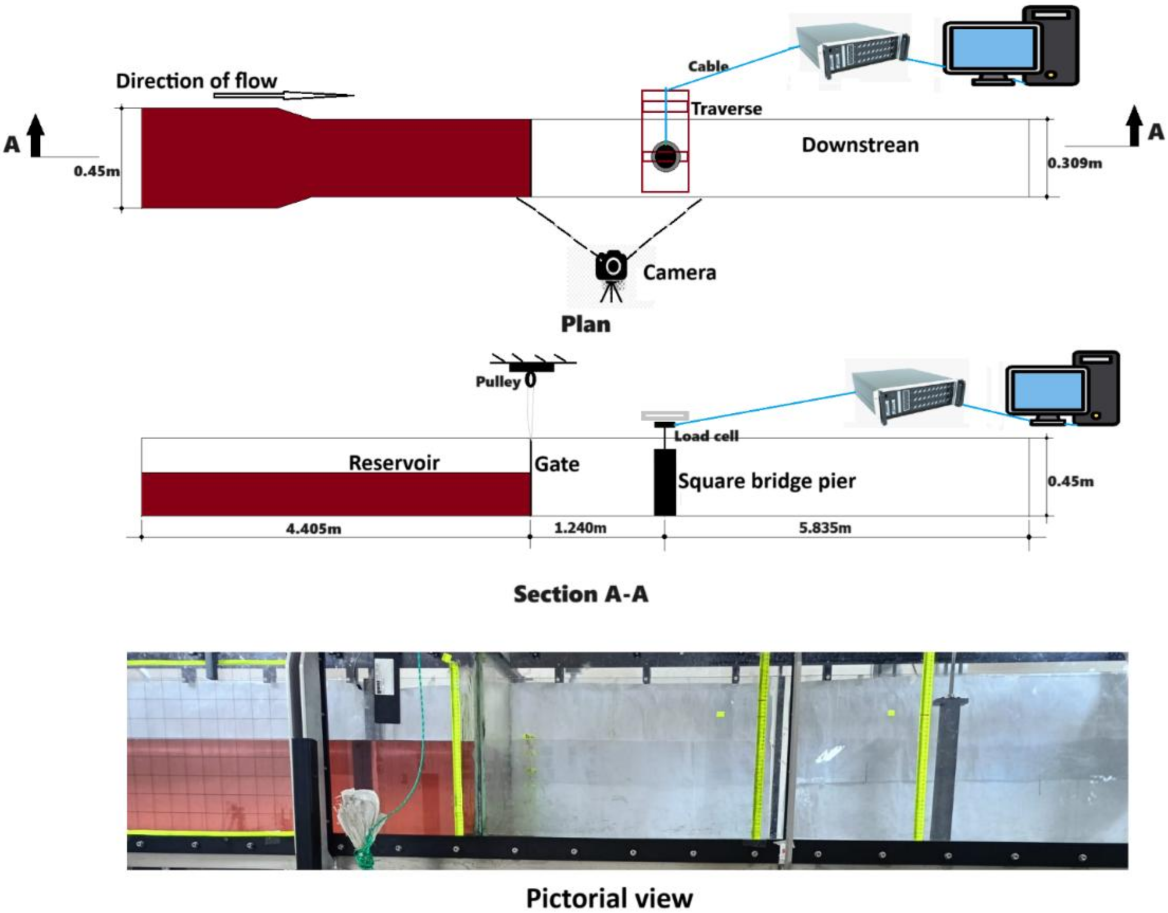

Fig. 2. The experimental setup showing the plan, cross sectional and pictorial view

2.1.1. Flow depth measurement

The advancements in science of fluid mechanics remains the bases for a true understanding of the qualitative data provided by images of flow visualization (Gharib et al., 1985). The correctness of such qualitative data is often determined by the use of quantitative tools like acoustic doppler velocimetry and water level gauges, but these methods are limited to data sampling at few spatial positions. This then explain the need for a quantitative flow visualization technique since it is capable of delivering both spatial and temporal data simultaneously in an accurate and non-intrusive manner (Ozmen-Cagatay & Kocaman, 2011). The image processing technique (IPT) adopted in this study is a form of quantitative flow visualization technique. It is used for the measurement of time history of flow depth at specific positions along the channel as well as for free surface profile measurements for the entire duration of the experiment. Following the works of Erduran et al. (2019), Erduran et al. (2024a) and (2024b) a python code was written by the authors to process the images obtained from the video recordings of the experiments. The IPT procedure is fully described in Erduran et al. (2024b). For this study, time history of flow depth at the upstream face of the bridge pier was digitized over a period of 20 s. This indicates that the code processed a total of 600 frames (30 FPS x 20 s) and output the flow depth at every 0.0333 s for every experimental run.

2.1.2. Impact force measurement

The bridge pier was attached to a load cell, and both were held in position by a 61 x 61 cm ranged Dantec 41T32 model traverse system as show in Fig. 4. A 6-Axis USA ATI Mark GAMMA model SI-32-2.5 load cell with a maximum Fx and Fy capacity of ±32 N and maximum Fz capacity of ±100 N was used for impact force measurement. The precision rating of the load cell at Fx, Fy and Fz is ±0.75%, ±1%, and ±0.75% respectively. To ensure that the impact force was entirely transmitted to the load cell, the bridge pier was positioned such that it was hanging at a few millimetres above the bottom of the channel. Data were transmitted from the load cell to the PC through a NI PCle-6323 DAQ card data acquisition system. The system has 32 single ended analog-to-digital converter channels with a maximum sampling frequency of 250 kHz (Fig. 4). Nevertheless, measurements were taken for this study at a sampling rate of 1000 Hz. for a period of 30 seconds. Hence, a minimum of 30,000 sample values were recorded for each test run and this was repeated 3 times. The average value of the 3 tests at every 0.001 s was computed and used for analysis to reduces the influence of random error and improve precision.

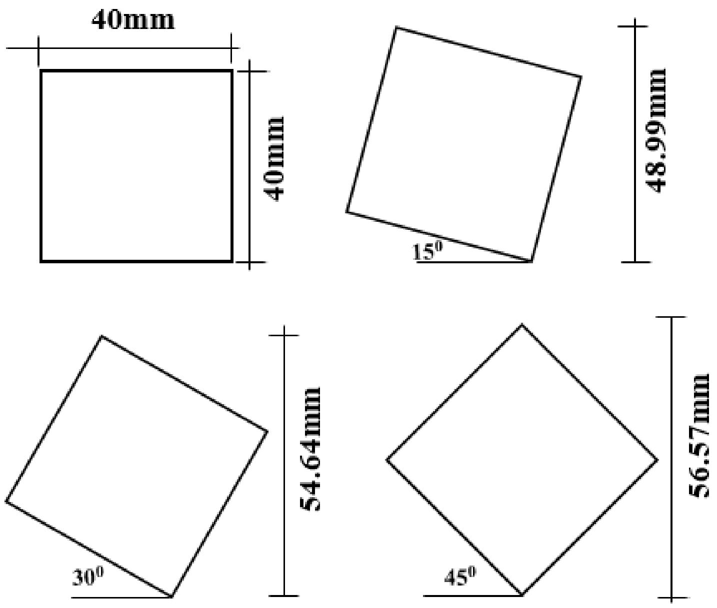

Fig. 3. Bridge pier blockage length variation with increasing skew angle

Table 1. Experimental outline

Skew angle	Reservoir depth (cm)	Experiment ID	Repetition
0^0 (0D)	15 (H15)	0D_H15	3
	20 (H20)	0D_H20	3
	25 (H25)	0D_H25	3
15^0 (15D)	15 (H15)	15D_H15	3
	20 (H20)	15D_H20	3

	25 (H25)	45D_H25	3

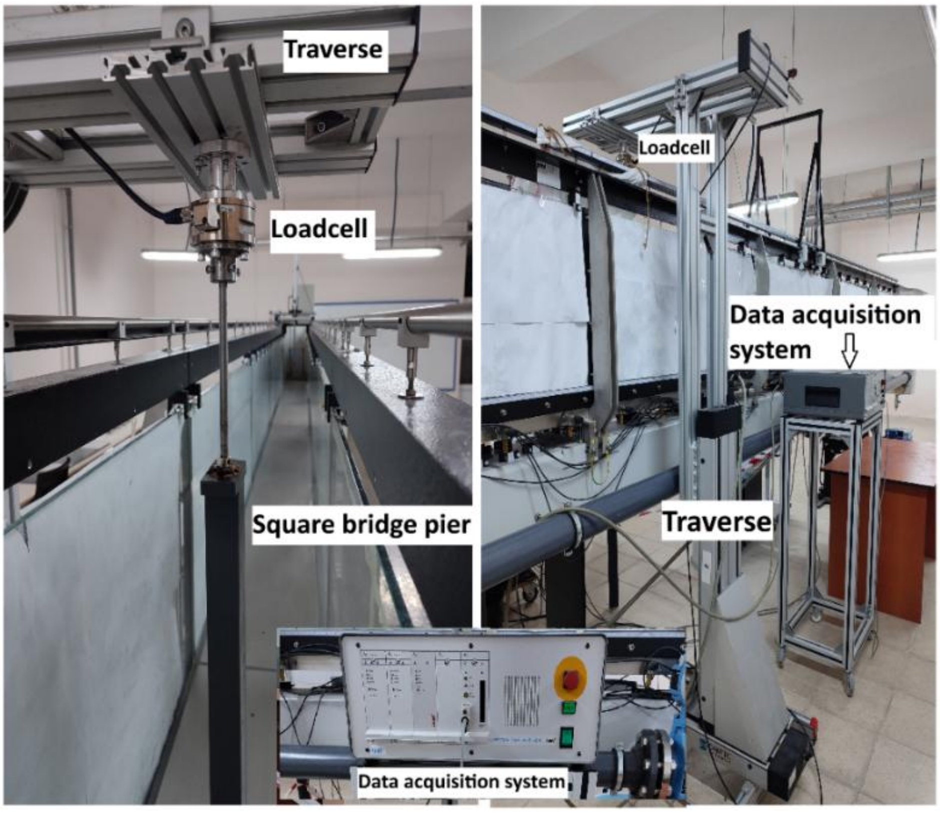

Fig. 4. Pictorial view of setup for Impact force measurement

2.2. Numerical models

The numerical study was carried out using a commercial software, Flow 3D. The software solves the RANS equation using the finite volume method (FVM) in a cartesian, staggered grid and tracks fluid surface using the Volume of Fluid (VOF) method. The program uses the fractional area/volume obstacle representation (FAVOR) method, which is a cell porosity technique, to model the geometry of structures within the computational domain (Ozmen-Cagatay & Kocaman, 2011; Hu et al., 2018; Erduran et al., 2024a).

The experimental setup described in section 2.1 was replicated. The computational domain was defined as 800 cm long, 30.9 cm wide and 45 cm high. A 440.5 cm long reservoir length was defined as initial condition with three initial reservoir water depth of 15 cm, 20 cm and 25 cm. A dry downstream condition (0 cm water depth) was defined for the downstream section of the computation domain (channel). A (4 x 4 x 37) cm square bridge pier was generated and positioned 124 cm downstream of the gate at the various skew angles.

The channel side walls (Y_{min} and Y_{max}) as well as the channel bed (Z_{min}) were defined as walls. So also was the upstream boundary (X_{min}) but the downstream boundary (X_{max}) was set as outflow since the downstream end of the computation domain was open. All sections connecting two cell blocks between the upstream (X_{min}) and downstream boundaries (X_{max}) were set as symmetry to ensure that the flow properties (velocity, pressure, etc.) remained consistent across these boundaries. The upper boundary (Z_{max}) was also set as symmetry in order to account for effect of the atmospheric pressure on the free water surface.

2.3 Validation and repeatability.

Lauber and Hager (1998a) introduced a criterion (Equation 1) which defines the maximum gate opening time for an instantaneous dam-break in a rectangular channel with dry downstream conditions (Yang et al., 2020) . The criterion was satisfied in this study. At 15, 20 and 25 cm reservoir water depths, the recorded gate opening times were 0.1166, 0.1332, 0.1499 and 0.1665 s respectively. These values are below the limit recommended by (Lauber & Hager, 1998a) which are 0.1262, 0.1546, 0.1785 and 0.1995 s for 10, 15, 20 and 25 cm reservoir water depths respectively. This criterion ensures that experimental models accurately represent real-world dam break scenarios. Haven satisfied the criterion; it could be said that the experimental model is validated.

$$t_{op} \leq 1.25\sqrt{h_o/g} \tag{1}$$

where t_{op} is the gate opening time, h_o is reservoir water level, and g is the gravitational acceleration.

The test cases were repeated three times to validate the repeatability of the experiment and the time history of the forces were compare (Fig. 5) for 0D_H15, 15D_H15, 30D_H15 and 45D_H15. The result indicated a similarity in trend for the three texts.

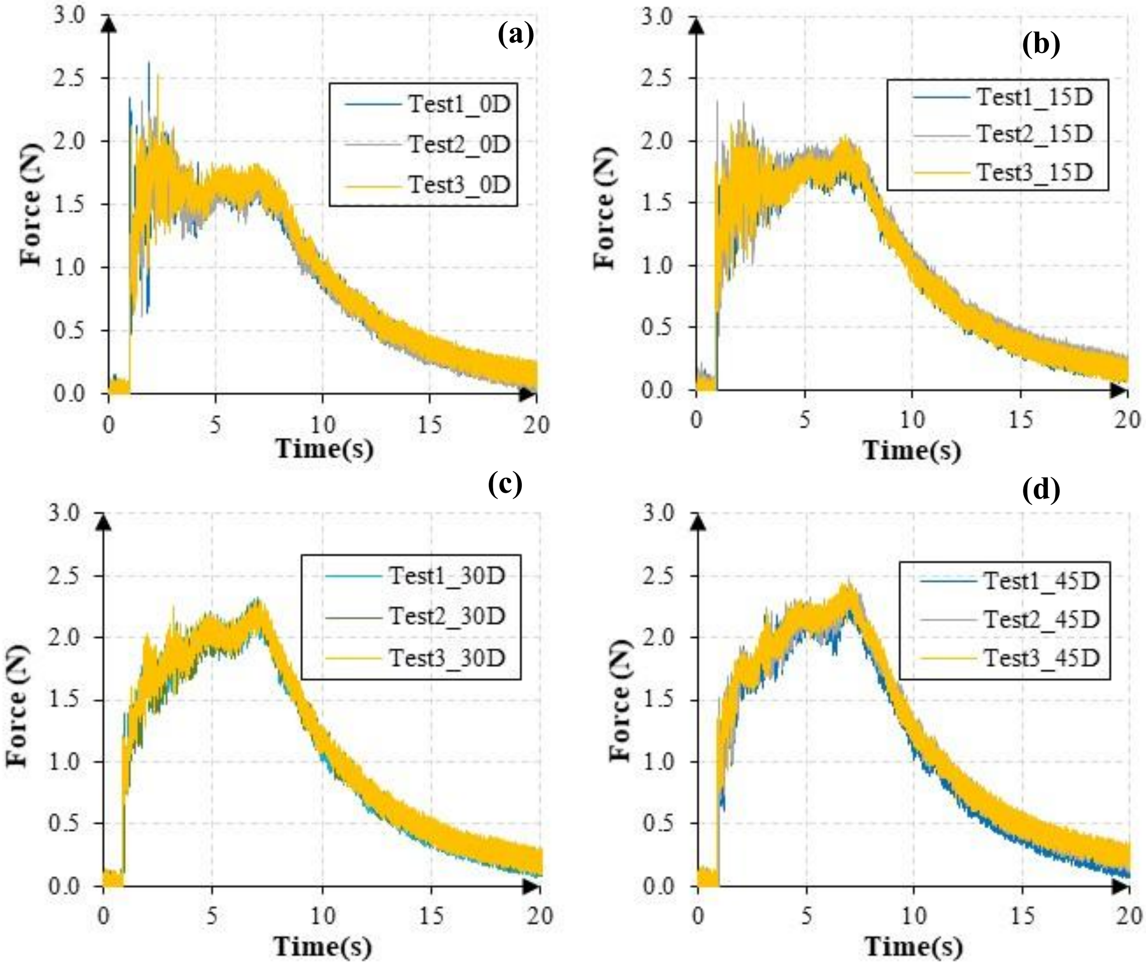

Fig. 5. The time history of the impact force for three repeated tests at: a) 0D b) 15D c) 30D d) 45D skew angles for H15

3. Results and discussion

3.1 Flow depth variation

The time-history of the flow depth near the upstream face of the square bridge pier for the various skew angles are shown in Fig. 6. The result reveals that at the initial stage, the flow depths started at a baseline, but as time increases, flow depth diverges based on the initial reservoir water depth. The rate of increase in flow depth was observed to depend on the reservoir water depth. The higher the reservoir water depth, the higher the rate of increase in flow depth. It could be said that the depth of flow upstream of the bridge pier is influenced by both initial reservoir depth and skew angle of the square bridge pier. The results further reveals that the time to peak flow depth decreases with increase in reservoir depth. A maximum drop of 31% in time to peak flow depth was recorded between 15D_H15 and 15D_H25. The effect of increasing skew angles also leads to slight decrease in the times to peak flow depth, the maximum in this case was 10 % drop between 0D_H20 and 30D_H20 reservoir depth.

3.2. Impact force

The time variation of the force induced on the bridge pier by the shock wave is shown in Fig. 7. The four plots show similar trend: an initial sharp increase in force (initial impact) followed by a peak, and then a gradual decay. The highest force was observed at H25 for all cases indicating a correlation between the initial reservoir water depth and the force. That is, an increase in the initial reservoir water depth leads to an increase in force. This is consistent with the result of the flow depth.

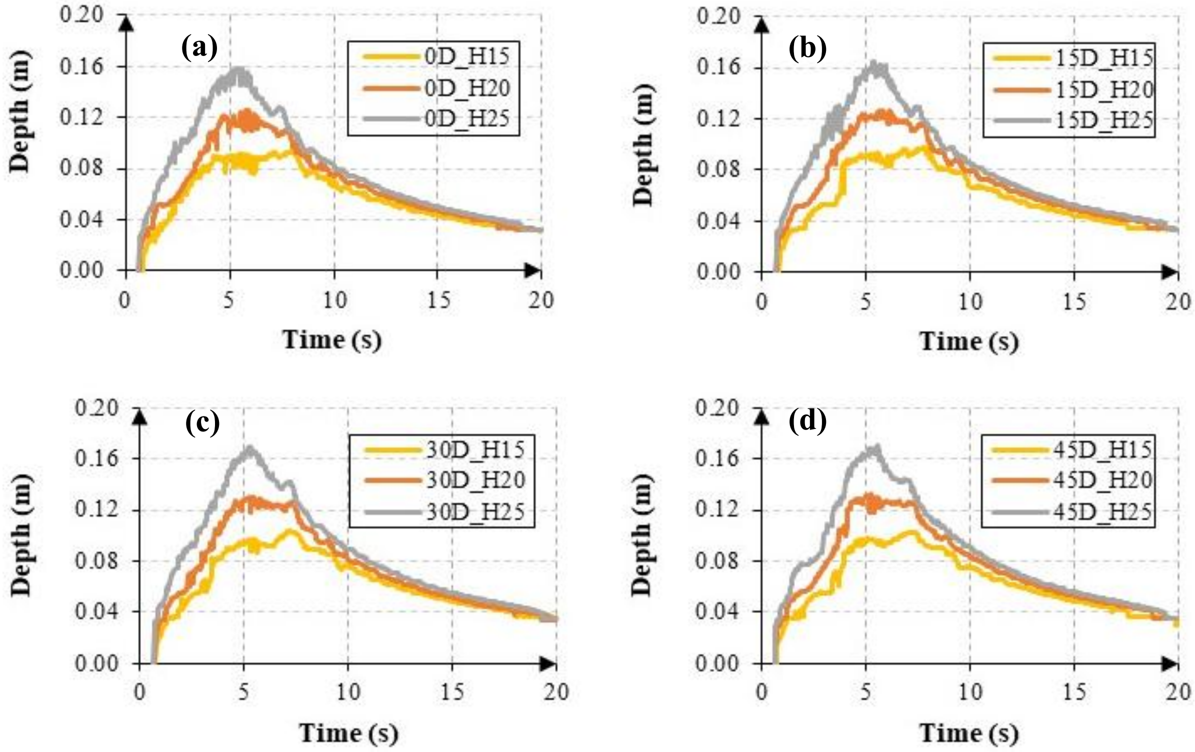

Fig. 6. The time variation of flow depth at: a) 0D b) 15D c) 30D d) 45D

The effect of the increase in skew angle on this trend shows a decrease in initial impact force. The impinging force is due to the initial impact of the shock wave influenced by the wave front celerity. This force is more pronounced at H25, however, it is mostly less than the subsequent hydrodynamic force. At 0D, it was observed that this force played a dominant role in the recorded peak force, hence, the peak force occurred earlier in 0D case when compared with other cases. The maximum total longitudinal and transverse forces caused by the first impact were considered in the study of (Mu et al., 2023) to avoid the influence of second impact resulting from the return wave induced by the right wall (enclosed channel). Hence the influence of backwater build-up was neglected. This explains the continuous decrease in peak force relative to the increase in impact angle (skew angle) in their study. According to Fig. 7, at higher skew angles, the influence of the impinging force (first/initial impact) reduces while the influence of the backwater build-up played the dominant role in the peak force value. Hence the delay in time to peak force at this skew angles. It can be observed in Fig. 8, that the peak force initially dropped at 15D with the largest drop being 12.19 % at H25. This followed the trend reported by (Mu et al., 2023). Then, it increased with increase in skew angle regardless of the reservoir water depth. Beyond 15D, maximum quasi-hydrostatic force corresponding to the build-up of backwater upstream of the bridge pier played the dominant role. In all the cases, the highest peak forces were recorded at 45D resulting in 1.1461, 1.0033 and 1.0062 times the force recorded for H15, H20 and H25 respectively at 0D. Although, the shape of the upstream face of the bridge pier at 45D allows for lower flow separation (Keshavarz et al., 2022), this result could be attributed to increase in blockage ratio and the corresponding build-up of backwater upstream of the bridge pier.

The force intensity was calculated as the arithmetic mean of the forces over a period of 20 s (or time averaged force). This represents a steady and constant component of the force over the period of study and reflects the average force induced on the structure by the flow. The result indicates that the highest recorded changes in force intensity were at 45D_H15, 45D_H20 and 45D_H25, which were 26.91 %, 25.02 % and 22.3 % more than the case at 0D_H15, 0D_H20 and 0D_H25 respectively. According to Fig. 9, there exist an almost perfectly linear relationship between the force intensity and reservoir water depth at the various skew angles.

Fig. 10 shows the influence of the skew angle on the time to peak force. It could be seen that at lower reservoir water depth, the impact of the skew angle was significant in delaying the time to peak force. A maximum of 3.29, 2.67 and 2.52 times the time to peak force at 0D was recorded at 15D, 30D and 45D respectively. This impact was also observed to reduce as the reservoir water depth increased.

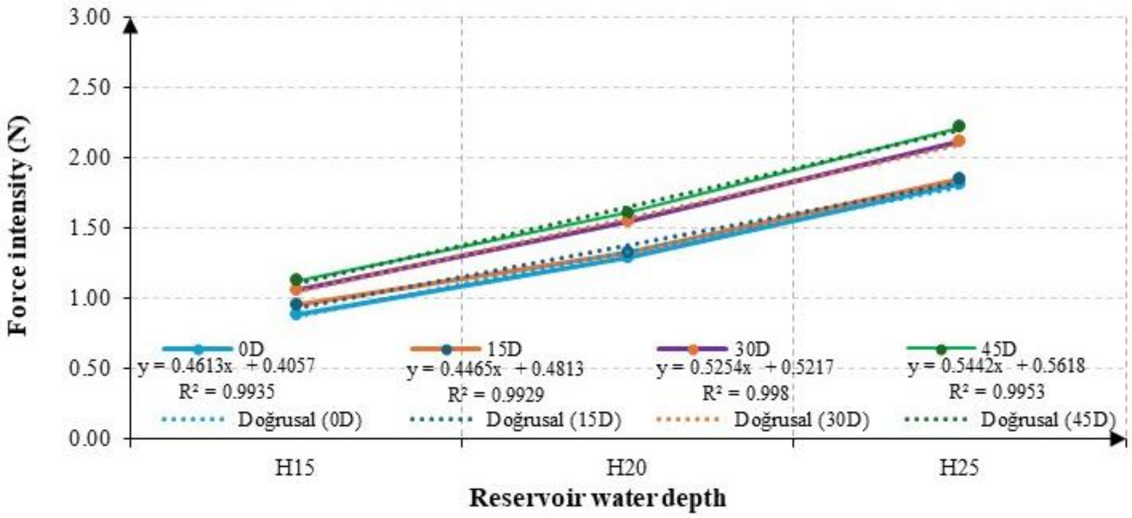

Fig. 9. Variation of force intensity relative to increasing reservoir water depth at the various skew angles

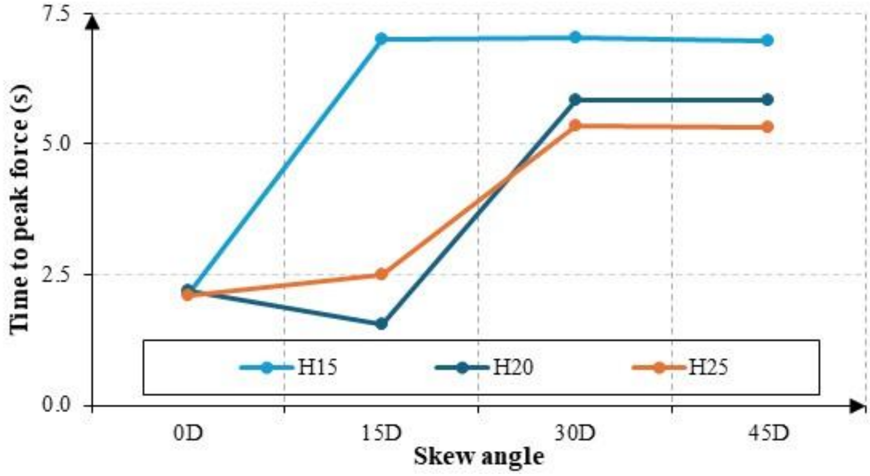

Fig. 10. The effect of skew angle on time to peak force at the various reservoir water depths

3.3. Result of numerical study

Sensitivity analysis was conducted for different mesh combinations for the main channel (1, 0.75 and 0.5 cm) and (0.2, 0.3, 0.4, and 0.5 cm) for the position around the bridge pier (15 cm upstream and downstream of the bridge pier. Based on the result, a 0.75 cm mesh size was adopted for the main channel while a 0.3 cm mesh size was adopted for the position around the bridge pier. This was done in order to model the geometry of the bridge pier more accurately as well as for a more accurate simulation of the fluid - structure interaction.

Similarly, a sensitivity analysis was carried out for the different turbulence closure schemes available in Flow 3D software and *k-w* was adopted for this study to save computational time. The Courant-Friedrichs-Lewy (CFL) time step was adopted, and the simulation time was set at 15 s. for this study. This is because, after 15 s according to the experimental results, the recorded forces were approximately zero.

$$\mathrm{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n} (y_i - \hat{y}_i)^2} \tag{2}$$

Fig. 11 compares the time history of force from experimental data and numerical model for different initial reservoir water depths under the four skew angles studied.

The evolution of the force over time can be seen to have followed a similar trend for all cases, with an initial rapid rise, a peak force phase, and a gradual drop as the flow receded. Nonetheless, some discrepancies were observed between numerical and experimental results, especially in terms of peak force magnitudes and the fluctuations in the peak force phase.

At 0D and 15D, the experimental result showed higher peak force, particularly for higher initial reservoir water depth cases (e.g., 0D_H25_Exp), where the fluctuations in the force were more pronounced. Although, the numerical model captured the general evolution of the force, it underestimated the peak forces.

Although a similar pattern was observed in the case of 30D, the observed divergence has reduced considerably, while at 45D the numerical model results appear to have converged more closely with the experimental data, thereby suggesting that the model performs better at higher skew angles. This suggests that although the numerical model reasonably simulated the impact force induced on the bridge pier by the dam break wave, further refinement may be required in terms of turbulence modeling or resolution in order to improve accuracy, especially for cases of lower skew angles (0D, 15D).

According to Table 2, the maximum RMSE (Equation 2) of 0.682883 were recorded at 15D_H25. In general, the result indicates that the numerical model is capable of replicating the evolution of force over time. Future work may include refining the resolution and application of advanced turbulence models to enhance the model accuracy.

Table 2. Calculated error between the experimental and numerical impact force result under the various conditions studied

Skew angle	RMSE		
	H15	H20	H25
0D	0.166198	0.310647	0.607319
15D	0.285183	0.413287	0.682883
30D	0.183784	0.298102	0.42856
45D	0.127019	0.223247	0.458527

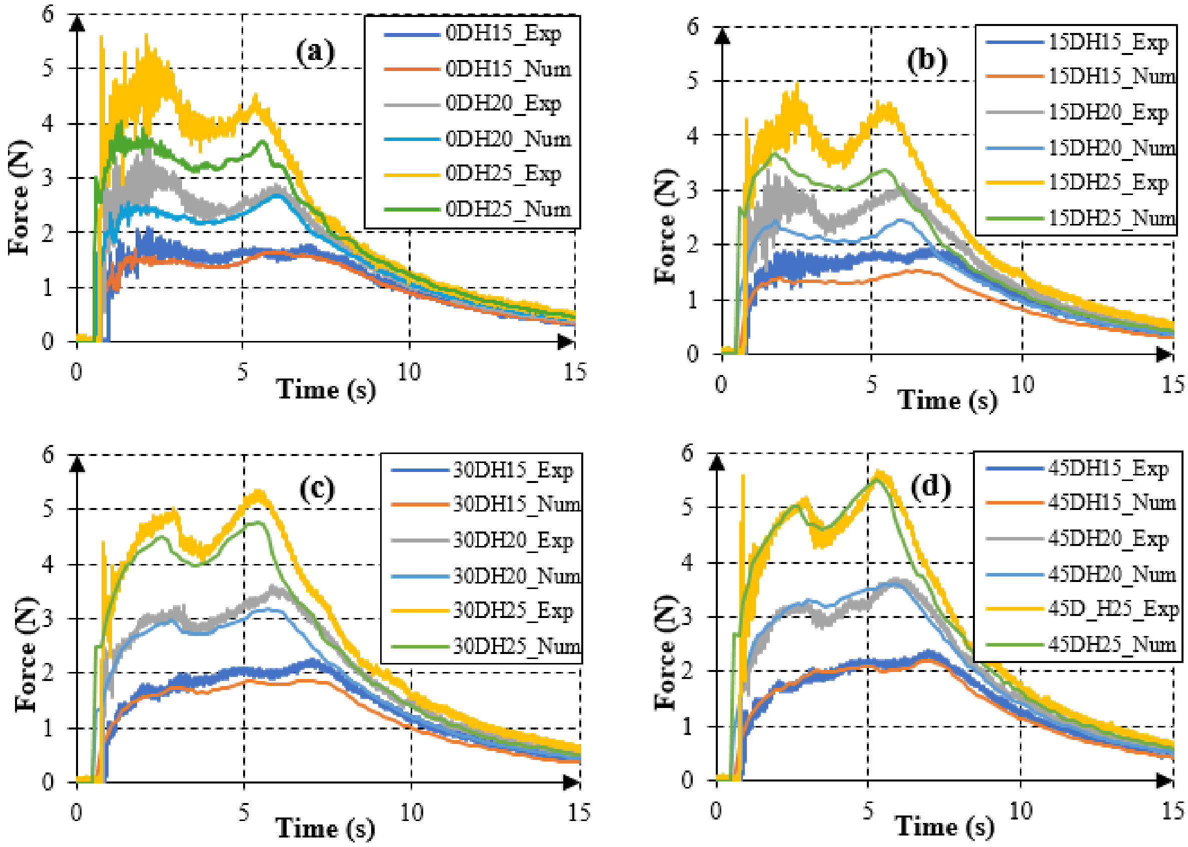

Fig. 11. Comparison of experimental and numerical results of the time history of force for various initial reservoir water depths at: a) 0D b) 15D c) 30D d) 45D skew angles

4. Conclusions

This study investigates the interaction between a dam-break flow and a square bridge pier with different orientations to the flow direction. The study aims to provide an understanding of the relationship between skew angle, flow dynamics, and force distribution, offering valuable insight for the design of bridge piers in dam-break-prone areas. Experimental and numerical studies were conducted and a good agreement between the numerical results and the corresponding experimental data is obtained. The following conclusions can therefore be drawn from this study:

- The rate of increase in flow depth depends on the initial water depth in the reservoir before the occurrence of the dam break. Higher the reservoir water depth, leads to higher the rate of increase in flow depth.
- The time to peak flow depth decreases with increase in reservoir depth and the maximum recorded drop was 31 % between 15D_H15 and 15D_H25. The effect of increasing skew angle also leads to a slight decrease in time to peak flow depth and the maximum in this case was a 10 % drop between 0D_H20 and 30D_H20 reservoir depth. An increase in the initial reservoir water depth results in an increase in the impact force. The highest forces were recorded at H25 in all the cases, while increase in skew angle leads to decrease in the impinging force which is more pronounced at H25.
- In all the cases (H15, H20 and H25), 1.1461, 1.0033 and 1.0062 times the force recorded at 0D were recorded at 45D and the force intensities at 45D, were 26.91 %, 25.02 % and 22.3 % more than the cases at 0D.
- Increasing skew angle delay the time to peak force and maximum of 3.29, 2.67 and 2.52 times the time to peak force at 0D were recorded at 15D, 30D and 45D respectively.
- The numerical model was found to have satisfactorily simulated the evolution of force over time. Nevertheless, future work may include refining the resolution and application of advanced turbulence models to enhance the model accuracy.

An experimental investigation of the effects of discharge height and angle on the dilution characteristics of dense brine effluents

Merve Bedir[1], Büşra Değirmenci[1], Damla Yilmaz Çelik[*1], Egemen Aras[1]

[1] *Bursa Technical University, Department of Civil Engineering, Turkey*

Abstract. Nowadays, the need for drinking water is increasing due to increasing population and industrialisation, which necessitates the search for alternative fresh water resources. Especially the uncertainties created by climate change in the water cycle and the pressures on existing freshwater resources have increased the importance of seawater desalination technologies. Although desalination is an effective method for converting seawater into potable freshwater, the direct discharge of high salt concentration wastewater generated as a result of the treatment process into the sea poses serious environmental risks. Since this concentrated wastewater is heavier than seawater, it settles on the seabed, causing stratification and a decrease in oxygen levels, adversely affecting the life of benthic organisms. Recent studies have focussed on reducing these environmental impacts by improving the performance of marine discharge systems. In particular, the effects of hydraulic parameters such as discharge angle and outlet height on flow propagation and dilution rate are investigated. In this study, 60-second experiments were carried out in a 150×50×60 cm glass-enclosed aquarium in three different configurations (10 cm-45°, 15 cm-45°, 10 cm-0°). Solution monitoring was performed with rhodamine tracer. The results show that the 15 cm high and 45° inclined discharge provides a more even dispersion and rapid dilution. The data obtained provide an important reference for the design of marine discharge systems and minimisation of environmental impacts.

Keywords: Brine discharge; Dilution; Outfall; Tracer; Discharge

1. Introduction

Today, with the rapidly increasing population, urbanisation and industrialisation processes throughout the world, the demand for water is constantly increasing. However, the fact that fresh water resources are limited and often difficult to access is insufficient to meet this increasing demand for water. Approximately 97.5 per cent of the world's total water resources consist of salt water, while only 0.3 per cent of the remaining 2.5 per cent of fresh water is directly usable (UN Water, 2021). This situation increases the importance of alternative water supply methods and desalination technologies, especially the treatment of seawater, come to the fore.

Desalination describes the process of bringing seawater to drinking or potable water quality and is now widely used especially in water-stressed regions such as the Middle East, North Africa, Australia and some Mediterranean countries (Ghaffour et al., 2013). It is reported that as of 2020, approximately 20,000 desalination plants are in operation worldwide and more than 100 million people use water obtained by this method daily (Global Water Intelligence, 2020). Although this process offers a great solution in terms of water supply, the environmental impacts of desalination technologies are too great to be ignored. In particular, the brine obtained from this process can pose a potential threat to marine environments due to its high salt concentration, heavy metals, chemical additives and low dissolved oxygen content (Panagopoulos and Haralambous, 2020; Pramanik et al., 2017). This dense brine is often discharged into the marine environment and inappropriate discharge methods can cause serious damage to marine ecosystems. Direct discharge of dense saline water into the sea can lead to stratification, reduced oxygen transfer and hypoxia, especially in areas with no current or closed sea areas. Such conditions threaten the survival of many marine organisms, especially benthic organisms (Roberts et al., 2010). Furthermore, since the temperature of the brine solution is usually above ambient temperature, thermal pollution creates an additional stress factor (Lattemann & Höpner, 2008). At this point, the conditions under which dense brine is discharged into the marine environment - in particular discharge height, outlet angle, flow rate and direction - stand out as physical parameters that directly determine the severity of these environmental impacts. Various studies in the literature show that by optimising these parameters, it is possible to spread the dense brine over larger areas and thus dilute it in a shorter time (Najafi & Ghazizadeh Hashemi, 2016). In particular, it is stated that sloping and medium-height discharge systems produce more effective results than vertical or horizontal discharge systems. Mixing and

https://doi.org/10.31462/icearc2025_ce_hyd_570

dilution processes in the marine environment are critical for reducing the environmental impacts of concentrated saline water. This dilution not only reduces the salinity level, but also enables the recovery of dissolved oxygen and stabilisation of temperature differences. Therefore, in the design of desalination plants, not only the water treatment efficiency but also the environmental compatibility of the discharge systems should be considered (Giwa et al., 2017).

This study aims to investigate the effects of different height and angle combinations on the spreading behaviour of dense brine through experimental studies conducted in a laboratory environment. In this context, it is aimed to create environmentally friendly systems by optimising mixing behaviour with water, discharge point design and physical parameters. The results of the study aim to contribute to engineering solutions to reduce the environmental impacts caused by dense brine.

2. Material and methods

In this study, the flow behaviour and dilution characteristics of a dense brine discharge with different elevation and angle combinations were observed in the laboratory. The experiments were carried out in a 150 cm long, 50 cm wide and 60 cm high experimental tank (aquarium) covered with glass on four sides. Thanks to the glass surface, the three-dimensional development of the flow could be observed from all angles and analysed in detail with video recordings.

The concentrated brine solution used in the experiments was prepared by adding 150 grams of sodium chloride (NaCl) and 0.15 grams of rhodamine B to 1 litre of deionised water. NaCl in this solution aimed to mimic the marine environment by increasing the density of the liquid, while rhodamine B served as a trace substance. Rhodamine was preferred because it provides high optical contrast even at low concentrations. The behaviour of the solution during the flow was qualitatively monitored by the colour changes provided by rhodamine.

The prepared brine solution was introduced into the experimental tank at constant flow rate by means of a peristaltic pump. Using a transparent hose with an internal diameter of 5 mm, the solution was discharged into the tank at three different outlet height and angle combinations. The pump outlet flow rate was fixed at 460 mL/min and each experiment was carried out continuously for 60 seconds. The equipment used during the experiments and their specifications are presented in the table below.

Table 1. Experimental equipment

Equipment / Material	Features
Aquarium	150 cm × 50 cm × 60 cm, glass
Dense saline solution	1 L deionised water + 150 g NaCl + 0.15 g rhodamine
Discharge system	Peristaltic pump
Hose	Transparent, 5 mm inner diameter
Camera	1080p, 60fps, stabilised

In each experiment, the outlet pipe was placed in the tank at different combinations of elevation and angle and flow was maintained at constant flow rate for a certain period of time. Three different experimental scenarios were determined as follows:

Table 2. Experiments

Experiment No	Elevation (cm)	Discharge Angles
1	10	45° inclined
2		0° horizontal
3	15	45° inclined

For imaging, a camera capable of recording at 60 fps and 1080p resolution was fixed outside the tank with a tripod. The camera remained in a fixed position throughout the experiment and recorded each flow behaviour with high resolution. The images were taken time-dependently throughout the experiment, so that the development of the flow was analysed second by second.

The colour changes of the rhodamine during its diffusion in the tank were carefully monitored; the initial bright red colour of the solution changed to lighter tones over time, providing qualitative information on the degree of dilution and mixing. The time for the flow to reach the bottom, the post-impact propagation and the mixing behaviour in the tank were evaluated both by visual analysis and colour intensity changes.

For each experimental condition, a fixed reference point in the tank was set and the colour change and the behaviour of the streamlines at this point were recorded. The evaluations were concentrated in the region closest to the camera and in the centre line of the tank. In particular, image frames from the 10th, 30th and 50th seconds of the experiments were compared to investigate the rate of progression, stratification tendency and spreading pattern of the mixture.

The experiments were conducted under constant illumination and temperature conditions and repeated at least three times for each configuration to ensure the reliability of the experimental data. With repeated observations, care was taken to maintain consistency between experiments and the general validity of the findings was increased. As a result, the data obtained in this methodological framework provided the opportunity to directly observe the effect of different height and angle combinations on flow propagation. In particular, it was observed that the flow reached the bottom in a shorter time and spread more uniformly in discharges with sloping outlets, while in horizontal discharges, the solution remained in the middle levels for a longer time and vertical mixing was limited. These observations will provide important contributions to future environmental modelling studies and the development of desalination discharge strategies.

