PROCEEDINGS – VOLUME 1: CIVIL ENGINEERING

PREFACE

The 4th International Civil Engineering & Architecture Conference (ICEARC'25) aimed to bring together academics, researchers, and practitioners in the fields of civil engineering and architecture from across the globe. Held in Trabzon, Türkiye on May 17–19, 2025, the conference served as a dynamic platform to review recent achievements, share emerging developments, and address both current and future challenges in these disciplines.

ICEARC'25 has once again demonstrated its truly international character, drawing over **500 participants from 33 countries**. The conference hosted **421 research presentations** delivered in **59 parallel sessions**, and provided participants with excellent networking and collaboration opportunities. In addition to the technical sessions, **four dedicated workshops**—focusing on contemporary themes such as sustainable buildings, hybrid structures, and advanced materials—offered attendees practical insights and knowledge exchange in specialized areas.

The **Proceedings of the 4th International Civil Engineering and Architecture Conference** includes all the accepted and presented papers, compiled in two volumes:

- **Volume 1: Civil Engineering**, comprising 303 papers under major categories such as Structural Mechanics, Earthquake Engineering, Hydraulics & Fluid Mechanics, Geotechnics & Soil Mechanics, Transportation, Structural Materials, Hydrology & Water Resources, Construction Management, and Waste Management.
- **Volume 2: Architecture**, featuring 118 papers grouped under topics such as Architectural Philosophy, Design & Practice, Architecture, Conservation & Restoration, Urban Planning & Landscape, Architectural Engineering, and Interior Design.

We are sincerely grateful to all authors for their valuable contributions. The papers included in these volumes were rigorously reviewed by field experts, and only those that were accepted and presented at the conference have been published. We extend our deepest appreciation to the reviewers for their meticulous evaluations, which significantly contributed to the quality of this publication.

We would also like to express our gratitude for the institutional support provided by **Karadeniz Technical University** and **the Chamber of Civil Engineers (Trabzon Branch)** of the **Union of Chambers of Turkish Engineers and Architects**. We sincerely thank our sponsors:

- **Platinum Sponsor:** Usta Grup
- **Gold Sponsors:** Cengiz İnşaat, Türen İnşaat, Odaş
- **Silver Sponsors:** Es Denizcilik, KCT Yol Yapı İnşaat
- **Bronze Sponsors:** Inosel, YaşarTek, AKM Yapı

Our special thanks go to the **Mayor of Trabzon Metropolitan Municipality**, **Mayor of Ortahisar Municipality**, and **Mayor of Yomra Municipality** for their valuable support.

We also acknowledge the outstanding efforts of the organizing committee, the student volunteers, and all the moderators who chaired our sessions with professionalism and dedication. Their contributions were instrumental in the success of ICEARC'25.

Finally, the conference concluded with a memorable **social tour to the iconic Sümela Monastery and Uzun Göl**, offering participants a taste of the region's rich cultural and natural heritage.

We look forward to welcoming you again at **ICEARC'27**.

[2] *Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye*
[3] *Uludag University, The Graduate, Department of Civil Engineering, 16285 Bursa, Türkiye*

Abstract. Turkey is recognized as one of the most seismically active regions in the world. The 1999 Kocaeli, 1999 Düzce, 2011 Van, 2020 Elazığ-Malatya, 2020 İzmir, and 2023 Kahramanmaraş earthquakes are among the significant seismic events in recent years that have resulted in substantial losses. These earthquakes have revealed that a large portion of the building stock in our country is vulnerable to earthquakes. Chapter 15 of the Turkish Building Earthquake Code-2018 (TBEC-2018) includes guidelines for evaluating existing building systems under seismic effects. In this study, the earthquake performance of a composite building consisting of reinforced concrete (RC) shear walls and steel frames was examined using a nonlinear time-history analysis method in line with the specified rules and calculation principles. Eleven real earthquake records were selected, scaled, and used for the nonlinear time-history analyses. The building under investigation is located in the Iskenderun district of Hatay province, and it sustained no damage during the February 6, 2023, Kahramanmaras earthquakes and is currently in active use. In the final section of the study, ground motion records from the February 6, 2023 Pazarcik (7.7 Mw) earthquake were obtained from two different stations and applied to the building model and the results obtained from the analyses were then examined.

Keywords: Existing Steel-RC Building; Nonlinear Analysis; TBEC-2018; Performance Assessment; February 6 2023 Pazarcik-Kahramanmaraş Earthquake

1. Introduction

Located on a geography where three different tectonic plates intersect, Turkey has a high potential to produce earthquakes in terms of seismic risk. For this reason, many earthquakes occur in this geography. The 1999 Izmit and Düzce earthquakes, 2003 Bingöl, 2011 Van, 2020 Elâzığ, 2020 İzmir and 2023 Kahramanmaraş earthquakes are the events that occurred in Turkey in recent years and caused great losses. On February 6, 2023, two major earthquakes with magnitudes of 7.7 Mw (Pazarcık) and 7.6 Mw (Elbistan) in Kahramanmaraş, Turkey, caused extensive damage and loss of life in 11 provinces in the region. As a result of these earthquakes, more than 700,000 buildings were affected and more than 230,000 were severely damaged or destroyed (Presidency of Strategy and Budget, 2023).

The results of all these earthquakes show that there are still many earthquake resistant structures in our country. Investigation of the structures that have been damaged, collapsed or are still in use and undamaged under the earthquake effect will be beneficial for the design of earthquake resistant structures.

There are guidelines in the literature on earthquake performance assessment of existing structures. Guidelines such as ATC-40 (Applied Technology Council, 1996), FEMA 356 (FEMA, 2000), FEMA 440 (FEMA, 2005), and TBEC 2018 (TBEC, 2018) are some of them.

In this study, the earthquake performance evaluation of Steel's Tower (A Block), which is known to be undamaged after the Kahramanmaraş earthquakes that occurred on February 6, 2023, was carried out according to TBEC 2018 code. This building is located in İskenderun district of Hatay province. The structural system of this building with a height of 52.2 m is composed of steel columns-beams and reinforced concrete walls.

ETABS software was used for nonlinear analysis and 3D modeling in time domain. Plastic rotational hinge are defined at both ends of columns and beams. Fiber hinge model was used for reinforced concrete shear walls. According to TBEC 2018, 22 (2x11) real earthquake records were selected, scaled and used for nonlinear time-history analysis. The earthquake performance level of the building was determined. Then, the ground motion