3. Results and discussion

Within the scope of laboratory scale experimental studies, the effect of discharging dense brine at different height and slope (angle) conditions on the mixing behaviour was analysed in detail. During the experiments, three different configurations of discharges were performed and the results showed that the mixing process is highly sensitive not only to the solution properties but also to the physical conditions of the discharge. In this context, the dispersion patterns under each experimental scenario were evaluated in terms of changes in colour intensity and observed flow characteristics, and meaningful interpretations were made in the light of the visual records and experimental observations.

3.1. 10 cm elevation and 45° slope

In the first experimental scenario, the discharge from a height of 10 cm and with a 45° inclination gave the most successful results in terms of continuity of mixing and even dispersion. In this experiment, a dense brine solution coloured with rhodamine dye was released into the aquarium tank at a constant flow rate. It was observed that the flow reached the bottom of the tank in about four seconds; when it reached the bottom region, it formed a thin layer and started to spread in the horizontal plane. A homogeneous decrease in colour intensity was observed throughout the experiment, indicating that the solution and ambient water were successfully mixed over time and a regular dilution was achieved in the vertical-vertical direction.

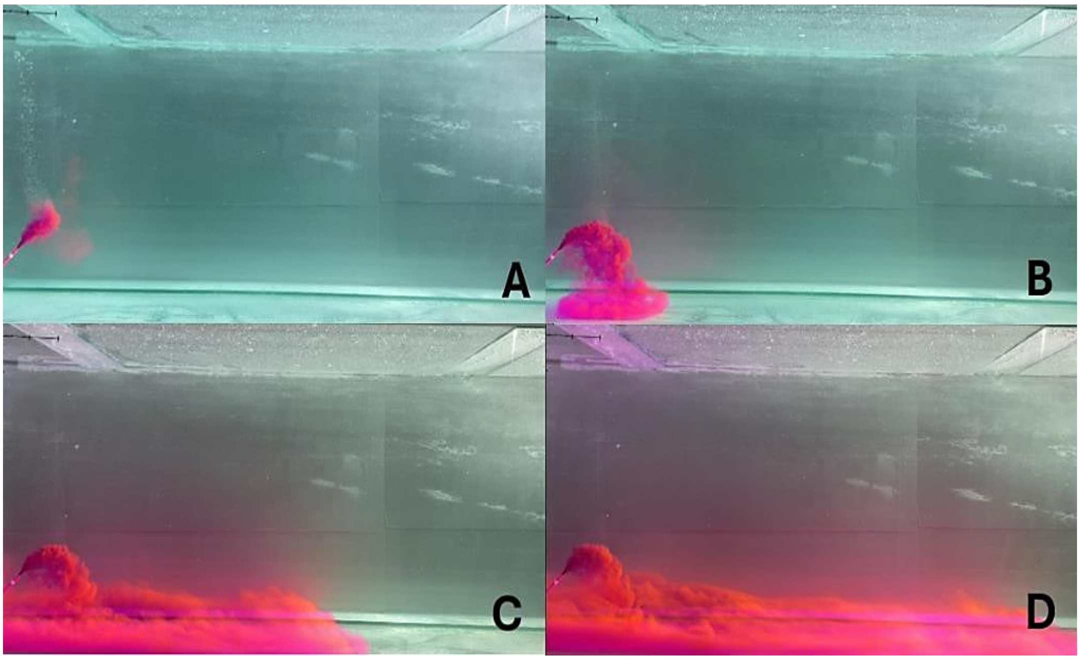

Fig. 1. Discharge configuration of 10 cm height and 45° angle

The sequential images illustrate the temporal progression of the dense rhodamine-brine jet released into the static ambient water during Experiment 1. In frame (A), the initial jet enters the water column with a downward trajectory influenced by the combination of outlet height (10 cm) and an inclined release angle (45°). Due to the higher density of the brine solution, the jet sinks rapidly while maintaining a coherent structure, indicating limited initial mixing and a strong momentum-driven flow.

In frame (B), the jet reaches the bottom of the tank, where the vertical momentum begins to dissipate. Upon impact with the tank floor, the plume starts to spread horizontally, forming a gravity current along the bottom boundary layer. This behavior is characteristic of negatively buoyant jets, which exhibit bottom-following propagation due to density stratification.

Frame (C) demonstrates an intermediate stage where ambient entrainment becomes more significant. The rhodamine dye begins to exhibit a lighter coloration, indicating the onset of dilution and mixing with the surrounding freshwater. The flow transitions into a more turbulent regime, where instabilities at the plume boundary enhance the lateral and vertical dispersion.

Finally, in frame (D), the plume has spread extensively throughout the tank. The diminished dye concentration and uniform coloration indicate substantial dilution and near-homogeneous mixing. At this stage, the stratification effect has weakened, and the brine solution has approached equilibrium with the ambient conditions, signifying effective dispersion under the applied discharge configuration.

3.2. 15 cm elevation and 45° slope

In the second experimental setup, where the brine solution was discharged from a height of 15 cm at a 45° angle, the increased initial momentum significantly influenced the hydrodynamic behavior of the flow. The images presented in Fig. 2 capture the temporal evolution of the plume during the discharge process.

In frame (A), the high discharge velocity resulting from increased free-fall height generates a compact and coherent plume structure as the brine rapidly descends toward the bottom. This behavior reflects a strong momentum-dominated flow with limited entrainment at the initial stage.

Upon impingement with the bottom boundary (frame B), pronounced turbulence and secondary flow structures emerge due to the high impact energy. The spreading pattern becomes more chaotic compared to the first experiment, and the formation of vortices is visually evident. At this point, the brine begins to propagate radially along the tank floor, initiating a bottom-driven mixing process.

Frame (C), captured approximately 30 seconds into the experiment, reveals non-uniform dilution dynamics. In some regions, the rhodamine dye fades quickly due to localized mixing, while in others the brine concentration remains high. These spatial inconsistencies are indicative of fluctuating turbulence intensity and uneven entrainment of ambient water, suggesting that elevated discharge height may compromise mixing uniformity despite promoting faster dispersion.

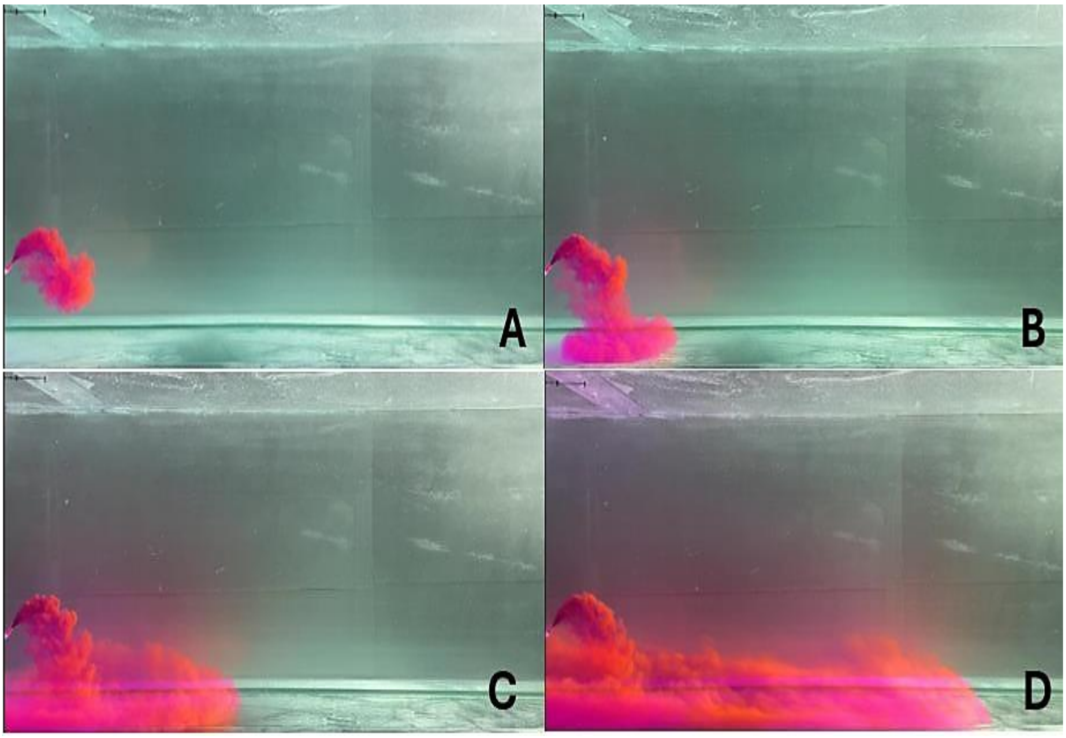

Fig. 2. Discharge configuration of 15 cm height and 45° angle

By frame (D), taken at around 50 seconds, the plume has spread across a large portion of the tank. Although substantial dilution has occurred, the persistence of visible density gradients and wavy color transitions highlights that complete homogenization has not yet been achieved. The observed stratification patterns and mixing asymmetries emphasize the role of discharge momentum in shaping both the efficiency and spatial characteristics of brine dispersion.

3.2. 10 cm elevation and 0° Horizontal Discharge

In the third experimental configuration, the dense brine was discharged horizontally at a height of 10 cm with a 0° inclination angle. This setup resulted in a plume trajectory that was predominantly confined to mid-depth levels of the tank, with minimal vertical dispersion. As illustrated in Fig. 3, the spatial distribution of the rhodamine-brine mixture reveals distinct stratification characteristics and limited mixing efficiency.

In frame (A), the horizontally discharged plume begins to propagate along the central axis of the water column, maintaining a focused and relatively undisturbed trajectory due to the absence of a vertical momentum component. This is consistent with typical behavior observed in horizontally oriented dense jets in quiescent environments.

At 10 seconds into the experiment (frame B), a clearly defined, dense layer of colored solution forms at mid-depth, indicating a high degree of lateral coherence and a lack of downward entrainment. The flow maintains its elevation, and interaction with both the surface and bottom boundaries remains negligible.

Frame (C), captured at 30 seconds, shows that the lateral expansion continues within a narrow vertical band, reinforcing the presence of a stratified flow regime. The color gradients remain sharp, and no significant plume deflection or downward penetration is observed, suggesting strong stability of the layered structure.

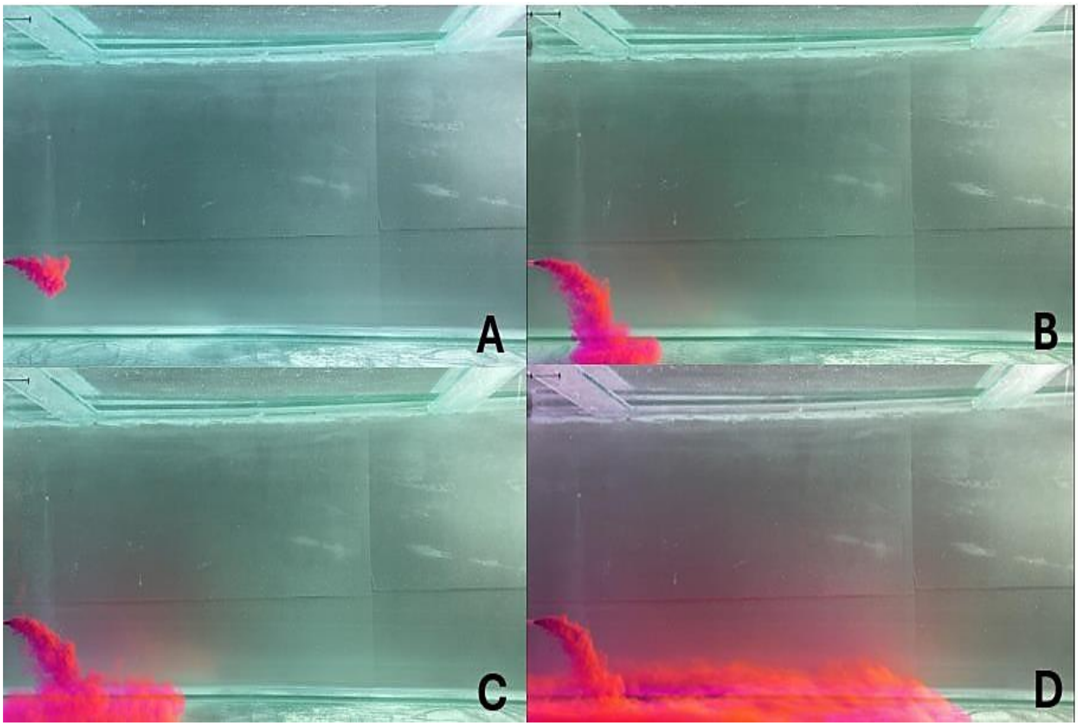

Fig.3. Discharge configuration of 10 cm height and 0° angle

By the end of the experiment (frame D, ~50 seconds), the brine remains concentrated in the upper-to-mid layers of the tank. Vertical mixing is still minimal, and a substantial portion of the tank volume remains unaffected by the brine discharge. This confirms that horizontal release conditions promote stratification and restrict full-volume mixing, a scenario which may lead to persistent high-salinity zones in real-world applications if not properly managed.

Overall, comparative evaluation of the three experiments demonstrates that a discharge configuration involving moderate elevation and inclined angle (e.g., 10–15 cm at 45°) is more favorable for achieving uniform mixing and reducing the environmental impact of dense brine. In contrast, horizontal discharges—even at moderate heights—tend to confine the brine within limited vertical regions, thus increasing the risk of localized salinity accumulation and ecological stress.

4. Conclusions and recommendations

This study, the dispersion and dilution behaviours of dense brine discharged into a stagnant freshwater environment under different height and angle conditions were experimentally investigated and the findings contributed to the determination of appropriate discharge strategies to reduce environmental impacts. The experiments were carried out in a transparent tank set up in the laboratory and the mixing dynamics of the dense saline solution were observed under different combinations of height (10 cm and 15 cm) and angle (0° and 45°).

The results obtained show that the discharge height and angle have a direct effect on the mixing efficiency. Especially at a discharge height of 10 cm and an angle of 45°, the brine solution mixed rapidly and uniformly with the ambient water, resulting in an almost homogeneous concentration profile throughout the experiment. This configuration was the most stable in terms of mixing and the most environmentally favourable option. On the other hand, when discharging at the same angle but from a height of 15 cm, the solution reached the bottom of the tank at a higher velocity, resulting in wavy, irregular mixing patterns in the bottom region. This irregularity caused the flow to concentrate more in the lower regions due to the higher solution density, resulting in undesirable density stratification. On the other hand, in the 0° (horizontal) angle discharge, the solution was mostly spread in the middle levels of the tank and mixing in the vertical direction was limited. This indicates an inadequate dispersion pattern in terms of dilution. In general, it was observed that discharging with a certain slope and from a moderate height allowed for more homogeneous and balanced mixing. This finding constitutes an important reference for determining the optimum conditions both in experimental systems and in real environmental discharge applications. Therefore, careful selection of discharge height and angle in the design of wastewater discharge systems is of great importance in terms of both increasing mixing efficiency and reducing environmental impacts. This study also contributes to the literature in terms of providing experimental data to provide a basis for advanced hydrodynamic modelling and field applications

Abstract. The study aims to investigate the aerodynamic behavior of different spoiler configurations in offshore pipelines to further explore the fluid dynamics surrounding subsea structures. The research investigates the influence of spoiler geometry on aerodynamic drag, wake behavior, and vortex shedding by performing computational fluid dynamics (CFD) combined with the Reynolds-averaged Navier-Stokes (RANS) equations and the Shear Stress Transport (SST) k-ω turbulence model via ANSYS Fluent. Rectangular shape spoiler was analyzed and compared against the baseline configuration. Regarding the numerical outputs, drag coefficient (C_D), pressure distributions, velocity contours, turbulent kinetic energy (TKE), and eddy viscosities were investigated in detail. The results highlighted that spoiler geometry profoundly affects the flow regime, significantly altering the friction coefficients and turbulence characteristics. Intermediate effects were observed for Type-1 spoilers, exhibiting a complex interaction between spoiler geometry and wake dynamics. These observations are valuable to enhance the design of pipeline spoilers with respect to both structural integrity and sediment matters

Keywords: Circular cylinder; Numerical simulation; Drag coefficient; Spoiler

1. Introduction

Offshore pipelines are crucial for oil and gas transportation, but they also introduce the generation of complex flow-induced phenomena due to their cylindrical shape and seabed and current interaction. Understanding the flow characteristics around cylindrical elements (such as pipelines) is essential for ensuring structural stability and preventing damage from hydrodynamic forces. Flow separation around a cylinder and associated vortex shedding when the pipeline is on or near the seabed cause substantial drag and lift forces, as well as oscillatory vortex-induced vibrations (VIV) leading to fatigue failures (Zhu et al., 2013). Flow can also affect erosion of the sediment around the pipe (local scour), generating spanning sections (free spans) for further exacerbation of VIV and stress on the pipeline. Conventionally, pipelines have been buried below the seabed to avoid these problems; however, trenching and backfilling are costly. To solve the economic problem, an effort has been made for research on the self-burial procedure, whereby the pipeline self-induces its burial because of scour. An important technique to facilitate self-burial is to put a small fin or spoiler on top of the pipeline. The spoilage effects contribute to more blockage to the flow, resulting in turbulence and sediment transport around the pipe faster so that the sediment gets eroded beneath and downstream of the pipeline (Zhu et al., 2013). Hulsbergen's early experiments showed that a pipeline fitted with a spoiler was able to bury itself around ten times faster than an unspoiled smooth pipe (Hulsbergen, 1986). Further studies went on to establish that spoilers increase both the tunnel scour underneath the pipe downstream thereby hastening the formation of scour holes and sand deposition inundating the pipe (Zhu et al., 2013).

In addition to inducing burial, spoilers also strongly affect the hydrodynamics around the cylinder. A spoiler protruding into the flow brings about early flow separation and a larger wake that tends to increase the drag on the cylinder and may also generate a downward lift (negative lift) due to the asymmetric pressure distribution. These effects concern not only scour but structural loadings and vibrations on the pipeline as well. In the past 10 years, different researchers have used numerical and experimental techniques to determine the effects of spoilers on flow patterns, vortex shedding, and force coefficients on cylindrical structures. Spoiler attachments have even been studied as passive flow control mechanisms to mitigate VIV or vortex-induced motion of cylinders (İlkentapar et al., 2023). At the same time, marine pipelines are often deployed in arrays or multiple configurations (e.g., dual

[*] Corresponding author, E-mail: kemal.koca@agu.edu.tr

https://doi.org/10.31462/icearc2025_ce_hyd_605

pipelines, pipe-with-piggyback cable, or clusters) rather than in complete isolation. Similar flow interference phenomena (wake shielding or shear layer reattachment) develop when two or more cylinders are found in close proximity significantly differing from single-cylinder behavior. Classical studies show that the relative positioning, such as tandem, side by side, staggered, determines the flow regime between the cylinders (Dehkordi et al., 2011). For instance, if two cylinders are placed in a tandem arrangement, then these two cylinders will experience different flow regimes depending on the separation distance: at very close spacing, the downstream cylinder may be in close wake of the upstream cylinder and therefore experience reduced flow velocity; at moderate spacing, the shear layers of the upstream cylinder may reattach to the surface of the downstream cylinder; and beyond certain inter-cylinder spacing, the upstream cylinder sheds vortices impinging on the downstream cylinder (İlkentapar et al., 2023). Accordingly, the interference effects vary between pipeline bundles and single pipes as far as force distribution and scour modes are concerned. Therefore, in offshore applications, it is vital to understand the combined effect of spoiler and cylinder interference on the flow characteristics.

2. Literature review

2.1. Flow around single cylinders with and without spoilers

Flow past a single circular cylinder has been a classic research topic in fluid mechanics, and extensive literature exists characterizing its behavior without any modifications. A smooth circular cylinder in cross-flow develops boundary layers that separate forming a von Kármán vortex street in the wake, associated with fluctuating lift forces and a drag coefficient on the order of 1.0 in subcritical Reynolds number regimes (İlkentapar et al., 2023) The presence of a nearby plane boundary (as in the case of a pipeline near the seabed) can modify this canonical flow. Early experiments by Bearman and Zdravkovich showed that a cylinder close to a plane wall experiences suppressed vortex shedding and altered pressure distribution due to the wall's influence, which in turn affects drag and lift (Bearman & Zdravkovich, 1978). More recently, numerical simulations by Kirkgoz et al. (2009) showed that even a small gap between a cylinder and a rigid bed (e.g., gap ratio $G/D = 0.3$) can cause asymmetry in the wake. This confirms that this can reduce the intensity of vortex shedding, but a near-thin-wall mesh resolution is required for accurate prediction. These studies highlight that the base flow around a pipeline (without a spoiler) can vary significantly depending on the proximity to the seabed.

When a spoiler is attached to the cylinder (typically a small plate or cylindrical rib mounted at the top of the pipe), the characteristics of flow alter drastically. The spoiler effectively induces flow separation earlier on the upper surface of the pipe, creating a larger recirculation region in the wake. There are numerous experimental studies in literature on this subject. İlkentapar et al. (2023) clarified that adding a spoiler to a cylinder in crossflow produces a pronounced low-pressure region in the near wake, which increases the average drag force compared to a smooth cylinder. They also observed that the spoiler produces a constant downward lift force on the cylinder which is opposite to upward lift force that would occur near the wall in a smooth cylinder (İlkentapar et al., 2023). This reversal of the lift is desirable for pipeline stability since an upward lift would tend to destabilize the pipe or reduce its width. Moreover, they reported that the spoiler modifies the vortex-shedding properties, which can influence vortex-induced vibration tendencies.

2.2. Effect of spoiler geometry

The spoiler performance relative to flow and scour changes according to various parameters, such as geometrical configurations and material parameters of the spoiler. One key parameter is the spoiler height (S) relative to the pipe diameter D. Higher spoiler stands out more into the flow, normally giving larger wake disturbance and separation bubble. As mentioned, Zhu et al. (2013) demonstrated a clear trend of increasing S/D from 0 (no spoiler) to 0.35 that precipitated more rapid self-burial of the pipe. The tallest spoiler increased flow acceleration at the pipe–bed gap and generated stronger vortices in their simulations, which facilitated sediment self-removal. However, very large spoilers may also impose significant drag forces for an actual design, there is probably an optimal height that balances scour benefits with structural loads. Zhao and Wang (2009) observed that there is a point at which adding a spoiler has little effect on bed shear stress, suggesting that beyond a certain point spoiler size results in diminishing returns. Another factor is spoiler length (spanwise extent): Bianchi et al. (2020) examined a low-aspect-ratio cylinder with a relatively short spoiler plate and modified the spoiler geometry. They observed that the spoiler would need to span sufficiently and extend sufficiently into the flow to effectively suppress vortex-induced motions. Shorter, shallower spoilers may be bypassed by the flow with minimum disruption to the vortex shedding. Hence, geometry optimizations (height, chord length if plate-like and span) are featured in several recent numerical parametric investigations.

3. Methodology

3.1. Mesh generation

In this study, a structured quadrilateral mesh structure was preferred using ANSYS FLUENT software for the measurement analysis of the effects of spoiler use on aerodynamic performance. As seen in Figure 4, the mesh was created to include an increasing number of layers (inflation) near the surface. The main reason for this is to ensure that the boundary layer behavior near the wall is correctly resolved and to obtain a representation closer to the real fluid profiles instead of the wall functions. In this way, the accuracy of the results is increased by providing sufficient y+ resolution. As stated in the literature, quadrilateral meshes provide low numerical diffusion, faster convergence, fewer element numbers and shorter solution time with more regular cell structures compared to triangular meshes (Lo, 2013). In addition, the proper alignment of quadrilateral cells, low curvature and orthogonality, especially in meshes parallel to the flow direction, contribute to more accurate capture of sharp gradients (Ye et al., 2023; Zhao et al., 2013).

In order to ensure that the numerical results are independent of the node number, 7 different node numbers were selected to conduct mesh independence tests on the pipe without spoilers and the change in the drag coefficient (C_D) with the change in the node number was examined. The mesh number, node number C_D values and percentage changes are given in Table 1. The change rate was 0.87 percent in the last case as seen in Figure 1. This rate shows that the results of our study are independent of the node number. However, for the convenience of calculation, the number 360000 was used as the mesh number.

Table 1. Comparison of drag coefficient (C_D) values obtained from different mesh numbers

Mesh	Mesh Number	Node Number	C_D	Error
1	1260000	1262600	1.844	0.87
2	360000	361400	1.86	-7.05%
3	216250	217325	1.72887	4.39%
4	150000	150900	1.804746	10.23%
5	111250	112025	1.98946	4.16%
6	93900	94610	2.0722	5.68%
7	25000	25375	2.19	--

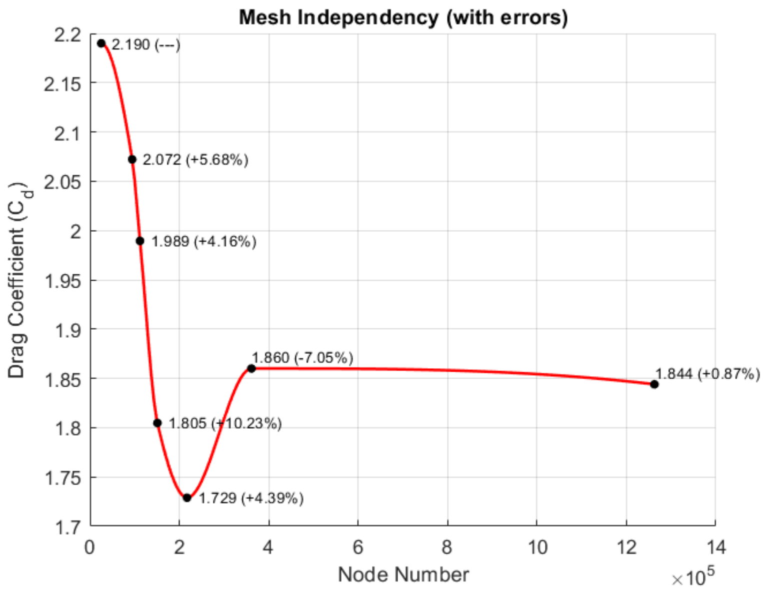

Fig. 1. Mesh independency results

3.2. Turbulence model selection

All simulations were conducted under two-dimensional. incompressible. and unsteady flow conditions. The governing equations consist of the continuity and momentum equations. along with the Reynold-Averaged Navier Stokes (RANS) coupled with the Shear Stress Transport (SST) k-ω turbulence model. The governing equations. including the continuity and momentum equations. are formulated as shown in equations 1 and 2. where a turbulence closure method based on the Boussinesq approximation is adopted Shi et al. (Shi et al. 2021)

$$\frac{\partial \bar{u}_i}{\partial t} + \bar{u}_j \frac{\partial \bar{u}_i}{\partial x_j} = -\frac{1}{\rho_f}\frac{\partial p}{\partial x_i} + \nu_f \frac{\partial^2 \bar{u}_i}{\partial x_j \partial x_j} - \frac{\partial}{\partial x_j}\left(\overline{u_i' u_j'}\right) \tag{1}$$

$$\frac{\partial \bar{u}_i}{\partial x_i} = 0 \tag{2}$$

Where $\bar{u}_i.\bar{u}_j$ are the time-averaged velocity components; u_i' and u_j' are the fluctuating components; x_i and x_j are spatial coordinates; ρ_f is the fluid density; p is pressure. and ν_f is the kinematic viscosity of the fluid. No slip boundary condition at the pipeline wall is considered in this study. Correspondingly. the velocity will be zero in the vicinity of this region. Ordinarily. for steady flow. since the flow is independent of the time parameter. the $\partial \bar{u}_i / \partial t$ term in equation (1) drops out. However. since the analysis was unsteady. this term should also be retained. Moreover. the Bousinesq hypothesis. which associates the Reynold stresses to the mean velocity gradients. are implemented in this study and expressed as:

$$-\overline{u_i' u_j'} = v_t\left(\frac{\partial \bar{u}_i}{\partial x_j} \frac{+\partial \bar{u}_j}{\partial x_i}\right) - \frac{2}{3} k \delta_{ij} \tag{3}$$

Where δ_{ij} is the Kronecker. equal to 1 when i = j and 0 otherwise. The term k is turbulent kinetic energy and v_t denotes the turbulent (eddy) viscosity (Shi et al. 2021). This approach makes computation less time-consuming since only two additional transport equations need to be solved. By the inclusion of these two equations. turbulence parameters such as specific dissipation rate. ω (or turbulence dissipation rate. ε) and the turbulent kinetic energy. k are resolved. Subsequently. turbulent viscosity (v_t) is computed as a function of these parameters (Elshawarby. 2020).

There also exists a more advanced hypothesis called Reynold Stress Model (RSM) that could be a resort when a more chaotic turbulence system is the case. This model contains seven transport equations which account for their accuracy in the modelling of these turbulence systems. However. these systems are computationally expensive. For this reason. in this study. the Bousinesq approach has been taken (Elshawarby. 2020).

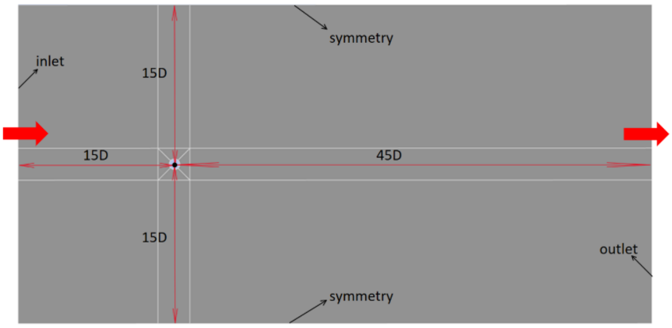

Fig. 2. The schematic of the flow domain and the boundary conditions

The rectangular flow. including the embedded submarine pipe of diameter. D=50 mm without spoiler inside. which is utilized in simulations. is schematized as shown in Figure 2. The length and width of this domain is specified as 50D and 30D. respectively from the center of the cylindrical section of the pipeline. In addition. the lengths of the upstream and downstream regions are regarded as 15D and 45D from the center respectively. This flow domain remains the same regardless of the spoiler types to appropriately realize how the characteristics of the flow and the parameters of interests are affected by geometrical variations. The gap effect which arises due to the region between the pipeline and the seabed is not the scope of this study. Other types of spoilers used with the domain for the analysis are shown in Figure 3.

Fig. 3. Sketches of the cylindrical pipe with and without spoiler

For all computational domains. two-dimensional quadrilateral elements are preferred to capture the von-Karman vortexes after separation more accurately. The meshed computational domain for the cylindrical pipeline without spoiler is depicted in Figure 4. Since near-wall effects are also considered for simulations. the surface mesh cells are refined while advancing nearer the surface. On the other hand. moving further from the surface. the mesh was gradually coarsened which substantially decreased the computational time without sacrificing from the accuracy of the expected results.

The height of the first layer was calculated using eq 4.1 to 4.4 to satisfy the condition of y^+ smaller than unity for a Reynolds number of $1.4x10^4$

$$y^+ = \frac{u_\tau \Delta y_1 \rho}{\mu} \tag{4.1}$$

$$u_\tau = \sqrt{\frac{\tau_w}{\rho}} \tag{4.2}$$

$$\tau_w = \frac{1}{2} c_f * \rho * u^2 \tag{4.3}$$

$$c_f = \frac{0.058}{R_e^{0.2}} \tag{4.4}$$

Freestream velocity of 5 m/s. air density of 1.225 kg/m^3 and dynamic viscosity of $2.1875x10^{-5}$ $kg/m * s$ were implemented as input variables for the simulations. Subsequently. the first layer thickness was found to be $4.5x10^{-5}$.

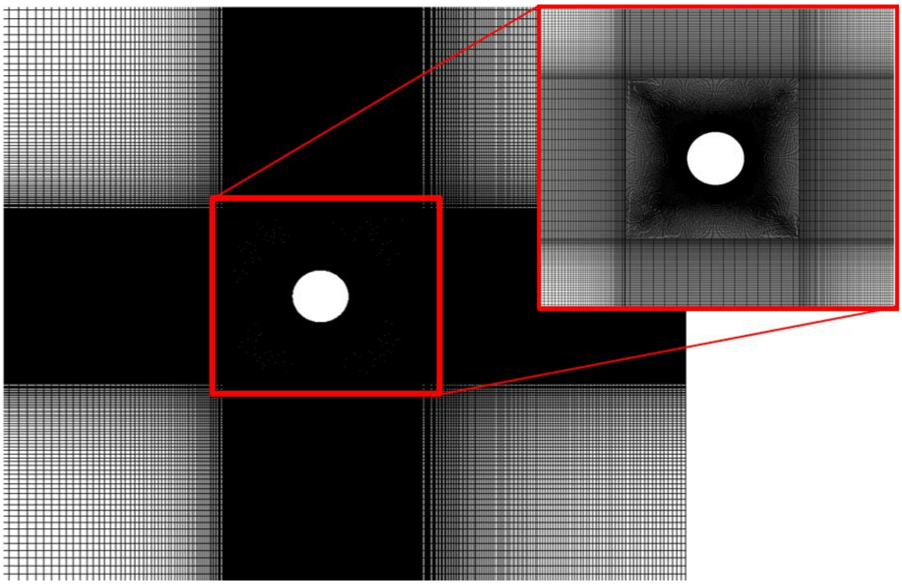

Fig. 4. The structured mesh used in the analysis for the pipeline without spoiler. Number of layers are increased near and in the vicinity of the surface.

Commercial computational fluid dynamics solver package. Ansys Fluent 2023 R1. was preferred to simulate the turbulent flow around and downstream of cylindrical seabed pipeline with and without spoiler in this study. Since Von Kármán vortex shedding. characterized by time-dependent oscillatory behavior. develops downstream of cylindrical bluff bodies. a transient solver was adopted. The coupling of Pressure–velocity was handled by using the SIMPLEC algorithm. while second-order upwind schemes were applied for spatial discretization and a second-order implicit method was used for time integration. This approach enables accurate prediction of unsteady vortex dynamics. which cannot be captured effectively by steady-state simulations. All the simulations were performed under 600 steps. each having a maximum 50 iterations. The time increments were fixed as 0.001 s throughout. The residual errors for the convergence criteria were kept on the order of 10^{-6}.

4. Results & discussion

To evaluate the precision of numerical data. the study conducted by (İlkentapar et al., 2023) was paid attention as a criterion. The rate of change between the two studies is shown at a Reynolds number of 1.4×10^4 in Table 2. The rate of change in the configuration without spoiler was 7.9%. while the rate of change between the configurations with Type-1 spoiler was 1.06%. These differences are within acceptable limits for CFD studies. where differences below 10% are generally considered reliable (Calautit et al. 2015). (Chaudry et al. 2015). The remarkably low difference (1.06%) observed in the Type-1 spoiler configuration indicates strong consistency with previously validated data. Consequently. the numerical results of this study can be considered reliable and thus provide a reliable validation of the numerical model used.

Table 2. C_D values obtained with different spoiler configurations

Type of spoiler	Experimental C_D values (İlkentapar et al.. 2023)	Numerical C_D values	Percentage Change
Without spoiler	1.73	1.867	7.9%
Type-1	1.89	1.87	1.06%

The drag coefficient results for the non-spoiler and spoiler configurations. as well as the percentages of change compared to the control case. are presented in Table 3. The drag coefficient (C_D) value of the control case is determined to be 1.867. Regarding the spoiler designs. it was observed that the drag coefficient values of Type-1 C_D = 1.87 closely approximate the control case.

Table 3. C_D values obtained with different spoiler configurations

Type of spoiler	C_D	Percentage Change
Type-1	1.87	0.2%

The counters of TKE. static pressure. eddy viscosity and velocity of cylinder with and without spoiler cases were illustrated in Fig. 5 and Fig. 6.

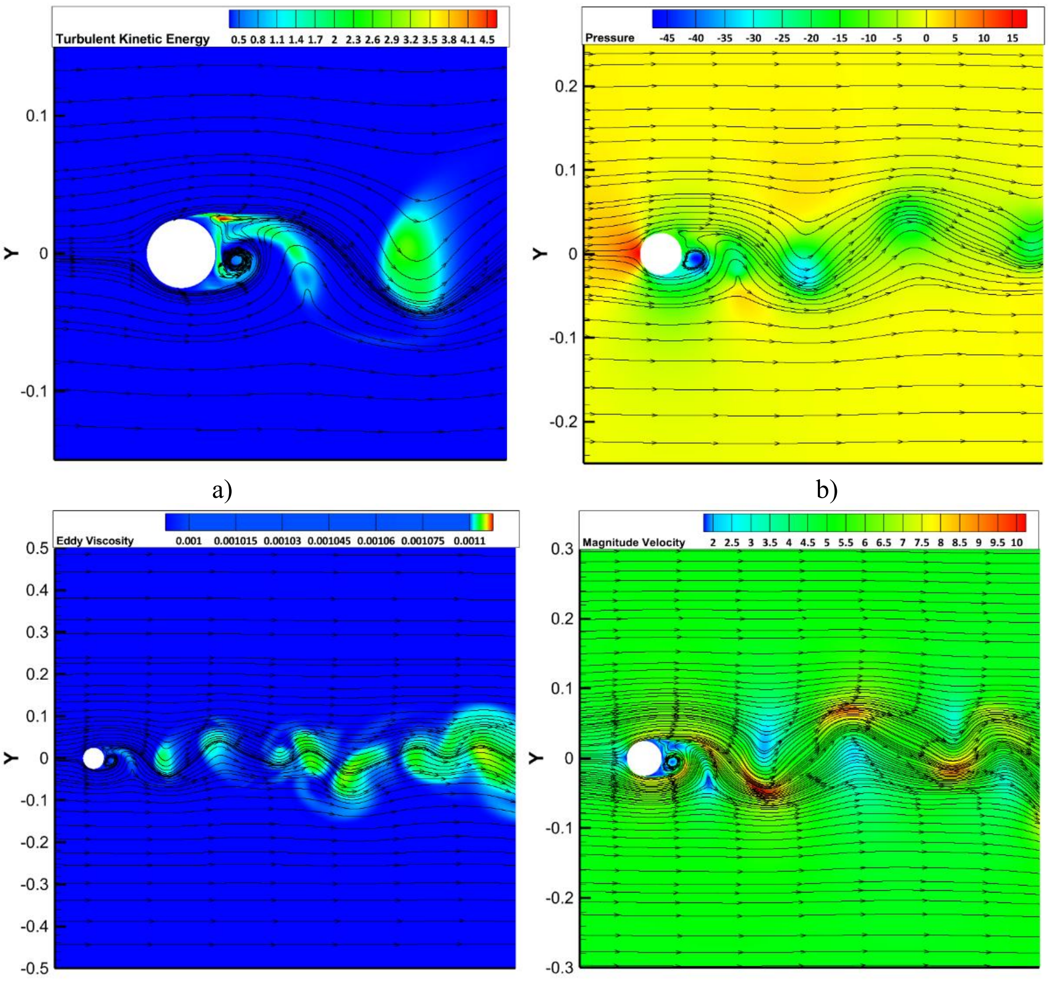

Fig. 5. Contours for cylinder without spoiler; a) *Turbulent Kinetic Energy. b) Static pressure c) Eddy viscosity. d) Velocity*

In the baseline configuration. the flow separates sharply from the rear. generating a broad. unsteady wake resembling bluff-body characteristics. The velocity contour for the no-spoiler case displays a substantial low-velocity region extending posterior to the pipe. suggesting the presence of a considerable separated wake. Correspondingly. the pressure contour reveals an expansive low-pressure zone at the back of the base line case. This low-pressure wake causes significant pressure drag. as the pressure difference between the front (high pressure) and rear (low pressure) is large. The turbulent kinetic energy (TKE) and eddy viscosity contours in the baseline case show high values in the shear layers detaching from the upper surface and sides. indicating strong vortex shedding activity. This suggests an unsteady von Kármán vortex street in the wake. with alternating vortices shedding from the case's trailing edges. Such vortex shedding maintains the low-pressure wake and broadens the wake region. According to Son and Çetiner (2016). a wider wake is associated with higher pressure drag. In summary. the no-spoiler configuration experiences substantial drag because the flow separates cleanly off the rear end. creating a large. turbulent wake with low pressure recovery.

Compared to the base cylinder without spoiler. the Type-1 configuration causes a negligible change in the flow behaviour. The drag coefficient (C_D) increases slightly from 1.867 to 1.87. indicating only a 0.2% increase. This minimal change suggests that the spoiler has a limited effect on the boundary layer separation and wake development in this configuration. The pressure contours show that the base pressure behind the cylinder remains almost unchanged. indicating that the pressure drag contribution is essentially preserved. In the eddy viscosity and turbulent kinetic energy (TKE) fields. only local increases are observed near the spoiler. while no significant concentration is observed in the downstream wake region. The velocity contours reveal a slight upward shift in the separation line due to the spoiler. However. the wake width and the size of the momentum deficit region remain almost the same as in the basic configuration. Overall. these results show that the Type-1 spoiler causes only a weak disturbance in the flow. a small change in wake symmetry and a negligible increase in total drag.