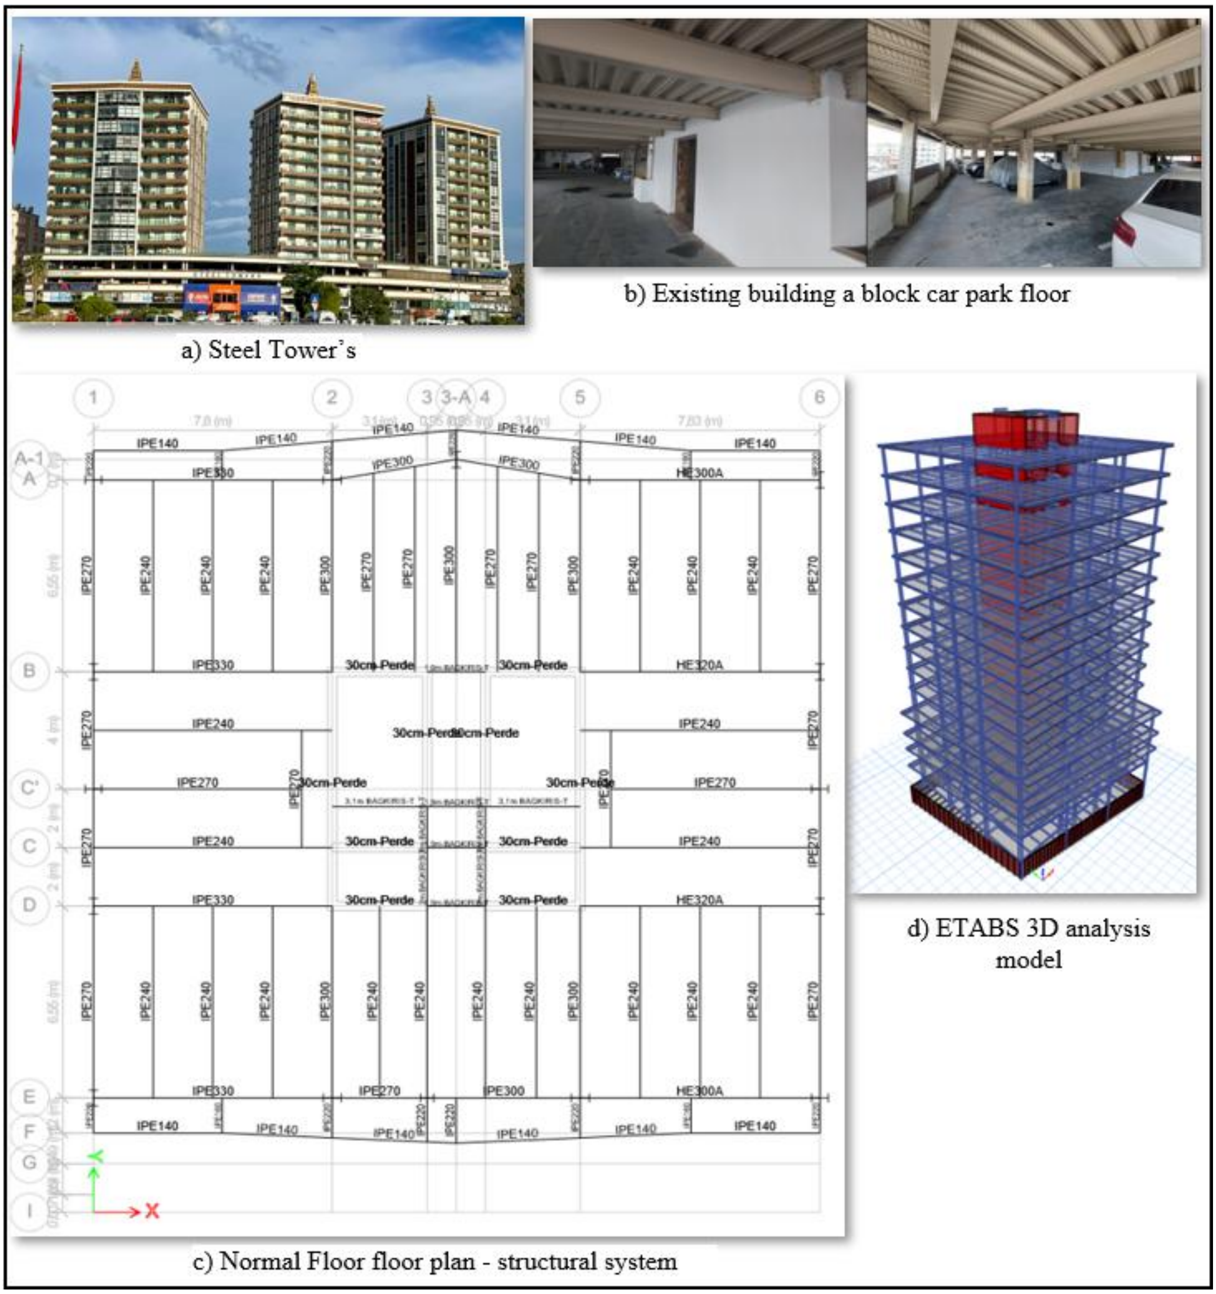
* Corresponding author, E-mail: sahinfaruk.ins@outlook.com

https://doi.org/10.31462/icearc2025_ce_eqe_020

acceleration records of the February 6, 2023 Pazarcık (7.7 Mw) earthquake, obtained from stations 3112 and 3115 located close to the building, were applied to the analysis model and the results were analyzed.

2. Building properties and seismicity of the region

Built in 2014, Stell Tower's buildings were designed within the scope of TEC-2007 (TEC, 2007) and constructed as three blocks separated by dilatation gaps. This study was carried out on block A. Columns are made of S275 quality HE240A, HE260A, HE300A, HE340A, HE360A, HE400A, HE450A, HE500A, HE550A, HE600A, HE650A, HE700A, HE700B, HE650B profiles. Beams consist of IPE and HEA profiles with different sizes. In the center of the building there is a core consisting of reinforced concrete shear walls. The width of the shear wall members is 30 cm. The shear walls are connected using reinforced concrete beams with dimensions of 30cm x 80cm. The structural slab system is a 12cm high composite slab composed of high strength trapezoidal plate, stud nails and concrete material placed on steel beams. In the analysis model, it is assumed that the floor system has rigid diaphragm behavior. The floor heights are 3 m in the basement, 4.2 m in the ground floor, 3.2 m in the first floor, 2.8 m in the second floor, 3.6 m in the third floor and 3.2 m in all other floors.



a) Steel Tower's

b) Existing building a block car park floor

c) Normal Floor floor plan - structural system

d) ETABS 3D analysis model

Fig. 1. Steel Tower's building views, floor structural plan and analysis model

Hata! Başvuru kaynağı bulunamadı. Fig. 1 (a) shows the exterior view of the building, (b) shows the structural system images taken from the parking lot floor, (c) shows the normal floor structural system plan and (d) shows the structural analysis model created using ETABS program.

Block A is 23.7 m in X direction and 21.1 m in Y direction and its structural system is geometrically close to a square. Reinforced concrete shear walls are placed to surround the stair and elevator shafts in the center of the building. These shear wall elements were placed in the building with a total of 6 pieces of 3.1 m in X direction, 2 pieces of 8 m and 2 pieces of 4.6 m in Y direction.

According to the geotechnical investigation conducted in 2013, the primary wave velocity (V_p) of the soil was found to be 668 m/s, the shear wave velocity (V_s) was 498 m/s, and the average shear wave velocity in the upper 30 meters ($V_{s(30)}$) was determined to be 474 m/s. The soil subgrade reaction coefficient was calculated as 3000 t/m³. Since the performance analysis of the relevant building will be conducted in accordance with TBEC 2018 within the scope of this thesis, the local soil class has been selected as ZE based on Table 16.1 of TBEC 2018, and the relevant parameters have been determined accordingly.

Hatay province is a city located on the Eastern Anatolian Fault Zone (EAFZ). Fig. 2**Hata! Başvuru kaynağı bulunamadı.** obtained from the Republic of Turkey Ministry of Interior Disaster and Emergency Management Presidency Turkey Acceleration Database and Analysis System, shows the earthquakes (Mw>5.0) that occurred in the region after 2000. The destructive February 6, 2023 Pazarcık 04:17 (7.7 Mw) and February 6, 2023 Elbistan 10:24 (7.6 Mw) earthquakes occurred on the EAFZ. When the ground motion records of the related earthquakes are analyzed, the largest ground acceleration of the Pazarcık earthquake was measured at station 4614 and was 2.005g in the E-W direction.

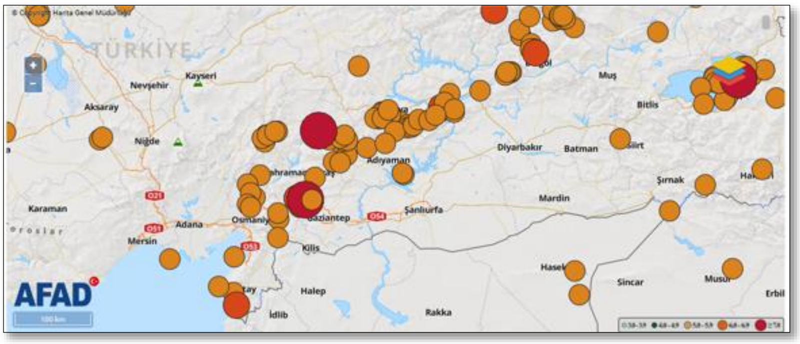


Fig. 2. Earthquakes in the region after 2000 (MW>5.0) (Turkey Strong Motion Database and Analysis System)

The performance analysis was performed using 22 (2x11) earthquake records selected in accordance with TBDY 2018. Then, acceleration records obtained from stations 3112 and 3115, which are the closest stations to the structure, were used in the analysis to examine the effect of the February 6, 2023 Pazarcık (7.7Mw) earthquake that occurred in the region (Fig. 3).

Fig. 3. Station locations 3112-3115

3. Analysis model and earthquake forces

Unconfined concrete, confined concrete and steel material models for reinforced concrete shear wall and beam elements were determined using the relations given in TBEC 2018 (Fig. 4**Hata! Başvuru kaynağı bulunamadı.**). Concrete characteristic compressive strength is defined as 35 Mpa, structural steel quality class is defined as S275 and reinforcing steel quality class is defined as B420C. Reinforced concrete beam section is 30 cm x 80 cm and 5 reinforcements with 18 mm diameter were used as top and bottom reinforcement and 5 reinforcements with 12 mm diameter were used as web reinforcement. Reinforcement with a diameter of 12 mm at 10 cm spacing was used as confined reinforcement. The length of the start-end zone of the shear walls was 60-100 cm and 14 longitudinal reinforcements with a diameter of 22 mm and 16 mm diameter reinforcements with a spacing of 10 cm were used as confined reinforcement. Longitudinal reinforcement with a diameter of 18 mm at 12 cm spacing and reinforcement with a diameter of 16 mm at 12 cm spacing were used as horizontal reinforcement in the middle parts of the wall. The nonlinear material models obtained by using the specified material and section properties were defined in ETABS program (Fig. 5).