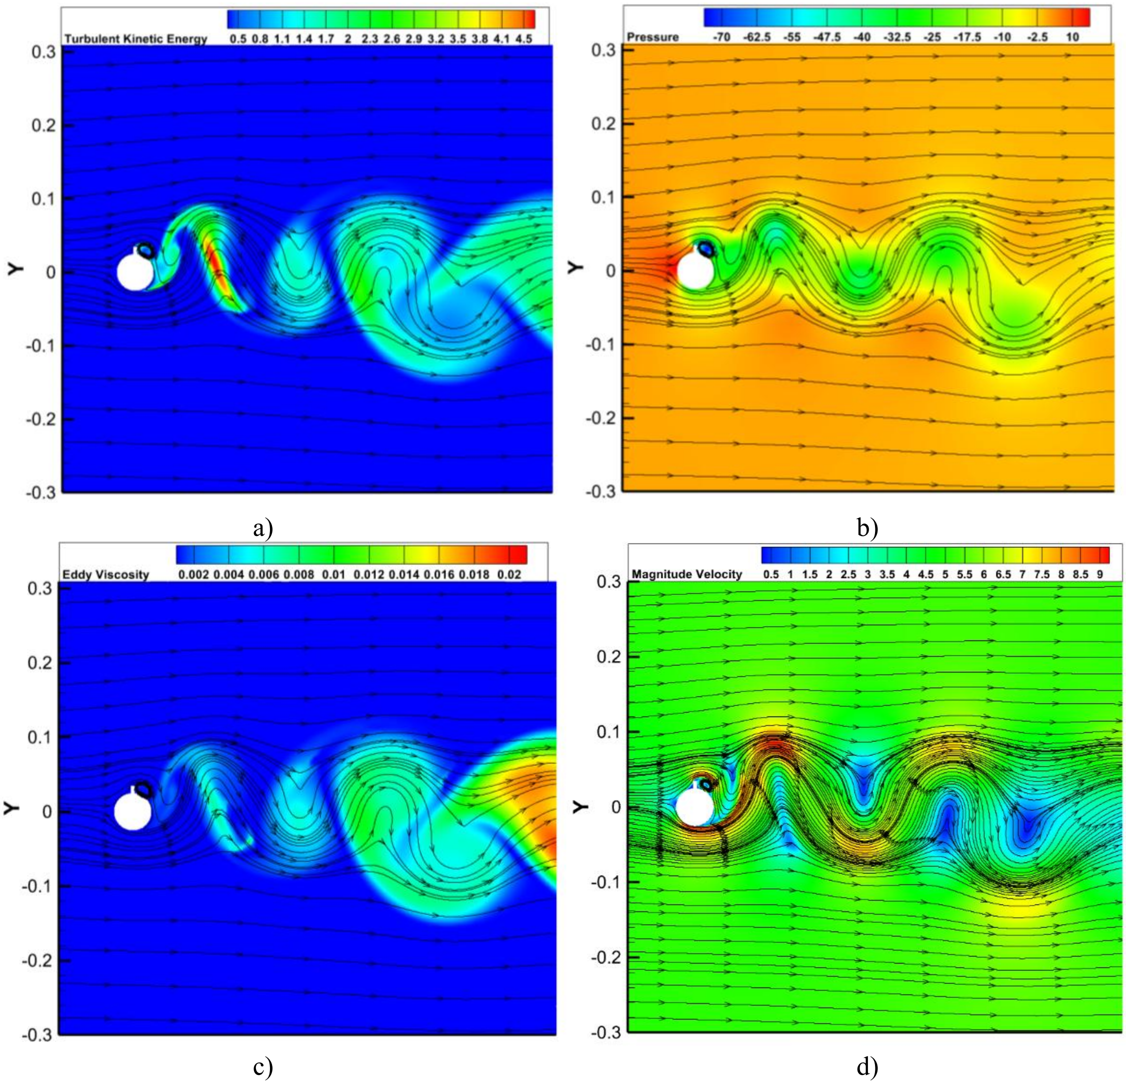

Fig. 6. Contours for Type-1 configuration; a) Turbulent Kinetic Energy. b) Static pressure c) Eddy viscosity. d) Velocity

5. Conclusion

This research presents detailed findings arising from their CFD studies on aerodynamic performances of offshore pipeline spoilers. Successively. it has emerged that spoiler geometry plays the most crucial role in defining aerodynamic drag and wake behavior around cylindrical submarine pipelines. It compared four different spoiler configurations determined by variable flow characteristics and different aerodynamic performances in comparison to a baseline configuration without spoilers.

Type-1 arrangement barely alters the flow behavior as compared to the base cylinder sans spoiler. Only a 0.2% increase is indicated by the drag coefficient (C_D). which rises marginally from 1.867 to 1.87. This slight alteration implies that the spoiler's impact on wake formation and boundary layer separation in this configuration is minor. The base pressure behind the cylinder stays nearly constant. according to the pressure contours. suggesting that the pressure drag contribution is largely maintained. There is no discernible concentration in the downstream wake zone. but only local increases in the eddy viscosity and turbulent kinetic energy (TKE) fields are seen close to the spoiler.

Present research highlights the complex relationship between spoiler geometry and flow dynamics. highlighting how subtle design changes can profoundly affect pipeline stability and sediment dynamics. Further analysis should be taken up in the form of three-dimensional simulations and extend to other parameters such as a slider's flexibility. vortex induced vibration (VIV) induced structural fatigue risk. and porosity. which can further optimize aerodynamic and hydrodynamic performance with varying oceanographic conditions. Such studies indeed fill in gaps in-the literature by as they were giving more comprehensive guidelines on spoiler applications- in addition to economically beneficial. structurally safe. and environmentally adaptable solutions.

Advances in breach formation modeling and flood risk assessment for dam failures

Hasan O. Marangoz*[1], Tuğçe Anılan[2], Veli Süme[1]

[1]Recep Tayyip Erdogan University, Department of Civil Engineering, 53100 Rize, Türkiye
[2] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. This study examines the breach formation mechanisms in dam failures and the parameters influencing this process. Empirical equations, practical methods, and physically-based models were utilized to estimate breach parameters. Empirical equations were developed based on data obtained from past dam failures and analyzed through hydraulic parameters. Physically-based models, on the other hand, incorporate more detailed hydraulic, structural, and geotechnical analyses, providing higher accuracy through computer-aided simulations. This study aims to enhance the understanding of breach formation mechanisms in dam failures and improve flood risk assessments using different modeling approaches.

Keywords: Dam breach formation, Flood risk assessment, Empirical; Physically-based models

1. Introduction

Dam failures have historically been recognized as among the most destructive natural hazards, often leading to catastrophic consequences including significant loss of life, severe economic damage, and long-term environmental impacts. The sudden release of large water volumes during a dam breach produces highly dynamic flood waves, whose propagation characteristics are strongly dependent on the breach formation process itself (Wang and Kahawita, 2002). Therefore, understanding the mechanisms of breach initiation and development is critical for improving the reliability of flood risk assessments and for designing effective early warning systems and emergency response strategies.

The modeling of breach formation presents unique challenges (West et al., 2018) due to the complex interactions between hydraulic forces, geotechnical properties, structural characteristics, and erosion processes. Early approaches to breach analysis primarily relied on simplified assumptions, treating breaches as fixed openings with steady discharge rates. However, subsequent observations from historical dam failures (Froehlich, 1995) have demonstrated that breach formation is a highly dynamic and nonlinear process involving rapid erosion, varying breach geometry, and changing outflow conditions over time.

To capture these dynamics, a range of modeling approaches has been developed (Guan, 2014). Empirical methods, based on regression analyses of historical dam failure data, provide quick estimations of key breach parameters such as breach width, side slope, and failure time. While useful for preliminary assessments, these models are subject to significant uncertainties due to their reliance on generalized data and simplifications. Practical estimation methods, established by organizations such as the United States Army Corps of Engineers (USACE,2016), the Federal Energy Regulatory Commission (FERC,1988), and the National Weather Service (NWS), offer standardized parameter ranges for different dam types, enhancing the practicality of breach prediction but still lacking in precision for site-specific conditions (Fread, 1984)

In contrast, physically-based models simulate breach formation through detailed mathematical representations of hydraulic behavior, soil erosion, sediment transport, and structural failure(Wang et al., 2006) mechanisms. These models require extensive input data, including dam material properties (Macchione and Rino, 2008), reservoir characteristics, and hydrodynamic conditions, but they offer superior accuracy in predicting breach development and the resulting outflow hydrographs. Recent advancements in computational power and numerical methods have made it increasingly feasible to apply such models to complex, real-world dam breach scenarios.

This study systematically reviews and compares empirical, practical, and physically-based approaches for breach parameter estimation, highlighting their respective advantages, limitations, and appropriate applications. By synthesizing information from historical data, theoretical analyses, and computational modeling efforts, the study aims to contribute to a deeper understanding of breach mechanics and to enhance the accuracy of flood risk

https://doi.org/10.31462/icearc2025_ce_hyd_703

assessments associated with dam failures. In doing so, it provides valuable guidance for engineers, researchers, and policymakers tasked with dam safety evaluations and disaster preparedness planning.

2. Material and methods

2.1. Methods for estimating breach parameters

Historically, due to the lack of sufficient observational data, it was assumed that dam failures involved the discharge of water through a fixed opening formed by a fragment breaking off from the dam body. However, in reality, modeling breach formation and determining breach parameters introduce significant uncertainties in dam failure flood analyses (Bayazıt & Önöz, 2008). To allow mathematical representation of the complex formation of breach characteristics, simplifications were made to render the process more accessible and understandable. Over time, these simplifications have been extended by generalizing failure mechanisms through simple empirical expressions based on data from past dam failures.

Directly predicting the failure mode and breach parameters for existing dams remains challenging. Nevertheless, approaches that provide reasonable approximations without diverging significantly from realistic failure scenarios offer sufficient criteria for conducting reliable risk analyses. The prediction of breach formation mechanisms in empirical equations typically depends on factors such as the dam's storage volume, height, width, and the type of construction material used. In other types of failures, rather than solving a breach problem, different investigations and time-dependent changes are involved.

2.1.1. Estimation of breach formation parameters using practical methods

Due to the severe damages and increased casualties resulting from dam failures, several breach-related parameters have been recorded over time, and efforts have been made to standardize breach parameter predictions based on the dam type. This approach aimed to provide a practical means of estimating breach parameters for existing dams. Initially, in the 1980s, the United States Army Corps of Engineers (USACE) published a set of practical breach parameters specific to dam failures. These were later expanded and supplemented by contributions from the Federal Energy Regulatory Commission (FERC) and the National Weather Service (NWS).

The estimation methods developed by these institutions have been periodically updated and adapted to various dam types. The expected ranges of breach parameters during failure scenarios, according to these practical methods, are presented in Table 1.

Table 1. Scour parameters expected to occur based on dam type (Gee, 2008)

Dam Type	Average Breach Width, B_{ort} (m)	Breach Edge Slope, z	Breach Time, t_f (sa)	Institution
Earth/Rock Fill	$0.5(h_d) < B_{ort} < 3(h_d)$	$0 < z < 1$	$0.5 < t_f < 4$	USACE (1980)
	$0.5(h_d) < B_{ort} < 5(h_d)$	$0 < z < 1$	$0.5 < t_f < 4$	USACE (2007)
	$(h_d) < B_{ort} < 5(h_d)$	$0 < z < 1$	$0.5 < t_f < 1$	FERC (1988)
	$2(h_d) < B_{ort} < 5(h_d)$	$0 < z < 1$	$0.5 < t_f < 1$	NWS (Fread, 2006)
Concrete Gravity	Monolithic Pieces	Vertical	$0.1 < t_f < 0.5$	USACE (1980)
	$B_{ort} \leq 0.5L$	Vertical	$0.1 < t_f < 0.3$	FERC
	$B_{ort} \leq 0.5L$	Vertical	$0.1 < t_f < 0.2$	NWS
	Entire Dam	Valley Junction	$t_f \leq 0.1$	USACE (1980)
Concrete Arch	$(0.8L) < B_{ort} < L$	$0 < z <$ V.B.	$t_f \leq 0.1$	USACE (2007)
	Entire Dam	$0 < z <$ V.B.	$t_f \leq 0.1$	FERC

The practical method technique for estimating breach parameters is still widely used today for predicting breach characteristics of many dams and for validating empirical equations.

2.1.2. Estimation of breach formation parameters using empirical equations

In the estimation method also known as the parametric model, simple empirical equations are employed. In this approach, a collection of historical dam failure data has been gathered and statistically analyzed using regression methods (West et al., 2018). Through the analysis of dozens of dam failure cases, empirical equations have been developed, which use certain dam parameters as inputs for calculating breach characteristics. Table 2 presents a chronological summary of various empirical equations commonly used for estimating breach parameters.

Table 2. Empirically derived equations for scour parameters

Average Breach Width	Break Time	Peak Discharge	
USBR (1988) $B_{ort}= 3(h_w)$	MacDonald, Langridge-Monopolis (1984) $t_f=0.0179V_{er}^{\ 0.364}$	Evans (1986) $Q=0.72V_w^{0.53}$	Kirkpatrick (1977) $Q=1.27(h_w+0.3)^{2.5}$

		Froehlich(2016a, b) $Q=0.0175k_3k_H\frac{\sqrt{gV_wh_wh_b^2}}{W_{ort}}$	

* B_{ort}: Average breach width (m), Q: Maximum breach discharge, t_f: Failure time (hours), C_b: Reservoir storage function, varying within the value range specified in the table, h_b: Total breach height, h_d: Dam height (m), h_w: Water depth remaining over the breach at the time of failure (m), h: Water depth remaining behind the dam, Vw: Reservoir water volume remaining above the breach base at the time of failure (m³), K_0, K_1, K_2, K_3: Coefficients used for overtopping failures (values are 1.4, 1.3, 1.5, and 1.85 respectively) and set to 1 for piping-type failures, S: Reservoir storage capacity (m³), V_{er}: Volume of eroded dam material until the breach reaches its final shape (m³), AF*: High erosion, AA*: Low erosion, TD*: Earthfill dam, TDD*: Non-earthfill dam, KH: A coefficient taken as 1 when $h_b < 6.1$, and $(h_b/6.1)$^0.125 when $h_b > 6.1$.

The simplicity of manual calculations in empirical expressions has introduced several assumptions and simplifications into the literature. Although the actual breach width continuously changes during the failure process, a constant average breach width parameter is generally used. Various failure assumptions are employed to estimate the final breach width based on the average breach width.

2.1.3. Estimation of breach formation parameters using physically-based methods

Physically-based models estimate breach parameters analytically and numerically by using hydraulic, structural, and geotechnical-based empirical values and coefficients (West et al., 2018). In recent years, physically-based methods have been increasingly utilized and diversified, with computational power typically required to solve the complex processes involved. Often referred to as the mathematical modeling of breach formation in the literature, these methods incorporate inputs such as slope stability, erosion, sediment transport, angle of repose, cohesion coefficient, type of embankment material, hydrological data, and soil properties into the governing equations. As a result, the breach geometry and outflow hydrograph derived from these models are achieved with higher accuracy compared to empirical or practical methods.

To date, more than 60 physically-based models related to breach mechanics have been developed. Some of the most commonly used models are categorized based on various criteria and are listed chronologically in Table 3.

Table 3. Some physics-based models used in scour problems

8	66856500	80.55	37	1.03	1.34	113

3.Results and discussion

In this study, eight distinct dam breach scenarios were evaluated by varying key parameters such as breach side slopes, breach bottom width, water depth at the time of failure, and failure duration. These parameters were chosen to represent a range of potential real-world failure cases, allowing for comparative assessment under different geometric and hydraulic conditions.

Using a set of widely accepted empirical models namely those proposed by MacDonald & Langridge-Monopolis (1984), Froehlich (1995a), Evans (1986), SCS (1981), USBR (1982), and Costa (1985) the peak outflow discharges (Q_{peak}) were calculated for each scenario (Fig. 1). The results demonstrated that while all methods produced values of similar magnitude, considerable variation exists depending on the governing assumptions of each model.

In the figure, the highest peak discharges were observed in Scenarios 5, 6, 7, and 8 based on the USBR approach, yielding a value of approximately 65,000 m^3/s. In comparison, the Froehlich method produced peak discharges around 30,000 m^3/s, the SCS method around 55,000 m^3/s, and the MacDonald, Evans, and Costa methods yielded values close to 10,000 m^3/s. Overall, an increase in upstream water depth was found to have a direct impact on the peak discharge resulting from dam failure. Since all breach scenarios were modeled as overtopping failures, the influence of failure mode could not be evaluated within the scope of this study.

In addition to discharge comparisons, trapezoidal hydrographs were generated for each scenario using both the MacDonald and Froehlich models. These hydrographs allowed a visualization of flow evolution over time and revealed that scenarios with wider breaches and higher heads result in steeper rising limbs and larger flow volumes. Moreover, failure time was found to have a direct influence on the shape of the hydrograph: shorter failure durations led to sharper peaks and shorter flood durations. When the results obtained from testing the same scenarios with a more reliable, physically-based model were compared to those from the empirical approach, it was found that the Froehlich method produced outputs closest to the physically-based model's results.

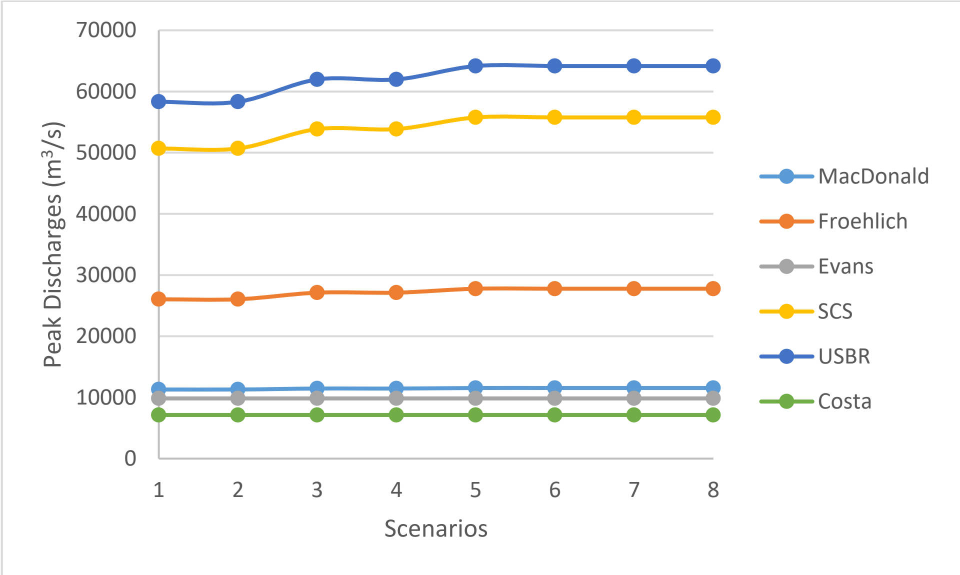

Fig. 1. Peak discharges results of the scenarios

4. Conclusions

This study presents a comparative evaluation of dam breach modeling approaches through the application of widely accepted empirical formulas to eight distinct overtopping failure scenarios. By varying breach geometries (bottom width and side slopes), water depth at failure, and failure duration, the study aimed to explore the sensitivity of peak outflow discharge to key physical parameters.

Six different empirical models; MacDonald & Langridge-Monopolis (1984), Froehlich (1995a), Evans (1986), SCS (1981), USBR (1982), and Costa (1985) were used to estimate the peak discharge (Q_{peak}) for each scenario. The Froehlich model produced peak discharges ranging from 26,044 m³/s (Scenario 1) to 27,765 m³/s (Scenarios 5–8), while the USBR approach yielded the highest values, up to approximately 65,000 m³/s, particularly under conditions of increased water depth and wider breaches. The SCS method consistently estimated discharges near 55,000 m³/s, whereas the MacDonald, Evans, and Costa models yielded lower values, close to 10,000 m³/s. These differences reflect the degree of conservatism or simplification inherent in each method.Notably, when these empirical estimations were compared against the results from a more robust, physically-based model applied to the same scenarios, the Froehlich method stood out by providing results that were closely aligned with the physically-based outcomes suggesting its comparatively higher reliability among empirical formulations.

Trapezoidal hydrographs were constructed using both the Froehlich and MacDonald models to better visualize flood propagation characteristics. The hydrographs clearly illustrated the influence of breach parameters on flood evolution: scenarios with shorter breach times such as Scenario 1 (0.40 hours) produced steep, narrow peaks, while those with longer breach durations, like Scenario 4 (1.98 hours), resulted in flatter hydrographs with extended durations.

Experimental study of temporal evolution of the breach and flowrate from the breach due to overtopping at earth-fill dams

Mehmet Ş. Güney*[1], Ruti Politi[1], Yiğit Kalyoncu[1], Kadri Dallı[1]

[1] Izmir University of Economics, Faculty of Engineering, Department of Civil Engineering, İzmir, Türkiye

Abstract. One of the most important reasons for earth-fill dam failures is overtopping. This complex phenomenon is affected by several geometrical, hydraulic and geotechnical parameters. Therefore, it is very important to perform experiments to reveal the breach mechanism and to investigate the temporal evolution of the breach and the flow rates from the breach. In this study, it was intended to obtain experimental results in the case of overtopping at homogeneous earth-fill dam. The experiments were conducted at Hydraulics Laboratory of Civil Engineering Department within İzmir University of Economics. A homogeneous earth-fill dam was built in a flume 0.96 m wide, 0.81 m high and 5.44 m long. Some common soil mechanics tests were also carried out before the dam was built. The dam body was constructed by using a mixture of 85% fine sand and 15% clay. High-precision cameras were used to record the temporal development of the breach resulting from overtopping. Gauss area formula was used to obtain the time-varied values of the breach areas. The temporal changes of water depth in the flume were also recorded. The water flowrate outgoing from the breach was determined by using the continuity equation. The so obtained experimental findings are presented and interpreted. The time corresponding to the peak values in discharge and breach areas was also determined. These experimental findings provide the opportunities for the calibration and validation of the numerical models used in the relevant numerical investigations. This study offers also guidance for strategies concerning emergency action plans related to the failure of homogeneous earth-fill dams because of the overtopping.

Keywords: Earth-fill dam; Overtopping; Breach geometry; Breach development; Discharge through breach

1. Introduction

One of the most important reasons for earth-fill dam failures is overtopping. This complex phenomenon is affected by several geometrical, hydraulic and geotechnical parameters. In an overtopping failure, water surges over the dam crest as a result of inadequate flood design or extreme rainfall, ultimately leading to the formation of a breach and the structural failure of the dam (Aman et al., 2023). Costa (1985) reported that approximately 34% of dam failures were caused by overtopping, 30% by foundation defects, and 28% by piping. Singh (1996) reported that more than 60% of earth dam failures result from either internal erosion (piping) or overtopping.

Regardless of the uncertainties, dam failures can be extremely catastrophic due to the severe floods they create at downstream, resulting in significant loss of life and property. It is critical to establish the flood flow rate that will result from the dam failure in order to assess the risk to any residential, commercial, or agricultural sectors. Nowadays, numerical model simulations are commonly used in works of literature. Despite decades of study, the basic mechanisms of overtopping and the most efficient ways for preventing and mitigating it in earth-fill dams are not completely known. Without artificial embankments or flood-discharge structures, overtopping occurs easily when the upstream water level surpasses the lowest point of the dam crest. The breach failure mechanism caused solely by overtopping has been extensively studied both experimentally and numerically (Chen et al., 2023).

Since the late 1990s, various simplified physical models have been developed. Laboratory experiments and numerical models have been created to simulate the progression of surface erosion and slope instability over time during an overtopping-induced dam failure (Verma et al., 2023). Ashraf et al. (2019) conducted a statistical and experimental analysis of dam failure caused by overtopping. A dataset of 126 embankment failures was analyzed using nonlinear regression in MATLAB to derive predictive equations for breach parameters. The models showed consistent performance across samples. Five large-scale overtopping tests on cohesive and non-cohesive soils validated the equations, with strong correlation observed for non-cohesive embankments. Their findings indicated that the derived equations aligned well with experimental results for non-cohesive soils. Chen et al. (2019)

developed a numerical model for earthen dam breach due to piping failure, incorporating an arched pipe channel geometry rather than traditional rectangular or circular cross-sections. The model simulates breach evolution by considering shear stress-based erosion, pipe roof collapse mechanisms, and transitions from pressurized to open-channel flow, ultimately leading to overtopping failure. Zhou et al. (2021) provided an analysis of the spatial and temporal evolution of breaching flows during various stages of overtopping failure. Their study conducted large-scale flume tests to analyze outburst discharge from landslide dams due to overtopping failure, focusing on the longitudinal evolution of breach flow and the effects of upstream inflows and loose deposits on flood dynamics. The study found that increasing the inflow discharge leads to a higher peak outburst discharge, as well as a reduction in the time required to reach both the peak and inflection points of the outburst hydrograph. Bereta et al. (2020) conducted small-scale model tests to examine the breaching process of cohesive embankment dams due to overtopping, using a simplified physical-based breach model. By testing five dam models, the results showed that head cut erosion was a key factor in breach development, with flow discharge and velocity estimated using hydraulic methods and the broad-crested weir formula. Experimental results demonstrated good agreement between calculated and measured breach parameters, including peak discharge, breach width, and formation time.

The objective of this research is to conduct experiments to investigate the development of dam failure resulted from the overtopping at homogeneous earth-fill dam. Understanding the temporal evolution of the breach and the resulting outflow characteristics is essential for improving dam safety. This study experimentally investigates the breach development process and the outflow hydrograph under overtopping conditions, providing valuable insights for predictive modeling strategies.

2. Experimental procedure

A homogenous earth-fill dam having 0.20 m height, 1.20 m bottom width, and a crest width of 0.20 m was constructed with a slope at the upstream and downstream sides of 1:2.5. The dam was built in a rectangular flume 0.96 m wide, 0.81 m high, and 5.44 m long (Fig. 1).

Some soil mechanics tests were carried out before building the dam. The soil mixture utilized at the construction of the dam was prepared by using 85 % fine sand and 15 % clay. The grain-size distribution of the mixture obtained from the wet sieve and hydrometer analyses is shown in Fig. 2.

From Fig. 2, some characteristic diameters were obtained as D_{10}= 0.014 mm, D_{30}= 0.056 mm, D_{50}= 0.13 mm, and D_{60}= 0.15 mm. The uniformity coefficient C_u equals 10.7 and the curvature coefficient C_c is equal to 1.49. The specific weight of the mixture was found to be G_s = 2.67, from the test ASTM D854 – 14. The permeability of the mixture was found as $k = 1.18 \cdot 10^{-3}$ cm/s from the falling head permeability test. The standard proctor tests (ASTM-698) were performed by applying both 13 and 25 blows, and the obtained curves are plotted in Fig. 3.

The maximum dry density and optimum water content were obtained as Υ_{drymax}= 1.653 g/cm^3 and w_{opt} = 15.4 % from the test with 13 blows and as Υ_{drymax}= 1.694 g/cm^3 and w_{opt} = 13.6 % from the 25 blows test.

Some construction stages and the completed shape of the dam body are shown in Fig. 4. Each layer was constructed in four sub-layers, each measuring 2.5 cm thick, to avoid any homogeneity issues that could arise.

4. Experimental findings

The evolution of the dam failure was recorded by six cameras placed at different locations. The camera recordings were also used to determine the water depths in the channel. The photos from the upstream and downstream cameras were analyzed to evaluate the shape of the breach and the changes in its geometry. The temporal developments of the breach recorded by the cameras located at downstream and upstream of the dam are given in Fig. 5 and Fig. 6, respectively. In these figures, the time t = 0 corresponds to the moment when the breach appeared at the relevant face of the dam. The time elapsed between the instances at which the breach appeared at downstream and upstream sides ($T_{elapsed}$) was approximately 15 s.

As shown in Fig. 5b, initial signs of erosion near the centerline of the dam crest became evident 45 s later. As seen in Fig. 5c, the breach became much larger at t = 95 s on the downstream side. When t = 145 s, the erosion became much more significant (Fig. 5d). The breach continued to be developed (Fig. 5e), followed by additional detachments from the downstream surface. After t = 300 s (Fig. 5f), no significant erosion observed, and the breach reached almost its final shape. The breach was much more visible as time progresses (Fig. 6b and Fig. 6c). When t = 145 s, the breach covered almost 10% of the upstream face (Fig. 6d). The final shape of the breach was reached almost when t = 300 s (Fig. 6f).

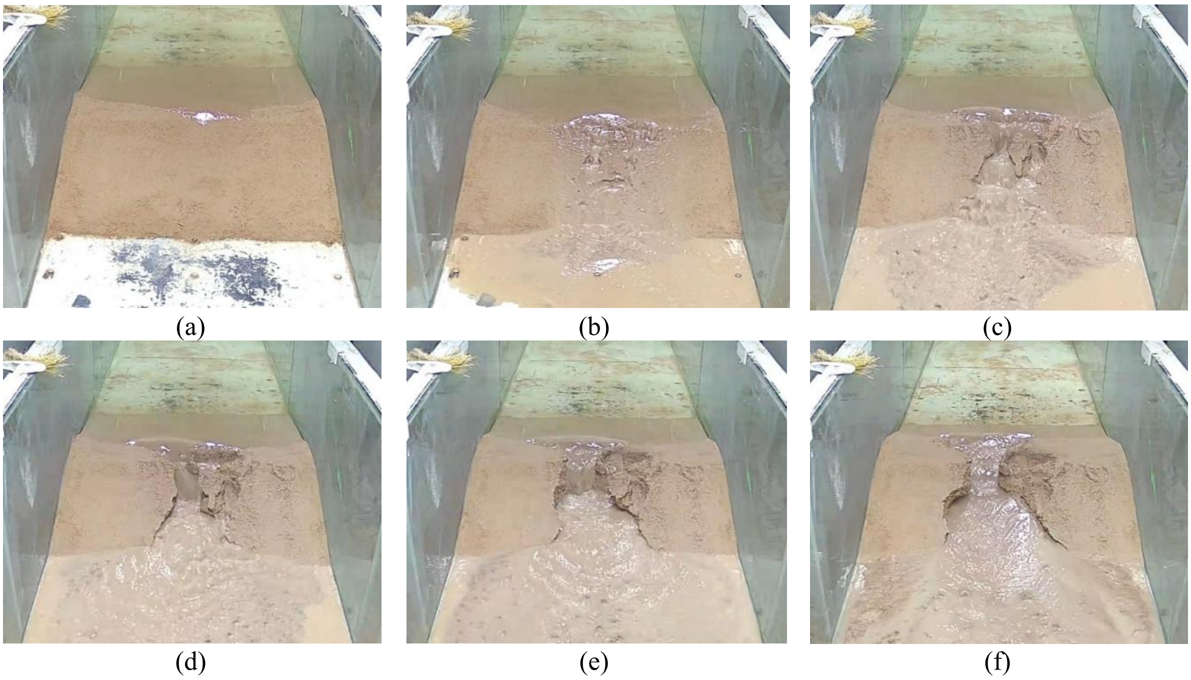

Fig. 5 The temporal development of the breach at downstream face of the dam; (a) t = 0 s, (b) t = 45 s, (c) t = 95 s, (d) t = 145 s, (e) t = 195 s, (f) t = 300 s

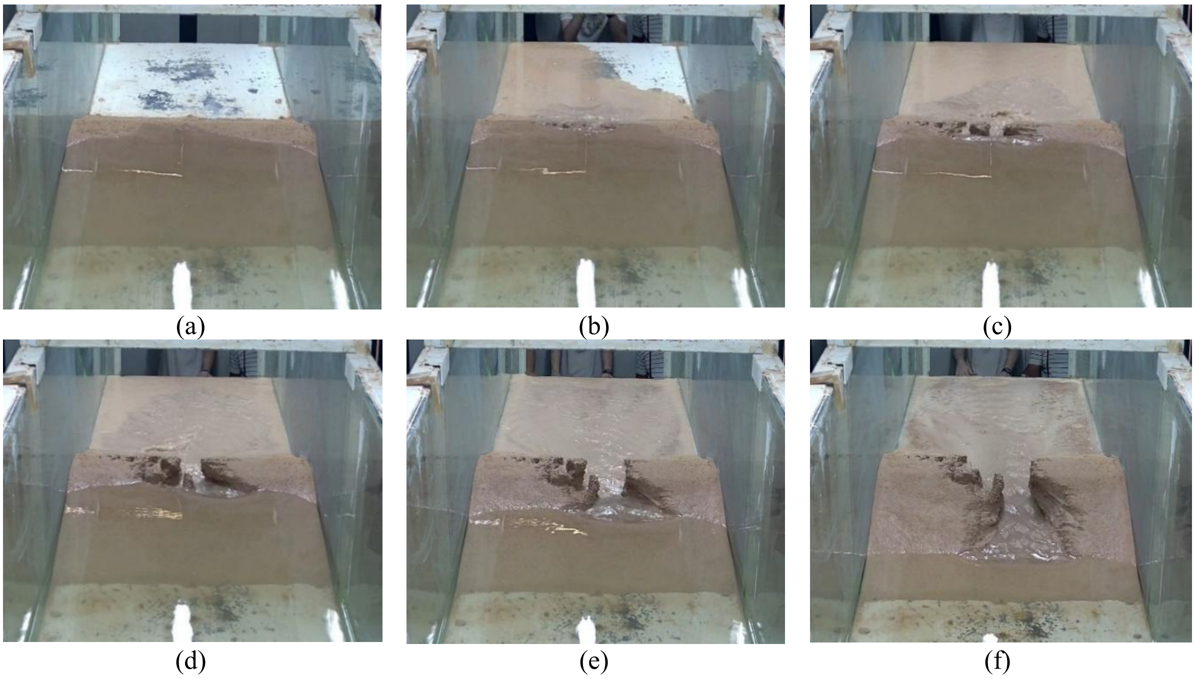

Fig. 6 The temporal development of the breach at upstream face of the dam; (a) t = 0 s, (b) t = 45 s, (c) t = 95 s, (d) t = 145 s, (e) t = 195 s, (f) t = 300 s

At Get-data Graph Digitizer 2.26 software, the images extracted from the records corresponding to a specific time were scaled, and the boundary coordinates of the breaches on the downstream and upstream sides were determined. The time-varied breach areas were calculated by using the Gauss area formula:

$$Area = \frac{1}{2}\sum_{i=1}^{n} x_i(y_{i+1} - y_{i-1}) = \frac{1}{2}\sum_{i=1}^{n} y_i(x_{i+1} - x_{i-1}) \tag{1}$$

where n is the number of sides, x_i and y_i represent the abscissa and ordinate in the coordinate i, respectively. The so obtained breach areas are plotted in Fig. 7.

The discharge of water outgoing from the breach was determined by using the continuity equation:

$$\Delta S=(Q_{inlet}- Q_{breach})\cdot\Delta t \tag{2}$$

where Q_{inlet} is the inflow rate to the reservoir, Q_{breach} is the discharge from the breach, and ΔS is the change in the reservoir storage during the time interval Δt.

Fig. 8a represents the time-varying water depths in the dam reservoir. The generated water depth-volume curve is given in Fig. 8b. The discharges outgoing from the breach, calculated by using Eq. (2), are given in Fig. 9.

The progress rate of the breach area at downstream side was much greater (Fig. 10a) compared to that of the upstream side (Fig. 10b). The final breach area at downstream side was obtained nearly 1.5 times greater than that of the upstream side. Fig. 10 illustrates the development of the breach areas for downstream and upstream sides.

The dimensionless parameters $Q_{breach}(t)/Q_{breach,max}$, $A_{down}(t)/A_{down,max}$, $A_{ups}(t)/A_{ups,max}$ and t/t_Q, t/t_d and t/t_u are generated in order to obtain the universal results. This approach enables the comparison of our experimental findings with the results of other experiments carried out in different geometrical and hydraulical conditions. The graphs of the curves $Q_{breach}(t)/Q_{breach,max} = f(t/t_Q)$, $A_{down}(t)/A_{down,max} = f(t/t_d)$ and $A_{ups}(t)/A_{ups,max} = f(t/t_u)$ are given in

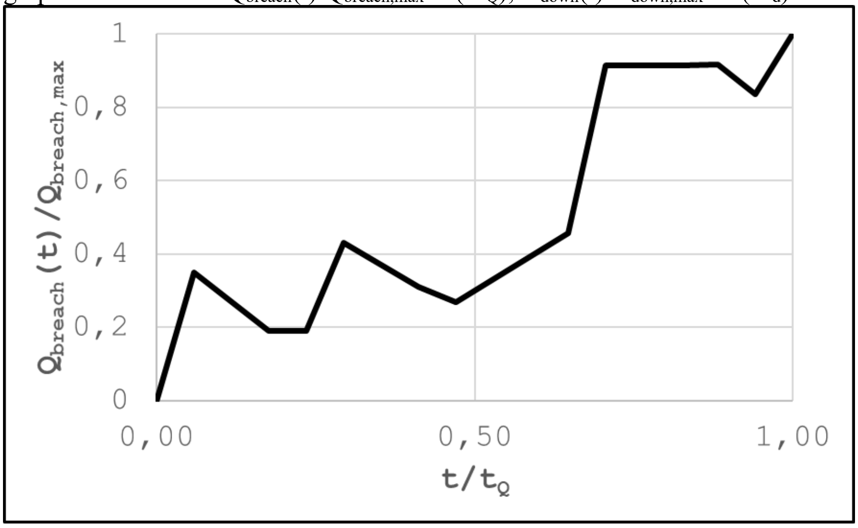

Fig. 11,
Fig. 12 and
Fig. 13, respectively. $Q_{breach}(t)$, $A_{down}(t)$ and $A_{ups}(t)$ denote time-dependent values of the discharges, the breach areas at downstream and upstream, respectively. $Q_{breach,max}$, $A_{down,max}$ and $A_{ups,max}$ correspond to the maximum values of the discharge, downstream breach area and upstream breach area, respectively. t_Q, t_d and t_u represent the time to reach the maximum values of discharge, downstream breach area and upstream breach area, respectively.

The dimensionless discharge curve can be simulated approximately to a linear line with some fluctuations due to the change in bridge geometry resulting from internal erosion.

The dimensionless downstream breach area curve looks like a logarithmic curve, while the dimensionless upstream breach area curve looks like linear.

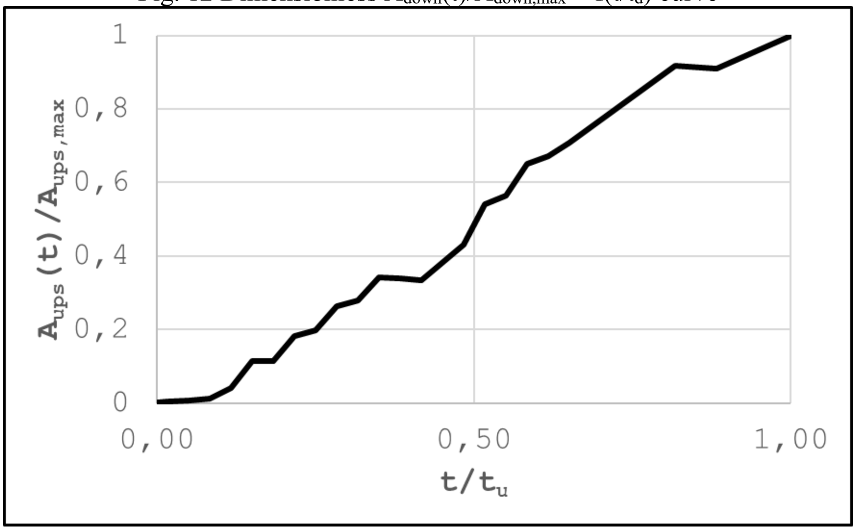

Fig. 13 Dimensionless $A_{ups}(t)/A_{ups,max} = f(t/t_u)$ curve

Table 1. Comparison of the experimental findings

Parameters		Experimental Findings
$Q_{breach,max}$ (L/s):	Maximum discharge outgoing from the breach	3.82
t_Q (s):	Time to reach $Q_{breach,max}$	170
$A_{down,max}$ (cm^2):	Maximum breach area at downstream	1884
t_d (s):	Time to reach $A_{down,max}$	300
$A_{ups,max}$ (cm^2):	Maximum breach area at upstream	1216
t_u (s):	Time to reach $A_{ups,max}$	300

4. Conclusions

In this study, the temporal evolution of the breach caused by overtopping at homogenous earth-fill dam was studied experimentally. The discharges from the breach at various instants were computed using the continuity equation.

The Get-Data Graph Digitizer was used to scale the boundary coordinates of the breach surface areas. The breach areas at each time were determined by applying Gauss-area formula.

The breach began on the downstream side and progressed to the upstream side, as expected. The breach at upstream side appeared 15 s later compared to downstream side. The comparative experimental findings are given in Table 1, where the maximum discharge through the breach was calculated as $Q_{breach,max} = 3.817$ L/s at t = 170 s. The maximum breach area at downstream was found to be $A_{down,max} = 1884$ cm^2 at t = 300 s, while at upstream $A_{ups,max} = 1216$ cm^2.

The findings of this study contribute to a better understanding of the breach development mechanisms in overtopping-induced dam failures, providing valuable insights for future modeling and risk assessment efforts. These experimental findings provide opportunities for the calibration and validation of the numerical models used in the relevant numerical investigations. This study offers also guidance for strategies concerning emergency action plans related to the failure of homogeneous earth-fill dams due to overtopping.

Modeling of the maximum rise height of a dense discharge using the teaching-learning-based algorithm

Arife Günay[1], Mahmut C. Sayıl[*1], Tuğçe Anılan[1]

[1]*Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye*

Abstract. Brine, the byproduct of the desalination process, is a type of wastewater and must be disposed of safely. Marine outfall systems are used to dispose of brine, which is discharged into the ambient environment through the discharge ports of the diffuser pipes. A proper hydraulic design of the diffuser pipe is crucial since it ensures sufficient dilution of the discharged wastewater. Jet behavior must be thoroughly analyzed for a successful diffuser design. In this context, jet trajectories are vital since they are directly related to the dilution efficiency of the wastewater discharged. In assessing the trajectories of dense jets from single-side diffusers, there are three main geometrical features: maximum rise height, impact distance, and near-field distance. In this study, the maximum rise height is modeled among these three features. Both classical regression analysis and teaching-learning-based algorithm (TLBO) were used in this concept. This study aims to demonstrate the feasibility of using TLBO in modeling the maximum rise height under dynamic ambient conditions with co-flowing ambient currents. For this purpose, current speed, Froude number, and port spacing were independent variables affecting the maximum rise height. In addition, different statistical indices (e.g. absolute mean error, relative error) were used to evaluate the performance of the models. The results of this evaluation revealed the success of TLBO in modeling the maximum rise height.