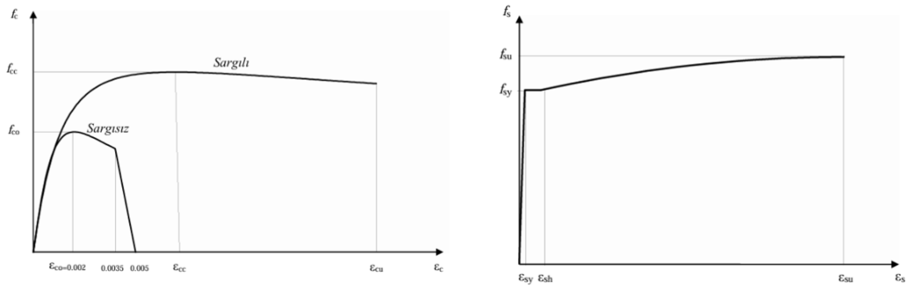

Fig. 4. Confined-unconfined concrate and steel material models *(TBEC, 2018)*

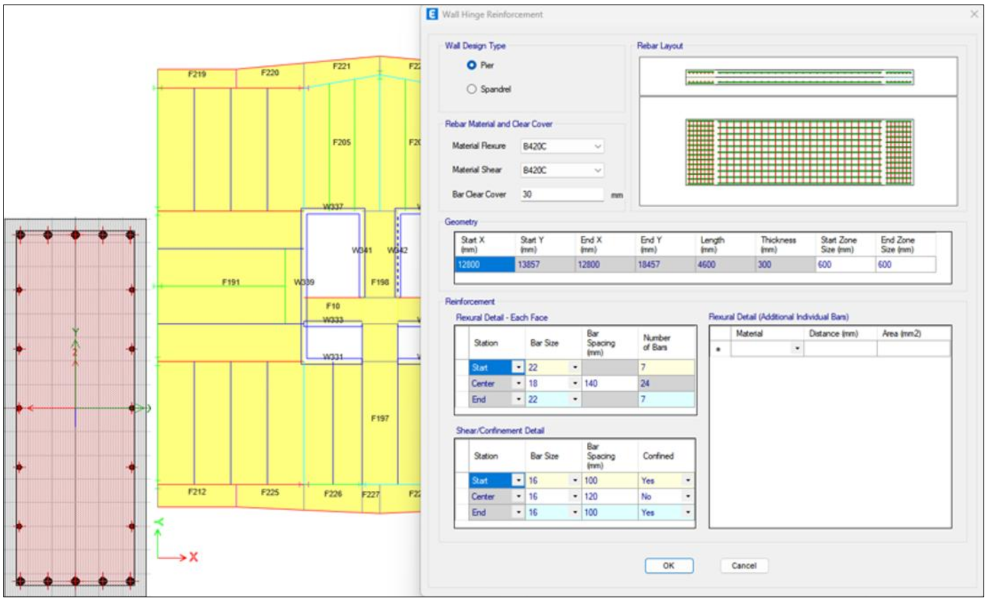

Fig. 5. Beam and shear wall models defined in ETABS program

3.1 Hinge properties

Steel column members are modeled as finite bar elements. In order to represent the nonlinear behavior of these members, lumped plastic hinges were defined at both ends of the members. The axial compressive-tensile strengths of each column section were determined according to the 'Regulation on Design, Calculation and Construction Principles of Steel Structures' (2016) and the interaction diagram (axial force-moment) yield surface was obtained. P-M2-M3 plastic hinge definitions were made through ETABS program.

In the existing structure, single-double angle joint details were used in the connections of steel beam members to shear walls and columns. The moment transfer capacity of this type of connections is very low compared to rigid connections. In this structure, it is assumed that the steel beam members do not transfer moment to the shear walls and columns and the beam ends are modeled as hinged. Since no plastic deformation is expected in hinged joints, no plastic hinge is assigned to the beam members (Fig. 6).

Fig. 6. Steel beam connection details of the existing structure

M3 lumped plastic hinge was defined for reinforced concrete beam elements. SAP2000 program was used to obtain moment-curvature graph for cross-sectional analysis. The yield moment value My=620 kNm and yield curvature value ϕy= 0.0052 were used in the analysis as read from the idealized curve (Fig. 7).

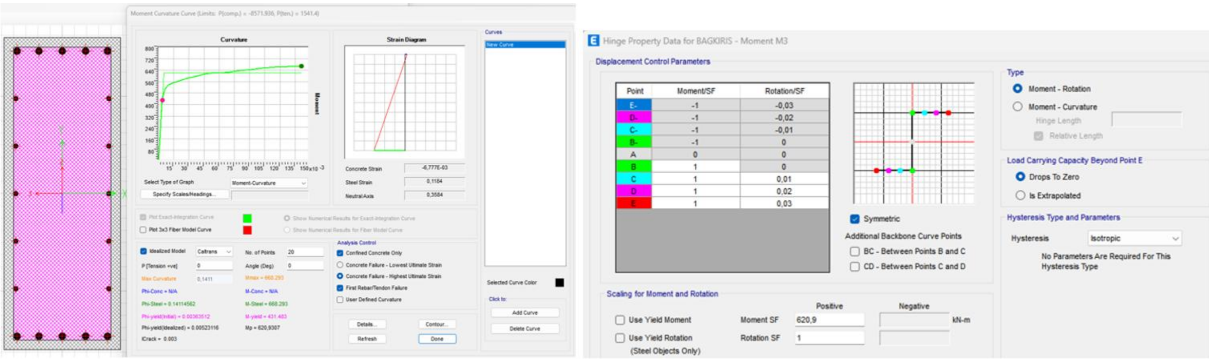

Fig. 7. Cross-sectional analysis and definition of M3 plastic hinge

Reinforced concrete shear walls were assigned fiber P-M3 hinge with the help of ETABS program and shear sections were divided into fiber elements (Fig. 8).

Fiber	Area cm²	Coord2 mm	Material	Color
1	436,7	-2225	C25/30	
2	873,4	-2000	C25/30	
3	436,7	-1775	C25/30	
4	26,6	-2150	B420C	
5	26,6	-1850	B420C	
6	628,6	-1593,8	C25/30	
7	1257,2	-1275	C25/30	
8	1257,2	-850	C25/30	
9	1257,2	-425	C25/30	
10	1257,2	0	C25/30	

Fig. 8. Reinforced concrete shear wall section fiber P-M3 hinge

The effective section stiffnesses of the beam members using lumped plastic hinges are included in the calculations using the equations given in TBEC 2018 (Eq. (1), Eq. (2)).

$$(EI)_e = \frac{M_y}{\theta_y}\frac{L_s}{3} \tag{1}$$

$$\theta_y = \frac{\phi_y L_s}{3} + 0{,}0015\eta\left(1 + 1{,}5\frac{h}{L_s}\right) + \frac{\phi_y d_b f_{ye}}{8\sqrt{f_{ce}}} \tag{2}$$

3.2 Loads and loading cases affecting the structure and seismic loads
The dead loads acting on the structure are as follows;
Slab Loads: Trapezoidal sheet plate under concrete + Slab Concrete (12cm) = 2.1 kN/m^2
Coating + Plaster = 1.6 kN/m^2
Partition Walls = 1 kN/m^2
Total Slab Dead Load = 4.7 kN/m^2
External Walls (20cm) = 4.9 kN/m
Roof Snow Load S = 0.75 kN/m^2
Slab live loads are considered as 2 kN/m^2 and 5 kN/m^2 depending on the floor usage purposes.

The earthquake loads to be applied to the existing structure and the horizontal elastic response spectrum to be used in determining the damage conditions of the structure under these loads were determined according to TBEC 2018 (Fig. 9).

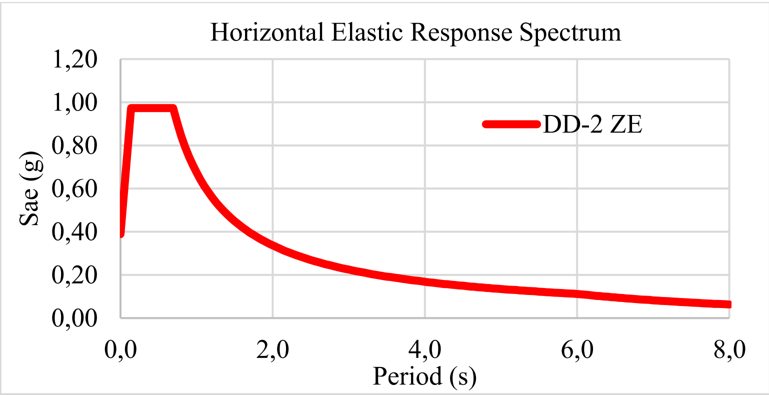

Fig. 9. Horizontal elastic response spectrum

In this study, the Pacific Earthquake Engineering Research Center Ground Motion Database (PEER) NGA West2 Data Bank created by the University of California was used to select the eleven acceleration records required for three-dimensional nonlinear analysis (**Hata! Başvuru kaynağı bulunamadı.**). SeismoMatch (Al-Atik & Abrahamson, 2010) program was used to convert the selected acceleration records to spectral matching (Fig. 10).

Table 1. Selected 11 earthquake acceleration records (PEER)

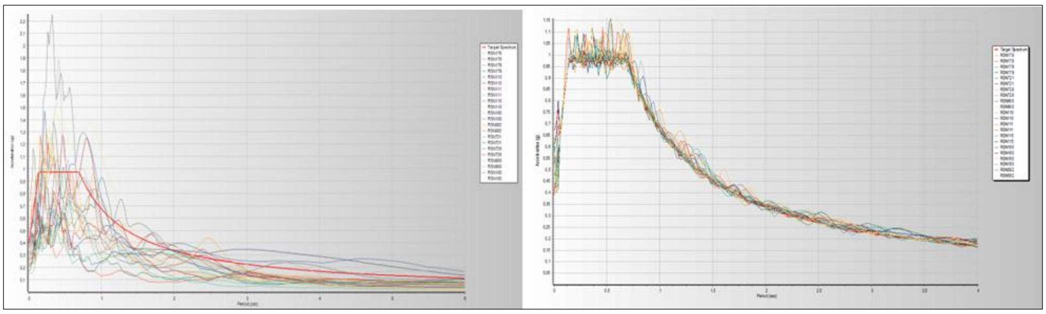

Fig. 10. Match to target spectrum *(SeismoMatch, 2022)*

3.3 Modal analysis results

Dynamic modal analysis of the structure for 50 mode numbers was performed in ETABS program. According to the modal analysis results, the 1st mode has the largest mass participation in the X direction (63.60%) and the 2nd mode has the largest mass participation in the Y direction (63.80%). The dominant mode in X direction is 1st mode with a period value of 2.07 s, and the dominant mode in Y direction is 2nd mode with a period value of 1.510 s.

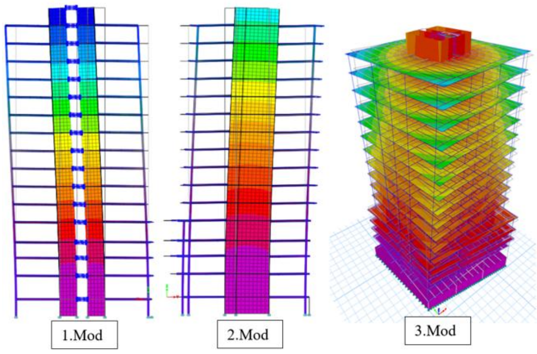

Fig. 11. Mode shapes *(ETABS, 2018)*

4. Nonlinear analysis and evaluation

In TBEC 2018, the condition where inelastic deformation starts significantly and the damage level remains negligible is considered as 'Immediate Occupancy ' (IO) performance level. The condition where the non-linear behaviour stops significantly is called 'Limited Damage' (LD) performance level. After large displacements, the reduction of the earthquake effect indicates that the strength is exhausted and this level is defined as 'Collapse Prevention' (CP) performance level. The limit at which the structural system can safely resist horizontal loads with limited inelastic deformations is defined as the 'Life Safety' (LF) performance level.

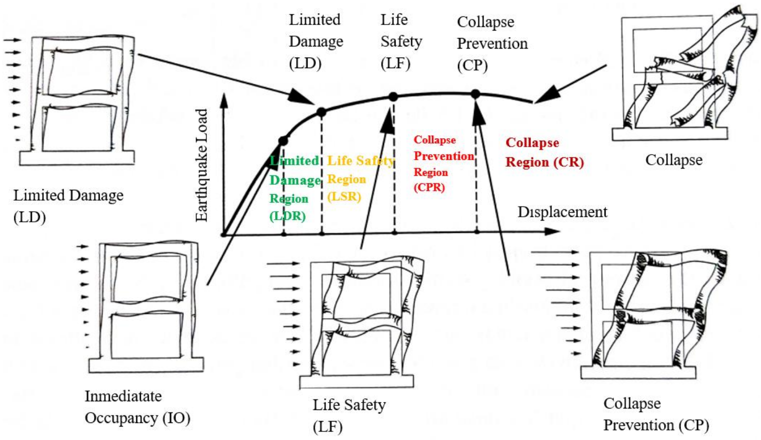

Fig. 12. Damage states TBEC 2018 *(Celep, 2020)*

22 earthquake ground motion acceleration records were used to determine the damage conditions of reinforced concrete beam, reinforced concrete shear wall and steel column elements for each floor level by averaging the maximum strain and rotation values obtained from the analysis results.

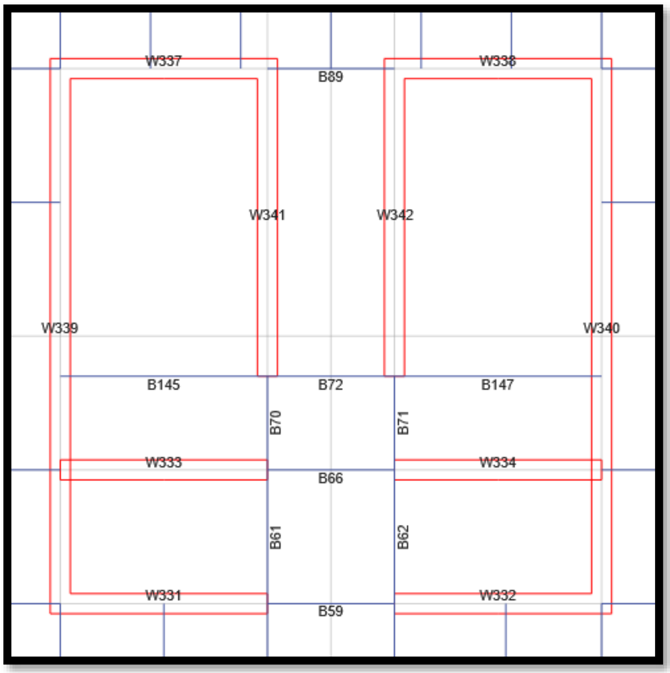

Figure 13. Shear walls and reinforced concrete beams

There are 10 reinforced concrete beams on each floor of the existing building. According to the results of the performance analysis, only the reinforced concrete beam elements in the X direction are damaged. No plastic deformation occurred in the reinforced concrete beam elements in the Y direction. Table 2 shows the proportional distribution of all reinforced concrete beams according to the damage levels.

Table 2. All structure beam damage level percentages

Total			
	Pieces	Ratio	
LDR	105	%LDR	61.76
LSR	43	%LSR	25.29
CPR	8	%CPR	4.71
CR	14	%CR	8.24

Shear force control of reinforced concrete beam elements in the existing structure was performed by following the steps in TBEC 2018 and TS500. In these controls, it was determined that the beam members were designed ductile.

When the flexural damages of reinforced concrete shear walls were analyzed, it was observed that each shear wall remained at 'Limited Damage Region'. The shear capacities of the reinforced concrete shear wall elements were determined using the formulas provided in TBEC 2018 and (Institute) ((Eq. (3), Eq. (4)). Capacity checks were performed by averaging the maximum shear forces obtained from the 22 analyses. It was observed that their shear capacities were sufficient.

$$V_r = A_{ch}\left(0{,}65 + f_{ctd} + \rho_{sh} f_{ywd}\right) \tag{3}$$

$$V_e \leq V_r$$

$$V_e \leq 0{,}85 A_{ch}\sqrt{f_{ck}} \tag{4}$$

$$V_e \leq 0{,}65 A_{ch}\sqrt{f_{ck}}$$

According to the results of the nonlinear analysis, no plastic rotations occurred at the ends of the steel columns. Since the plastic rotation values at the ends of the columns are zero, all columns remain at 'Limited Damage' (SH) performance level.

4.1 February 6, 2023 effects of Kahramanmaraş (Pazarcık) Earthquake on the structure
7.7 Mw Pazarcık earthquake acceleration records were obtained from stations 3112 and 3115 (Fig. *13*) located close to the structure (Fig. 13). The related records were applied to the existing building model and the results such as base shear force values, relative story drifts, peak displacement values were analyzed.