Keywords: Diffuser pipe, Dense jet, Maximum rise height, Teaching-learning-based algorithms, Trajectories of brine jet

1. Introduction

Desalination, which is defined as the process of removing excess salts and other dissolved chemicals from seawater and has gained importance in the last few decades, has become an important concept, especially in arid regions with freshwater shortages (Sepehr et al., 2017; Darre and Toor, 2018). As a solution to a significant problem, this process results in a type of wastewater that contains very high concentrations of salts and is typically referred to as brine (Bashitialshaaer et al., 2015; Baawain et al., 2015; Abessi and Roberts, 2018; Sayıl and Anılan, 2024). In addition to high salinity, the resulting brine may contain hazardous pre-treatment chemicals, organics, and heavy metals. For this reason, many researchers have investigated the negative environmental impacts of brine disposal on the marine environment, groundwater, and soil quality and have proposed appropriate solutions (Panagopoulos et al., 2019). Among these proposals, the most preferred worldwide is the discharge to marine outfall systems. These systems focus on reducing pollutant levels to safe values by ensuring sufficient dilution in the receiving environment (Nemlioğlu, 2001).

Adequate dilution in the receiving environment can be achieved by a diffuser pipe with an appropriate hydraulic design (Bleninger and Jirka, 2008; Sayıl et al., 2025). Here, appropriate hydraulic design means designing a diffuser that minimises energy losses, provides a homogeneous discharge distribution between all diffuser ports through which wastewater is discharged to the ambient water, and prevents seawater ingress into the pipe through the ports. A good diffuser design is mainly influenced by pipe diameter, length, roughness, number of ports, port diameters, and port spacing (Bleninger et al., 2002). Furthermore, the jet behaviour should be analysed thoroughly for a successful diffuser design. In the case of dense discharge, since the effluent is denser than the ambient water, it moves upwards for a while due to the discharge turbulence and high jet velocity. Eventually, it starts to move downwards after reaching a terminal rise height (Darama, 2009). Three main geometric features are used to describe this behaviour of dense jets: maximum rise height, impact distance, and near-field distance. These three most critical geometrical features that significantly affect the dilution of dense jets are given in Fig. 1.

Experimental studies to understand the behavior of jets and calculate rarefaction can be quite difficult. For this reason, researchers find it more appropriate to use numerical modeling methods to perform analyses, which are

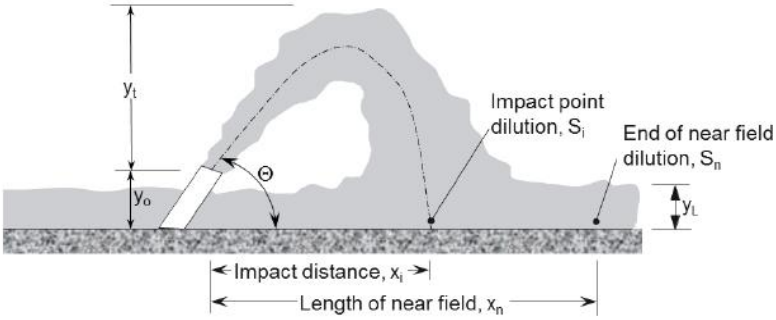

Fig. 1. Geometrical properties of a typical inclined negatively buoyant jet (Roberts et. al., 1997)

easier to implement, time-saving, and a cost-effective solution. Additionally, new techniques such as machine learning and deep learning have gained popularity in recent years due to the advances in computer science and their advantages. Artificial neural networks are one of the most notable methods in outfall. Many researchers have used ANN in various discharge topics (Lankasena, 2001; Etemad-Shahidi, et al., 2010; Er et al., 2022; Alvir et al., 2023). In addition, many different algorithms have begun to be used in discharge with the developing technology (Lankasena, 2001; Alvir et al., 2023).

In this study, the maximum rise height of the jets was modeled by classical regression analysis (CRA) and teaching-learning based optimization (TLBO) methods depending on the Froude number, port spacing, and current speed. For this purpose, experimental data available in the literature was used. The results of the two methods were compared, and the method that best modeled the maximum rise height was determined.

2. Material and methods

2.1. Reference study and the dataset used

The dataset used was obtained from the experimental results of Abessi and Roberts (2017). Abessi and Roberts (2017) performed experiments to investigate the effects of independent variables Froude number (F), port spacing (s), and ambient current speed (ua) on jet characteristics maximum rise height (yt), impact distance (xi), and impact dilution (S_i). Different series of experimental work were conducted to cover all possible scenarios including one-sided diffuser with co-flowing ambient currents, one-sided diffuser in counterflowing currents, unblocked two-sided diffuser in which the diffuser is elevated from the sea bottom and blocked two-sided diffuser in which the diffuser pipe is laid on the sea bottom. Fig. 2 shows the diffuser configurations and ambient current directions used in the study. jet densimetric Froude number as in Equation (1) where u is the jet velocity, $g_0'=g(\rho_0-\rho_a)/\rho_a$ is the modified gravitational acceleration, and ρ_0 and ρ_a are the densities of effluent and ambient water, respectively:

$$F=\frac{u}{\sqrt{g_0' d}} \tag{1}$$

To discuss the effects of port spacing, they nondimensionalized port spacing by dividing by the product of port diameter (d) and Froude number. In cases where nondimensionalized parameter s/dF was significantly greater than 1, jets were assumed to be so widely spaced that the jet merging phenomenon did not occur and solution methodology valid for single jets could be employed, and vice versa. Parameter urF was used to discuss the effects of ambient currents, where $u_r=u_a/u$ was the ratio of ambient current speed to jet velocity. In cases where $u_rF \ll 1$, jets were not significantly affected by ambient currents, and vice versa.

In our study, a dataset belonging to the case where the ports were located on one side of the diffuser and ambient currents were in the same direction as the discharged effluent was used. Teaching-learning-based algorithm (TLBO) was used to predict maximum rise height using independent variables Froude number, port spacing, and current speed. In addition, a Conventional Regression Analysis (CRA) was performed for a comparison.

2.2. Teaching-learning based optimization algorithms (TLBO)

TLBO is a population-based stochastic optimization algorithm inspired by the teaching-learning process in a classroom and developed by Rao et al. (2011). In this study, it will be used for the first time in modeling the maximum rise height in the subject of dense jet. In the algorithm consisting of two phases, teaching and learning, the most suitable student for the solution is determined, and this student is selected as the teacher for the teaching phases. In the teaching phase, students try to improve their results by getting information from the teacher. At the same time, the learning phase is the phase where students improve their performance by interacting with other

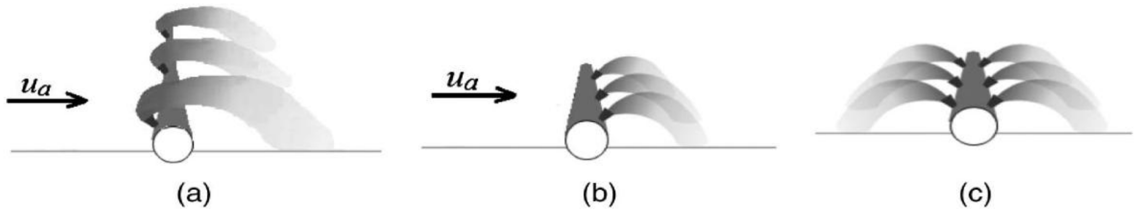

Fig. 2. Diffuser configurations where the port spacing is s: (a) one-sided counterflow; (b) one-sided co-flow; (c) two-sided (Abessi and Roberts, 2017)

students (Ermis et al., 2023). The flow diagram of the TLBO algorithm is given in Fig. 3. The simple digitised structure of TLBO and the independence of a set of control parameters to define the algorithm's performance is why it is preferred in this study over other algorithms. TLBO has two control parameters, the maximum number of cycles and the population size equal to the number of students.

The data normalised using Eq. 1 is used as input for the TLBO algorithm whose objective function is the total squared error (SSE). The performances of TLBO and CRA models were evaluated using different statistical criteria for training and testing sets. These are root mean square error (RMSE), mean absolute error (MAE), and Nash-Sutcliffe Efficiency (NSE). SSE, RMSE, and MAE, NSE are obtained by Equation (2-6) respectively.

$$Normalized\ value = \left(\frac{Raw\ value - minimum\ value}{Maximum\ value - minimum\ value}\right) \times (0.9 - 0.1) + 0.1 \tag{2}$$

$$\mathrm{SSE} = \sum_{\mathrm{i}=1}^{\mathrm{N}} (\mathrm{P_i} - \mathrm{O_i})^2 \tag{3}$$

$$\mathrm{RMSE} = \left[\frac{1}{\mathrm{N}}\sum_{\mathrm{i}=1}^{\mathrm{N}} (\mathrm{P_i} - \mathrm{O_i})^2\right]^{\frac{1}{2}} \tag{4}$$

$$\mathrm{MAE} = \frac{1}{\mathrm{N}}\sum_{\mathrm{i}=1}^{\mathrm{N}} |(\mathrm{P_i} - \mathrm{O_i})| \tag{5}$$

$$\mathrm{NSE} = 1 - \left(\frac{\sum_{\mathrm{i}=1}^{\mathrm{N}} (\mathrm{P_i} - \mathrm{O_i})^2}{\sum_{\mathrm{i}=1}^{\mathrm{N}} (O_i - \bar{o})^2}\right) \tag{6}$$

where N: Number of observations; O_i: ith observed value; $\bar{o}$: Mean of observed value; P_i: ith estimated value for the regression functions. The value of RMSE is expected to decrease as the differences between observed and predicted values decrease since RMSE measures the standard deviation of the prediction errors. This implies an improvement in the model's accuracy (Tuc et al., 2024; Günay and Akbaş, 2025). NSE can take values between negative infinity and zero, with values closer to zero indicating a better model performance (Qian et al., 2025).

3. Results and discussion

TLBO and CRA analyses were carried out to predict maximum rise height based on Froude number, port spacing, and current speed. Hyperbolic function (HF), Linear function (LF) and Exponential function (EF) were employed for both TLBO and CRA. 70% of the data were used to train models, whilst 20% were used for the testing and 10% for validating them. The values of the control parameters maximum number of iterations (NMI) and population size (SP) were set as 3000 and 100, respectively. Performance assessment and comparison of TLBO and CRA methods were made considering RMSE, MAE and NSE criteria. Tables 1-3 present the results for training, testing and validation sets, respectively. In tables, the function that yielded the best result was highlighted in bold for all performance criteria values.

It is evident from Tables 1-3 that, although for training and testing sets and in the case of HF and LF CRA yielded slightly lower error values and subtly higher NSE from time to time, in the case of exponential function, which gives the best overall results, the success of TLBO over CRA is obvious as the error values were clearly lower and NSE values were higher. As aforementioned, in overall, EF performed best since when all sets of data were considered together smallest values of RMSE and MAE and the highest value of NSE were obtained through

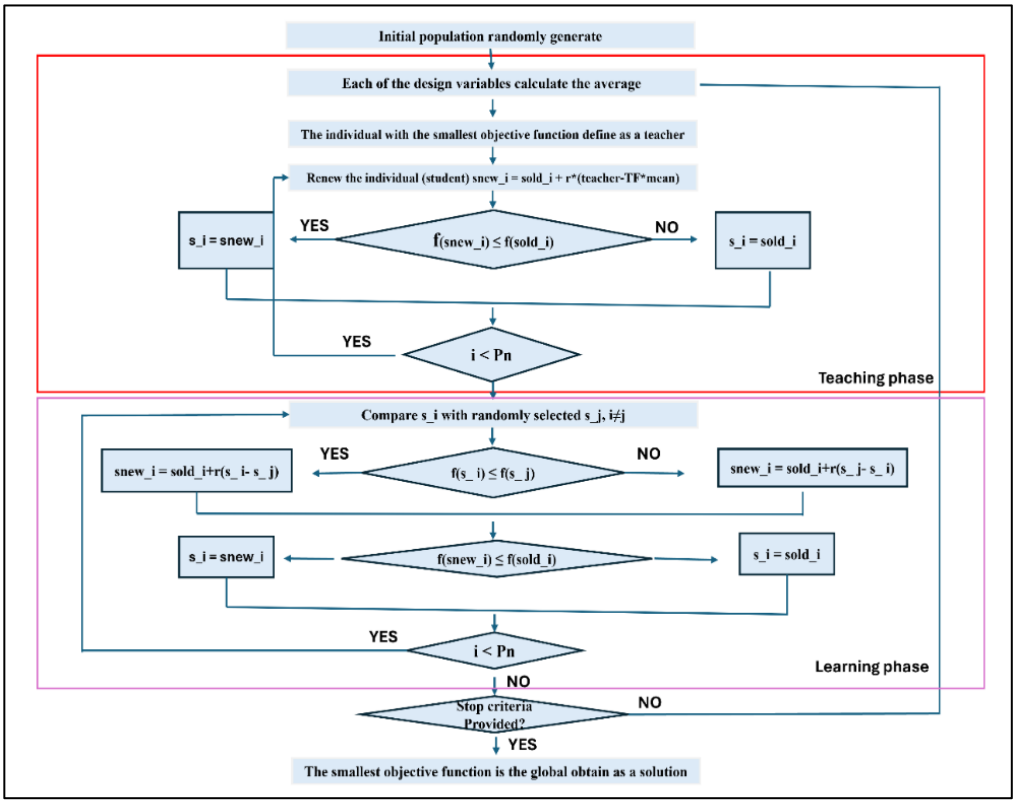

Fig. 3. Flow diagram of TLBO algorithm (Günay and Akbaş, 2025)

EF, with theses values being 0.117, 0.082 and 0.925, respectively. Based on these, Equation (7) in the form of an exponential functions is suggested for the estimation of maximum rise height of dense jets in dynamic ambient environments, using independent parameters Froude number, port spacing and current speed:

$$y_t = -0.0222 + \exp(0.1036 - 0.5476xF + 0.1039xs - 1.7912xu_a) \quad (7)$$

4. Conclusions

In this study, effects of Froude number, port spacing and current speed on the maximum rise height of dense jets discharged into dynamic ambient environments, and the applicability of TLBO algorithm to predict the maximum rise height under the given hydraulic and ambient conditions were investigated. The conclusions are as follows:

- While determining the optimum values of control parameters for the TLBO algorithm, different scenarios were tested. Accordingly, it was decided to use maximum number of iterations and population size values as 3000 and 100, respectively.
- In training and testing sets, in the case of HF and LF, CRA performed equal to or slightly better than TLBO. However, when EF, which had the best overall performance, was adopted, a clear superiority of TLBO was observed, indicating that, in general, TLBO was more successful than CRA.
- EF, when compared to HF and L, gave the best results for both error values and NSE criterion. The lowest values of RMSE and MAE across all datasets were 0.117 and 0.082, obtained by EF. The highest value of NSE was 0.925, again obtained by EF.
- Based on the related analysis' results, optimum coefficients obtained for exponential function were used to develop an expression that can be used to estimate the maximum rise height of dense jets discharged into dynamic ambient environments using Froude number, port spacing, and current speed as input variables.

Experimental and numerical investigation of tsunami impact force on an square obstacle

Kutsi S. Erduran*[1], Uğur Ünal[1], Olusola O. Adekoya[1]

[1]Niğde Ömer Halisdemir University, Department of Civil Engineering, 51240 Niğde, Türkiye

Abstract. This study experimentally and numerically investigates a tsunami impact force on a square obstacle. The impact force under four different reservoir water depths and dry downstream flow condition in a rectangular horizontal flume was evaluated. The maximum impact force, the impact time, the maximum flux and its occurrence time and the averaged wave front and wave front celerity for each flow condition were obtained. The experiments were carried out in a flume with 10m long, 0.309m width and 0.45m height. The variation of the impact forces with time were recorded using a 6-Axis USA ATI Mark GAMMA model SI-32-2.5 load cell. A 2D finite volume – shallow water numerical model was used to determine wave front celerities, impact time, the maximum fluxes and their occurrence times. The numerically obtained maximum fluxes were embedded into a well-known hydrodynamic force equation to compute the numerical hydrodynamic forces. The wave front celerities were also computed by using a previously introduced analytical solution for dry bed condition. The experimental and numerical outputs with regard to the impact force, impact time and the wave front celerity have been compared. The results indicated that the numerical celerities are in good agreement with the experimental ones as well as those obtained by the exact solution. The experimental maximum forces were found to be higher than the numerical ones. However, with a slight adjustment in drag coefficient, much better agreement was obtained. The comparisons with respect to the other parameters listed above were also made and presented.

Keywords: Tsunami impact force; Wave front celerity; Maximum flux; 2D finite-volume model, Experiment

1.Introduction

Tsunami wave poses a substantial threat to the coastal communities. It produces a highly destructive impact force and more often results in devastating damage to buildings and coastal infrastructures, flooding and loss of life. Therefore, a comprehensive understanding of the destructive feature of tsunami wave travelling over dry and wet inland is crucial to mitigate the tsunami impacts. Despite many numerical and experimental studies that led to developments of hard and soft countermeasures (Oetjen et al., 2022), there is still a considerable amount of ongoing research to minimize the harmful effects of the tsunami-induced force.

Tsunami generated force can be classified as hydrostatic force, hydrodynamic force, buoyant force, surge force (slamming), impact of debris and debris damming (Nouri et al., 2007; Nistor et al., 2009; Nouri et al., 2010; Samasindhi & Parikh, 2022). However, depending on the location and type of structure, not all tsunami-induced force components have been taken into account but an appropriate load combination has been applied in the design of a structure in the tsunami prone area (Nistor et al., 2009).

Tsunami induced pressures/forces can also be classified into three phases namely impact phase, transition phase and quasi-steady phase. In the impact phase, the initial impact force occurs and the pressure in this phase is mostly hydrodynamic. In the transition phase, wave run-up force is developed and the mixture of hydrostatic and hydrodynamic pressures occurs. In the quasi-steady phase, the pressure is mainly due to the hydrostatic pressure and the resulting force is a quasi-static hydrodynamic/hydrostatic force (Wüthrich et al., 2018a; Harish et al., 2021; Kihara et al., 2024).

Many tsunami force estimation equations have been proposed (Cross, 1967; Ramsden & Raichlen 1990; Ramsden, 1996; Asakura et al., 2002; Yeh, 2006; Yeh, 2007; Nistor et al., 2009; Fujima et al., 2009; Wüthrich et al., 2018a; Harish et al., 2021). Most of the equations are about the estimation of horizontal forces including impulsive force and quasi-static hydrodynamic or hydrostatic force (Harish et al., 2021). When the tsunami forms a bore like wave and it impacts a structure, it creates horizontal forces, which include an initial impingement force followed by a quasi-steady force due to its very long wave period (Lukkunaprasit et al., 2009). The impingement/impulsive force covers the initial impact force and bore/run-up force whereas the quasi-steady force

*Corresponding author, E-mail: kserduran@ohu.edu.tr

https://doi.org/10.31462/icearc2025_ce_hyd_826

includes quasi-static hydrodynamic or hydrostatic force. This study mainly focused on the horizontal force component of the tsunami force and the other forces listed above are outside the scope of this study.

The well known equation to compute hydrodynamic/hydrostatic force is;

$$F = \frac{1}{2}\rho B C_d \left(h_s u^2\right) \tag{1}$$

Where F is the hydrodynamic force, ρ is the density of the water, B is a width of a structure, C_d is the drag coefficient, h_s is the bore/surge height (wave propagating on dry bed is referred toas surge whereas wave propagating on wet bed is called a bore) and u is the bore/surge celerity/velocity in the absence of obstacles. The term $h_s u^2$ is a momentum flux.

With regard to structural safety, the maximum load and its impact duration are paramount. Equation (1) indicates that maximum force occurs when the momentum flux term is maximum. However, Yeh (2007) and Fujima et al. (2009) showed that $h_{s\max} u_{\max}^2 \neq \left(h_s u^2\right)_{\max}$, in other words, maximum inundation depth and maximum velocity does not occur simultaneously. Therefore, the estimation of the maximum flux term is crucial to accurately computing the maximum hydrodynamic force. On the other hand, there is no simple way to estimate the maximum flux term even though some approaches exist in literature. Yeh (2006) suggested an analytical solution to obtain the maximum force, based on simplified and idealized situations (one-dimensional spatial variation on a uniformly sloping beach) together with some other assumptions. Later, Yeh (2007) provided a better solution including the effect of change in ground elevation for more realistic cases. But, the solution is still limited to uniformly sloping beach. Wüthrich et al., (2018a) introduced a modified momentum flux term, which is $h_s(t)[\min(\chi U; V_m(t))]^2$, where $h_s(t)$ is the time development of the wave profile without an obstacle, χ is a reduction coefficient, U is the bore front celerity, and V_m is the depth-averaged profile velocity. Shafiei et al. (2016) also used an alternative equation to compute the momentum flux. The maximum flux can also be numerically evaluated provided that a very fine grid size is employed to ensure the adequate accuracy (Yeh, 2007).

An initial impact force also known as surge/slumming force is as a result of the leading edge of running-up water impinging on a structure (Yeh, 2007). In comparison with the quasi-hydrodynamic force, this force is not pronounced when the front face of the bore is not steep. This situation occurs when the bore is large enough or the propagating surface is dry. Smoother surfaces can also produce a bore with a front face having a mild slope (Yeh, 2007; Arnason et al., 2009; Lukkunaprasit et al., 2009). Arnason et al. (2009) also highlighted that the initial impact force on the square column was larger than that of circular cylinders. They also observed that the initial peak impact force on the square column was about %50 higher than the subsequent maximum hydrodynamic force. Similar conclusion was reported by Lukkunaprasit et al. (2009), who found out that the impingement force was about 1.5 times the hydrodynamic force. Moroever, FEMA P646 (2008) recommended the use of Equation (1) by taking C_d as 3, which is 1.5 times higher than the actual value for the square and rectangular structure. There is also an equation for the estimation of the initial peak impact force (Dames & Moore, 1980), which is given as

$$F = 4.5\rho g B h^2 \tag{2}$$

Where g is the gravitational acceleration.

Tremendous effort has been made towards an accurate estimation of the wave front celerity and the averaged wave celerity over dry and wet bed conditions as they play not only a crucial role on the magnitude of the tsunami impact force but they also play a significant role on evacuation plan. Many analytical, experimental and numerical studies have been devoted and the average wave celerity is generally expressed as

$$\overline{U} = \alpha\sqrt{g d_0} \tag{3}$$

Where $\overline{U}$ is the average wave celerity, α is a coefficient (ranging from 0.66 to 2) and d_0 is the initial reservoir water depth.

The most widely recognized analytical solution for estimation of the wave front celerity was introduced by Chanson (2009) and it is given in Equation (4).

$$\left(\frac{4}{13}\right)\frac{\left(1-\frac{1}{2}\frac{U}{\sqrt{g d_0}}\right)^{7/2}}{\left(\frac{0.0778\left(\frac{k_s}{d_0}\right)^{1/4}}{8}\left(\frac{U^2}{g d_0}\right)\right)} = \sqrt{\frac{g}{d_0}}\,t \tag{4}$$

Where k_s is the equivalent sand roughness height and t is time.

Tsunami wave impact was experimentally modeled by either solitary waves or dam-break bores (Kihara et al., 2024). Wüthrich et al. (2018a) gave the details of the experimental studies on the tsunami impact force acting on the impervious structures and classified them based on the wave type as solitary wave or dam break wave. Chanson (2006) illustrated the analogy between the dam-break flow and tsunami-induced bores. In this study, dam-break like tsunami induced force was investigated.

The variations of the horizontal impact force with time on a square structure under four different reservoir water depths were experimentally obtained. A 2D finite-volume shallow water model was also employed to model the same experimental flow conditions. Numerically obtained maximum momentum fluxes were implemented in Equation (1) to compute the maximum quasi-steady hydrodynamic forces. The surge forces and average wave celerities and wave front celerities were also estimated by Equations (2-4). Experimental and numerical results have been compared to assess the applicability of the aforementioned equations.

2.Materials and methods

Experimental studies were carried out in a channel (HM162-GUNT) with dimensions 10.0x0.309x0.45 m in the Hydraulic Laboratory of the Civil Engineering Department of Niğde Ömer Halisdemir University (Fig. 1).

Fig. 1. General view of the experimental setup

All the experiments were conducted in a rectangular cross-section channel with a horizontal bottom and a dry downstream bed. A metal gate with a thickness of 11mm, representing the dam body was located 4.4m downstream of the channel inlet. The dam-break like tsunami bore was generated by a sudden release of impounded water in the reservoir (upstream of the gate) by an instantaneous opening of the gate. Then, the wave impacted a rigid square structure with a size of 4x4 cm, which was placed 1.22 m downstream of the dam (Figs. 2 and 3). The gate was opened by freely dropping a 15 kg load attached to it through a pulley system from a platform fixed at position 40 cm high.

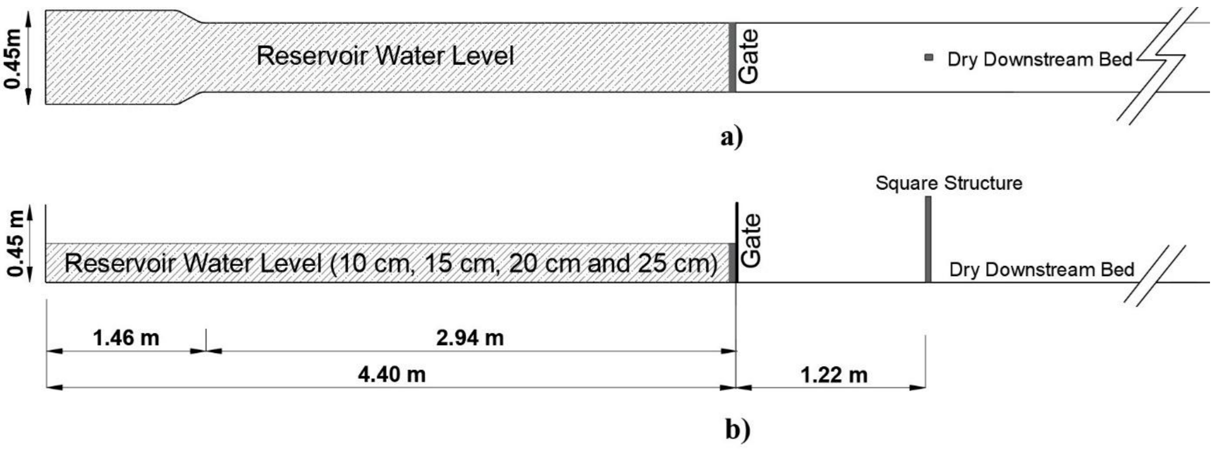

Fig. 2. Schematic view of the experimental setup a) plan view b) longitudinal cross-section view

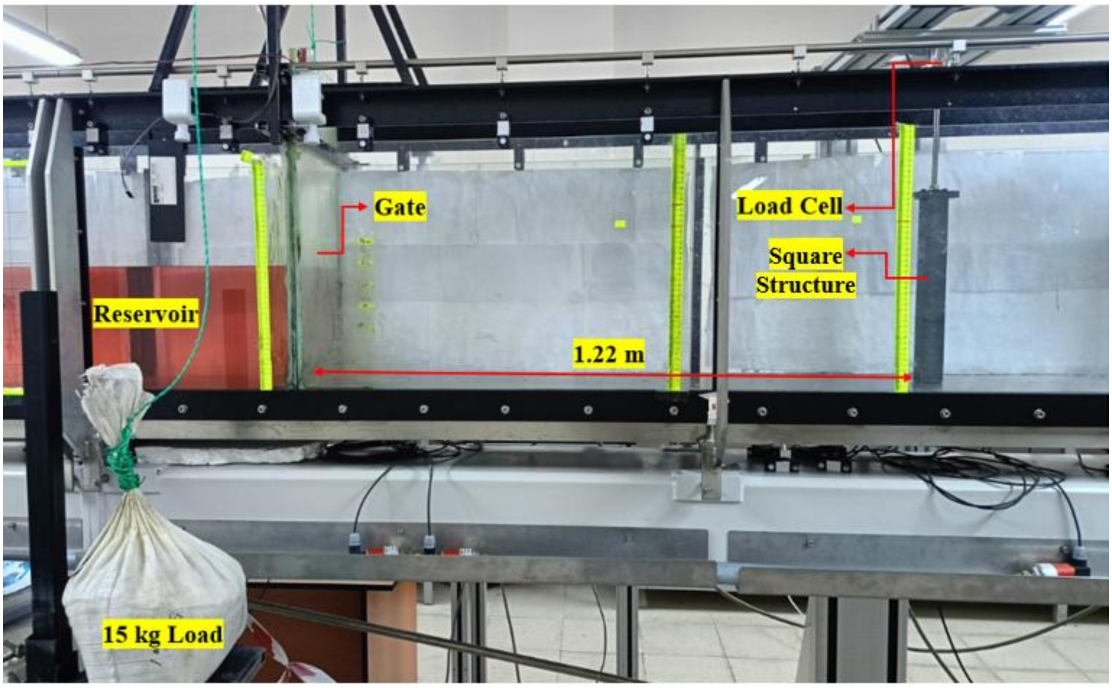

Fig. 3. Longitudinal view of the experimental setup

The impact force on the square structure was measured with the help of a USA ATI Mark Gamma SI-32-2.5 model load cell and traverse system (Fig. 4) over a period of 20s for each experiment. The load cell has a diameter of 75.4 mm and a height of 33.3 mm and six components. It can measure up to 32 N in horizontal forces and up to 100 N in vertical forces whereas it can measure moment in the x, y and z directions up to 2.5 Nm. The data obtained from the load cell is transferred to the computer with the NI PCIe-6323 DAQ card data acquisition system. The load cell was connected to a computer-controlled Dantec 41T32 model traverse system that can move in the x and y directions with a range of 610 mm x 610 mm.

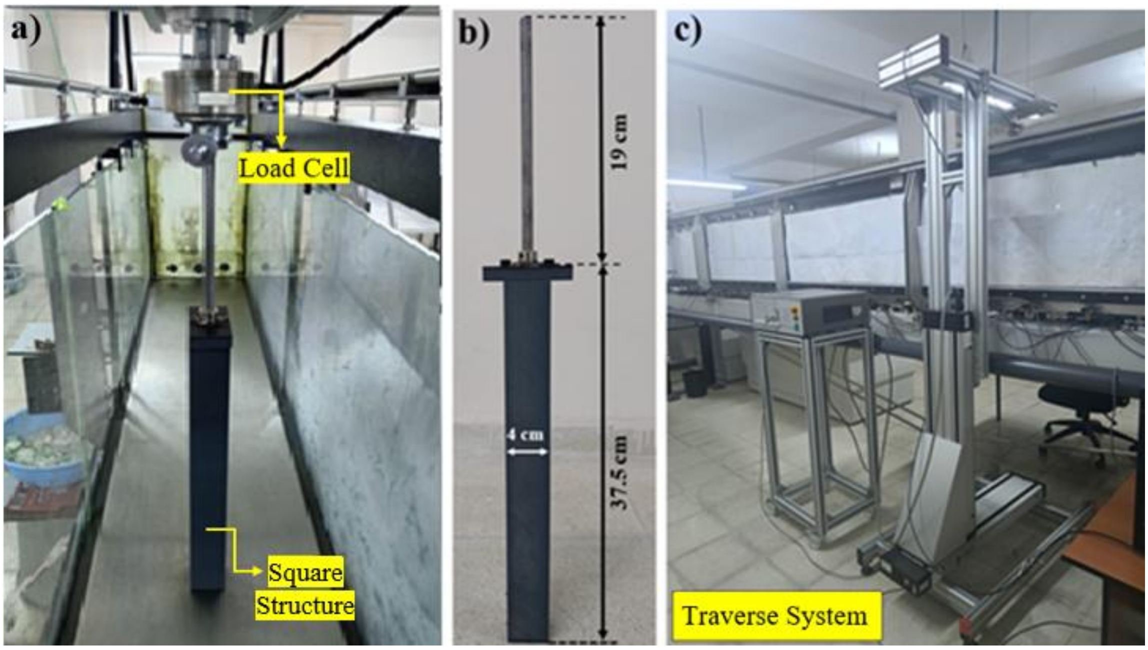

Fig. 4. Force measurement a) load cell and square structure b) size of the structure c) traverse system

The dam-break like tsunami wave propagation was also recorded using a a mobile phone camera with 1080p resolution and 30 fps shooting feature (Fig. 5) and the video recordings were later used to extract the experimental impact time and compute the average wave celerity.

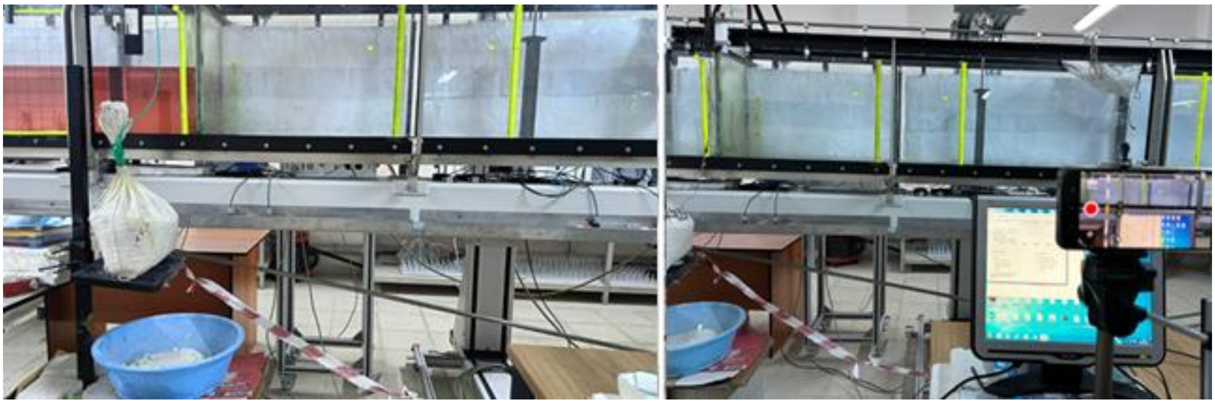

Fig. 5. Position of cell phone camera in experimental studies

The experiments were carried out at four different reservoir water levels; 10 cm, 15 cm, 20 cm and 25 cm and repeated three times for each water level. The arithmetic averaged of every three experimental data represents the corresponding experimental tests and was named after the reservoir water level as H10, H15, H20 and H25.

The gate opening times were recorded to ensure that they satisfied the sudden dam-break condition (the formation of fully developed surge/bore). The condition was introduced by Lauber and Hager (1998) and defined as $t_{op} = 1.25\sqrt{d_0 / g}$ where t_{op} is the gate opening time. The condition is met when the recorded gate opening time is less than the computed gate opening time obtained from the expression for the sudden dam-break condition. Recorded and computed gate opening times for each reservoir water level are given in Table 1. It can be seen that the condition for each reservoir water level was met.

Table 1. Recorded and computed gate opening times for each reservoir water level

Test Case	H10	H15	H20	H25
Recorded t_{op} (ms)	75	95	118	153
Calculated t_{op} (ms)	126	154	178	199

Repeatability of each experiment was validated by conducting each experiments three times and plotting the resulting forces over a period of 20s. Fig. 6 is given as an example of a validation test indicating that all three test results are compatible with slight variations immediately after the initial impact. This is most likely due to the structural vibration. Similarly, for each test case, a satisfactory repeatability was achieved (Fig. 7).

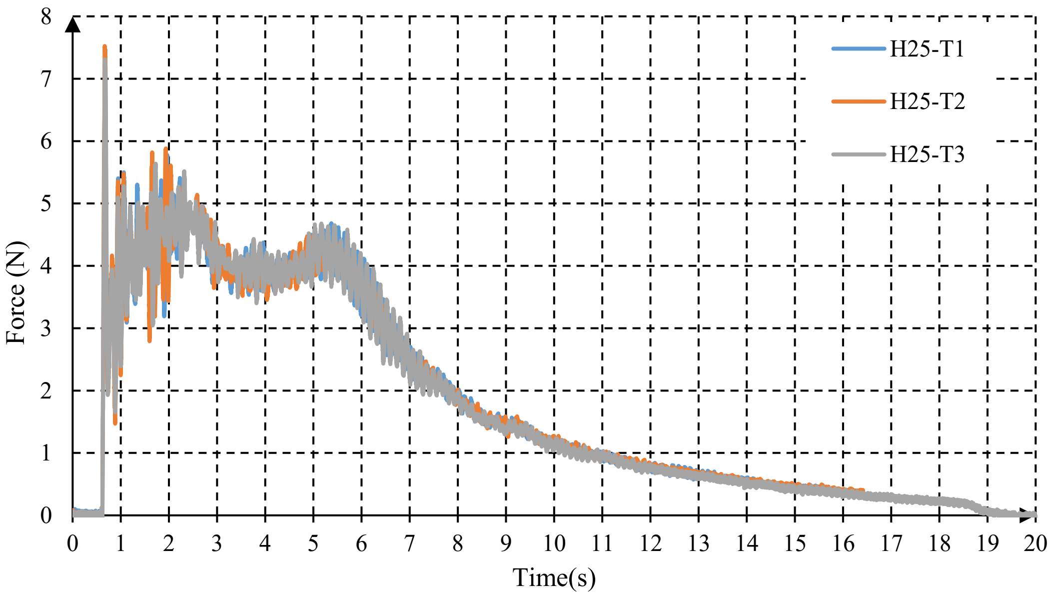

Fig.6. The time history of the force induced on the square structure for H25

A two-dimensional (2D) numerical model developed by Erduran et al. (2002) was used to reproduce the experimental flow conditions. The model solves the shallow water equations given in Equations (5-7) by using the finite volume method with one of the 5 available shock capturing schemes. In this study HLLC scheme was chosen.

$$\frac{\partial h}{\partial t}+\frac{\partial (hv_x)}{\partial x}+\frac{\partial (hv_y)}{\partial y}=0 \tag{5}$$

$$\frac{\partial (hv_x)}{\partial t}+\frac{\partial (hv_x^2+gh^2/2)}{\partial x}+\frac{\partial (hv_x v_y)}{\partial y}=gh\left(So_x-Sf_x\right) \tag{6}$$

$$\frac{\partial (hv_y)}{\partial t}+\frac{\partial (hv_x v_y)}{\partial x}+\frac{\partial (hv_y^2+gh^2/2)}{\partial y}=gh\left(So_y-Sf_y\right) \tag{7}$$

where h is the water depth, v_x and v_y are the depth-averaged velocities in x and y directions respectively, S_{0x} and S_{0y} are the bottom slope terms in x and y direcitons respectively and S_{fx} and S_{fy} the friction slope terms in x and y directions respectively.