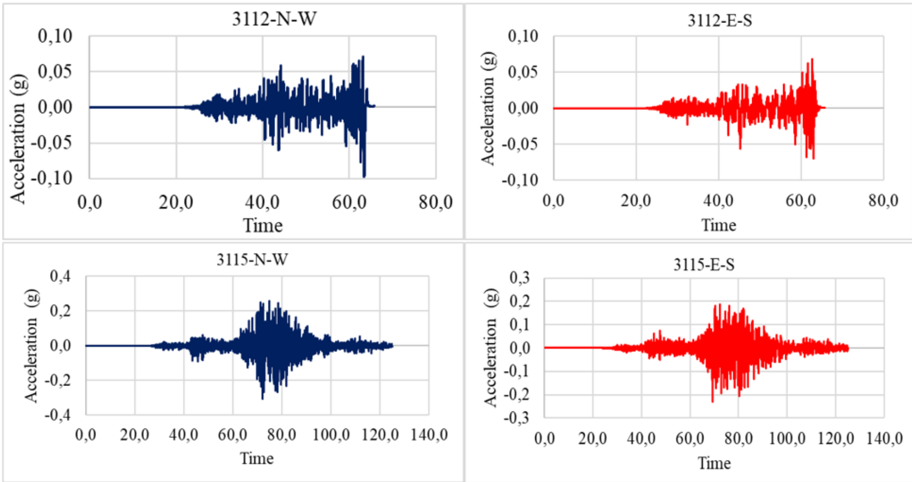

Fig. 13. February 6, 2023 Pazarcık earthquake 3112 and 3115 station acceleration records

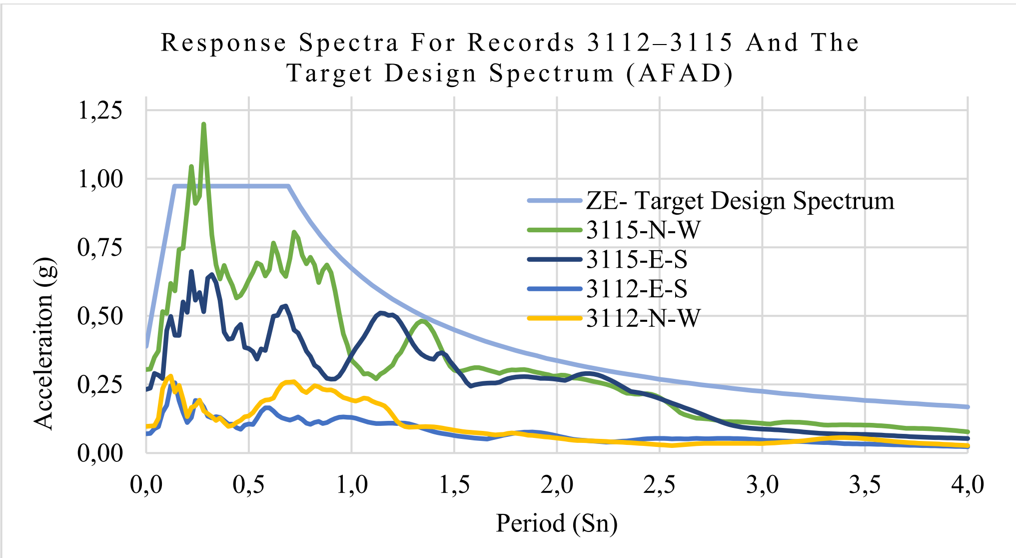

Fig. 14. Response Spectra For Records 3112–3115 And The Target Design Spectrum

When the spectral acceleration values obtained from horizontal ground motion records are compared with the horizontal elastic design spectrum values derived from the Earthquake Hazard Map, it is observed that the actual earthquake at Station 3112 remained below the design spectrum for DD-2 (Design Earthquake) level (Fig. 14). When the spectral acceleration values obtained from the horizontal ground motion records are compared with the horizontal elastic design spectrum values derived from the Earthquake Hazard Map, it is observed that the response spectrum values of the N-W component at Station 3115 exceed the DD-2 target spectrum for period values between 0.20 and 0.26 seconds. On the other hand, the spectral acceleration values of the E-S component remain below the DD-2 target spectrum (Fig. 14).

The earthquake ground motion records of the processed data from stations 3112 and 3115 were defined in ETABS program and loading cases were created. Loading cases were defined to impact the structure from both directions. Then, the directions of the acceleration records were turned 90 and the structure was again affected. The graphs of 'Relative Story Displacement', 'Story Shear Forces' and 'Story Displacements' values are given in (Fig. 15).

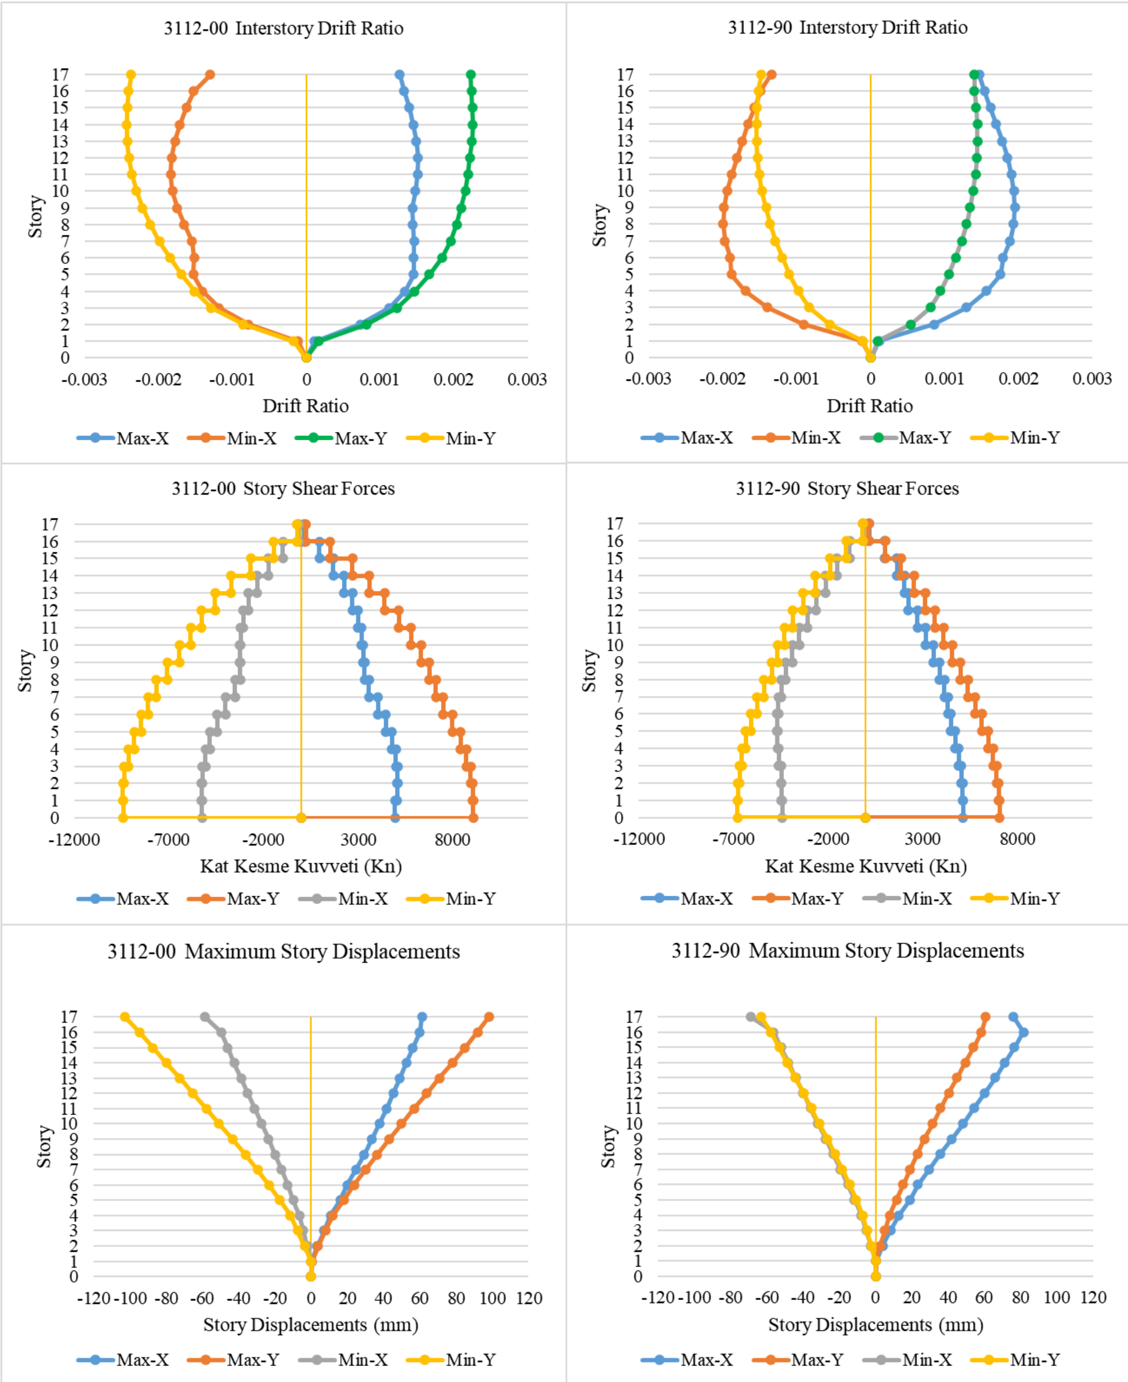

Fig. 15. 'Interstory Drift Ratio', 'Storey Shear Forces' and 'Storey Displacements' graphs for RSN3112-00 / RSN3112-90 loadings

Based on the analysis of ground motion acceleration records from the 3112 station for the February 6 Pazarcık (Kahramanmaraş) earthquake, the maximum peak displacement was observed to be approximately 0.102 meters. The interstory drift ratios remained around 0.2%. According to the records of the Pazarcık earthquake, the maximum base shear force was calculated as 9401.35 kN. As a result of the analyses conducted using the 3112 station records, all steel column, reinforced concrete beam, and shear wall elements in the existing structure remained within the Limited Damage (LD) performance level, and no brittle failure behavior was observed.

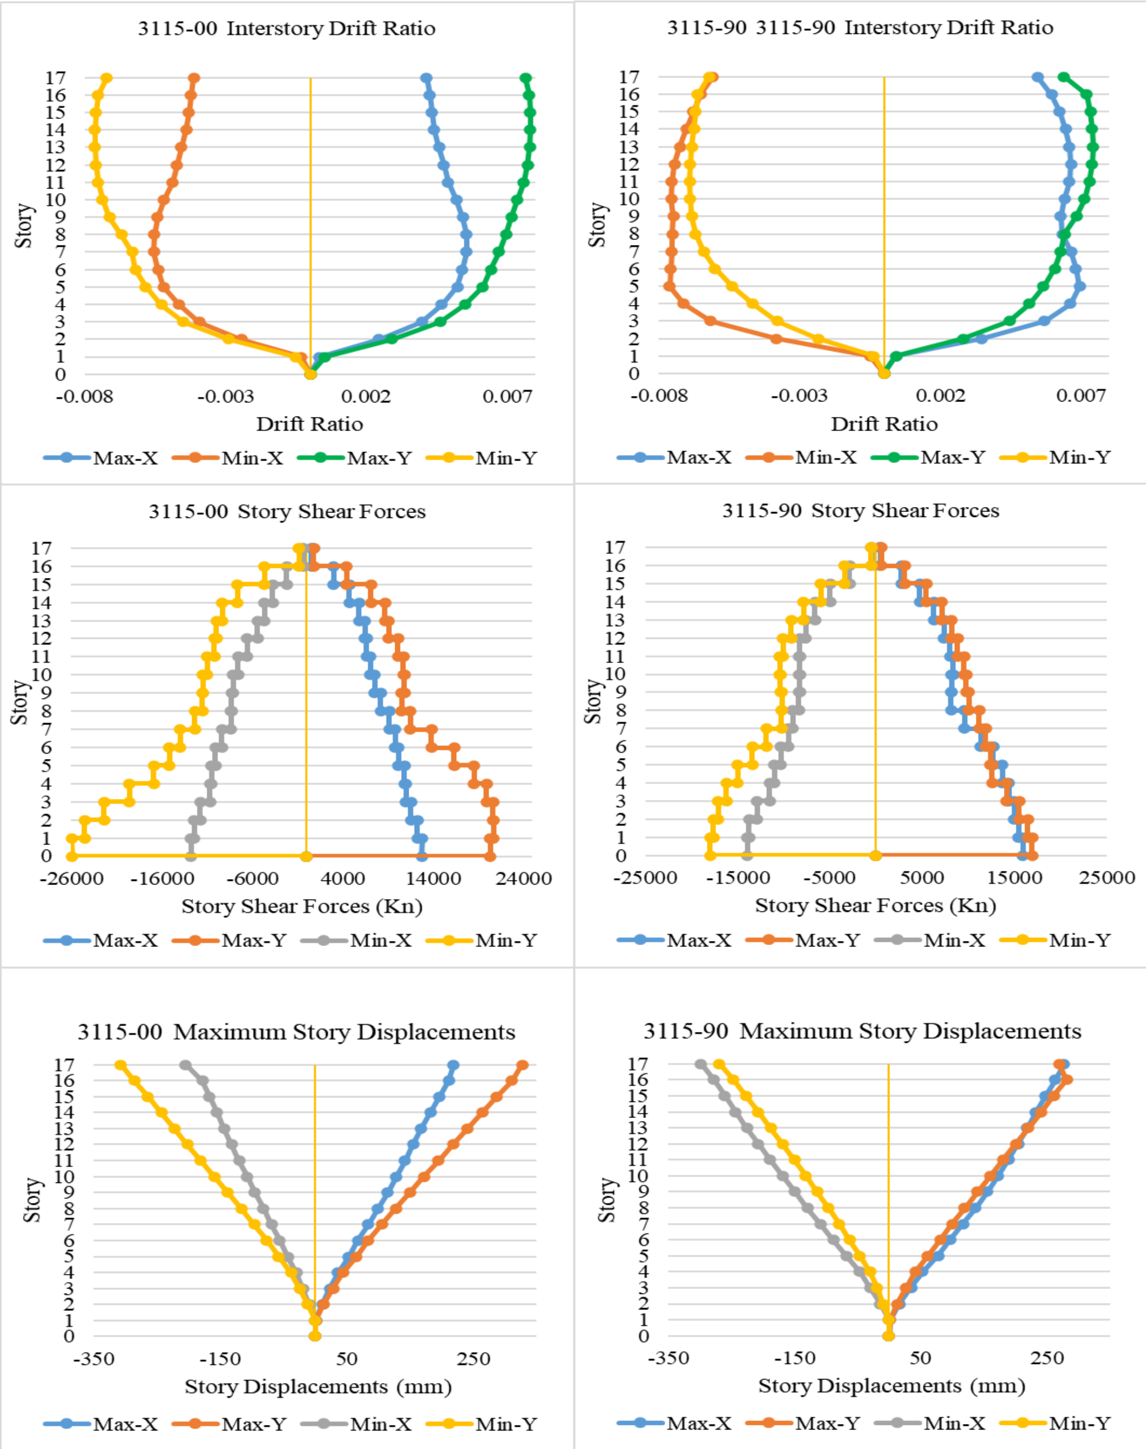

Fig. 16. 'Interstory Drift Ratio', 'Storey Shear Forces' and 'Storey Displacements' graphs for RSN3115-00 / RSN3115-90 loadings

Based on the ground acceleration records obtained from Station 3115 for the February 6 Pazarcık (Kahramanmaraş) earthquake, the maximum peak displacement was observed to be approximately 0.32 meters. The interstory drift ratios remained around 0.7%. According to the records of the Pazarcık earthquake, the maximum base shear force was calculated as 25933 kN.

5. Conclusions

The results obtained from the two stations show noticeable differences. According to the data recorded at Station 3112, no seismic effects significant enough to cause damage were observed in the building. In contrast, the results from Station 3115 indicate that the seismic demand may have caused minor damage specifically in the reinforced concrete beam elements of the structure. However, post-earthquake inspections revealed no visible damage in the building. It is important to recognize that the ground motion records from these stations may not fully represent the actual seismic demands experienced by the building during the February 6 earthquakes, due to factors such as the distance between the stations and the structure, and differences in local site conditions. Station 3112 is located closer to the building, near the coastal area, while Station 3115 is situated further inland compared to Station 3112.

According to the data from Station 3115, the peak ground acceleration (PGA) reached approximately 0.304g, whereas the maximum PGA value recorded at Station 3112 was around 0.101g. In İskenderun district of Hatay province, the level of building damage varied significantly across different areas—while some regions experienced severe structural damage, others were affected much less. One possible reason for this variation could be the differences in ground accelerations, even between nearby locations. The area extending from İskenderun's PAC Square toward the 'Steel Towers', and slightly beyond, contains buildings that suffered heavy damage. Moving from PAC Square toward the coastline, the severity of damage gradually decreases. The building stock between the PAC Square and the coast is notably old, with sandy soil conditions and a high groundwater level. Based on regional damage patterns and the ground motion values recorded by nearby seismic stations, it can be concluded that the February 6 earthquakes caused spatially variable ground accelerations in this region.

Determining the collapse mechanism of a historical minaret under the earthquake effect by finite element simulation

Esin Ertürk Atmaca[1], Ali F. Genç[1], Süleyman Adanur[1], Ahmet C. Altunışık*[1]

[1] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. One of the structural parts of the mosques is the minarets, which have a special symbolic significance as well as their functionality. Minarets, which are long and thin in terms of their structure, are very sensitive to earthquake effects compared to the main structures of mosques. They are among the first structures to be damaged or destroyed during and earthquake. In the last century, several devastating earthquakes have occurred in Türkiye and many minarets have been damaged in these earthquakes. One of them is minaret of the historical Yenipazar Mosque. It is narrated that the minaret collapsed in the 1939 Erzincan Earthquake. The purpose of this study is to examine the accuracy of this narration from a technical point of view and determine how the collapse mechanism of the minaret occurred. The finite element (FE) method was used to determine the collapse mechanism of the minaret. The FE model was created in the Abaqus, and nonlinear dynamic analysis was carried out by using 1992 Erzincan Earthquake. It has been observed that the damage mechanism occurred transition segment of the minaret. Tensile stresses occurred locally in this region. This situation can be caused by the difference in stiffness between the slender body and the more rigid pedestal. So, it is very important to determine the collapse mechanisms under the effect of a possible earthquake and take the necessary precautions for this type structures.