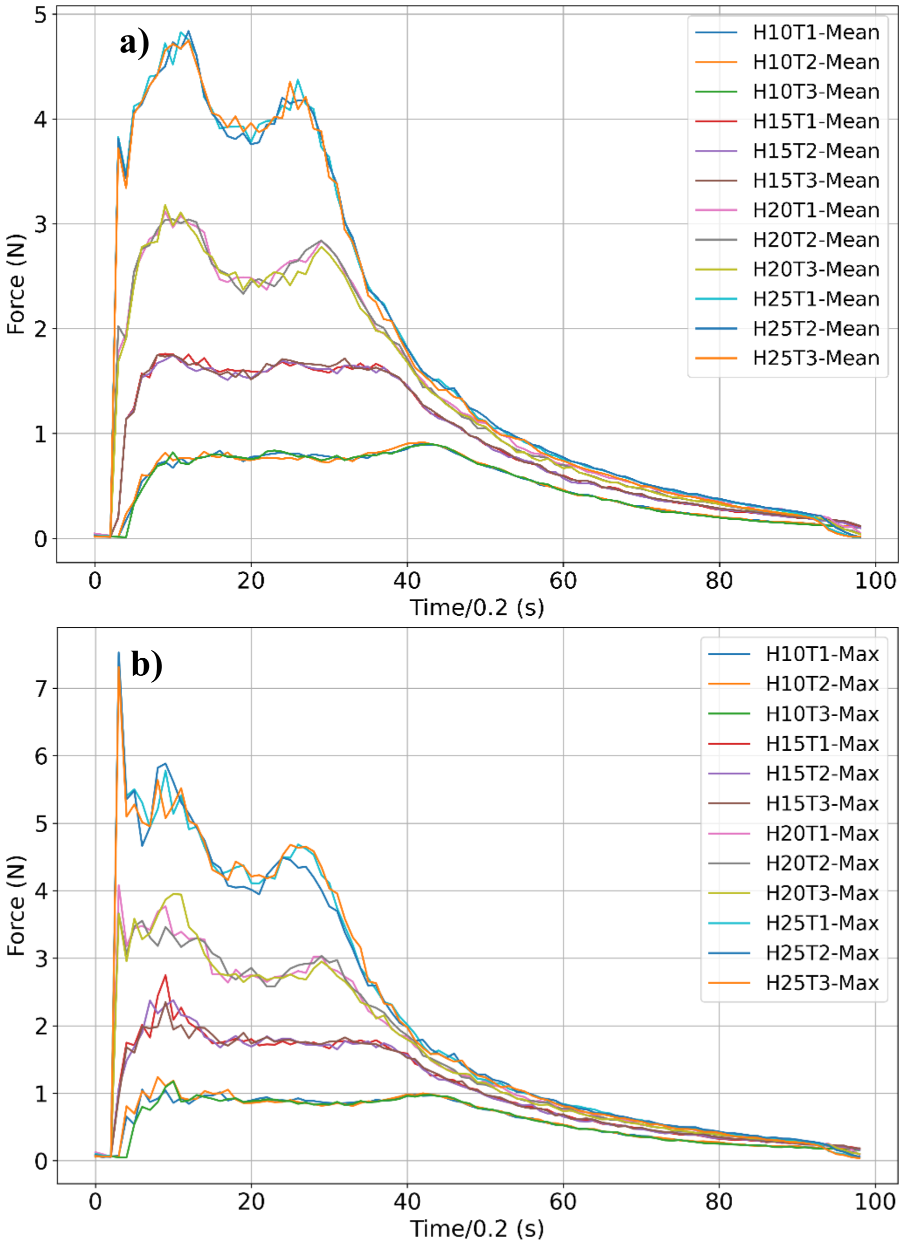

Fig. 7. Experimental lateral forces for a) mean forces b) maximum forces and c) minimum forces

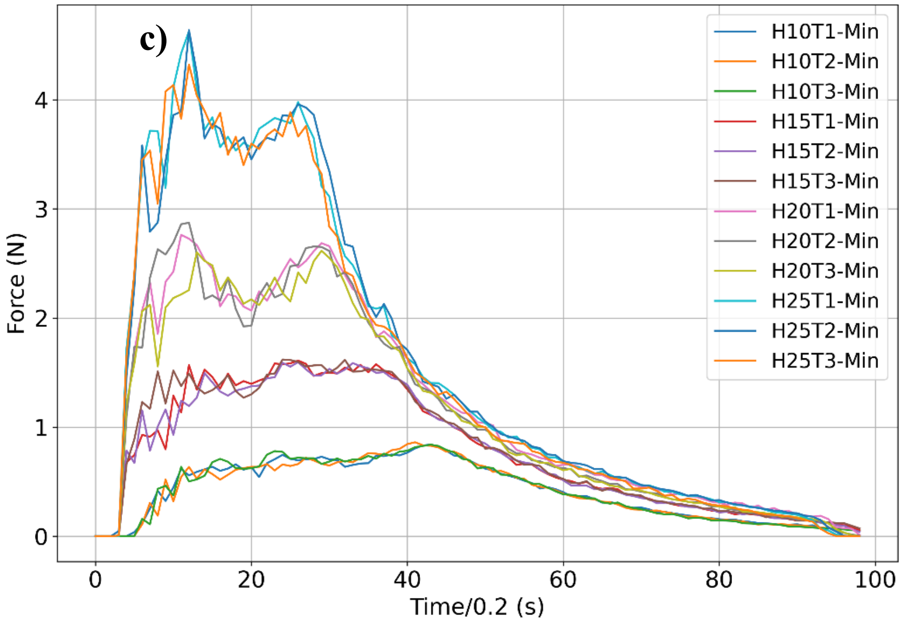
Continued Fig. 7



The computational domain (experimental channel) was divided into 31000 cells with the size of 0.01×0.01m. Initial flow condition was defined as the water depth upstream of the dam in the reservoir with a dry downstream bed condition. Upstream boundary was defined as a close boundary whereas downstream boundary was defined as an open boundary. A detailed solution to the shallow water equations and definitions of boundary and initial flow conditions are given in Erduran et al. (2002). The dam is removed instantaneously and the model is run for 12 s for each test. The time step is chosen to be 0.002s to ensure the numerical stability.

The numerical model produced the time variation of the flow characteristics (velocity and water depth) over 12s at the location of the square structure in the absence of the structure as well as the time variation of the flow characteristics along the channel for each test case. Hence, desired values for the impact time, averaged wave celerity, wave height, wave front celerity and the maximum flux term $\left(h_s u^2\right)_{\max}$ for each test were acquired.

3. Results and discussion

The experimental impact time was taken to be the duration between gate opening and the first impact and it was extracted from the video recordings by splitting them into frames with a time-interval of 0.0333 s. The numerical impact time was obtained from the numerical output file in the absence of the structure. The impact times were later used to compute the average wave celerities. Table 2 shows the experimental and numerical impact times and the average wave celerities. It also indicates the absolute percentage differences in the celerities. It is seen that the maximum absolute percentage difference between the numerical and experimental wave celerity is 5.67. Using Equation (3) and the averaged wave celerities, numerical and experimental, α values were also computed and it was found that they ranged approximately between 1.2 and 1.3, which are close to 1.25 reported by Wüthrich et al. (2018b).

Table 2. Experimental and numerical impact time and averaged celerity

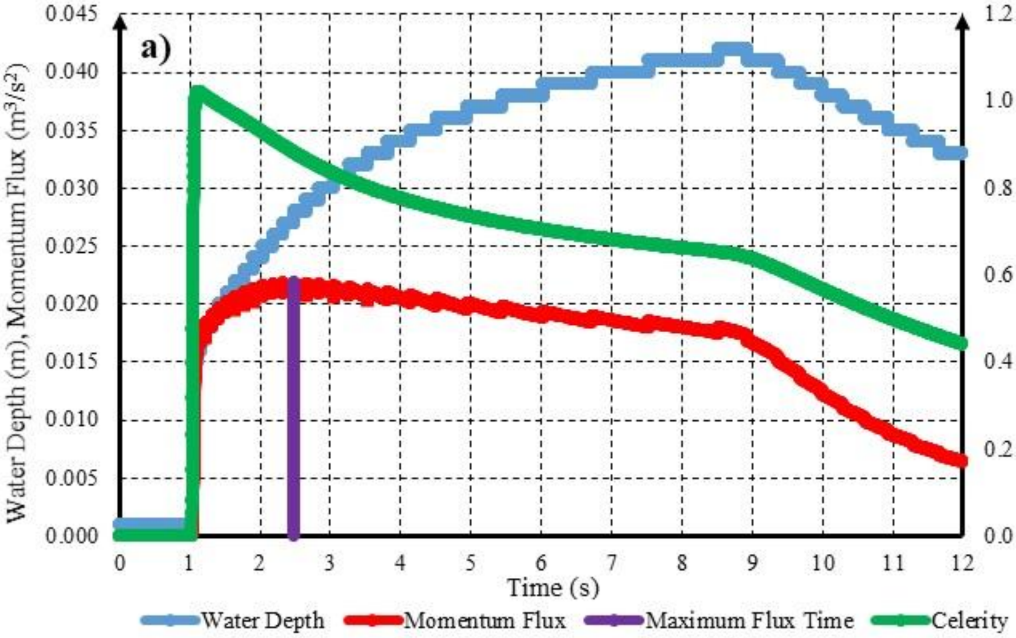
Test Case	Impact Time (s)		Average Wave Celerity (m/s)		Absolute Difference in Celerity (%)
	Numerical	Experimental	Numerical	Experimental	
H25	0.590	0.620	2.068	1.9677	4.84
H20	0.674	0.665	1.810	1.8346	1.35
H15	0.802	0.759	1.521	1.6074	5.67
H10	1.030	1.026	1.184	1.1891	0.39

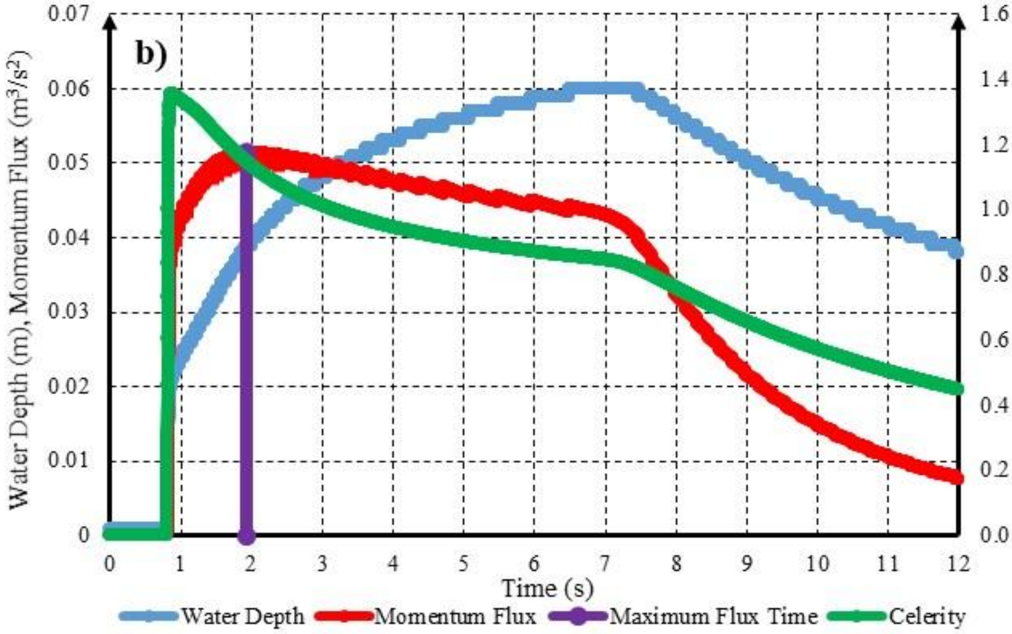
The numerical and analytical wave front celerites were obtained by using the 2D model and Equation (4) respectively. They were compared and it was seen that Chanson (2009) analytical equation produced a quite similar results with a maximum absolute percentage difference of 6.93 (Table 3).

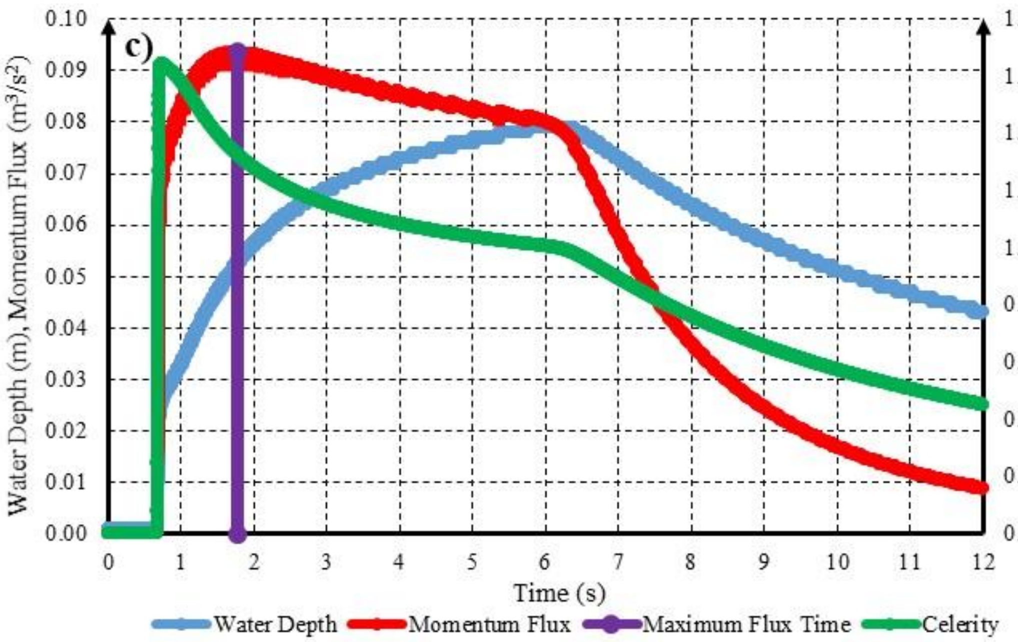
Table 3. Numerical and analytical wave front celerity at the structure location

Test Case	Numerical (m/s)	Chanson (2009) (m/s)	Absolute Difference in Celerity (%)
H25	1.906	2.028	6.39
H20	1.646	1.760	6.93
H15	1.356	1.423	4.93
H10	1.022	1.054	3.11

The maximum momentum flux, its occurrence time, water depth at maximum flux time as well as the maximum inundation depth at the structure location were numerically evaluated in the absence of the structure and given in Tables 4 and 5 as well as in Fig. 8. As can be seen, the maximum momentum flux occurred when the water depth was around 65-67 % percent of the maximum inundation depth. This result also agreed with that of Wüthrich et al. (2018b), who stated that the maximum momentum occurred 65-70 % of the maximum wave height for dry bed surges. It was also observed that the maximum momentum flux occurred at around 25-28 % of the initial reservoir level and approximately 2.4-2.6 times the impact time.







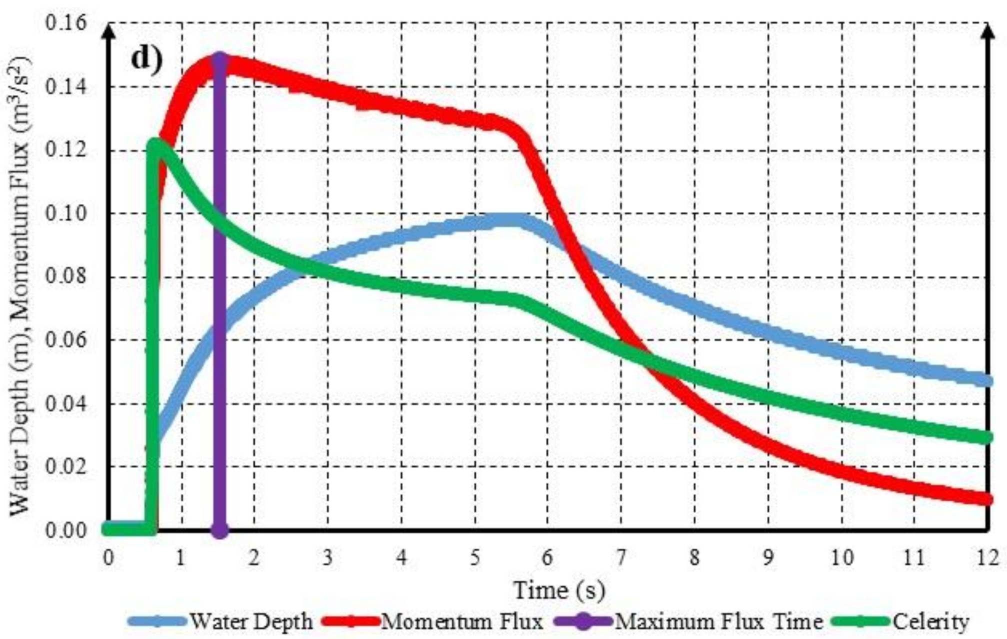


Fig. 8. Numerical momentum flux, water depth and celerity for all test cases a) H10 b) H15 c) H20 d) H25

Table 4. Numerical water depths and depth ratios at the structure location

Test Case	MF (m)	MI (m)	MF/MI (%)	MF/d_0 (%)
H25	0.064	0.098	65.3	25.6
H20	0.053	0.079	67.1	26.5
H15	0.039	0.060	65.0	26.0
H10	0.028	0.042	66.7	28.0

MF: Water depth at maximum flux time; MI:Maximum inundation depth

Table 5. Occurrence of maximum flux time (numerical)

Test Case	Impact Time (s)	Maximum Flux Time (s)	Impact time / Maximum flux time
H25	0.590	1.524	2.58
H20	0.674	1.772	2.63
H15	0.802	1.924	2.40
H10	1.030	2.488	2.42

The lateral hydrodynamic force for each test case and for two different drag coefficients was computed using Equation (1) and shown in Fig. 9. The results showed that the hydrodynamic force with a drag coefficient of 2 overestimated the hydrodynamic force in the quasi-steady phase. This drag coefficient is suggested by FEMA (2011) for rectangular objects. Taking drag coefficient as 1.65 resulted in much better estimate for the maximum hydrodynamic force. Similar to the present study, Shafiei et al. (2016) study also produced a drag coefficient of 1.65 for a square prism structure, perpendicular to the flow direction.

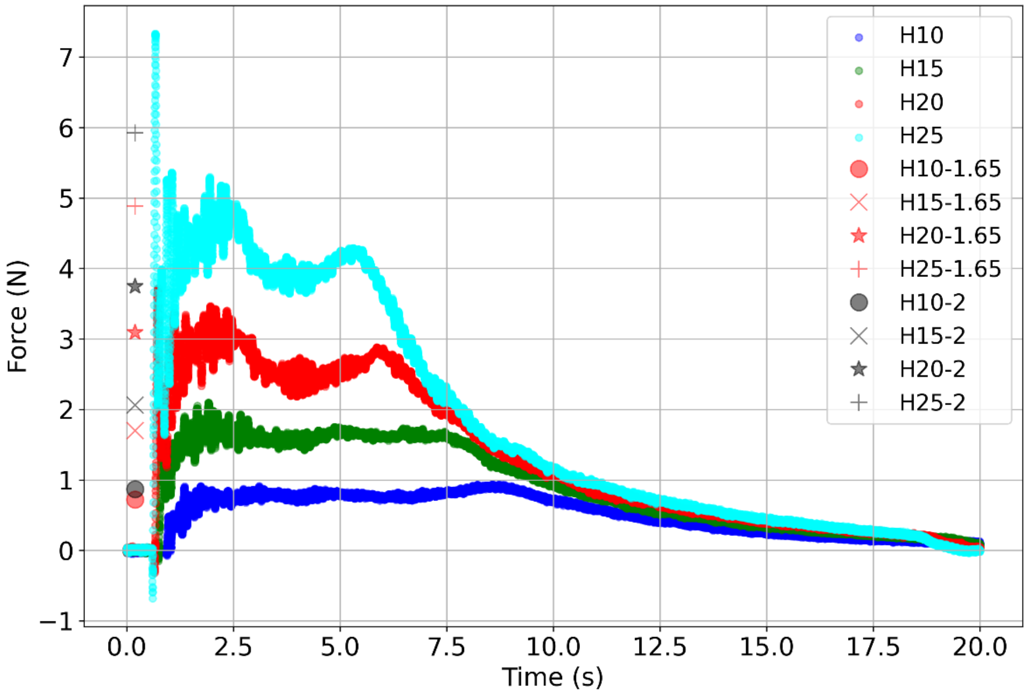

Fig. 9. Experimental and analytical lateral forces

Fig. 9 clearly illustrated that the higher the reservoir initial water depth, the higher the experimental and numerical impact forces. The rate of increase in the forces was larger than that of the water depths. Taking initial reservoir water depth and corresponding force for H10 as base, the force and the initial water depth ratios were computed and given in Table 6. An increase of 2.5 times in water depth resulted in an increase of 7.88 times in the impact force whereas double the initial water depth ended in 3.99 times the force.

Table 6. Calculated force and water depth ratios

Test Case	Recorded Maximum Impact Force (N)	Force Ratio	Depth Ratio
H25	7.33	7.88	2.5
H20	3.71	3.99	2.0
H15	2.10	2.26	1.5
H10	0.93	1.0	1.0

The recorded experimental forces also showed that the initial peak impact force was only dominant in H25 and it was higher than the subsequent hydrodynamic force (Fig. 9). The initial peak impact force was 7.33 N whereas the maximum hydrodynamic force was around 5 N, resulting in a force ratio of 1.47. The experimental studies of Ramsden (1993) and Arnason (2005) indicated that the peak overshoot at the initial impact was approximately 1.5 times the subsequent maximum hydrodynamic force. However, they draw this conclusion for a wet downtream bed, creating a bore wave rather than a surge as is the case in this study . In fact, they realized that there was no significant initial impulse force for the dry-bed surges. Except for H25, this study also supported their conclusions and the maximum force was due to the hydrodynamic force and not for the initial impact force. This can be attributed to the fact that the observed surge waves did not produce the significant initial impact force because the wave fronts were not sufficiently steep.

The force-time variations given in Fig. 9 aligns with the reported force phases in the literature, particularly the initial impact phase and the quasi-steady phase. The initial impact and run-up force occurred in a very short time, roughly in the order of 10^{-1} s (Lobovský et al, 2014). Once the wave reflected and the reflected wave traveled upstream, the quasi-steady phase started. The sudden drop in the force-time curves was mainly due to the impounded water in the reservoir. However, it was seen that the sudden drop occurred later when the initial reservoir water depth was lower.

4. Conclusions

The dam-break like tsunami induced forces acting on the square structure were experimentally and analytically obtained with the help of 2D numerical models. The following conclusions were drawn;

1- Equation (4) gave a quite good estimate for the wave front celerities. The experimental average wave celerities were compatible with those of 2D numerical model. α coefficient given in Equation (3) was found to be 1.25.
2- The maximum momentum fluxes and their occurrence time were numerically evaluated. Then the maximum hydrodynamic forces were computable using Equation (1). The calculated maximum hydrodynamic forces were in a good agreement with those of the experimental ones when the drag coefficient of 1.65 was taken. The drag coefficient of 2 produced overestimated values.
3- Numerical results indicated that the maximum flux occurred when the water depth was around 65-67% of the maximum depth recorded at the structure location. The maximum flux also occurred 2.4-2.6 times the impact times depending on the initial reservoir water depth. The result also indicated that the maximum flux occurred when the water depth at the structure location was 25-28 % of the initial reservoir water depth.
4- It was seen that the maximum impact forces were mostly due to the quasi-static forces, only at H25, was the initial peak impact force more pronounced and higher than the subsequent maximum quasi-static force.
5- The impact forces increased with the increasing water depth. However, the rate of increased in the force was much more than that of initial reservoir water depth.

Hydraulic Analysis of Multi-outlets Submains-II: Implementation

Gürol Yıldırım*[1]

[1] Giresun University, Engineering Faculty, Civil Engineering Dept., 28100, Giresun, Türkiye

Abstract. In this paper, the methodology covering design constraints to sensitively determine the operating inlet pressure head by trial-and-error-procedure, to achieve the design criteria (initial and boundary conditions), was presented. For any desired uniformity level, the procedure also provides an opportunity to evaluate the influence of different uniform line slopes on the pipe geometric characteristics (pipe size and length), and on the corresponding hydraulic variables (required operating inlet pressure and downstream end pressure heads and total friction head losses). The examination results of design applications covering various combinations of irrigation design parameters were depicted for outlet characteristics, and zero-slope condition (S0 = 0) graphically in dimensionless form, for practical purposes. For different design applications, the results of the present computer program (Multi-flowCAD) has the highest accuracy and sensitivity rather than those of the alternative analytical and numerical methods earlier presented, because only the basic equations of the hydraulics of steady pipe flow were efficiently used in each segment of lateral length which was divided by successive individual emitters. .

Keywords: Smooth pipe-flow; Steady-state analysis; Software; Computer-aided design (CAD)

1. Methodology

1.1. Initial and boundary conditions for software implementation
An important objective of the present analysis is the sensitively determination of the proper value of the operating inlet pressure head, H0I (Hin), which can be varied within limited constraints in the design algorithms (initial and boundary conditions) (Yıldırım, 2023a,b; Yıldırım, 2014a,b; Yıldırım, 2015a,b; Yıldırım, Yıldırım & Singh, 2013a). It clearly means, preliminary increase in average piezometric head (Δ_0) varies ranging from minimum inlet pressure head range [$\overline{H}_{min}$ = $H_{0I(min)}/H_{av}$] toward maximum inlet pressure head range [$\overline{H}_{max}$ = $H_{0I(max)}/H_{av}$]. The proposed computer program (Multi-flowCAD) sensitively performs the following calculations, in a stepwise manner:

a. Determine operating inlet pressure head ranges in which the operating inlet pressure head is located ($\overline{H}_{min}$ and $\overline{H}_{max}$ = minimum and maximum ranges for the operating inlet pressure head);
b. Obtain minimum operating inlet pressure head range [$\overline{H}_{min}$] based on the design algorithms (for H_{0I}, if smaller values than are designed, this would indicate that a negative value of the pressure head at any outlet would be apparent);
c. Obtain maximum operating inlet pressure head range [$\overline{H}_{max}$], based on the design algorithms (for H_{0I}, if larger values than $\overline{H}_{max}$ are designed, this would indicate that the sum of outflows is greater than the initial pipe discharge, Q_I, which means that back-flow occurs from the downstream end toward the upstream direction of the pipeline);
d. As the proper interval of the reduced operating inlet pressure head [$\overline{H}_{min}(=H_{01(min)}/H_{av}) \le (H_{01}/H_{av}) \le \overline{H}_{max}(=H_{01(max)}/H_{av})$] is obtained, the favorable value of H_{0I} should be investigated. In line with this concept, the following considerations should be taken into account:
e. For H_{0I} determination, if $\overline{H}_{min}$ is selected for sub-main line design, the value of residual flow rate at the downstream end from the last outlet is larger than the acceptable small quantity (ε), approximately zero.

* Corresponding author, E-mail: gurol.yildirim@giresun.edu.tr

https://doi.org/10.31462/icearc2025_ce_hyd_870

Obviously, an important boundary condition for the downstream end does not keep to the right in the design algorithm. Meanwhile, the residual pipe discharge decreases from $\overline{H}_{min}$ toward $\overline{H}_{max}$, increasingly; then, for $\overline{H}_{max}$ it has a sufficiently small value, approximately zero.

f. For sub-main line design, the design parameters should be determined in order to minimize the total friction drop at the end of pipeline. In this respect, if $\overline{H}_{min}$ is selected, the total friction drop would have major values and then, from $\overline{H}_{min}$ toward $\overline{H}_{max}$, have minor values, increasingly. However, if $\overline{H}_{max}$ is selected, the total friction drop is minimized.

g. In the design procedure, the water application uniformity is an unknown parameter; other parameters should be varied to have the highest level of uniformity. Obviously, water application uniformity increases from $\overline{H}_{min}$ toward $\overline{H}_{max}$, with the highest value at $\overline{H}_{max}$.

h. Resulting, the proper operating inlet pressure head is finally achieved at $\overline{H}_{max}$, and total friction drop ($h_{f(L)}$) and residual flow rate (Q_r) for the pipe segment from the last outlet toward to downstream closed end are minimized, whereas the water application uniformity (U_C) of the system is achieved to be maximized.

i. For all performed simulations it should be pointed out, for the Multi-flowCAD, the required design parameters ($H_{f(L)}$, Q_r, U_C and/or D_{ULQ}) vary versus the operating inlet pressure head range (H_{0I}/H_{av}) to achieve its acceptable proper value within the design criteria, while the available alternative procedures may have fixed values, for these unknown variables.

1.2. Design configurations

Design procedure based on the manifold flow hydraulics principles covering various required parameters can be ordered in the following four steps (Sadeghi et al., 2016; Scaloppi & Allen, 1993; Yıldırım, 2016b, Yıldırım & Kose, 2016a):

1. To give a series of values for the design parameter (pipe diameter or length) from smallest to largest.
2. To find the required operating inlet pressure head (H_{in}) that can create the required average outlet discharge (q_{av}), and to evaluate the total friction head losses (H_f), and the uniformity coefficients of water application (U_C and/or DU_{LQ}), for each given design value.
3. To plot the dimensionless design curves of the uniformity of water application, the required operating inlet pressure head and the total friction head losses versus the required design parameter (pipel diameter or length).
4. To find the best solution of the required design parameter (pipe diameter or length), the required operating inlet pressure head and the total friction head losses from the dimensionless design curves plotted in the third step according to the required level of water application uniformity.

2. Design applications

In designing of the pipeline in a submain unit system, it is commonly assumed that the outlet outflow-pressure head relationship, average flow rate and hydraulic characteristics of the outlet model examined, and acceptable level of water application uniformity are known, a priori (Sadeghi & Peters, 2013; Sadeghi & Peters, 2011; Singh et al., 2000). It often remains to design either the pipe length or the inside diameter, the operating inlet pressure head, pressure head at the downstream closed end, the extreme pressure heads with their locations, total head losses due to friction along the lateral, with the remaining variables previously known (Singh & Mahar, 2003; Valiantzas, 1998). The following are the various design examples based on each design concept, incorporating various design configurations. For the following design examples, the dimensionless curves which can be efficiently used as the design charts will be provided to directly determine any of the required hydraulic design parameters (Valiantzas, 2002).

2.1. Design example-I: Determination of pipeline length with operating inlet pressure head, total friction head losses and uniformity coefficients using design curves

It is given that the outflow-pressure head relationship : $q = 3.58\ 10^{-7}\ H^{0.5}$, average flow rate of outlet: $q_{av} = 4\ lh^{-1}$ ($1.111\ 10^{-6}\ m^3s^{-1}$), spacing between successive interior outlets: S = 1.0 m, design uniformity coefficient : U_C = 0.95, the inside diameter of pipeline : D = 14 mm, the kinematic viscosity of water at 20 ^{0}C $\nu = 1.01\ 10^{-6}\ m^2s^{-1}$. The values that must be determined are: (1) Length of pipeline, (2) the proper value of operating pressure head at the pipe inlet, (3) total frictional head losses along lateral.

Solution with Design Curves:

On the basis of the present algorithm discussed, the direct design procedure can be better illustrated if the values of the operating inlet pressure head H_{in}, the friction head loss H_f, and the uniformity coefficients UC, DU_{LQ} are plotted for various lengths of lateral, ranging from 25 to 250 m, for the lateral internal diameter, D = 0.014 m.

In each calculation the values of design parameters are obtained from the Multi-flowCAD, then depicted in dimensionless form for practical purpose which could also be efficiently used as the design charts.

From Fig. 2.b and for design uniformity coefficient UC = 0.95; length of the lateral, L = 125 m is found. On the other hand, from Figure 6a and for L = 125 m; we have relative pressure head at the inlet, $H_{in}/H_{av} = 1.26$. From the emitter outflow-pressure head relationship we finally compute

$$H_{av} = \left(\frac{q_{av}}{c}\right)^{1/y} = \left(\frac{1.111\times 10^{-6}}{3.58\times 10^{-7}}\right)^{1/0.5} = 9.631 \text{ m} \tag{1}$$

Resulting; $H_{in} = 1.26 \times 9.631 = 12.135$ m is found.

From Fig. 2.c and for L = 125 m ; we have relative friction drop, $H_F/H_{in} = 0.326$ and then the frictional head loss along the lateral, $H_F = 0.326*12.135 = 3.956$ m is found. For the second uniformity design parameter DU_{LQ}, from Fig. 3d and for L = 125 m; $DU_{LQ} = 0.915$ is found.

2.2. Design example-2: Determination of pipeline diameter with operating inlet pressure head, total friction head losses and uniformity coefficients using design curves

Determine the following parameters for the design uniformity coefficient UC = 0.95 and the pipeline length L = 150 m using the same data given in the Design Example-1. (1) the inside diameter of the lateral, (2) the proper value of operating pressure head at the lateral inlet, (3) total frictional head losses along lateral.

Solution with Design Curves:

The values of the inlet pressure H_{in}, the frictional head loss H_f and the uniformity coefficients U_C, DU_{LQ} are evaluated for various pipe internal diameters ranging between 10 mm and 21 mm (L = 150 m). In each calculation the values of design parameters are obtained from the present computer program; then depicted in dimensionless form for practical purpose which could also be used as a design chart (Fig. 7 (a,b), (c,d)).

From Fig. 7b and for design UC = 0.95; inside diameter of the lateral, D = 16.4 mm is found. On the other hand, from Fig. 7a and for D = 16.4 mm; we have relative pressure head at the inlet, $H_{in}/H_{av} = 1.195$. From the emitter outflow-pressure head relationship we find,

$$H_{av} = \left(\frac{q_{av}}{c}\right)^{1/y} = \left(\frac{1.111\times 10^{-6}}{3.58\times 10^{-7}}\right)^{1/0.5} = 9.631 \text{ m} \tag{2}$$

Resulting ; $H_{in} = 1.195\times 9.631 = 11.51$ m is found.

From Fig. 3.c and for D = 16.4 mm; we have relative friction drop, $H_F/H_{in} = 0.277$ and then the frictional head loss along the lateral, $H_F = 0.277*11.51=3.188$ m is found. For the lower-quarter distribution uniformity coefficient (DU_{LQ}), from Figure 4.d and for D = 16.4 mm; $DU_{LQ} = 0.925$ is found.

3. Conclusions

An important objective of the present computer-aided design technique is the sensitively determination of the proper value of the operating inlet pressure head, H_{0I} (H_{in}), which can be varied within limited intervals in the design algorithms (initial and boundary conditions). It clearly means, preliminary increase in average piezometric head (Δ_0) varies ranging from minimum inlet pressure head range $\overline{H}_{min}$ toward maximum inlet pressure head range $\overline{H}_{max}$. When the operating inlet pressure head range increases from $\overline{H}_{min}$ toward its proper value at $\overline{H}_{max}$, the total friction drop ($H_{f(L)}$) along the line, and residual lateral flow rate from the last downstream emitter (Q_r) decreases, whereas the water application uniformity coefficient (U_C) increases, in all design cases examined. It clearly means, the proper value of the operating inlet pressure head can be sensitively achieved at the upper limit of the design interval, $\overline{H}_{max}$. Otherwise, when the operating inlet pressure head range was selected as the smaller value than $\overline{H}_{max}$, the parameter ε, which is the ratio of residual discharge to the total lateral inlet discharge (Q_r/Q_{in}) had the negative value at the downstream closed end from the last emitter; in that case, the back-flow occurred from the downstream closed end toward upstream direction; namely, an important boundary condition for the downstream lateral end did not keep to the right, in the design criteria. For all performed simulations it should be pointed out, for the Multi-flowCAD, the required hydraulic design parameters vary within the operating inlet pressure head interval to achieve its acceptable proper value based on the design criteria, while the available alternative procedures may have fixed values, for these unknown hydraulic variables.

Mechanical and fresh properties of self-compacting mortars containing silica fume and waste marble powder

Fethi İŞSEVER*[1]

[1] Bingol University, Department of Civil Engineering, 12000 Bingol, Türkiye

Abstract. The paper presented herein investigates the results of experimental work on the strength and durability performances of self-compacting mortars (SCMs) manufactured from silica fume (SF) and waste marble powder (WMP). In this study, 16 mortar mixtures were designed with a total binder content of 600 kg/m3 and a water/binder ratio between 0.34-0.45. The control mixture contained only Portland cement (PC) as the binder. The cement was partially replaced with 5, 7.5, 10 of SF and 10, 15 and 20% of WMP as binary mixes. Also, ternary mixtures were prepared by the incorporation of WMP and SF at different replacement dosages by weight. In total, 16 different combinations of mixes were studied. Firstly, the fresh properties of mortars were tested for slump flow, V-funnel flow times. Then the mechanical properties of SCMs were examined by the tests of compressive strength and flexural strength for the age of 7, 28, and 180 days. The results of the study reveal that increase in the dosage of WMP increases SCMs flow but increase in the dosage of SF decreases flow. The best compressive strength was obtained in the SF5WMP10 mixture, while the best tensile strength was obtained in the control mixture of 180 days. The best compressive strength value was measured 73.64 MPa, and the best tensile strength value was measured as 10.46 MPa. The ternary use of PC, SF, and WMP improved the shortcomings of SCMs with binary mixtures of WMP. After the optimum ratio SF5WMP10 mixture, a decrease in compressive and tensile values was observed with each increasing pozzolan amount.

Keywords: Self-compacting mortar, Silica fume, Waste marble powder, Fresh properties, Mechanical properties.

1. Introduction

Today, the vast majority of structures built on earth are constructed using concrete. Cement is one of the main materials of concrete. To build safe, economical and aesthetic structures, it is important to produce concrete with good mechanical and durability properties.

Mineral and chemical additives have been used to improve the fresh mechanical properties of concrete for a long time. For minerals used instead of cement, the term pozzolan and cement-based materials are also used. Cement based materials are the most widely used building materials in the world. Cement based materials are defined as green building materials. With the use of these materials, while protecting the environment from waste, economic benefits are also achieved. Cement based materials are easy to process and place during the production stages. In addition to these advantages, materials produced in accordance with appropriate production procedures have high strength throughout their service life and show durability against environmental impacts. In addition, one of the most important features that makes cement-based materials superior to other building materials is that they can be shaped as desired.(Tuğrul Erdem & Öztürk, 2012) Many potential substitutes of cement such as, waste marble slurry (WMS), silica fume (SF), granite waste, rice husk ash, fly ash (FA), metakaolin, etc. are there (Aliabdo et al., 2014; Rana et al., 2016)

Inclusion of additional cementitious and waste materials such as silica fume (SF)(Gesoglu & Al-goody, n.d.; Jalal et al., 2015; Song et al., 2018), fly ash (FA) and marble cutting sludge waste (MCSW) has a greater potential in minimising the cost of concrete(Bhavan, 2018; Singh et al., 2017; Uysal & Yilmaz, 2011). Through the use of waste materials, negative impacts on the environment are reduced, environmental efficiency is improved and solutions to waste storage problems are found. In studies conducted with silica fume, it has been observed that the use of silica fume at certain ratios improves the strength and durability properties of concrete. In fresh concrete, it was stated that it decreased the workability, but this problem was overcome by using plasticisers.(Amudhavalli & Mathew, 2012; Mazloom et al., 2004; Sasanipour et al., 2019)

Marble dust and silica fume are widely used in sustainable concrete mixes.(Demir & Alyamaç, n.d.) Silica fume are the most widely used mineral additives in concrete/mortar.(Wang et al., 2012) A large amount of natural

* Corresponding author, E-mail: fissever@bingol.edu.tr

https://doi.org/10.31462/icearc2025_ce_mat_015

resources is used for the production of self-compacting concrete (SCC). The continuous use of so many resources is not sustainable. Researchers have focused on reducing(Mazloom et al., 2004) construction costs and partially replacing cement with industrial waste. It is possible to effectively use various industrial wastes instead of cement or aggregate in concrete production. Among these wastes, waste marble powder is a useful choice and researchers have been interested in using WMP in concrete for some time(Ahmad et al., 2023)

Marble is processed industrially by cutting, polishing and using it for decorative purposes and is therefore economically valuable. In marble quarries, stones are cut into blocks using different methods. During the cutting process, 20-30% of a marble block becomes waste marble dust. Marble dust is a waste material produced in significant quantities around the world. Marble waste also causes a serious environmental problem. Therefore, the use of waste marble as an additive or aggregate in concrete production has become an increasingly important issue(Demirel & Alyamaç, 2018; Ulubeyli & Artir, 2015)

Super plasticizing and/or viscosity regulators which reduce water at high levels in SCC/SCM production are used (Sonebi, 2004). Polycarboxylate (PCE) superplasticizers play a crucial role in preventing cement coagulation by effectively adsorbing onto the surface of cement particles, enhancing dispersibility, and maintaining dispersion performance.(Yang et al., 2024)

In this study, firstly, fresh mortar properties of SCMs were investigated by determining the spread and v-funnel values. In order to evaluate the characteristics of fresh properties of SCMs, mini V-funnel flow and mini slump flow tests recommended by EFNARC were carried out. Then, binary and ternary combinations were formed by partial substitution of silica fume and waste marble dust, which were kept in water cure for 7, 28 and 180 days. Thus, the compressive and tensile strengths of these SCMs were analysed. For the compressive and tensile tests of SCMs, 40x40x160 mm specimens were produced with different proportions of silica fume and waste marble dust. The apparent density values of the specimens were also measured.

2. Materials and methods

The aim of this study was to measure the spreading, V-funnel and strength properties of double and triple combination SCMs using partial silica fume and waste marble dust instead of cement after 7, 28 and 180 days of water curing. For the compressive and tensile tests of SCMs, 40x40x160 mm specimens were produced from different substitution ratios of silica fume waste marble dust. The specimens were first broken in the flexural tensile test press machine and three tensile strengths were measured and averaged. Then, 6 specimens were broken in the compressive press machine and compressive strengths were obtained. Mini spreading and mini V-funnel testers were used to measure the spreading and flow properties of self-compacting mortars in fresh state. In addition, the apparent unit weight values of the mortars were also measured.

2.1 Materials

Normal Portland cement (CEM I 42.5N) produced in Elazığ Altınova Cement Factory was used in the study. The slurry obtained from the cutting wastes of the marble factories in Elazığ 2nd Small Industrial Site was dried, sieved and marble powder (WMP) was obtained. Silica fume (SF) was obtained from Antalya Ferro Metallurgy Plant. The properties of cement, waste marble powder (WMP) and silica fume (SF) are shown in Table 1.

The sand used in the mixtures is natural river sand extracted from the Murat River in Palu with a specific gravity of 2.63 g/cm3, a fineness modulus of 3.29 and a water absorption of 1.91% . The maximum particle size of the sand is 4.00 mm (Fig. 1). In order to obtain a suitable workability with a low water/binder (w/b) ratio, a modified polycarboxylate based polymer type Sika Viscocrete superplasticiser from Sika Construction Chemicals was used.

2.2. Mix proportions and fresh mortar tests

A total of 16 different mixtures containing 600 kg/m3 binder, including the control sample, were prepared to observe the properties of SCM in fresh and hardened states. To evaluate the fresh properties of SCMs containing SF and WMP, mini slump flow diameter, mini V-funnel flow time experiments were performed. SCMs were produced by replacing Portland cement with silica fume (SF) at 6, 10 and 14 wt% and waste marble powder (WMP) at 10, 15 and 20 wt%. The mixing ratios of the produced mortars for 1 m3 by weight are given in Table 3. The SCMs were designed to give a slump flow diameter of 240-260 mm, which was obtained by varying the superplasticiser (SP) amounts. Experimental batches were produced for each mix to obtain the proposed slump flow diameter. V-funnel flow time and slump flow diameter were obtained according to EFNARC recommendations. The number after each SF and WMP letter indicates the amount of each mineral mixture in the mortar. For example, FS5WMP10 mortar consists of 5% silica fume and 10% waste marble dust.

Table 3.Mix proportion of mortars (kg/m^3).

*SP = superplasticizer.