Keywords: Collapse mechanism; Finite element simulation; Nonlinear dynamic analysis

1. Introduction

Historical masonry minarets are as enduring icons of architectural and cultural significance across various regions of the world. These magnificent structures, which is primarily associated with Islamic architecture, serving as symbols of religious devotion, architectural mastery, and cultural identity. They are characterized by their towering, slender, and often ornate designs, making them essential components of mosques.

These iconic historical structures have endured for centuries, witnessing various environmental challenges, including seismic events that threaten their structural integrity. Minarets, which are long and thin in terms of their structure, are very sensitive to earthquake effects compared to the main structures of mosques. During an earthquake, they are often among the first structures to be damaged or destroyed. The vulnerability of masonry minarets, which constructed using a variety of materials such as brick, stone, and mortar, lies not only in their height and slender profiles. Also, the intricacy of their designs can cause complex structural behaviour during seismic events. As a matter of fact, understanding the seismic performance of masonry minarets is of importance to safeguard these historical culture and ensure continuity to future. So, it is very important to determine the collapse mechanisms under the effect of a possible earthquake.

In understanding the seismic behaviour of masonry minarets, it has made significant strides in recent years. Studies employing have advanced analytical methods, including finite element analysis and experimental testing, have shed light on their seismic response (Mirtaheri, et al., 2017;Erdoğan et al., 2019;Hökelekli et al., 2020; Hökelekli and Al-Helwani, 2020; Altıok and Demir, 2021a, 2021b; Yurdakul et al., 2021; Işık et al., 2022; Maras et al., 2022; Trešnjo et al, 2023). In addition, innovative retrofitting techniques have been proposed to mitigate seismic risks while preserving their historical and architectural value (Turk, 2013; Bayraktar and Hökelekli, 2021; Şentürk et al., 2022; Demir et al., 2023).

This paper aims to evaluate the seismic performance of a historical masonry minaret, determine the collapse mechanism, and offering insights into the complex behaviour of these type structures, which are located in seismically active regions. Within the scope of this purpose, a historical masonry minaret, which is rumoured to have collapsed in the 1939 Erzincan earthquake, was selected and its seismic behaviour was examined. Modal analysis, and nonlinear dynamic analyses were carried out. The collapse mechanism was evaluated and the results obtained were evaluated according to the relevant guide.

2. Description of historical minaret

Yenipazar Mosque is located in Ordu province of Turkey and was built in 1870 (Fig. 1). It is narrated that the minaret collapsed in the 1939 Erzincan Earthquake. In addition, no study has been carried out on the minaret of the mosque until today. In order to reconstruct the historical minaret, the minaret types of the demolished or standing mosques in its immediate vicinity were determined. Although some of the mosques were destroyed, a restoration project was prepared using the minarets of that period as an example.

Fig. 1. Some views of Yenipazar Mosque and minaret

The pedestal part of the historical minaret has a square geometry and the body part has a circular geometry. The minaret has a total length of 22.17m. The wall thickness is 20cm at the pedestal and 16cm in other sections. The inner diameter of the cylindrical body is 1.26m and the outer diameter is 1.58m. Step length and height of the stairs are 60cm and 22cm, respectively. The minaret is supported on the mosque from one side along the pedestal. Views and sections of survey drawings prepared by taking into account the geometric data of the historical minaret are given in Fig. 2.

3. Evaluation of structural performance

The finite element (FE) method was used to determine the structural behaviour of the historical minaret. The FE model was created in the Abaqus software taking into account the macro modelling technique (Abaqus, 2022) (Fig. 3). Linear tetrahedron C3D4 finite solid element with 4 nodes was used in the FE model. To evaluate the structural behavior of the historical minaret, modal and nonlinear dynamic analysis were carried out.

The collapsed minaret was reconstructed with ashlar stone. Also, rubble stone was used in the filling part of the pedestal of the minaret. As know, the material properties of historical buildings are often difficult to precisely know and destructive and/or non-destructive methods are required to obtain the material properties. In this study, values specified in the guideline called Earthquake Risk Management Guide for Historical Structures were considered in the selection of the material properties (GMERHS, 2017) (Table 1). The guideline, which is published in Turkey, purpose the assessment the seismic performance level of historical masonry structures. On the other hand, Concrete Damage Plasticity (CDP) material model, which is a constitutive model based on a combination of theory of plasticity and damage mechanics, was considered in nonlinear dynamic analysis. The relevant nonlinear parameters (Table 2 and Table 3) considered in the analysis for the masonry units were selected from the literature (Bayraktar and Hökelekli, 2021).

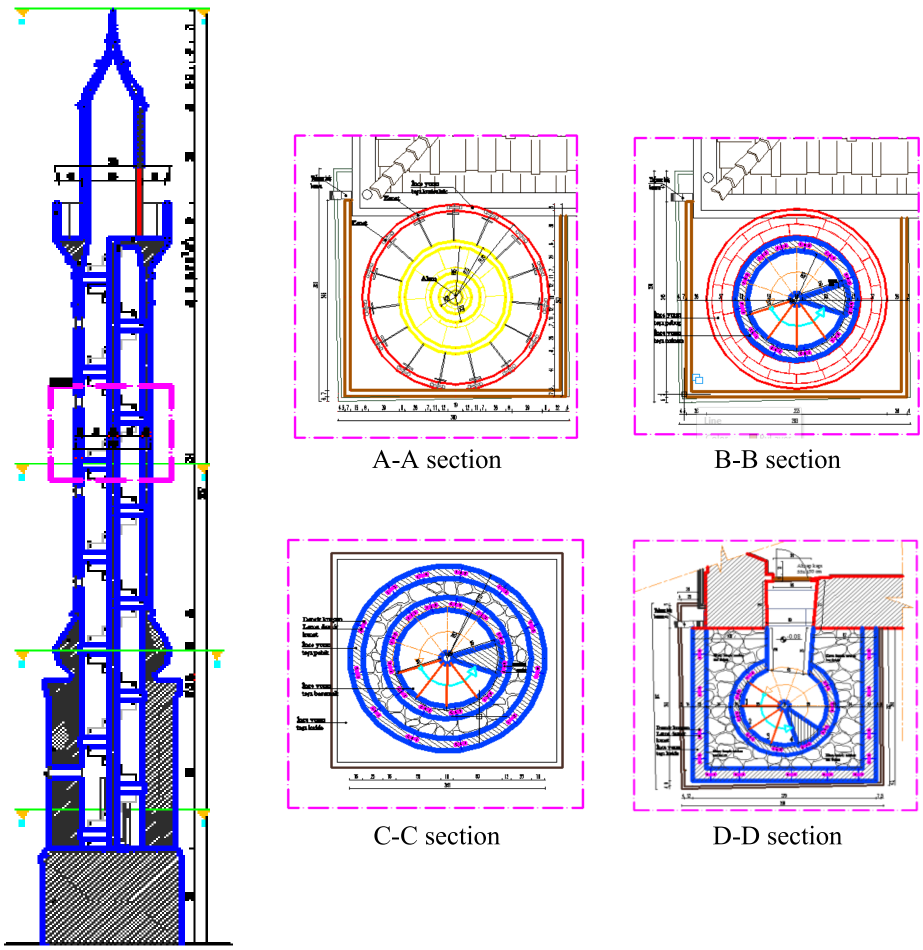

Fig. 2. View and sections of survey drawings prepared for minaret

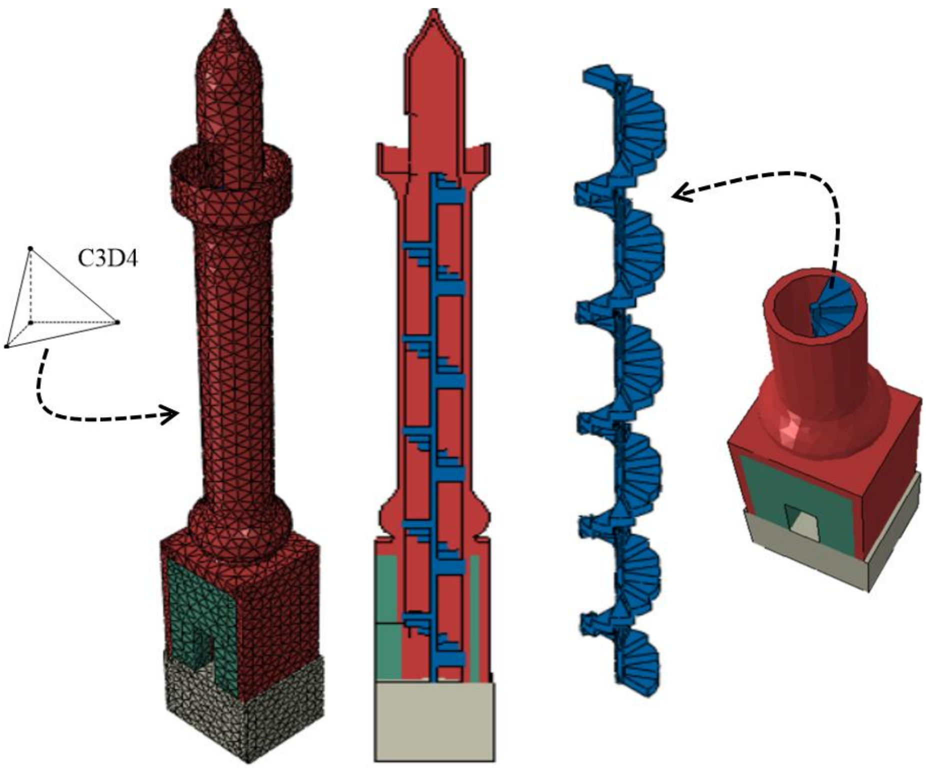

Fig. 3. Some views of the FE model for historical minaret

Table 1. Material properties used in finite element analyses (GMERHS, 2017)