2.3. Production of test specimens
In all mixtures, cement, mineral additives and fine aggregate were mixed first by hand for half a minute and then by machine for 1 minute. Then (water + SP) was added to this mixture and mixed by machine for 3 more minutes. The workability of the fresh mortar was obtained by mini-collapse and V-funnel tests according to EFNARC standards. Compressive and flexural tensile strengths were performed on 160 x 40 x 40 mm prisms after 7, 28 and 180 days of water curing. 3 flexural tensile tests were performed for each mixture. 6 specimens obtained were used in compressive tests

2.4. Curing of test specimens
All specimens produced from 16 different mixtures were kept in moulds under laboratory conditions for 24 hours and then subjected to water curing in a water tank at 20±2°C for 7, 28 and 180 days (Figure 2).

2.5. Test methods

2.5.1 Workability tests for fresh mortar
To measure the workability of SCM, mini-slump flow test and V-funnel flow test were performed according to EFNARC (2005) standards. In the mini-slump flow test, the truncated cone was filled with mortar on a flat glass plate and lifted upwards. The diameter was evaluated by averaging two perpendicular dimensions of the spread mortar. In the V-funnel flow test, after the funnel was completely filled with mortar, the bottom outlet was opened to allow the mortar to flow out. The V-funnel flow time is the time (t) from the onset of light to the opening of the bottom outlet and the exit of the funnel. The workability values of SCMs were evaluated according to EFNARC (2005) acceptance criteria, which are 24-26 cm and 7-11 s for the slump flow diameter and V-funnel flow time, respectively.

2.5.2. Compressive and tensile strength tests
Firstly, fresh mortar tests were completed. After the fresh mortar tests, the mortars were poured into 40x40x160 mm steel moulds and the set specimens were demoulded after 24 hours. After demoulding, the specimens were subjected to water curing at a temperature of (20 ± 2) C until the test age. Compressive and flexural strength tests were carried out at 7, 28 and 180 days according to ASTM C109 on 48 prismatic specimens, three 40x40x160 mm specimens each, obtained from 16 mixtures. Initially, the tests were performed for tensile strength and two halves were obtained, then 96 specimens were used for compressive strength tests(ASTMC109). The compressive strength and tensile strength tests were carried out on a testing machine with a capacity of 250 kN in compression and 150 kN in bending (Fig. 2).

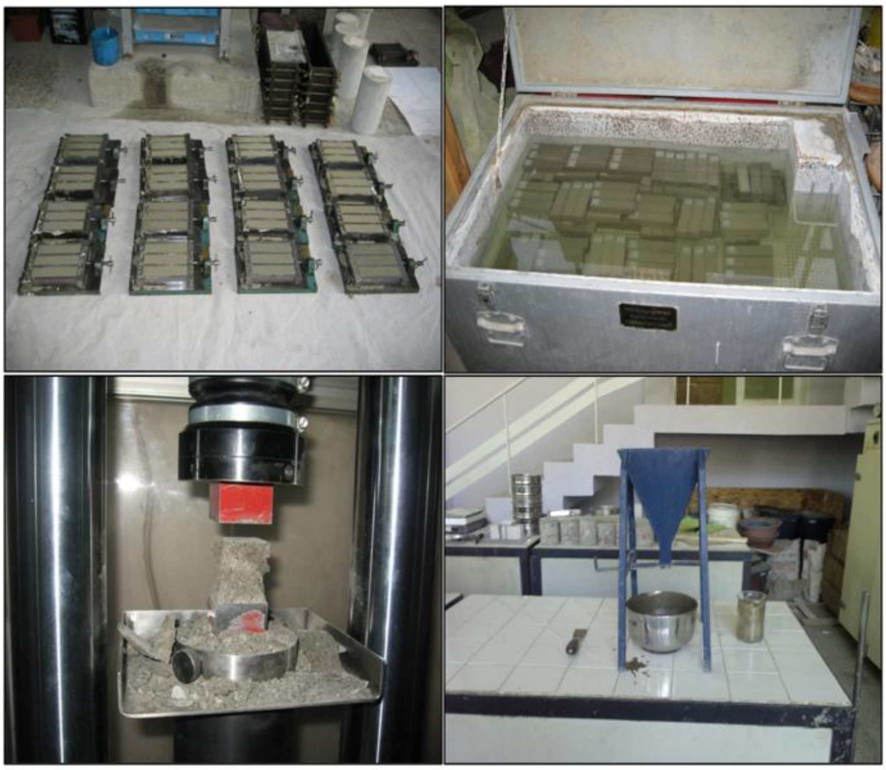

Fig. 2. Curing conditions, fresh and mechanical tests

3. Results

3.1. Fresh SCMs properties

Fig. 3 shows the relative slump and relative V-funnel time values. It is understood that SCM mixtures meet EFNARC (2005) spreading and f-funnel standards. When the spreading (24-26 mm) and V-funnel (7-11 s) values are analysed, it is seen that all values are within the reference range. SF mixtures generally have low spreading values (Felekoğlu et al., 2006; Karatas et al., 2010). As both SF and WMP ratios increased, the water requirement for workability increased (Table 3). Since the amount of SP was taken constant in the fresh mortar experiments, EFNARC (2005) standards for spreading and V-funnel were achieved in all mixtures by selecting the amount of water at appropriate ratios. No segregation occurred in the mixtures and workability and flowability were quite good (Fig. 3).

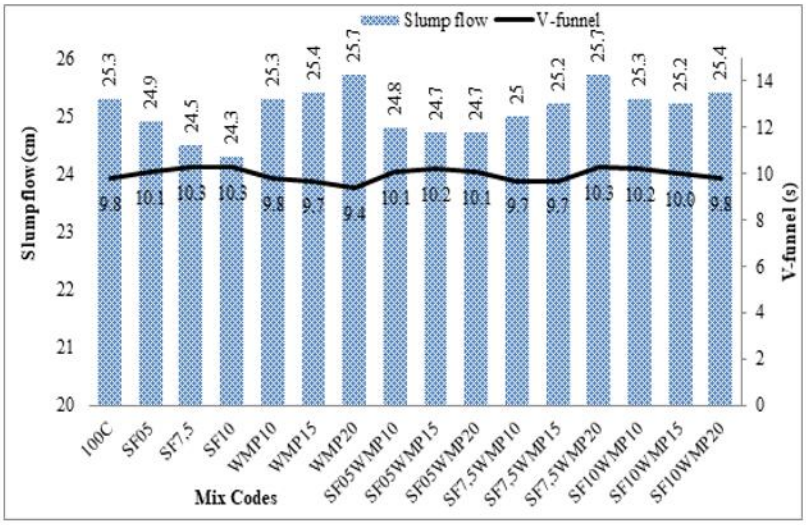

Fig. 3. Mini Slump and V-funnel test results

3.2. Hardened properties
Both compressive strength and tensile strength were lower in WMPs than in SFs, especially in terms of early age strength. However, as the curing time increased, the compressive strength and tensile strength of all SCM specimens increased. This weakness of WMPs was compensated by the fast hydration property of SFs. It is possible to see this in ternary mixtures (Fig. 4).

3.2.1 Compressive strength
When all values of compressive strength measured at 7, 28 and 180 days were analysed, magnitudes between 32.4 MPa and 73.6 MPa were observed. The smallest value belonged to the 7-day binary blend of WMP20 and the highest value belonged to the 180-day ternary blend of SF05WMP10. The compressive strength changes of all SCMs at 7, 28 and 180 days are plotted in Fig. 4. The compressive strength increased gradually with increasing curing time in water. The use of SF increased the 7-day strength faster than WMP. After 28 days, the proportional contribution of WMP was higher. This was more evident especially in binary mixtures. Both materials worked harmoniously in both binary and ternary mixtures.

The rapid pozzolanic reaction of SFs was observed in all mixtures. The binary mixtures of SF had higher compressive strength than the binary mixtures of WMA. This can be explained by the fact that SF has a greater pozzolanic reaction and micro-filling effect (Wongkeo et al., 2012). Silica fume-containing mixtures demonstrated 15-20% higher early-age (7-day) strength compared to the control, highlighting SF's pozzolanic reactivity.

Excessive WMP replacement (particularly 20%) caused long-term strength reduction, indicating diminished binding capacity beyond optimal substitution levels. The strength development rate between 28-180 days was slower in SF mixtures, confirming their predominant early-stage contribution. These findings establish that the SF05WMP10 combination provides optimal balance between short- and long-term mechanical performance(Hamada et al., 2023; Kawsarul et al., 2023).

3.2.2 Tensile strength
When the tensile test results of SCMs were analysed, the highest value was 10.46 MPa at the end of 180 days curing period in parallel with the compression tests. This value was obtained from SF05WMP10 mixture. The lowest value was 6.11 MPa in the 7-day WMP20 mix. While the early age values were lower than the mixtures with SF, the effect of advanced ages was proportionally better. While SF increased 7-day flexural strength by 12-18%, this advantage diminished over time due to reduced late-stage pozzolanic activity. WMP mixtures showed linear strength reduction with increasing replacement ratios, demonstrating its filler-dominated behavior.Ternary blends (SF+WMP) displayed more balanced performance than binary mixtures, indicating synergistic effects between additives.These observations substantiate that matrix toughness is predominantly governed by binder composition and interfacial transition zone quality (Fig. 5).

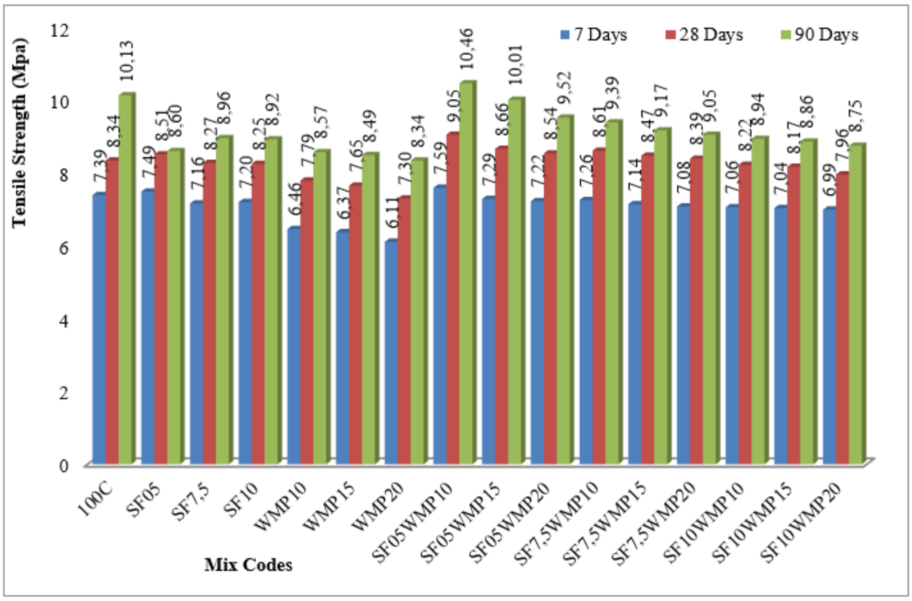

Fig. 5. 7, 28 and 180 days Tensile Strength of all SCM Mixtures

4. Conclusions

This study experimentally investigated the effects of waste marble powder (WMP) and silica fume (SF) on the properties of self-compacting mortars. The results demonstrate that the optimal combination of these materials provides significant advantages in terms of mechanical strength and sustainability.

- The SF05WMP10 mixture showed the highest performance with a compressive strength of 73.64 MPa after 180 days of hydration, while WMP improved workability and SF contributed to early strength gain.
- Exceeding the optimal ratios caused a 15-20% decrease in mechanical properties due to agglomeration and micro-crackformation.
- WMP's potential to reduce environmental waste burden strengthens the sustainability aspect of this research.

In conclusion, the synergistic use of SF and WMP enables both high-performance mortar production and recycling of industrial waste. However, careful determination of material ratios is crucial to prevent negative effects. These findings may guide future studies aimed at developing green construction materials. This study also highlights the technical and environmental advantages of utilizing waste materials in the construction sector.

Investigation of the properties of ground granulated blast furnace slag-based geopolymer concretes with recycled aggregates impregnated with pozzolanic slurry

Memduh Nas*[1], Şirin Kurbetci[1]

[1] *Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye*

Abstract. Cement production processes are characterized by high energy consumption and substantial carbon emissions, making them a significant concern for environmental sustainability. Adopting sustainability-focused approaches within the construction industry plays a crucial role in mitigating these adverse impacts. In this context, geopolymer concretes (GPC) emerge as a promising, eco-friendly alternative to conventional cement-based concretes. GPCs contribute to both waste management and natural resource conservation by using industrial waste as a binder and replacing natural aggregates with recycled concrete aggregates (RCA). Aggregates, which account for approximately 70% of concrete, significantly contribute to the rapid depletion of natural resources during production. Recycling concrete waste provides an effective solution to reduce construction-related waste and minimize environmental impacts. However, residual mortar adhered to the surface of RCAs often compromises the mechanical strength and long-term performance of the concrete. To address these issues, various treatment methods have been developed to improve RCA properties. Techniques such as carbonation, acid treatment, mortar residue removal, and impregnation with slurries or solutions are aimed at enhancing the physical and mechanical characteristics of RCAs. In this study, RCAs were treated with cementitious pozzolanic slurries to fill voids and repair structural deficiencies, resulting in improved permeability and mechanical performance. These enhanced RCAs were subsequently used to produce geopolymer concretes based on ground granulated blast furnace slag. The mechanical and durability properties of the resulting concretes were comprehensively evaluated through tests such as compressive strength measurements, ultrasonic pulse velocity assessments, Schmidt hammer readings, and electrical resistivity evaluations. The results of this study highlight significant improvements in the performance of geopolymer concretes and contribute to the advancement of sustainable building materials. Additionally, the research underscores the potential for efficiently reusing construction waste, aligning with global efforts to promote environmentally friendly construction practices and resource efficiency.

1. Introduction

In recent years, the sustainable management of construction and demolition wastes has become a critical challenge for the global construction industry. The depletion of natural aggregates, coupled with mounting environmental pressures, has driven researchers and practitioners to seek alternative materials that both conserve virgin resources and mitigate waste disposal issues (Pan et al., 2017; Qiu et al., 2014). Recycled concrete aggregates (RCAs) offer a promising solution: by re-using crushed concrete as coarse aggregate, RCAs can substantially reduce the consumption of natural quarry stone while diverting large volumes of demolition debris from landfills. However, RCAs inherently exhibit higher porosity, greater water absorption, and a weaker interfacial transition zone (ITZ) than their natural counterparts, owing to the presence of residual mortar and microcracks. If left untreated, these deficiencies can compromise the mechanical performance and durability of concrete (Silva et al., 2014).

A variety of pre-treatment methods have been proposed to improve RCA quality. Acid leaching can dissolve and detach the adhered cement paste, while carbonation treatments densify the remaining mortar and reduce connectivity of pores. Alternative approaches employ chemical solutions—such as glasswater or other silicate-rich liquids—to passivate surface pores and limit water ingress. Among these, impregnation with a pozzolanic slurry (a suspension of cement and supplementary cementitious materials) has shown particular promise: the slurry penetrates the RCA's pore network, reacts with free lime and aluminates, and precipitates C–S–H and other

* Corresponding author, E-mail: memduhnas@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_mat_022

hydrates at the RCA surface, thereby refining pore structure and strengthening the aggregate–matrix ITZ (Ouyang et al., 2023).

While traditional Portland cement concrete is the backbone of modern infrastructure, its production is energy-intensive and responsible for up to 8% of global CO_2 emissions, and the material often exhibits limited chemical and thermal resistance (Amran et al., 2020). Geopolymer binders—synthesized from aluminosilicate precursors activated by alkaline solutions—represent a low-carbon alternative, offering rapid strength gain, excellent sulfate and acid resistance, and substantially lower embodied energy. In particular, blast furnace slag (BFS), an industrial by-product of ironmaking, is an abundant aluminosilicate source ideally suited for geopolymerization. BFS-based geopolymer concretes have demonstrated compressive strengths comparable to, or even exceeding, those of OPC concrete, alongside superior durability in aggressive environments (Parathi et al., 2021).

In the present study, RCAs were first treated by immersion in a cement-puzolan slurry to seal surface pores and improve the ITZ, then incorporated as coarse aggregate in BFS-based geopolymer concrete mixtures. The influence of treated RCAs on compressive strength, ultrasonic pulse velocity, Schmidt rebound number, and electrical resistivity was systematically investigated. By combining aggregate pre-treatment with sustainable geopolymer technology, this work aims to unlock the full potential of RCAs in high-performance, low-carbon concrete, thereby advancing resource conservation and environmental stewardship in construction practice.

2.1. Experimental investigations

The 28-day-old GPC specimens were subjected to tests for compressive strength, UPV, schmidt hammer and electrical surface resistivity tests in accordance with TS EN 12390-3, ASTM C597, ASTM C805 and AASHTO TP 95-11 standards, respectively. The specimens used for these tests included cubes with side lengths of 10 and 15 cm, as well as 10x20 cm cylindrical specimens.

2.2. Materials and methods used

Concrete cubes with a side length of 15 cm and a compressive strength class between C25 and C40 were initially fractured using a demolition hammer and subsequently crushed to the desired particle sizes using a jaw crusher. The resulting RCAs were sieved into two fractions within the size ranges of 16–8 mm and 8–4 mm. In the production of GPC, natural aggregates consisting of limestone-based crushed stone, crushed sand, and river sand were utilized. In concrete mixtures incorporating RCAs, all coarse natural aggregates were fully (100%) replaced by RCAs. The maximum aggregate size used in the mixtures was set at 16 mm. Both in the reference concretes containing natural aggregates and in the RCA-based concretes, crushed sand and river sand were used as fine aggregates. The aggregate blend proportions were adjusted to 60% crushed stone, 15% crushed sand, and 25% river sand. The physical and mechanical properties of the aggregates are presented in Table 1.

Table 1. Physical properties of aggregates

Properties	Crushed limestone (16-4 mm)	Crushed sand (< 4 mm)	River sand (< 4 mm)	RCA (16-8 mm)	RCA (8-4) mm
Spesific gravity (g/cm3)	2.71	2.69	2.65	2.54	2.46
Water absorption (%)	0.61	0.96	2.11	5.31	7.63
Water content (%)	0.33	2.69	2.65	1.67	2.72

For the impregnation of RCAs with a pozzolanic slurry, Class F fly ash (FA), ground granulated blast furnace slag (GBFS), silica fume (SF), and CEM I 42.5 R grade Portland cement sourced from the Trabzon Aşkale Cement Plant were employed. The particle size distributions of all binder materials utilized in the study were characterized using a Malvern Mastersizer 2000 laser diffraction particle size analyzer. The chemical compositions and pozzolanic activity indices of the binders are detailed in Table 2. The mean particle diameters for GBFS, FA, SF, metakaolin (MK), and cement (C) were determined to be 15.87 µm, 23.41 µm, 17.46 µm, 11.9 µm, and 28.01 µm, respectively.

Table 2. Chemical composition of pozzolanic materials used

Composition	FA	GBFS	MK	SF
SiO_2	61.81	36.7	56.1	93
$Al2O_3$	19.54	14.21	40.25	0.58
Fe_2O_3	7.01	0.98	0.85	2.79
TiO_2	-	-	0.55	-
CaO	1.77	32.61	0.19	0.6
MgO	-	10.12	0.16	1.0
Na_2O	2.43	0.42	0.24	1.0
K_2O	-	0.76	0.55	0.10
SO_3	0.31	0.99	-	0.50
Pozzolanic Activity Index	76	78	101	87.4

2.3. Improvement of aggregates

The RCA enhancement procedure followed the impregnation technique reported by Shaban et al. (Shaban et al., 2019). In this approach, a pozzolanic slurry was prepared by mixing binder materials with water in a concrete mixer. Subsequently, RCAs were immersed in the slurry and allowed to soak for four hours to facilitate deep penetration of the slurry into the aggregate pores. The mix proportions for the slurry were set at 2 kilograms of water and 400 grams of binder per kilogram of RCA. In addition to pure cement slurry, pozzolanic slurries containing varying replacement levels of SF, metakaolin (MK), fly ash (FA), and ground granulated blast furnace slag (GGBFS) were also utilized. The effect of different slurry compositions on reducing the water absorption capacity of the RCAs was systematically investigated to identify the most effective formulations.

2.4. GPC design

Ground granulated blast furnace slag served as the principal binder in the preparation of geopolymer concrete. The mixing process began with the introduction of pre-wetted coarse aggregates into the mixer, followed sequentially by fine aggregates and the calculated amount of saturation water. After preliminary mixing, the pozzolanic binder was added, and blending was continued until a homogenous mixture was achieved. The alkaline activator solution—consisting of sodium hydroxide (NaOH) and sodium silicate (Na_2SiO_3)—was then incorporated slowly, along with a superplasticizer to improve workability. The activator-to-binder ratio was fixed at 0.5, with an SS/SH ratio of 2 and a NaOH molarity of 12 M. After approximately three minutes of mixing, fresh concrete properties were assessed immediately.

The freshly prepared GPC was placed into molds in two layers on a vibrating table, ensuring proper compaction and minimizing entrapped air at each stage. After molding, the specimens were subjected to steam curing at 80°C for a duration of three hours. They were then demolded and stored in a controlled environment until testing.

The mix proportions, detailed per cubic meter, are summarized in Table 3. The coding system used in the table includes three components: the coarse aggregate type and the type of surface treatment applied to the RCAs. For example, the code "NA" indicates a mix containing natural aggregates, while "RCA-C" denotes a mix incorporating RCAs pretreated with a pure cement slurry alongside fly ash.

The pozzolanic slurries used to treat the RCAs were prepared using the following combinations: 100% cement, cement blended with 30% SF, 20% MK, 50% FA, and 40% GBFS.

Table 3. Material quantities of GPCs (kg/m^3)

Sample Code	GBFS	16/8 Aggregate	8/4 Aggregate	Sand
NA	400	730.25	365.13	710.42
RCA	400	662.48	317.15	710.42
RCA-C	400	735.36	354.80	710.42

3. Results and discussion

3.1. Water absorption of RCAs

Figure 1 shows the water absorption percentages of the aggregates. While the water absorption percentages of NA in 16/8 and 8/4mm sizes were determined as 0.45 and 0.61, the water absorption percentages of RCA in the same size were determined as 5.31 and 7.63, respectively. When the figure is analyzed, it can be seen that the pozzolanic slurry impregnation process improves the water absorption percentages of RCAs by approximately 20% to 55%. The most effective slurries in terms of reducing the water absorption percentages of the RCAs were pure cement slurry, 30% SF, 20% MK, 50% FA and 40% GBFS substituted with cement, respectively. As can be seen in the figure, as the fineness and pozzolanic activity of the pozzolan used increased, the decrease in the water absorption percentage of the RCAs became more pronounced. The reason for this is that the pozzolans used both fill the defects in the RCA with new binder gels due to their pozzolanic effect and physically act as fillers due to their fineness.

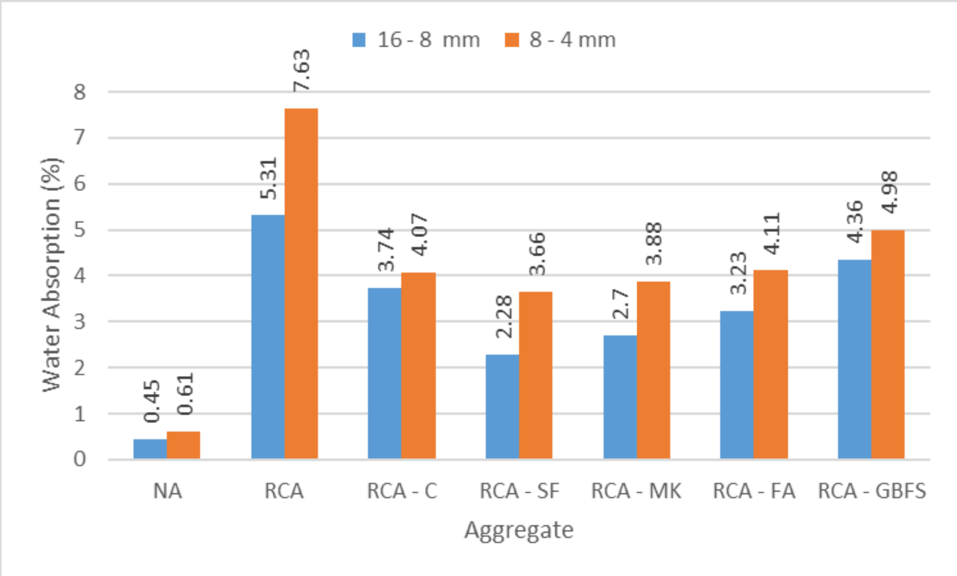

Fig. 1. Water absorption values of GDAs impregnated with slurry

3.2. Compressive strength and UPV results

Figure 2 shows the 28-day compressive strength of GPCs. The compressive strength of the reference GPC produced using NA was determined as 79.59 MPa. The compressive strength of GPC produced with RCA without any treatment decreased by about 24% and was determined as 60.42 MPa. The main reason for the decrease in compressive strength with the use of RCA is that the old mortar layer on the surface of RCA is more porous, weak and contains defects such as cracks compared to NA. Moreover, the presence of this old mortar layer causes the interfacial zone between the RCA and the new mortar to have lower strength than the concrete produced with NA. This weak interfacial zone cracks easily under applied force, creating a mechanically weak point in the concrete (Thomas et al., 2018). In the case of impregnation of RCAs with pozzolanic slurry, an increase in the compressive strength of the concretes was observed up to a maximum of 14%. The reason for this increase is that pozzolans react with the calcium hydroxide in the old mortar layer on the surface of the GDA to form new calcium silicate gels. This reaction fills the voids in the RCA, making the old mortar layer denser and stronger citation needed (Han et al., 2023).

When the UPV results of the concretes are analyzed, the UPV value of the reference concrete with natural aggregate was determined as 5 km/h, while the UPV value of the concrete with untreated RCA decreased by approximately 10% to 4.55 km/h. The UPV values of the slurry-impregnated RCA GPCs did not change enough to be detected by the device and the UPV values of these GPCs remained almost constant.

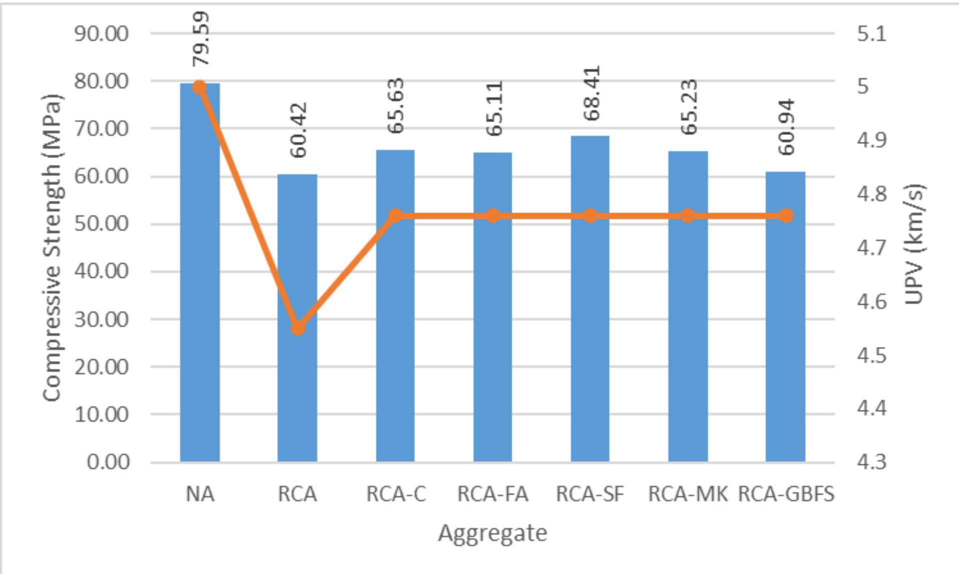

Fig. 2. 28-day compressive strength and UPV values of GPCs

3.3. Schmidt hammer rebound values of concretes

Figure 3 shows the Schmidt hammer rebound values of GPCs. As can be seen in the figure, while the rebound value of GPCs with natural aggregates was determined as 55.85, the hammer rebound value of GPC with RCA without any slurry impregnation process decreased by 23% and was determined as 43. The reason for this decrease is the presence of hollow and defective structure on the old mortar in the RCA. An increase was observed in the hammer rebound values of GPCs with RCA impregnated with slurry, although not very significant. This increase varies between 2.32% and 11.74%. The highest rebound value was obtained from GPC with RCA impregnated with silica fume slurry. The concrete sample with denser and more compact aggregate structure exhibited a higher rebound index in the Schmidt hammer test. This is attributed to its improved surface hardness and internal homogeneity, which enhance the material's ability to resist localized impact.

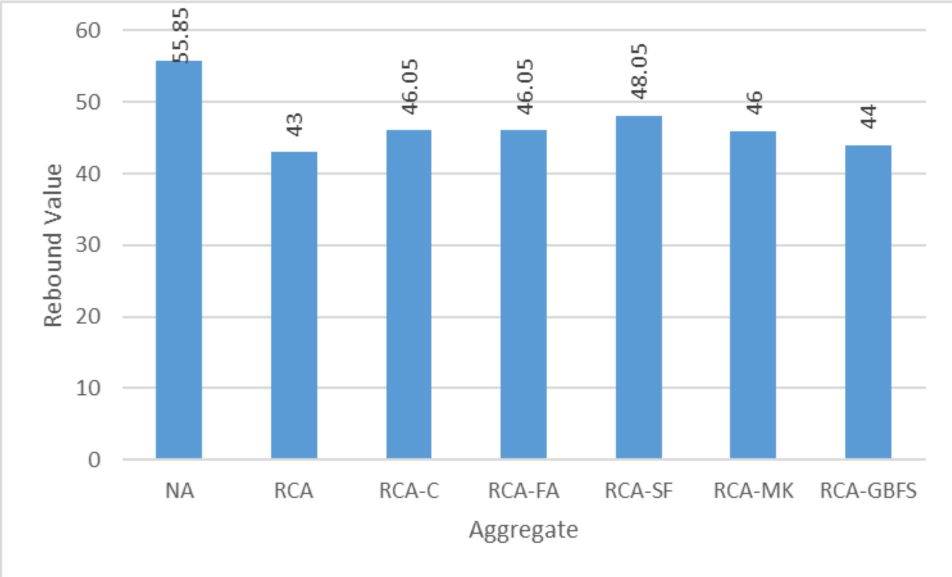

Fig. 3. Rebound values of GPCs

3.4. Electrical resistivity results of GPCs

While the resistivity of the reference GPC produced using NA was determined as 64.2 kΩ.cm, the resistivity value of the GBC with RCA without any treatment decreased by approximately 24% and was determined as 48.7 kΩ.cm. According to these results, it can be said that both the reference concrete with NA and the GPCs with RCA have a very low level of chlorine permeability according to AASHTO TP 95-11 standard. As expected as a result of the hollow and imperfect structure of the RCA, the resistivity value of the RC concrete was low. This indicates that the concrete is more hollow and more sensitive to chlorine and that in a reinforced concrete structure, the concrete will have difficulty in protecting the iron inside from rust. The electrical resistivity values of GPCs with RCAs impregnated with slurry showed a trend similar to the water absorption percentages of RCAs. The pozzolanic slurry impregnation process increased the resistivity values of the GPCs by about 1.6% to 12%. This indicates that the voids and imperfections in the RCAs were reduced and the chlorine resistance of the concretes produced with these aggregates was increased. SF and MK were the most effective pozzolans in terms of increasing the electrical resistivity of the concretes. Since GBFS-based GPCs with both NA and RCAs have a very low permeability class according to AASHTO TP 95-11 standard, the slurry impregnation of RCAs did not allow the GPCs to pass to a lower or higher class according to this standard.

Chloride ion penetration in concrete is closely governed by the absorptive and transport properties of the aggregates, particularly in mixtures containing RCAs. The presence of adhered mortar on RCA surfaces, along with its intrinsic microstructural quality, significantly influences both the capillary absorption capacity and the ionic diffusivity of the composite material. Owing to their elevated porosity and permeability relative to NAs, RCAs tend to facilitate more rapid and deeper chloride ingress. However, numerous investigations have confirmed that improving the physico-chemical characteristics of RCAs—through surface densification or pore refinement techniques—can markedly mitigate chloride transport within the concrete matrix (Du et al., 2024; Shi et al., 2023).

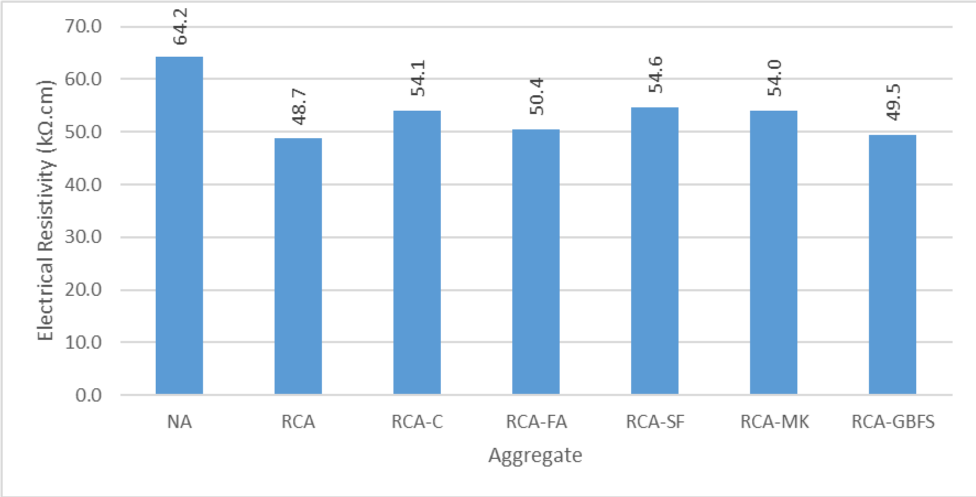

Fig. 4. Electrical resistivity values of GPCs

4. Conclusions

The results of the study can be summarized as follows:

- The application of pozzolanic slurry impregnation significantly enhanced the pore structure of recycled concrete aggregates, leading to a marked reduction in their water absorption rates.
- The use of RCA in GBFS-based GPCs resulted in a decrease of approximately 24% in 28-day compressive strength, 10% in UPV, 22% in Schmidt's attractive rebound index and 23% in electrical resistivity.
- Compared to GPCs with RCA without any slurry impregnation, 28-day GPCs produced using RCA impregnated with pozzolanic slurry showed an ultimate increase of 14% in compressive strength, 11.74% in Schmidt's hammer rebound index and about 12% in electrical resistivity values.
- No significant change was observed in the UPV values of the concretes.
- In conclusion, it was observed that slurry impregnation of RCAs can improve the properties of GBFS-based GPCs.

Enhanced compressive strength prediction using concrete mix parameters and feature importance analysis: Using alternative ML algorithms

Talip Çakmak[1], İlker Ustabaş[*1]

[1] Recep Tayyip Erdoğan University, Department of Civil Engineering, 53000 Rize, Türkiye

Abstract. Concrete is one of the best commonly applied building materials due to its various advantages as such high strength, durability, resistance to high temperatures, etc. However, due to the CO_2 emissions abput the production and consumption of the raw material cement, research has long been conducted into various alternatives. Various supplementary cementitious materials with pozzolanic properties are at the leading of such options. In addition to reducing the CO_2 emissions of these materials, it is possible to improve various properties, especially strength and durability. However, obtaining the properties that occur when various materials are used together with concrete results from long laboratory processes and labour. Therefore, ML algorithms allow us to reduce this time and effort. In this study, a variety of ML algorithms such as RF, ET and GBR were used to predict the properties of concretes with different mix parameters such as different proportions of FA, GGBS, aggregate quantity and curing time. In addition, feature importance analyses based on different algorithms were performed to elucidate the background functioning of these algorithms. As a result of the analysis, the GPR algorithm showed the highest prediction and generalisation performance with an R^2 value of 0.871. The ET and RF algorithms follow this performance. In addition, as a result of the feature importance analyses, the most important mixing parameters for all algorithms were found to be cement ratio and setting time. The values obtained as a result of the study show the suitability of using ML algorithms to detect different properties of concretes.

Keywords: Machine learning, Feature importance, Cement, Supplementary cementitious materials, Fly ash

1. Introduction

Concrete is commonly utilised in the construction industry owing to its features such as high strength and durability, high workability, economy, and long service life (Tran, 2022; Zhang & Zhang, 2025). Concrete is a building material that can be easily produced from a mixture of aggregate, cement and water (Moodi et al., 2025). Today's urbanization creates a significant demand for concrete. A large amount of cement is used to meet this demand. However, the use of cement increases CO_2 emissions into the atmosphere. Because cement production leads to a significant amount of CO_2 emissions. A significant amount of CO_2 is emitted during the calcination process in cement production and the generation of energy required for heat treatment. These emissions account for 5-9% of global emissions (Cakmak & Ustabas, 2025, 2025; Cakmak et al., 2025). Approximately 1 ton of CO_2 is released into the atmosphere to produce 1 ton of cement (Nguyen et al., 2025; Jungclaus et al., 2024). In addition, the consumption of limestone and clay, the raw materials of cement, leads to the depletion of natural resources. This situation paves the way for environmental pollution and land degradation, as well as CO_2 emissions (Nguyen et al., 2025; Jungclaus et al., 2024). Considering the environmental impact caused by the production of OPC, researchers suggest that the amount of cement in concrete production should be reduced and eventually eliminated. There are several important alternative methods to do this. The most important of these is the use of waste materials with pozzolanic features to reduce the amount of cement used.

The substitution of waste materials such as fly ash and GGBS, which are by-products of industry and commerce, in cementitious mixtures has been widely used to reduce carbon emissions from cement (Wang et al., 2024; Liu et al., 2024). The use of these materials as supplementary cementitious materials not only contributes positively to the strength properties of the materials, but also to the reduction of carbon emissions from cement. Previous studies have shown that the substitution of SCMs in cementitious mixtures significantly reduces greenhouse gas emissions. It also allows concrete to be a sustainable material (Phul et al., 2019). These materials

[*] Corresponding author, E-mail: ilker.ustabas@erdogan.edu.tr

https://doi.org/10.31462/icearc2025_ce_mat_052

have a very wide range of applications, such as marine structures, high-performance concretes, durable repair materials, and green building technology.

Data-driven science is recognized as the fourth scientific paradigm due to its profound impact on engineering and technology (Moodi et al., 2025). In the past, complex computational techniques have been proposed to accurately predict values. However, in recent years, the machine learning method offers significant advantages for various fields, especially engineering sciences, due to its superior predictive ability and no prior knowledge required. Machine learning offers significant time and cost advantages over time-consuming laboratory experiments and numerical simulations. In addition to reducing computational costs, it also enables the identification of relationships between input and output features in the data set. All of these benefits contribute to solving problems faster and more effectively. If the developments in data science are carefully analyzed, the importance of data-driven science will continue to grow in the future (Moodi et al., 2025; Tariq et al., 2025). Especially in the last two decades, it is clear that there have been significant improvements in the computational methods and capabilities of ML algorithms. Experimental investigation of the properties of mortar specimens requires significant effort in terms of energy, time, and costs such as material consumption, labor, etc. (Ebrahimzadeh et al., 2025; Tang et al., 2024). This has led researchers to analyze the datasets previously available in the literature and examine the relationships between the data that make up the dataset. Moghaddas and Bao (2025) used ML algorithms to predict the wear depth of concrete. Different ML algorithms such as XGBoost, CatBoost, LightGBM, ET and RF were used in the examination. The outcomes obtained from the study demonstrated that ML algorithms have significant potential in predicting the wear depth of concrete. Rajiv et al. (2025) used linear regression, LASSO regression, DT, RF and multilayer perceptron algorithms to anticipate the mechanical features of concrete including treated wastewater and fly ash. Within the scope of the study, the RF algorithm showed the highest compressive strength performance and demonstrated the usability of wastewater in concrete mixes. Similarly, Moodi et al. (2025) used various machine learning approaches to foretell the CS of green concretes containing copper slag aggregates. Lan et al. (2025)used different machine learning approaches to predict tensile strength and fracture toughness of concrete. The XGB algorithm showed the highest prediction accuracy, demonstrating the feasibility of utulising ML models instead of laboratory experiments to foretell size-independent fracture parameters of concrete. Ulloa et al. (2025) evaluated distinct ML frameworks to predict the compressive strength of geopolymers containing industrial waste. The results of the study show that the applicability of ML frameworks in compressive strength prediction paves the way for the use of these models in various projects. These studies in the literature show that ML algorithms are suitable for predicting the properties of building materials and reveal the potential of using machine learning approaches in different fields.

A review of recent studies in the literature shows that supplementary cementitious materials with pozzolanic properties are an important alternative for reducing carbon emissions from cement. However, these studies have generally been carried out at considerable cost and time, requiring extensive labor, materials, and time. However, there are gaps in the application of ML frameworks for predicting the strength of mixtures containing cementitious admixtures. Previous examinations have used various ML approaches to fill this gap. Although significant and promising results have been obtained, there are still gaps in determining the applicability of tree-based machine learning algorithms for predicting the compressive strength of mortars. In this study, in order to fill this gap, tree-based ML algorithms such as RF, ET, and GBR were used to foretell the CS of concrete containing fly ash. In addition, feature importance analyses based on these algorithms were performed and the effects of input parameters on output parameters were investigated. It is believed that the findings and results obtained from this study will provide important and valuable contributions regarding the utilize of ML algorithms in the prediction of concrete properties. In this way, it aims to promote the use of ML algorithms in construction projects.

2. Materials and method

2.1. Research framework and significance

Fig. 1 shows the general research steps performed in the study. As part of the study, a literature review was conducted to obtain a secure dataset with input features and output features. Then, the dataset was randomly divided into training and test datasets with different proportions. Three different ML algorithm models were trained utulising the training data set. Then, feature importance analyses based on three different ML algorithms were performed to determine the importance levels of the input features that make up the dataset. In this study, all programming and analysis was done using MATLAB.

The main objectives of the examination are to

- To improve a predictive model for determining the changes in the compressive strength of concretes in the case of substitution of complementary cementitious materials with pozzolanic properties,
- To determine the importance levels of the input features in the data set and to perform mixture calculations by paying attention to the importance levels of the input parameters in future studies,
- To determine the usability of ML models in predicting the features of building materials and to promote the use of these models in construction projects.

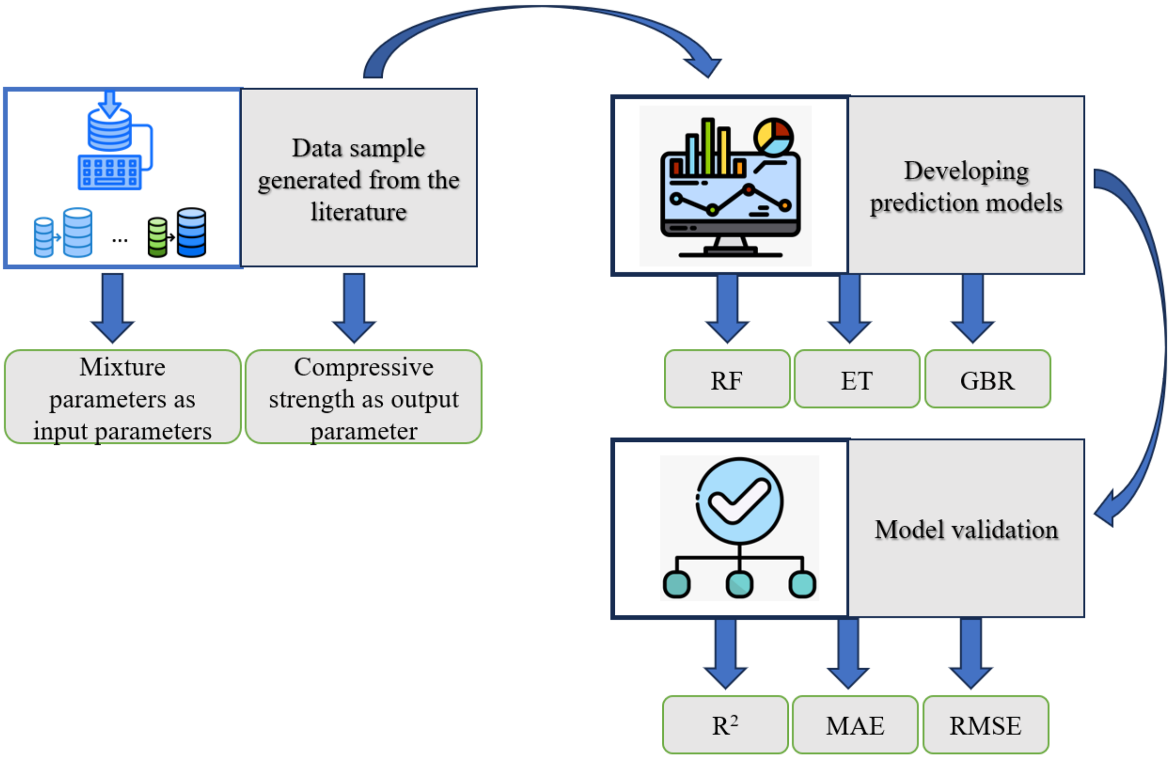

Fig. 1. Dataset scatter matrix

2.2. Data collection and analysis

2.2.1. Data collection
The data set used in this examination was obtained from a publicly available experimental study investigating the properties of fly ash-replaced concretes (Yeh, 1998). The compressive strength of concretes is influenced by important factors such as the amount of cement, fly ash replacement ratio, and water/cement ratio. Based on these factors, six main input properties have been identified as mentioned below. These properties are cement, GGBS, FA, water, aggregate quantities and curing times of the concretes, respectively. Based on these input properties, compressive strength was determined as an output parameter. These input properties were selected as parameters that have a significant effect on compressive strength, taking into account previous studies. The scatter matrix showing the properties that make up the data set and their relationships to each other is shown in Fig. 2.

2.2.2. Data preprocessing and analysis
The data set was pre-processed before analysis. Fig. 2 demonstrates the relationships among the six input parameters and one output parameter. In Fig. 2, we can see that the input parameters have a wide distribution and there is significant variability between different features. These variations have the potential to have a significant impact on the performance of ML frameworks.

2.3. Machine learning models and metrics
A series of preliminary examinations of the dataset revealed that there was no clear linear relationship among the six input properties and the CSs. The following three ML models were applied to this data set. These machine learning models are ET, RF, and GBR, respectively. The details of these models are described below.

The Random Forest algorithm is a model that allows regression performance to be improved by using multiple decision trees together. This model basically creates multiple sample sets using the training data set. These sample sets are used to train different decision trees. The model averages the performance of all decision trees to produce the final prediction at the end of the analysis. In this way, it shows higher generalization and prediction performance than individual decision trees.

Another important algorithm used in the study is ET. The main difference between this model and the Random Forest model is that it incorporates more randomness into the decision tree building process. In this way, significant improvements in model performance are expected.

The last algorithm used in the study is GBR. This algorithm basically builds each model on the residuals of the previous model. In this way, it gradually reduces the errors by taking into account the errors obtained from the

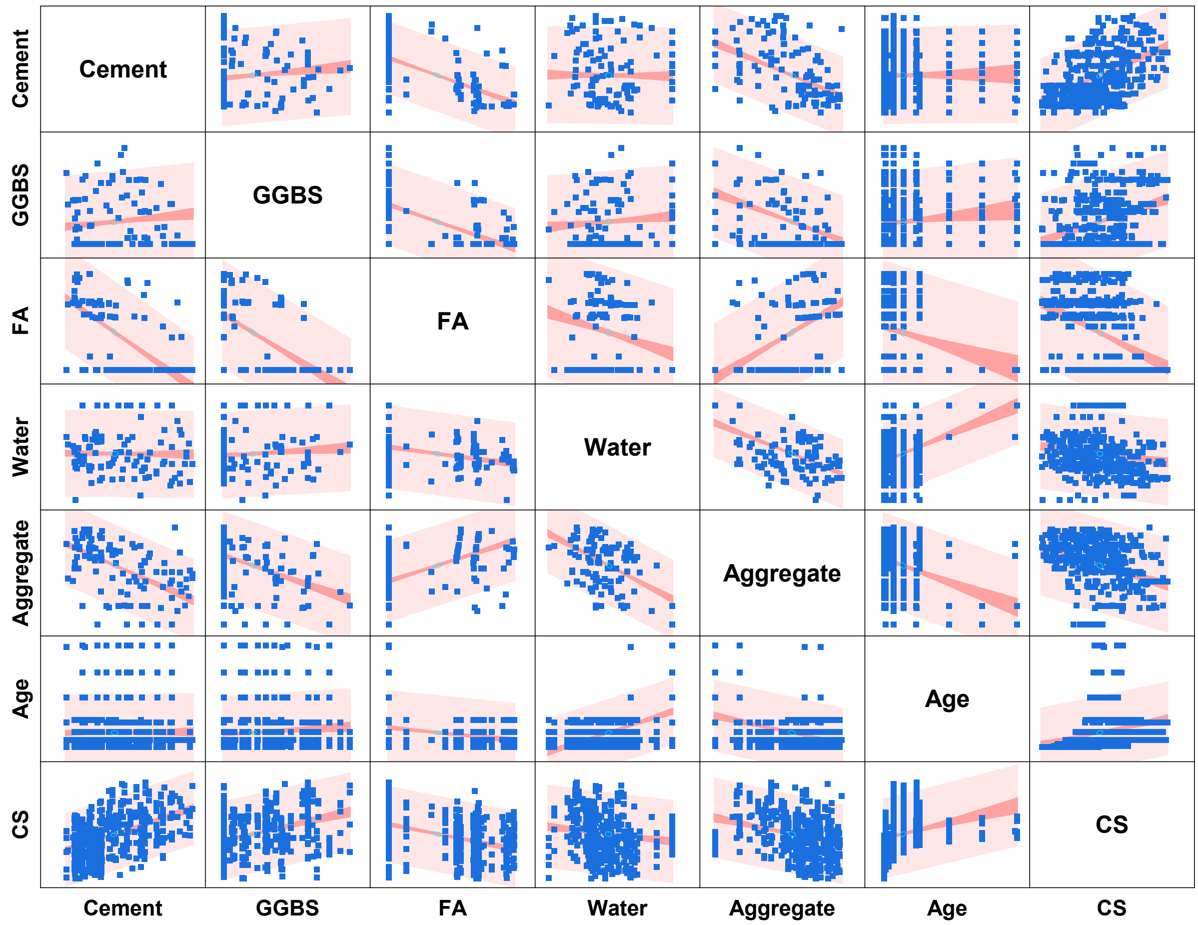

Fig. 2. Dataset scatter matrix

previous model. Finally, the predictions from the model are generated by the contribution of each tree. In this way, the errors of poorly learning trees are eliminated.

The general working principles of the models are shown in Fig. 3. To evaluate and compare the anticipation performance of these three different machine learning models, a number of important statistical metrics such as MAE (Mean Absolute Error), MAPE (Mean Absolute Percentage Error), MSE (Mean Squared Error), RMSE (Root Mean Squared Error), R^2training (Coefficient of Determination for Training Data), R^2testing (Coefficient of Determination for Testing Data) and R^2adjusted (Adjusted Coefficient of Determination) were used.

3. Result and discussion

The statistical performance outcomes obtained from 3 different ML frameworks used to foretell the CS of fly ash and GGBS substituted concretes are shown in Table 1. The GBR algorithm demonstrated the highest prediction and generalization performance with an R^2 value of 0.87. It is followed by ET and RF algorithms with R^2 values of 0.86 and 0.60, respectively. Analyzing the MAE and RMSE values in Table 1, the lowest error worths are acquired from the GBR algorithm. This is followed by the ET algorithm with MAE and RMSE values of 4.70 and 6.14, respectively. In parallel with the R^2 values, the RF algorithm showed the worst performance.

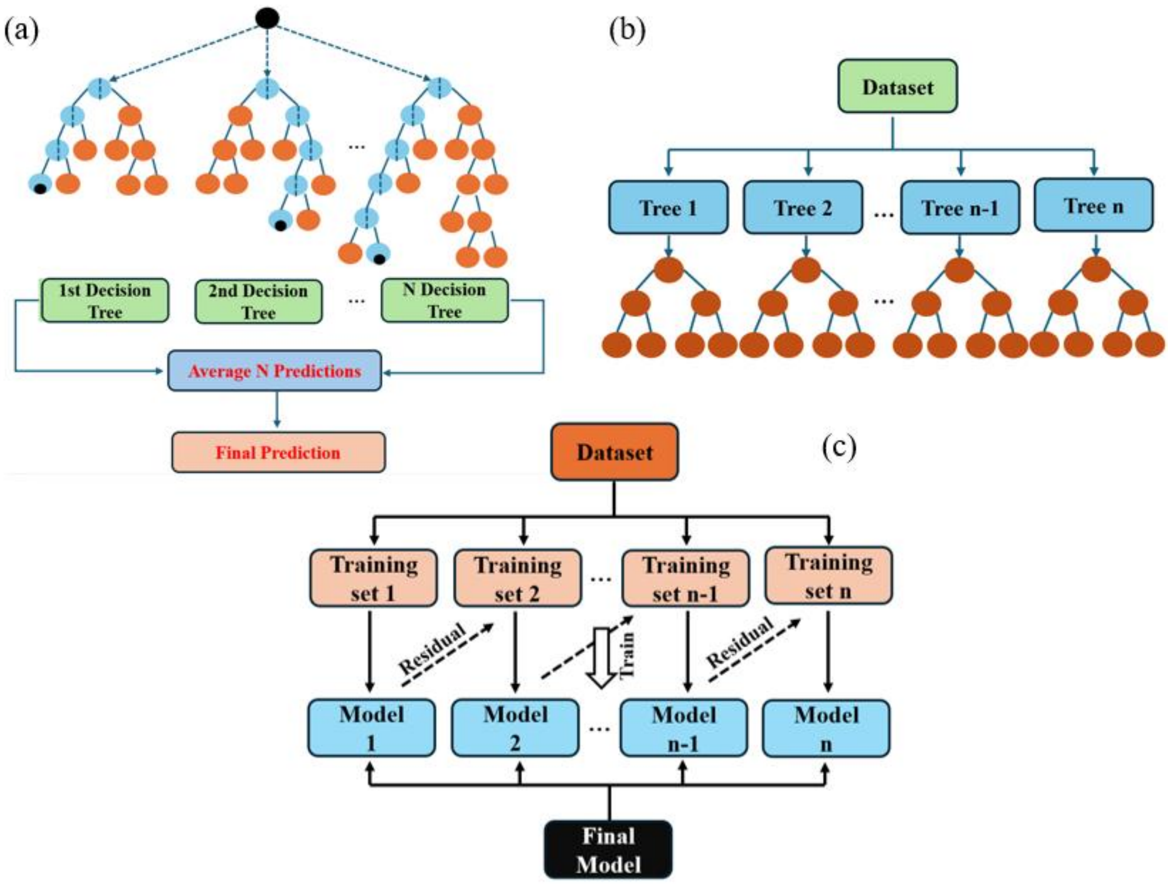

Fig. 3. Model's principles framework (Cakmak & Ustabas, 2025)

Table 1. Model's performance metrics

Metrics	Algorithms		
	RF	ET	GBR
MAE	7.39	4.70	4.44
MSE	109.76	37.65	35.41
RMSE	10.48	6.14	5.95
MAPE	31.20	17.84	14.19
R2-training	0.99	0.93	0.92
R2-test	0.60	0.86	0.87
R2-adjusted	0.59	0.86	0.87

To evaluate the R^2 worths acquired from the frameworks in general, while the RF algorithm showed a significant R^2 training performance of 0.99, it showed a low prediction performance with an R^2 value of 0.60. The main reason is overfitting. Although the RF model remembers the training data very well, its prediction performance on the test data is poor. The Random Forest algorithm uses multiple decision trees as a general operating principle. It also tends to produce more stable results by reducing the variance values obtained from the models. However, in the dataset used in this study, due to the low variance values between the input features, the RF algorithm showed high performance by memorizing the dataset during training. Since the RF algorithm memorized the test dataset, it had difficulty in predicting the test dataset. Therefore, it showed low generalization performance.

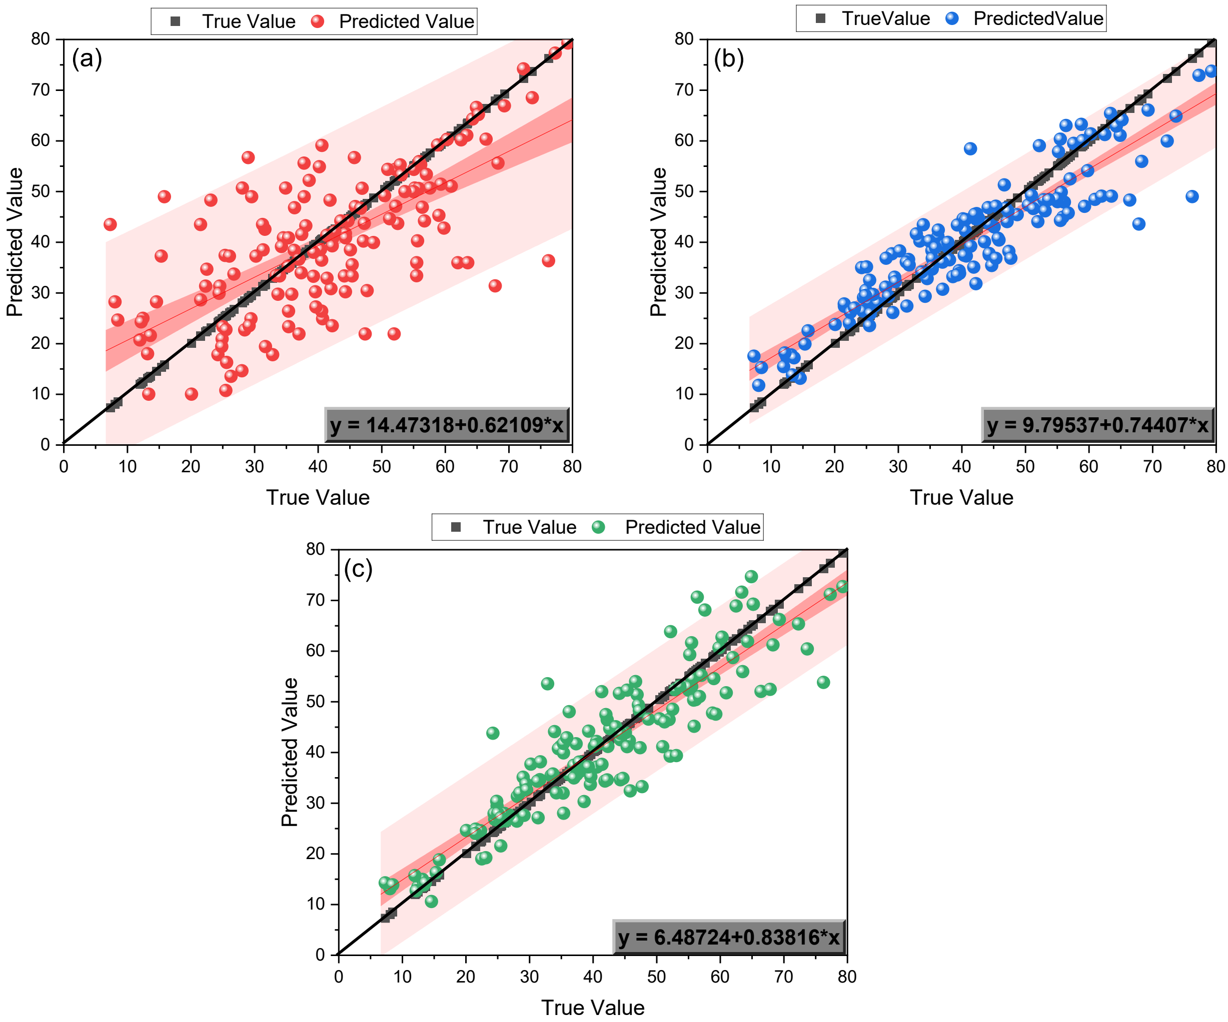

Fig. 4. a) RF, b) ET, C) GBR models predicted and real values

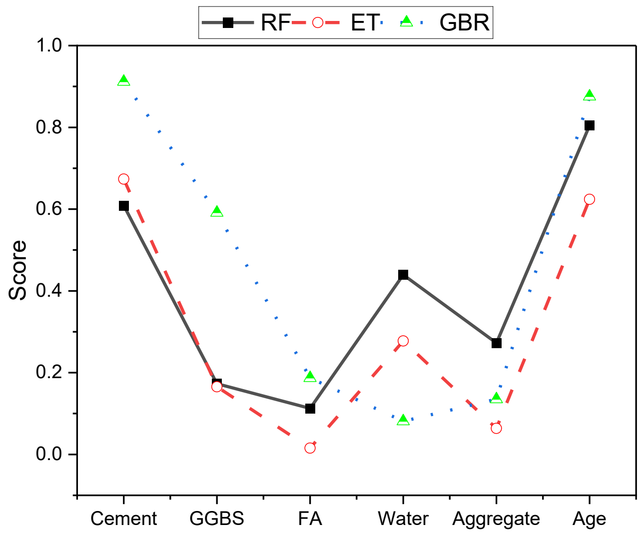

Fig. 5. Feature importance analysis values

The ET algorithm, another important prediction model, showed a better prediction performance with an R^2 worth of 0.86 compared to the RF algorithm. In addition to the R^2 values, significant decreases were observed in other performance metrics such as MAE and RMSE. The main reason for the significant increase in prediction performance is that the ET algorithm, unlike the RF algorithm, randomizes the splitting points in the trees. This random splitting reduces the variance of the model. As a result of the reduction in variance, the tendency of the model to overlearn is also reduced.

The algorithm used in the study with the highest generalization performance is GBR. The main reason for the highest prediction performance is the sequential learning mechanism of decision trees. Since decision trees are built on the previous decision tree and continue by correcting the errors of the previous decision tree, each new generation of decision trees performs better.

To summarize the results of the study in general, the RF algorithm showed lower performance due to overfitting, while the ET and GBR algorithms showed higher performance due to the working principles of the models. This study shows that GBR-based models provide more reliable results when there are non-linear relationships between the mix properties of concretes.

Fig. 4 demonstrates the prediction worths obtained from the RF, ET, and GBR algorithms. Fig. 4(a) demonstrates that the prediction worths are far from the y=x line and show a scattered distribution. This shows that the predicted values of the model are far from the actual values. However, Fig. 4(b) and Fig. 4(c) show that the predicted values are close to the y=x line and the predicted values are close to the actual values. This provides a clearer understanding of the prediction performance of the models.

Fig. 5 shows the feature importance analyses obtained using different machine learning models. Feature importance analyses are generally performed to determine the degree of importance that the models give to the parameters when making predictions. In this study, 3 different feature importance analyses were performed based on prediction algorithm models. In this way, the importance levels of the parameters in the prediction studies of the models were determined. It is seen that the most important parameters in all models are cement ratio and age of concrete. The least important parameters are fly ash and water content in the concrete mix.

4. Conclusions

In this study, RF, ET and GBR algorithms were used to predict the compressive strength of fly ash and GGBS substituted concretes. Among these machine learning algorithm models, GBR algorithm showed the highest prediction performance. This is followed by ET and RF algorithms respectively. Although the RF algorithm showed a significant performance on the training dataset, it could not maintain this performance for the test dataset. This is mainly because the RF algorithm is sensitive to overfitting. In the feature importance analyses based on RF, ET and GBR, the most important parameter common to all models is cement and concrete age. Again, the least important parameters for all models are fly ash and water content. As a result, GBR algorithm gave the most reliable prediction values for the compressive strength of concretes containing fly ash and GGBS. GBR algorithm showed higher prediction and generalization performance compared to other models. In future studies, the study team aims to investigate the relationships between capillary permeability and carbonation amounts of concretes.

Structural performance of concrete and steel pedestrian overpasses in Ortahisar: Experiences and innovations

Abdullah Bostancı*[1], Sina Atabey[2]

[1] Avrasya University, Department of Construction Technologies, 61000 Trabzon, Türkiye
[2] Avrasya University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. This study focuses on evaluating the user experience and structural performance of concrete and steel pedestrian overpasses along the coastal road in Trabzon's Ortahisar district under current conditions. Built upon practitioner feedback and observations, it considers the advantages and potential challenges of each material. Concrete's durability and steel's lightness are discussed in relation to the region's climate and urban context, while long-term maintenance requirements and usage patterns are also addressed. No technical measurements or laboratory tests were employed; instead, field inspections and expert opinions shaped the research framework. This approach aims to provide a straightforward yet insightful perspective on the daily functionality of overpasses and their contribution to urban life. It offers guidance to decision-makers and designers regarding material selection, maintenance planning, and user comfort.Particularly in Ortahisar, the potential increase in pedestrian traffic is expected to bring various material and design options to the fore in future projects. Thus, efforts should be made to extend the service life of overpasses that harmonize with the city's aesthetics and ensure pedestrian safety. Regular maintenance and judicious material choices could facilitate a more sustainable approach to pedestrian infrastructure, meeting evolving urban mobility needs. The study highlights the role of local governments in siting overpasses and underscores the significance of materials for user safety and comfort. It points out the need to periodically maintain existing structures and consider diverse material alternatives in new projects, aiming to promote sustainable, aesthetic, and functional pedestrian circulation.

Keywords: Pedestrian overpasses; Concrete structures; Steel structures; Sustainable materials; Innovative solutions

1. Introduction

Pedestrian overpasses are indispensable elements of urban transportation infrastructure, constructed to ensure pedestrian safety and maintain the uninterrupted flow of motor vehicle traffic (Hasan et al., 2020; Truong et al., 2019). In densely populated cities, especially along major arterial roads and multi-lane highways, managing pedestrian crossings is of vital importance for urban traffic safety and pedestrian comfort. In this context, pedestrian overpasses not only improve the quality of life for users but also support the continuity of intra-city mobility. Additionally, overpasses are evaluated as components of strategies aimed at reducing traffic congestion, organizing pedestrian-vehicle interactions, and enhancing urban accessibility.

The choice of structural system (steel, reinforced concrete, composite, etc.), material properties, aesthetic concerns, and compliance with accessibility standards in the design, construction, and operation of pedestrian overpasses directly influence both structural performance and user satisfaction. Each of these factors is decisive in terms of cost-effectiveness, longevity, and maintenance requirements. The comparative analysis of steel and reinforced concrete systems is supported by a broad literature, emphasizing aspects such as ease of construction, durability, maintenance needs, and environmental impacts. Steel systems stand out for their ease of assembly, lightweight nature, and allowance for aesthetic design, while reinforced concrete systems are preferred for their high compressive strength, low initial investment cost, and local production capabilities. Composite systems, combining the advantages of both materials, offer potential benefits but require special engineering calculations and detailed design solutions.

In recent years, climate change, the use of sustainable materials, recycling technologies, and societal expectations have transformed decision-making processes in infrastructure projects, including pedestrian overpasses. Studies such as those by Pan (1992) and Jiang & Yang (2012) highlight the decisive role of climatic effects on the service life and maintenance costs of structures exposed to outdoor conditions. Environmental factors

* Corresponding author, E-mail: abdullah.bostanci@avrasya.edu.tr

https://doi.org/10.31462/icearc2025_ce_mat_053

such as high humidity, temperature fluctuations, heavy precipitation, and saline atmospheres reduce the durability of both reinforced concrete and steel systems and complicate maintenance and repair processes. Moreover, environmental variables such as wind loads, freeze-thaw cycles, and air pollution are also among the key parameters affecting the service life of overpasses. Therefore, accurate analysis of climatic effects and material selection based on environmental compatibility are essential for ensuring long-lasting and sustainable overpasses.

Sartori & Hestnes (2007), discussing the integration of sustainability into the construction sector, argue that environmental impacts such as energy consumption and carbon emissions must be considered not only during the building's lifespan but also during production, use, and deconstruction stages. In this regard, the use of recyclable materials not only reduces direct environmental impact but also contributes to economic sustainability. In examples developed particularly in Europe and North America, structural steel systems with reduced carbon footprints and green infrastructure solutions have become increasingly common in pedestrian overpass projects. A growing awareness of this issue in Turkey has led various municipalities and local governments to begin promoting environmentally friendly construction practices.

Ivorra et al. (2015) and Ribeiro da Silva & Santos da Silva (2018) examined the potential use of modern construction materials such as recycled steel, sustainable concrete mixtures, and cross-laminated timber (CLT) in pedestrian bridges. These materials offer new design possibilities in terms of durability, aesthetics, and ecological balance. Such applications can render pedestrian overpasses not only functional but also exemplary structures in terms of environmental sustainability. Additionally, pedestrian overpass projects evaluated within environmental certification systems such as LEED and BREEAM play a significant role in helping cities achieve their sustainability goals.

User behavior and socio-demographic characteristics also influence pedestrian overpass usage rates and design decisions. Patra et al. (2020) developed a method combining Revealed Preference (RP) and Stated Preference (SP) data to understand pedestrian crossing behaviors. Their study found that environmental, physical, and personal factors significantly affect pedestrian preferences at signalized intersections; thus, the location, design, and accessibility of pedestrian overpasses directly impact user choices. Factors influencing user behavior include pedestrian flow density, waiting time, alternative crossing options, weather conditions, and accessibility for the disabled.

Similarly, a study conducted in Pakistan by Ghafoor & Khan (2021) investigated usage differences across age and gender groups, revealing that women and elderly individuals use overpasses more frequently than young men. These findings underscore the need to tailor design parameters such as ramp gradients and stair heights to socio-demographic structures. Designs sensitive to user habits are of great importance for the effective management of pedestrian traffic in urban areas. Furthermore, in urban planning, addressing the needs of vulnerable groups such as the elderly, women, and people with disabilities is critical to the success of accessibility policies.

From a structural performance perspective, Eremeev et al. (2021) investigated the dynamic behavior of composite reinforced concrete systems used in pedestrian bridges, noting that these systems require special engineering solutions. The stiffness contrast between concrete and steel components directly affects vibration behavior and service life. Innovative solutions such as shear connector placements, industrial manufacturing processes, and the use of multi-profile columns contribute to the development of composite systems. In this context, next-generation pedestrian bridges equipped with advanced vibration control systems, active dampers, and lightweight material combinations play a key role in enhancing structural safety.

The design of pedestrian overpasses should not only be approached from a technical perspective but also from environmental and user-oriented angles. Heldak et al. (2021) emphasized that strong wind effects, humidity with marine salt, and soil properties are the primary factors influencing structural behavior in coastal regions. Hence, beyond material selection, the compatibility of the design with the climatic and geographic context is also crucial. In coastal cities, it is expected that structures be built using weather-resistant, low-maintenance, and long-lasting systems.

This study conducted in the Ortahisar district of Trabzon systematically analyzes the structural systems (steel, reinforced concrete, composite), design features, material choices, and spatial contexts of pedestrian overpasses, particularly along the coastal road. Akyüz (2023) examined the impact of pedestrian overpasses in high-density areas using microsimulation analyses and emphasized the importance of integrating such methods into the design process. These analyses show that factors such as pedestrian flow density, waiting times, movement directions, and group crossing behaviors must be taken into account during overpass design.

The overpasses in Ortahisar were built in different periods, and choices of structural systems, enclosed or open design elements, accessibility options, and maintenance status vary according to the construction years. This diversity reflects evolving design approaches, technological developments, and user demands over time. In a study by Aydın (2024), the technical specifications, geographical locations, and topographic conditions of overpasses along the coastal road in Trabzon were classified in detail.

In addition, Aksoy (2024) analyzed pedestrian violations and crossing behavior, showing that factors such as waiting time, group size, and the presence of parked vehicles influence the decision to use overpasses. Kawther & Mohammad (2024), examining the role of overpasses in urban transportation systems, emphasized that overpasses should be considered not only structural but also social and urban elements in relation to user habits and accessibility. Correspondingly, evaluations in Ortahisar revealed that overpasses located near the coast are more frequently used, and in these areas, design is given greater importance in terms of aesthetics and functionality.

The aim of this study is to emphasize the significant impact of pedestrian overpasses on urban life, particularly in rapidly developing coastal cities like Ortahisar. Pedestrian overpasses are critical infrastructure elements that enhance pedestrian safety while minimizing disruptions to vehicular traffic flow in densely urbanized areas. This study will focus on the effect of these structures on urban life in Ortahisar, with particular attention to how their design and material selection influence their performance and usability. Although the study does not include direct measurements, it will rely on field observations and expert opinions to evaluate the functionality of pedestrian overpasses in the region. The primary objective is to examine the structural performance of pedestrian overpasses in the context of user experience and material properties. By focusing on the reasons behind the preference for reinforced concrete and steel systems, as well as the physical and urban characteristics of Ortahisar, this study aims to provide an in-depth understanding of the performance of these structural elements.

2. Methodology

This study adopts a qualitative research approach to evaluate the structural performance and user experience of pedestrian overpasses located in the Ortahisar district of Trabzon. Primary data collection methods include field observations and expert interviews. The main objective of the research is to examine key factors—such as material characteristics, environmental impacts, and maintenance requirements—in order to understand how these overpasses fulfill their intended functions within the urban context.

2.1. Study area and sample

The study focuses on 16 pedestrian overpasses situated along the coastal highway in Ortahisar, comprising 14 steel and 2 reinforced concrete structures. The overpasses were selected to represent a variety of structural systems. This sample offers a comparative analysis of the performance and user experience associated with different material types under the unique environmental conditions of the district. These overpasses are located in areas with high pedestrian traffic, including densely populated residential zones, and are exposed to the coastal climate of the region. Such geographical and environmental features significantly influence both the design and operational efficiency of the structures.

2.2. Data collection methods

Data were gathered through two primary methods: field observations and semi-structured expert interviews.

2.2.1. Field observations

Unlike studies that rely on direct physical measurements, this research employed observational techniques to assess the physical condition, aesthetic integration, user comfort, and overall functionality of the overpasses. Special attention was given to environmental factors such as coastal weather conditions, strong winds, and salt exposure, all of which can significantly contribute to material degradation. The observations also emphasized the importance of routine maintenance and timely repairs to ensure structural safety and durability.

2.2.2. Expert interviews

Eight professionals from various disciplines—civil engineering, architecture, urban planning, and transportation engineering—were interviewed using a semi-structured format consisting of 30 open-ended questions. These questions were developed based on insights from seven subject-matter experts and are presented in Table 1. These interviews provided valuable insights into the structural performance, material selection, and maintenance strategies of pedestrian overpasses. Experts were also asked about challenges related to repair costs and how design can be improved to align with sustainability goals. Furthermore, concerns related to climate and its impact on the lifespan of structures, particularly in coastal regions such as Ortahisar, were also discussed.

2.3. Data analysis

The data collected through field observations and expert interviews were analyzed using qualitative techniques. Observational data were categorized into themes focusing on structural condition, environmental adaptation, and user experience. Interview responses were analyzed through thematic coding, allowing for the identification of recurring issues related to design and performance factors affecting the functionality of pedestrian overpasses. This analysis provided insights into the factors shaping the current condition of these structures and helped identify areas for improvement.

Table 1. Open-ended questions

No	Questions
1	What type of structural system (reinforced concrete or steel) have you most frequently encountered in pedestrian overpass projects? What do you think is the reason for this prevalence?
2	What are the fundamental differences in application, maintenance, and repair processes between reinforced concrete and steel pedestrian overpasses?
3	How do climate conditions, traffic density, and topography affect the design, planning, and construction processes of pedestrian overpasses?
4	What are the major technical challenges you face during the design and construction of reinforced concrete or steel pedestrian overpasses?
5	What problems do you encounter most frequently during maintenance and repair processes? What solutions do you apply to address them?
6	What logistical problems do you experience at the construction site or during project delivery? How do you overcome these challenges?
7	What are the main factors (cost, strength, aesthetics, maintenance duration, etc.) influencing decision-makers in material selection (reinforced concrete vs. steel)?
8	When you need to strike a balance between cost-effectiveness and durability, what criteria do you consider?
9	How and through which channels do you receive feedback on user satisfaction? Does this feedback affect the design or implementation processes?
10	What are the advantages and limitations of composite structural systems combining concrete and steel? Under which engineering conditions can these systems be used more efficiently?
11	What are your observations regarding the impact of pedestrian overpasses on traffic safety and pedestrian comfort in the area?
12	How have maintenance and repair costs of pedestrian overpasses changed over time? What measures can be taken to optimize these processes?
13	What do you think about composite systems combining reinforced concrete and steel? Under what conditions can they offer advantages in practice?
14	How will the increasing pace of climate change affect the long-term durability and cost-effectiveness of overpasses? What strategies should be adopted?
15	How do costs evolve over time considering maintenance and repair processes?
16	Can cost advantages be achieved in projects by using recycled materials?
17	According to which criteria is the durability of steel and reinforced concrete overpasses assessed?
18	Which material is more resistant to natural disasters (earthquakes, floods, wind loads, etc.)?
19	How are quality control processes conducted for the structural materials used?
20	How do weather conditions, traffic load, and environmental factors affect the durability of pedestrian overpasses?
21	How can structural performance be improved by using more durable and long-lasting materials in pedestrian overpasses? What new materials or technologies stand out in this regard?
22	What are the most common structural problems requiring maintenance?
23	What are the most frequent problems encountered during the repair process of reinforced concrete pedestrian overpasses?
24	How often should the corrosion protection methods of steel pedestrian overpasses be renewed?
25	How is the routine maintenance frequency determined for different types of pedestrian overpasses, and what is the cost of this process?
26	To what extent are user feedbacks integrated into maintenance processes? According to what criteria are these feedbacks evaluated?
27	How important is the recyclability of the materials used in the construction of pedestrian overpasses in the decision-making process?
28	How common is the use of recycled reinforced concrete and steel materials in current projects?
29	How can the use of sustainable materials in pedestrian overpasses reduce environmental impact?
30	How are the dismantling and recycling processes of decommissioned pedestrian overpasses managed?

2.4. Limitations

It is important to acknowledge that this study relies on qualitative data and therefore has limited capacity to produce quantitative performance assessments. Additionally, the research is confined to pedestrian overpasses within the Ortahisar district. While the findings are valuable for this specific region, they may not be directly generalizable to areas with different climatic or urban characteristics. The study does not include direct physical measurements; instead, its conclusions are based on observational data and expert opinions. As such, while the study offers important insights into the current condition of the overpasses, it does not provide precise structural performance evaluations.

3. Findings

This study focused on a total of 16 pedestrian overpasses located along the coastal highway of Ortahisar district in Trabzon, Turkey. The location and distribution of these overpasses are illustrated in Fig. 1., which provides a satellite overview of their geographical context. These structures span various neighborhoods and urban zones, reflecting different levels of pedestrian traffic, urban development, and exposure to coastal environmental conditions.

To systematically assess their structural performance, user accessibility, and design characteristics, detailed data were collected through field observations and expert interviews. Each overpass was examined in terms of span number, structural system type, presence of diagonal or vertical load-bearing elements, accessibility features, and whether it is covered or not. Table 2 presents a summarized inventory of the pedestrian overpasses included in the study

As evident from the inventory, the majority of pedestrian overpasses are constructed using steel portal frames integrated with diagonal tension rods. Only two structures (Nos. 7 and 15) employ precast reinforced concrete frames. While some overpasses include features such as full enclosure and ramps for accessibility, many lack essential inclusive design elements such as disabled access. Additionally, a number of the overpasses remain uncovered, leaving them more vulnerable to environmental degradation from coastal conditions.

These variations in structural type, protection, and inclusivity provide the foundation for thematic and comparative evaluations in subsequent sections of the findings. The diversity in design reflects not only evolving engineering preferences but also changing urban needs, environmental conditions, and user demands over time.

Analysis of the construction timeline and associated structural details reveals evolving patterns in the selection of materials and systems. Early overpasses built between 2009 and 2011, such as Nos. 15, 9, 7, 10, and 5, reflect diverse structural typologies, including both tied-arch and precast reinforced concrete systems. These structures were primarily focused on functional delivery with little emphasis on accessibility or environmental protection measures.

From 2014 onward, however, a marked preference for steel portal frame systems with diagonal tension rods emerged, indicating a standardization in structural design. This is particularly evident in overpasses built between 2015 and 2016 (Nos. 14, 4, 3), which incorporate both enclosed features and repetitive use of portal configurations. Between 2018 and 2019, newer overpasses such as Nos. 1 and 2 reflected continued reliance on portal frames, but with more careful integration into dense urban zones.

This trend suggests a growing reliance on lightweight steel structures, which offer ease of installation and reduced foundation demands compared to concrete. Despite the efficiency of this typology, a persistent shortcoming is observed in accessibility—many overpasses, including the most recent ones (e.g., No. 13 and No. 16), still lack ramps or elevators, thus limiting usage for people with disabilities or mobility constraints.

In summary, while structural systems have evolved toward efficiency and uniformity, inclusive design considerations have not advanced at the same pace, creating a critical area for future improvement.

From a historical perspective, the construction of these overpasses reveals a chronological progression reflecting evolving design preferences and infrastructure policies. Between 2009 and 2011, a significant wave of construction occurred with the establishment of Overpasses 15, 9, 7, 10, and 5, marking the initial phase dominated by basic structural utility with limited accessibility features. During the 2011–2014 period, Overpass 11 was added, indicating gradual but limited evolution.

The 2014–2015 period saw the construction of Overpass 6, followed by another wave between 2015 and 2016 with Overpasses 14, 4, and 3. These later structures began to incorporate more standardized design elements such as steel portal frames with diagonal tension rods and covered walkways. Between 2016 and 2018, Overpass 12 was constructed, continuing this trend.

A notable design shift emerged between 2018 and 2019 with the construction of Overpasses 1 and 2, introducing broader coverage and improved integration with adjacent urban facilities. The construction of Overpass 16 between 2019 and 2021, and Overpass 8 between 2021 and 2023, further extended the overpass network eastward.

Most recently, Overpass 13 was constructed from 2023 to the present, signifying the latest stage of expansion. However, despite advancements in structure and aesthetics, many newer overpasses still lack critical accessibility features such as ramps, highlighting the ongoing gap between functional expansion and universal design compliance.

This chronological development underscores the influence of urban growth, climate exposure, and user expectations in shaping the evolving typology of pedestrian overpasses in Ortahisar.

14	Pedestrian Overpass in Front of Yalıncak I Avrasya University		1	Steel Portal frame, Diagonal tension rods, No disabled access, Covered
15	Pedestrian Overpass at Yalıncak II DSİ II		2	Precast reinforced concrete frame, No disabled access, Uncovered
16	Yalıncak III Pedestrian Overpass		1	Steel Portal frame, Diagonal tension rods, No disabled access, Uncovered

3.1. Thematic analysis of expert interviews

A total of 30 open-ended questions were posed to experts from various fields related to civil and transportation infrastructure. The responses were analyzed thematically and categorized under key areas reflecting recurring insights and observed patterns. The main themes emerging from the qualitative analysis include material selection criteria, structural system performance, maintenance and repair challenges, environmental influences, user satisfaction, accessibility, and sustainability considerations. Fig. 2 represent thematic frequency based on expert interview responses.

Expert interviews revealed several recurring issues related to the structural performance, durability, sustainability, and user experience of pedestrian overpasses in Ortahisar. Among these, six key themes emerged as the most prominent, both in frequency and impact. Fig. 3 represent key recurring issues from expert interviews.

Firstly, corrosion in steel structures was cited by seven experts as the most common and severe maintenance challenge. This observation is particularly relevant in the context of Trabzon’s coastal climate, where humidity and salt-laden air accelerate material degradation. Jiang and Yang (2012) similarly emphasized that steel elements exposed to marine environments suffer from high corrosion rates, increasing long-term maintenance needs and reducing structural lifespan.

Secondly, cracking in reinforced concrete components was mentioned by five experts. These cracks, often caused by dynamic pedestrian loads and environmental stressors such as freeze-thaw cycles, can significantly undermine the structural integrity of overpasses if not promptly repaired. This aligns with Eremeev et al. (2021), who highlighted the vulnerability of composite concrete systems under fluctuating load and climate conditions.

A third recurring theme was the use of recycled steel, emphasized by six experts. Recycled materials were viewed as beneficial for reducing environmental impact while maintaining structural strength and serviceability. Supporting this, Ivorra et al. (2015) and Ribeiro da Silva & Santos da Silva (2018) found that recycled steel, when properly processed, can be effectively used in infrastructure without compromising mechanical performance.

The impact of environmental factors on durability was highlighted by five experts. Wind exposure, salt spray, and coastal humidity were identified as primary contributors to material fatigue and system degradation. Heldak et al. (2021) supported these observations by underlining the necessity of climate-adapted structural designs in coastal bridge construction.

Accessibility issues were also brought to the forefront, with six experts criticizing the lack of ramps and elevators in many pedestrian overpasses. These deficiencies create barriers for elderly users, individuals with disabilities, and parents with strollers. Ghafoor and Khan (2021) demonstrated that pedestrian overpass usage varies significantly across demographic groups, and that accessibility features are essential to ensuring equitable urban mobility.

Lastly, increasing maintenance costs over time were underscored by eight experts. They noted that while steel structures are efficient in early phases, their upkeep becomes increasingly costly due to corrosion and weather-induced deterioration. Sartori and Hestnes (2007) similarly advocated for lifecycle cost analysis in sustainable infrastructure planning, emphasizing that initial savings may be outweighed by long-term operational expenses.

These findings, supported by both field observations and literature, provide a multi-dimensional understanding of the strengths and shortcomings in the current state of pedestrian overpass infrastructure in Ortahisar. The expert insights validate the observed conditions and also offer strategic guidance for future improvements focused on durability, accessibility, and sustainability.

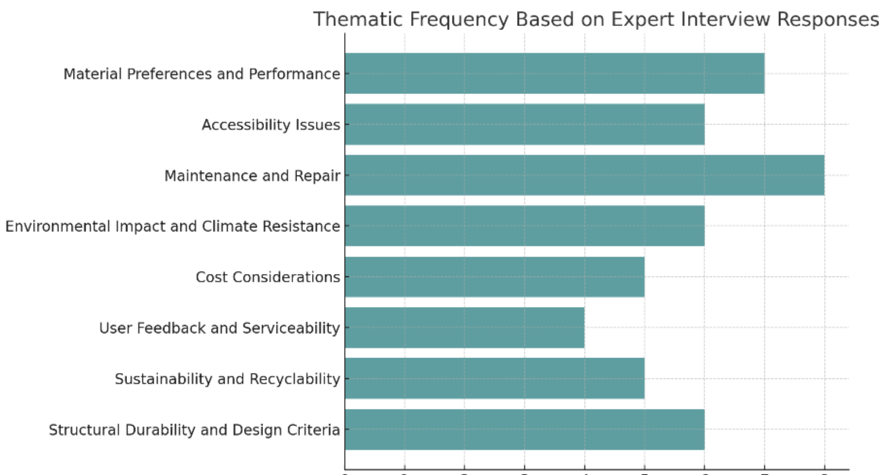

Fig. 2. Thematic frequency based on expert interview responses

Fig. 3. Key recurring issues from expert interviews

In addition to the primary thematic findings, several question-specific insights emerged from expert responses that further clarify critical considerations in pedestrian overpass design. For instance, in discussions related to cost and durability (Q8), experts emphasized the importance of achieving a balance between cost-efficiency and structural longevity. While eight experts prioritized cost-effectiveness in construction and maintenance, five others underscored the need for durability, especially in harsh environmental conditions. Material selection and climate responsiveness were cited as determining factors in this trade-off.

Regarding composite systems (Q10), expert opinions reflected both appreciation and concern. While four experts valued composite structures for their lightweight nature and resilience under dynamic loads, others noted significant limitations. In particular, concerns were raised about initial investment costs and the long-term vulnerability of composite materials to corrosion, especially in humid and coastal environments.

The safety and comfort impact of pedestrian overpasses (Q11) was also highlighted, with six experts identifying accident reduction as the primary benefit. Additionally, several experts noted that pedestrian comfort and structural accessibility contribute significantly to public satisfaction and the broader goals of socially sustainable urban infrastructure.

Sustainability concerns were further addressed in relation to the use of recycled materials (Q16). Six experts supported the adoption of recycled steel and other eco-friendly materials in overpass construction. While cost advantages were recognized, concerns regarding long-term durability and material quality control were also frequently mentioned.

Overall, these detailed insights complement the broader thematic analysis by offering a more nuanced understanding of expert priorities. The convergence of opinions around durability, environmental responsiveness, user accessibility, and sustainability underscores the multidimensional nature of overpass design in coastal urban settings like Ortahisar. Fig. 4 represents expert tendencies across multiple Interview questions.

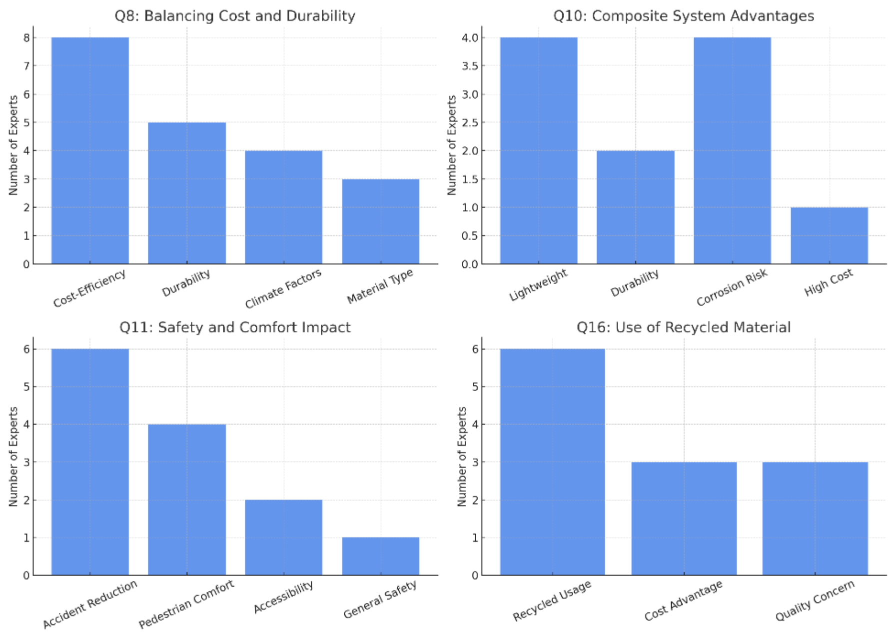

Fig. 4. Expert tendencies across multiple Interview questions

4. Conclusions

This study presented a comprehensive assessment of the structural characteristics and user-centered performance of 16 pedestrian overpasses located in the Ortahisar district of Trabzon. Through field observations and thematic analysis of expert interviews, key insights were drawn regarding the performance of both steel and reinforced concrete systems in coastal urban environments. The following conclusions have been drawn based on the findings of the study.

- Steel portal frame systems are preferred due to lightweight construction and ease of installation, but their long-term performance is compromised by corrosion, particularly in coastal climates like Trabzon.
- Reinforced concrete systems offer better resistance to environmental factors such as salt and humidity but are heavier and more time-consuming to install.
- Accessibility limitations remain widespread. Many pedestrian overpasses, including newly built ones, lack essential inclusive features such as ramps and elevators.
- Lifecycle-based design and preventive maintenance strategies are essential due to rising maintenance costs—especially in steel structures exposed to marine conditions.
- Recycled materials (e.g., recycled steel) are gaining favor among professionals for their cost-effectiveness and environmental benefits, though their application is still limited.
- CLT (Cross-Laminated Timber) and other engineered wood materials have potential for pedestrian bridge applications thanks to their lightness, aesthetic value, and sustainability. However, challenges related to environmental durability and regulatory standards must be addressed.
- Design decisions should not rely solely on cost or engineering practicality. User inclusiveness, urban integration, and sustainability must guide the future of pedestrian infrastructure in coastal cities like Ortahisar.

Abstract. Cement, which requires a temperature of 1300-1400 °C for its production, is responsible for approximately 8-10% of industrial greenhouse gas emissions. Harmful gases emitted during cement production are caused by the firing of clinker and the decomposition of calcium carbonate. Substituting clinker or cement with various mineral additives contributes to reducing emissions by limiting cement consumption. Traditional substitutes are pozzolanic additives such as fly ash, blast furnace slag, silica fume, volcanic tuff, calcined clay. This study covers calcareous clay (marl), which has not yet received sufficient attention. Calcareous clays are a type of clay that contains significant amounts of calcium carbonate, in addition to the typical clay minerals such as kaolinite, illite, and montmorillonite. These clays are found in various regions around the world and have been studied for their potential use as pozzolanic materials. Marl, which is cheaper and more readily available than sources containing pure clay minerals, can have sufficient pozzolanic activity when calcined under appropriate conditions. In this study, marl obtained from local sources was calcined at different temperatures (600, 700, 800, 900 °C). Calcined samples were ground in a laboratory type mill to obtain pozzolanic material. In order to determine the pozzolanic activity of the obtained samples, pozzolanic activity test was performed according to TS-25. As a result, it was determined that marl should be calcined at 800 degrees for maximum pozzolanic activity.

Keywords: Calcined marl; Pozzolanic activity; Cement substituting

1. Introduction

Cement production constitutes a significant portion of industrial energy consumption and carbon dioxide emissions (Monteiro et al., 2017). The literature presents various methods to mitigate harmful gas emissions from cement production. Among the frequently researched approaches globally are emission reduction techniques such as enhancing production technologies and partially or fully substituting cement with natural and artificial pozzolans, including slag, fly ash, and calcined clay (Jokar & Mokhtar, 2018; Scrivener et al., 2018). These materials, which possess pozzolanic activity and can replace cement in specific proportions, are referred to as cement replacement materials (CRM).

Naturally available materials containing clay minerals such as kaolinite, illite and montmorillonite, which can show high pozzolanic reactivity after heat treatment (calcination), are considered in the CRM class. Among these most abundant clay minerals in nature, kaolinitic clays are the most reactive clay type after calcination (Fernandez et al., 2011). Thermal treatment of kaolinitic clays (650-900 °C) results in the formation of metakaolin, a highly reactive pozzolan. As a result of this thermal treatment, the structure of kaolin changes; hydroxyl ions are removed and defects occur between the alumina and silica layers. The result is a highly reactive and amorphous material suitable for use in cement applications (Kostuch et al., 2000). The high pH of the cement pore solution results in Al ions dissolved from metakaolin forming an aluminum-rich calcium silicate hydrate gel (C-S-A-H). With water present in the system, alumina hydrates and calcium silicate alumina hydrates form, with their composition influenced by the AS_2/CH ratio and thermal conditions (Bergaya & Lagaly, 2013). Furthermore, the pozzolanic reactivity of metakaolin is enhanced in the presence of gypsum (Kurdowski & Pomadowski, 2001). A partial substitution of cement with metakaolin leads to a reduction in pore volume and a shift in pore distribution towards smaller sizes (Frías & Cabrera, 2000). Employing less porous cements containing metakaolin in mortar or concrete improves their strength and enhances their resistance to harsh environments, such as those containing sulfate or chloride (Gruber et al., 2001).

Due to the high demand for kaolinitic clays and low availability, there are limitations to their industrial use. In addition, in many regions raw clay is naturally combined with limestone (calcite). Consuming more costly

https://doi.org/10.31462/icearc2025_ce_mat_080

resources that contain a high proportion of clay minerals raises some sustainability concerns. Therefore, the availability of more accessible and cheaper resources containing calcite and various clay minerals (marl) should be investigated in the cement and concrete sectors. Marl is a type of sediment consisting of a mixture of clay minerals (smectite, illite, kaolinite, etc.), feldspar and quartz with various carbonates (Bucher et al., 2002). Compared to kaolinitic clays, marl is a very abundant resource with low economic value.This study was conducted on calcareous clay (marl), which is not as common as other CRMs. Calcination was carried out at different temperatures to determine the performance of marl as CRM. After calcination and grinding, pozzolanic activity test was performed according to TS-25.

2. Materials and method

2.1. Materials

Calcareous clay obtained from Konya region was used as mineral additive in this study. Firstly, raw marl was sieved through a 2.36 mm sieve. The sieved material was calcined in a laboratory type muffle furnace at 600-700-800 and 900 °C for 30-60-90 minutes. The calcined material was ground in a laboratory type ball mill for 60 minutes. The pozzolanic material obtained was used as pozzolan in TS-25 mixtures. Photographs of the marl are presented in Figure 1 and physical and chemical properties are presented in Table 1.

Slaked lime ($Ca(OH)_2$) is used in the pozzolanic activity test according to TS-25. Within the scope of the study, $Ca(OH)_2$ with a density of 2.36 g/cm^3 from Tekkim company was used. A photograph of the $Ca(OH)_2$ used is presented in Fig. 1. CEN standard sand and city municipal water were used in the preparation of mortars.

2.2. Preparing of mixtures

The prepared powder materials were dry mixed at low speed for 60 seconds. Water was added to the homogenized powder mixture and the mortar mixing protocol described in TS EN 196-1 was applied. The prepared mortars were taken into 4x4x16 cm molds and the molds were covered with a glass plate to prevent evaporation and kept for 24 hours. The specimens were then placed in an oven at (55 ± 2) °C for a further 6 days without removal from the mold. At the end of 6 days, the samples removed from the oven were subjected to compressive strength test according to TS EN 196-1. The prepared mixtures are presented in Table 2.

3. Results and discussion

Fig. 2 presents the compression strength test results of the pozzolanic activity test carried out in accordance with TS-25 standard, based on marl samples calcined at various temperatures (600-900 °C) and durations (30, 60, 90 min). Generally, the strength increases with rise in temperature and duration. In particular, the performance at 600 °C (7.51-7.87 MPa) showed the lowest activity, and one can see a remarkable rise in strength when the processing temperature is up to 700 °C (9.00-10.55 MPa). This rise suggests an increase of the amorphous phases and the reactive silica-alumina present in the marl.

The compressive strength of the sample calcined at 800 °C for 90 min is the highest (12.12 MPa). This indicates that the best activation is at around 800 °C and higher time periods. But the strength is decreasing at 900 °C (minimum 8.96 MPa). This reduction may be attributed to acceleration of crystallization and decrease of reactive amorphous phase. Finally, on the basis of pozzolanic activity, the optimum calcination conditions are for a temperature of 800 °C and a time range of 60-90 min. These results demonstrate that calcined marl can successfully be used as a supplementary cementitious material.

It is already known that materials containing clay minerals have a certain degree of pozzolanic activity after heat treatment, depending on the amount of kaolinite in the material. Moreover, there are various, albeit limited, studies on clays containing calcite impurities. For example, it has been shown that calcite impurities (10-15%) present in raw clays of smectite, illite and kaolin origin have positive effects on pozzolanic reactivity (Zunino et al., 2020) and can be a good pozzolanic material when calcined between 400 and 800 °C (Rakhimov et al., 2017).

Generally, increasing the calcination temperature up to a certain level positively affects the pozzolanic activity (Nawel et al., 2020). However, it has been reported that after a critical point, the specific surface area decreases with increasing calcination temperature and consequently the pozzolanic activity decreases (Castillo et al., 2010). This study also revealed that appropriate calcination process should be applied to obtain maximum pozzolanic activity.

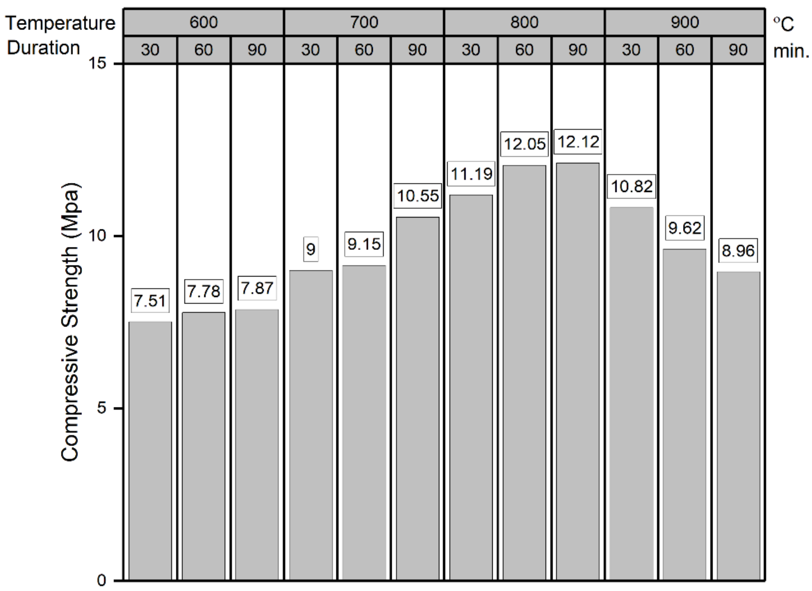

Fig. 2. Result of pozzolanic activity test

4. Conclusions

In this study, calcareous clay was calcined at different temperatures and for different times. It is generally known that clays containing high proportions of kaolinite minerals have high pozzolanic activity. However, this research is based on calcareous clay, which is not commonly used as CRM. In this study, calcareous clay was exposed to different conditions for maximum pozzolanic activity and the following conclusions were reached.

- The maximum pozzolanic activity of calcareous clay was obtained at 800 °C.
- Even at the lowest temperature (600 °C) considered within the scope of the study, strength above the limit of TS-25 standard (4 MPa) was obtained.
- Increasing the calcination temperature up to 800 °C positively affected the pozzolanic activity.
- By increasing the calcination temperature to 900 °C, the pozzolanic activity decreased compared to the material calcined at 800 °C.
- Increasing the calcination time positively affected the pozzolanic activity.

Acknowledgments

The authors would like to thank Konya Cement for their support in this study.

[4] *Düzce University, Department of Civil Engineering, 81100 Düzce, Türkiye*

Abstract. Concrete is one of the most widely used construction materials worldwide, and its production process has a significant impact on global warming and climate change due to its high carbon emissions. Emissions from the use of cement in concrete production trigger climatic imbalances by increasing greenhouse gas intensity. Therefore, determining the carbon footprint of the ready-mixed concrete sector and developing emission reduction strategies are critical for sustainability. In this study, corporate carbon footprint calculation was carried out using 2023 operational data of 28 ready-mixed concrete facilities operating in different regions of Türkiye and it was aimed to determine the processes that cause the highest greenhouse gas emissions within business activities. The calculations were made based on the internationally accepted GHG Protocol, ISO 14064 and IPCC (Intergovernmental Panel on Climate Change) guidelines in the field of greenhouse gas reporting and management. In the study, emission sources related to the ready-mix concrete production process were analyzed comprehensively and sources in Scope 1 (direct emissions), Scope 2 (indirect emissions) and Scope 3 (other indirect emissions) categories were evaluated in detail. The findings showed that the highest emissions across the sector came from Scope 3, followed by Scope 1 and Scope 2. In particular, the largest impact within Scope 3 stems from the category 'Purchased Goods and Services'. It has been determined that the main emission source in Scope 1 is "mobile combustion emissions" (such as vehicles and construction equipment), and in Scope 2 it is "grid electricity use". In the ready-mixed concrete sector, it is a critical step to adopt sustainability policies, especially to reduce Scope 3 emissions, and to promote energy efficiency and the use of alternative raw materials in supply chain processes. In order to reduce Scope 1 emissions, solutions such as low emission engine technologies, use of alternative fuels and fleet management systems can be applied in construction machinery and vehicles. In addition, the use of renewable energy sources and the integration of energy efficient technologies are recommended to reduce Scope 2 emissions.

Keywords: Corporate carbon footprint; ready-mix concrete industry; climate change; sustainability assessment; greenhouse gas emissions

1. Introduction

Today, climate change has become one of the greatest environmental threats to humanity. The intensive use of fossil fuels, rapid industrialization and increasing energy demand constitute the main sources of greenhouse gases (GHG) released into the atmosphere (IPCC, 2022). These emissions threaten ecosystems with consequences such as global temperature increases, melting of polar ice caps, extreme meteorological events and yield losses in agricultural production. This situation has necessitated the development of various strategies at national and international levels to measure and reduce carbon emissions (Bulut et al., 2024).

The concept of 'carbon footprint' has been developed for the calculation of greenhouse gas emissions, and the environmental impacts of sectors can be clearly revealed, especially through assessments made at the corporate scale. The corporate carbon footprint is calculated by determining the direct (Scope 1), indirect (Scope 2) and other indirect (Scope 3) emissions resulting from energy consumption and supply chain processes (Harangozo et al., 2017a; World Resources Institute, 2003). These calculations are based on internationally recognised standards, notably the GHG Protocol, ISO 14064 standard and IPCC guidelines (Ranganathan et al., n.d.).

[*] Corresponding author, E-mail: emrahyilmaz@duzce.edu.tr

https://doi.org/10.31462/icearc2025_ce_mat_107

golden light publishing

The construction sector is one of the sectors that cause high carbon emissions, especially due to cement and concrete production processes and raw material consumption. CO_2, one of the six main greenhouse gases defined in the Kyoto Protocol, is released intensively during the cement production process and this process corresponds to 7-8% of global CO_2 emissions (Downie et al., 2012). According to the data of the European Ready Mixed Concrete Organization (ERMCO), Türkiye ranks high in Europe in both cement consumption and ready-mixed concrete production per capita (European Ready Mixed Concrete Organization, 2020). The 2023 report of the Turkish Ready Mixed Concrete Organization revealed that there is a direct relationship between cement domestic sales and ready-mixed concrete production, and that production in the sector has increased steadily over the years (Turkish Ready Mixed Concrete Organization, 2024).

Despite this, studies on the carbon footprint of ready-mixed concrete plants in Türkiye are limited and there is a need to evaluate emission sources, especially at the institutional level, with a holistic approach. In the limited number of studies in the literature, only the effects of production and transport processes on emissions have been addressed, and the sector-wide emission distribution has not been comprehensively analysed (Çümen et al., 2023).

In this study, the corporate carbon footprint of 28 ready-mixed concrete plants operating in Türkiye was calculated using data for 2023. The calculations were carried out within the framework of the GHG Protocol, ISO 14064 and IPCC guidelines and the processes that cause the highest greenhouse gas emissions within the facility activities were determined. The study aims to contribute to the development of sustainability policies in the ready-mixed concrete sector and to support emission reduction strategies with concrete data.

2. Sustainability and ready-mixed concrete industry

2.1. Corporate sustainability

The concept of sustainability is based on the principle that all living and non-living beings included in the life cycle continue their existence by preserving the existing natural balance of the planet. In this context, sustainability refers to the protection of natural resources without depletion, in a way that will maintain the functioning of the ecosystem, and to meeting the needs of humanity today while not endangering the needs of future generations (United Nations, 1987).

According to the generally accepted approach, sustainability is addressed in three basic dimensions: environmental, social and economic.

- Environmental sustainability aims to protect the environmental resources and conditions that ensure the natural functioning of the ecosystem so that it can continue to exist in the future.
- Social sustainability involves maintaining the welfare of societies in a fair, inclusive and long-term manner and respecting the rights of all life forms.
- oduction and consumption processes within the framework of sustainable resource utilisation and to secure the continuity of economic activities.

The reflection of this triple structure at the corporate level is called corporate sustainability. It is inevitable that organisations create environmental, social and economic impacts during their activities. For this reason, corporate sustainability is related to the fact that businesses recognise these impacts, minimise the negative ones and develop policies to increase the positive impacts (Elkington et al., 1999). This approach is not only a responsibility for the environment and society, but also a strategic imperative that strengthens corporate reputation and supports long-term success.

As the effects of climate change become more apparent each year, the concept of corporate sustainability has gained an important place in the management strategies of businesses. International regulations and incentive mechanisms developed within the framework of the United Nations Sustainable Development Goals (SDGs) are among the elements that increase this importance (United Nations, 2015). In particular, the European Commission plays an active role in the development of legislation to encourage responsibilities towards corporate sustainability. Among the basic policies developed in this context, the determination of labor standards, social management principles, the "polluter pays" principle and producer responsibility policies stand out. These regulations are designed to cover all processes from raw material supply to the final consumer (Herzig Christianand Schaltegger, 2011).

In order for organisations to effectively benefit from such policies and support mechanisms and successfully implement their sustainability strategies, they should firstly determine the environmental impacts of their activities, especially their corporate carbon footprint accurately and comprehensively. After this determination, enterprises are expected to set concrete targets to reduce their carbon footprint and develop action plans that can be implemented within a certain period of time to achieve these targets.

2.2. Corporate carbon footprint

Corporate carbon footprint is an environmental measure obtained by calculating the greenhouse gases emitted directly and indirectly into the atmosphere as a result of the activities of an enterprise in 'tonnes of CO_2 equivalent' (Wiedmann et al., 2007). This calculation forms the basis of sustainability strategies by covering not only an organisation's own operations, but also the emissions generated throughout the supply chain and product life cycle.

In carbon footprint calculations, internationally valid standards such as the Greenhouse Gas Protocol (GHG Protocol) (World Resources Institute, 2003), PAS 2060, ISO 14064 are used. These standards categorise direct (Scope 1), indirect emissions related to energy consumption (Scope 2) and indirect emissions related to the supply chain (Scope 3) and provide detailed guidelines on calculation methods (World Resources Institute, 2011). The most widely used of these methods is the GHG Protocol, which was reported to be implemented by 63% of Fortune 500 companies in 2007 (Harangozo et al., 2017b; *NQA-PAS-2060-Implementation-Guide*, n.d.).

The GHG Protocol is one of the first comprehensive approaches that provides a framework for measuring, monitoring, reporting and reducing greenhouse gas emissions at the organizational level (Kolk et al., 2008). At the same time, this protocol is structured under the ISO 14000 Environmental Management System standard, forming the basis of the ISO 14064 series. The ISO 14064 standard includes principles for organizations to measure, monitor and report their greenhouse gas emissions transparently (Ranganathan et al., n.d.). In comparing these two methodologies, it is seen that the GHG Protocol allows for more voluntary, integrated analyses with market mechanisms such as carbon trading, while ISO 14064 presents the technical requirements for the calculation and verification of greenhouse gas emissions at the organizational level in a more systematic way (Çolak et al., 2023)).

The first stage of corporate carbon footprint calculation is to determine the activity boundaries of the business (such as production, supply, logistics, export). Then, direct and indirect greenhouse gas sources within these boundaries are identified and classified. Carbon footprint calculations are performed based on inventory data prepared by identifying emission sources and applying emission factors. In this process, the six main greenhouse gases defined in the Kyoto Protocol (CO_2, CH_4, N_2O, HFCs, PFCs, SF_6) are taken as basis. The global warming potential (GWP) of each of these greenhouse gases is taken into account and the calculation is made in terms of a common metric, CO_2 equivalent (Çolak et al., 2023).

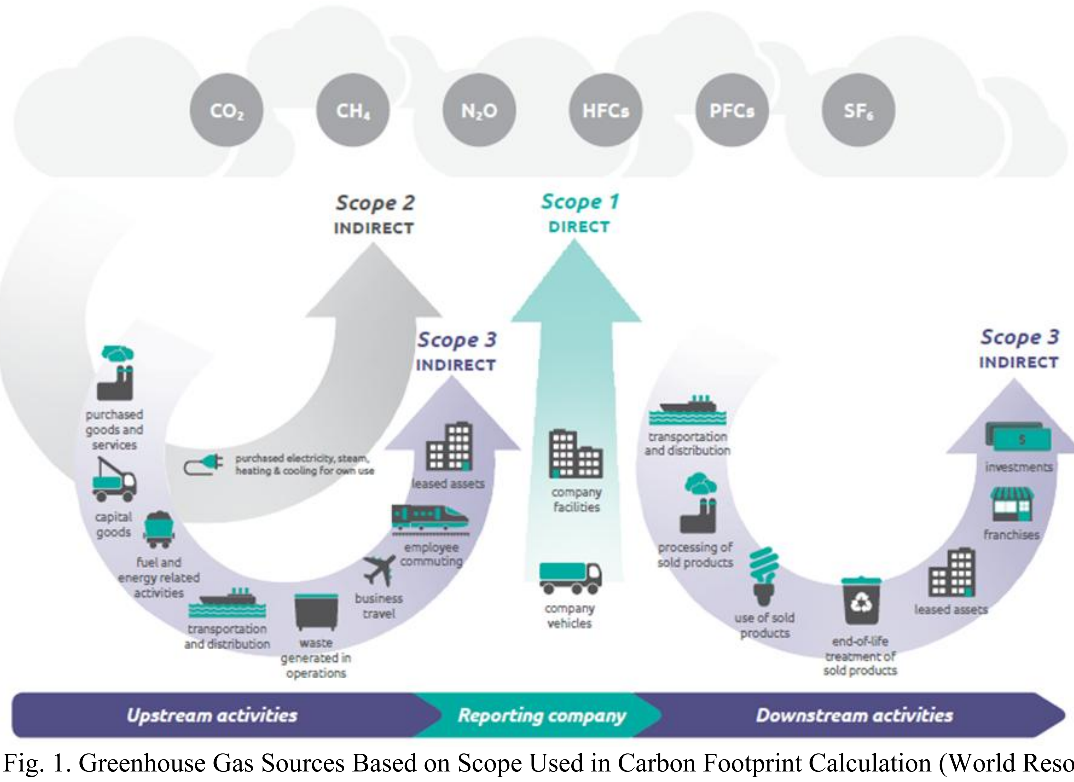

Fig. 1. Greenhouse Gas Sources Based on Scope Used in Carbon Footprint Calculation (World Resources Institue, 2011)

Carbon footprint calculations are classified into three scopes:

- Scope 1: Direct emissions from fixed and mobile sources in the institution's facilities (e.g. fuel use in truck mixers),
- Scope 2: Indirect emissions resulting from the use of externally supplied energy such as electricity, steam, cooling,
- Scope 3: Other indirect emissions related to the supply and use chain, such as raw material supply, transportation, employee transportation, waste management.

The Green Deal policy published by the European Union in 2019 aimed to achieve net zero carbon by 2050 and to decarbonize all sectors in line with this target (European Green Deal Call, 2020). As part of this process, a carbon tax will be gradually applied to imports of products from sectors with high carbon intensity into the EU under the Border Carbon Adjustment Mechanism (CBAM). This application will be evaluated in line with the corporate carbon footprint reports of the enterprises. The sectors included in the scope of the application in the first phase include cement, electricity generation, fertiliser, iron-steel, aluminium, organic chemicals and plastic products. The reason for selecting these sectors is that they significantly contribute to greenhouse gas emissions due to their high energy and raw material use. (World Resources Institue, 2011)

In light of these developments, corporate carbon footprint reporting for industrial sectors has become critical not only in terms of environmental responsibility but also in terms of economic sustainability and international trade harmonisation. As a matter of fact, according to the data in Türkiye's national greenhouse gas inventory, cement production accounts for 49% of greenhouse gas emissions due to industrial production and product use, and 78% of emissions from the mineral industry (Republic of Türkiye, 2023).

2.3. Ready-mixed concrete and cement sector in the World and Türkiye
Cement is one of the basic components of the construction sector and its most intensive use is in the production of ready-mixed concrete. Ready-mixed concrete is an important building material produced using cement-based binders and used directly in construction applications. According to the 2020 data of the European Ready-Mixed Concrete Organization (ERMCO), Türkiye was the country with the highest cement consumption in Europe in 2018 and 2019. In terms of ready-mixed concrete production, Türkiye ranked second after the United States in 2018 and third after Japan in 2019. In terms of production per capita, Türkiye is well above the European average and ranks among the top five countries (Europan Ready Mixed Concrete Organization, 2020).

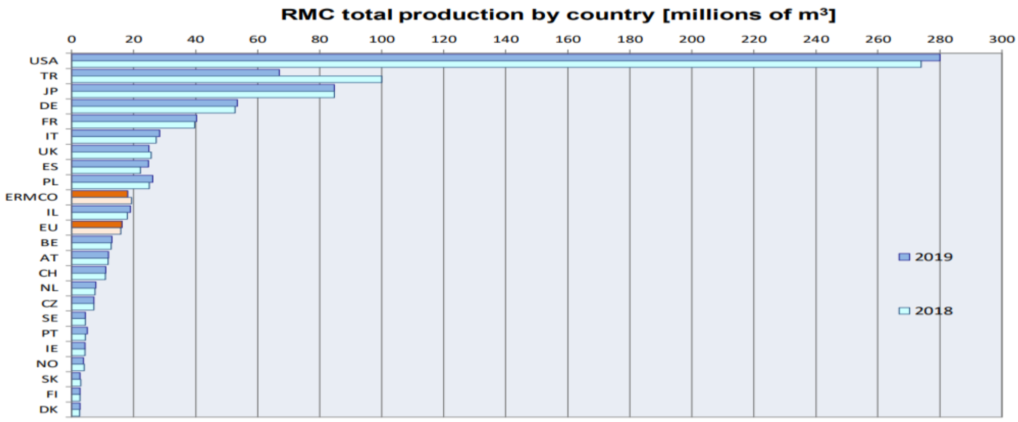

Fig. 2. Total Ready Mixed Concrete Production by Countries (Europan Ready Mixed Concrete Organization, 2020)

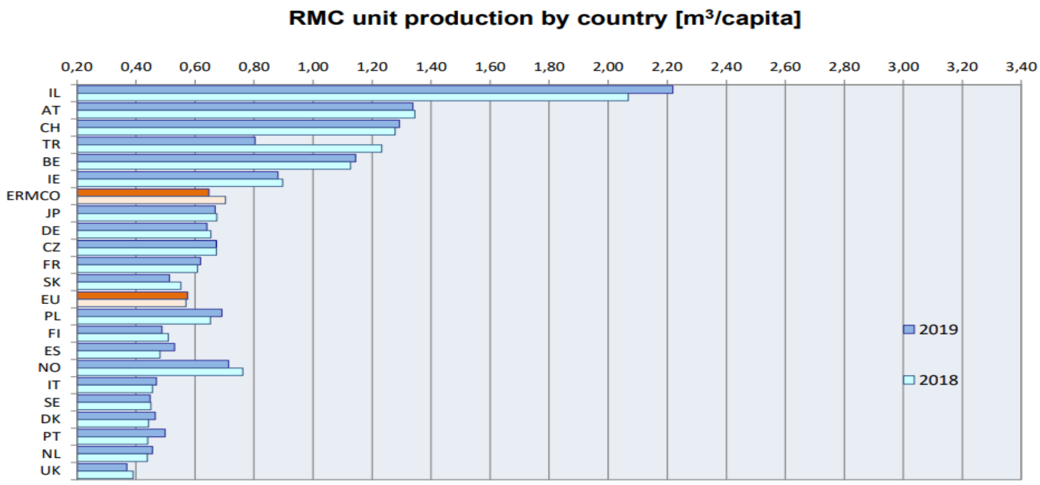

Fig. 3. Ready-mixed Concrete Production Per Capita (Europan Ready Mixed Concrete Organization, 2020)

According to the 2022 “Ready-Mixed Concrete Sector Report” published by the Turkish Ready-Mixed Concrete Association (THBB) in April 2023, ready-mixed concrete production in Türkiye has been showing a continuous increase trend since 1988, excluding the pandemic period. As can be seen in Fig. 9, this increase in production clearly reveals the growth momentum of the sector. In addition, it has been determined that there is a strong linear relationship between domestic sales quantities of cement and ready-mixed concrete production, and that these two variables move together (Turkish Ready-Mixed Concrete Association, 2024).

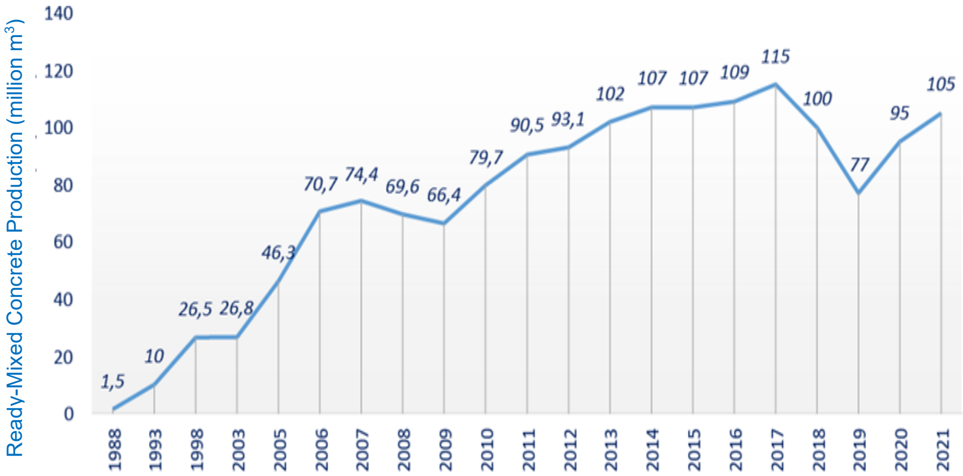

Fig. 4. Ready-mixed concrete production in Türkiye by year (Turkish Ready-Mixed Concrete Association, 2024).

According to the THBB report, the total capacity of ready-mixed concrete plants in Türkiye varies between 225 and 343 million m³. In addition, the total carrying capacity of approximately 18,500 transmixers operating in the country is estimated to be 178 to 305 million m³, and the total capacity of mobile pumps is approximately 110 million m³. Considering that approximately 80% of the ready-mixed concrete produced is poured by mobile pumps, the actual operational capacity is calculated to be around 137.5 million m³ (Turkish Ready-Mixed Concrete Association, 2024).

When the capacity utilization rates were examined, it was determined that 70% of the existing installed capacity was used for 2018 and 50% for 2019 (Europan Ready Mixed Concrete Organization, 2020; Turkish Ready-Mixed Concrete Association, 2024).

In case of an increase in capacity utilisation rates, cement consumption will increase in parallel with this increase and this will lead to an increase in greenhouse gas emissions. In this context, Figure 10, which shows the linear relationship between cement domestic sales and ready-mixed concrete production, demonstrates the importance of the sector in terms of emission potential.

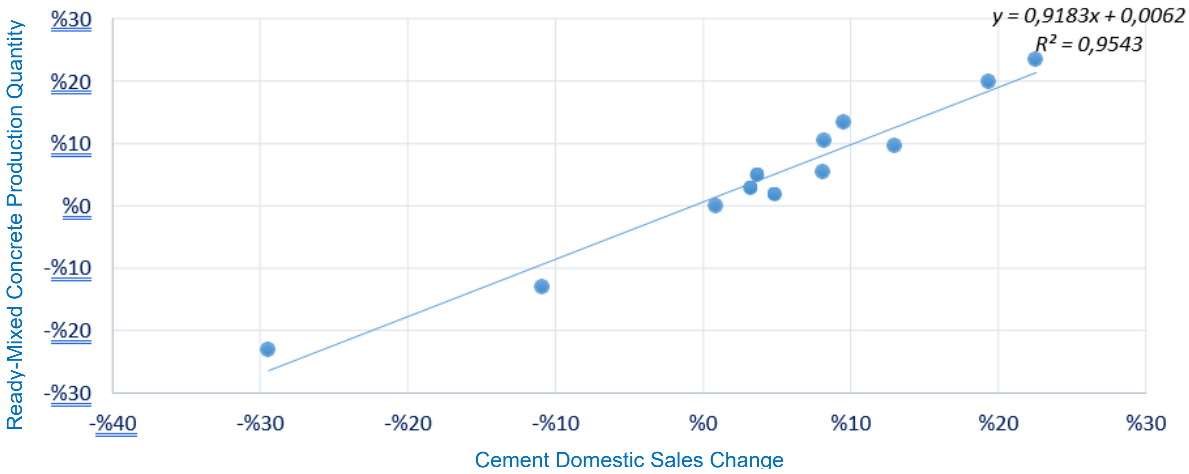

Fig. 5. Cement Domestic Sales - Ready-Mixed Concrete Production Relationship (Turkish Ready-Mixed Concrete Association, 2024)

In order to reduce the environmental impact of the sector, solutions such as low carbon technologies, alternative binders, energy efficiency applications and the use of electric vehicles in transportation processes are gaining importance. The dissemination of such strategies will contribute to the ready-mix concrete sector's compliance with both national climate policies and international obligations shaped within the framework of the European Green Deal.

As a result, the ready-mix concrete sector stands out as the second sector with the highest potential to reduce Türkiye's carbon footprint after the energy sector. The size of the sector and its direct relationship with cement consumption necessitate that this area be evaluated as a strategic priority in policies to combat climate change (Turkish Ready-Mixed Concrete Association, 2024).

3. Materials and methods

3.1. Materials