Element	Elasticity modulus (N/m2)	Poisson Ratio (-)
Stone masonry	2.1E9	0.2
Filling part	1.0E9	0.2

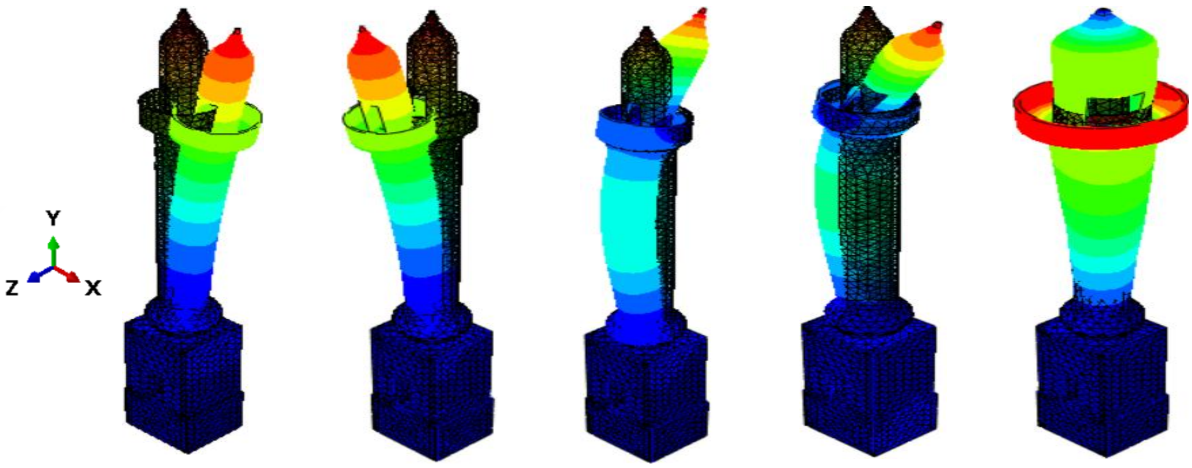
0.2000	0.2000	0.000	0.000
0.0005	0.0005	0.950	0.007
0.0005	0.007		

3.1. Modal response

Modal analysis of the historical minaret was carried out to determine the natural frequencies and mode shapes, called dynamic characteristics. As a result of the analysis, the frequencies of the first five modes were obtained between 1.502-11.391Hz. The first five mode shapes are translational modes in x and y directions, bending modes in x and y directions, and torsional modes, respectively. The first five mode shapes and relevant natural frequency values are given in Fig. 4.



1st mode f1=1.502Hz | 2nd mode f2=1.507Hz | 3rd mode f3=7.812Hz | 4th mode f4=7.956Hz | 5th mode f5=11.391Hz

Fig. 4. The first five mode shapes and relevant frequency values

It is narrated that the historical minaret collapsed in the 1939 Erzincan Earthquake. It is aimed to carried out the nonlinear dynamic analysis to examine the accuracy of this narration from a technical point of view and determine the collapse mechanism of the historical minaret under the earthquake effect. The 1939 Erzincan Earthquake is a very old earthquake and it is very difficult to obtain an acceleration record of the earthquake under the conditions of the time. Only the intensity and magnitude of the earthquake are known. Essentially, since the starting point is to evaluate the collapse mechanism of the historical minaret under dynamic effects, it was approved to use the records of the 1992 Erzincan earthquake, which occurred in the same geography approximately fifty years after the 1939 earthquake and had a high impact. Fig. 5 shows the acceleration components of the 1992 Erzincan Earthquake. In the nonlinear dynamic history analysis, EW component of the earthquake was considered.

The Earthquake Risk Management Guide for Historical Structures sets targeted performance levels based on the order of importance of historical structures. The historical minaret is classified as a local important historical structure, and the Collapse Prevention (CP) performance level is expected at DD-2 seismic ground motion levels, according to the guide. The CP evel is the threshold at which serious damage occurs in structural system elements, the structure is on the verge of partial or total collapse, but migration is prevented. Table 4 and Table 5 show the targeted performance levels as well as the limit values for these performance levels.

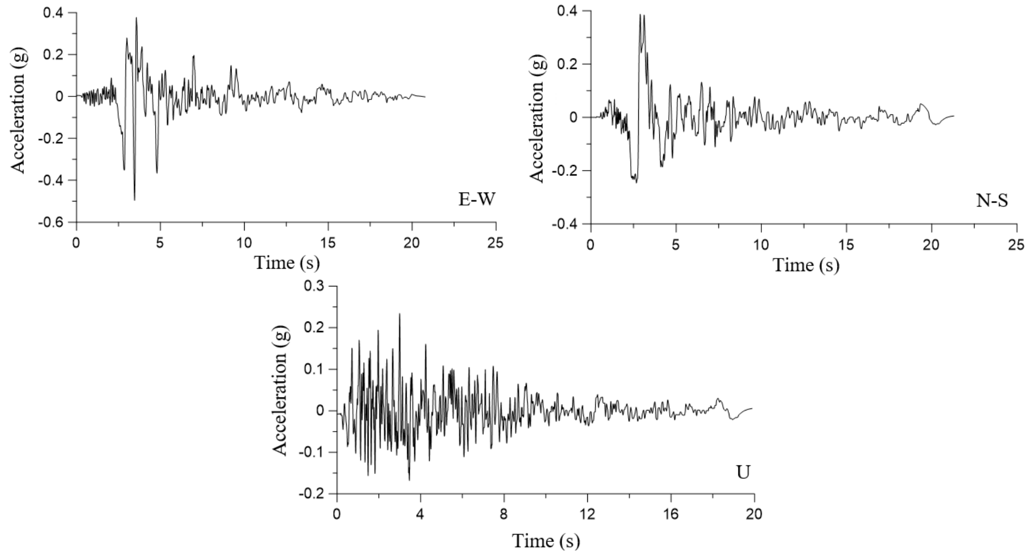


Fig. 5. The acceleration components of the 1992 Erzincan Earthquake

Table 4. Recommended target performance levels (GMERHS, 2017)

Performance Levels to be Selected According to the Importance of Historical Structures	The nationally important historical structure	The internationally important historical structure	
	DD-3 Limited Damage (LD)	DD-2 Limited Damage (LD)	DD-1 Limited Damage (LD)
The locally important historical structure	DD-3 Controlled Damage (CD)	DD-2 Controlled Damage (CD)	DD-1 Controlled Damage (CD)
	DD-3 Collapse Prevention (CP)	DD-2 Collapse Prevention (CP)	DD-1 Collapse Prevention (CP)

Table 5. Calculation methods and limit values related to performance levels (GMERHS, 2017)

Performance Level	Analysis Method/ Limits
Limited Damage Level (LD)	Linear analysis is employed: ✓ Ultimate stresses of the material or ultimate strength of the structural element and joints are not exceeded ✓ Drifts do not exceed 0.3%
Controlled Damage Level (CD)	Linear analysis is employed: ✓ Ultimate stresses of the material or ultimate strength of the structural element and joints are not exceeded, when the structure is subjected to vertical and earthquake loads reduced by Ra≤3 ✓ Drifts do not exceed 0.7% Nonlinear analysis is employed: ✓ Ultimate strains of the material are not exceeded ✓ Drifts do not exceed 0.7%
Collapse Prevention Level (CP)	Linear analysis is employed: ✓ Ultimate stresses of the material or ultimate strength of the structural element and joints can be exceeded with a certain ratio (i.e. 50%), when the structure is subjected to vertical and earthquake loads reduced by Ra≤3 ✓ Drifts do not exceed 1.0% Nonlinear analysis is employed: ✓ Ultimate strains of the material can be exceeded by a certain ratio (i.e., 20%) ✓ Drifts do not exceed 1.0%

*Ra: Seismic Load Reduction Factor

The contour diagram of the horizontal displacement in the moment of the earthquake when the horizontal drift ratio reached 1%, which is specified for CP performance level in Table 5, is given in Fig. 6a. Also, the change of drift ratio with time is shown in Fig. 6b. As can be seen in Fig. 6b, the drift ratio exceed the 1% value first time aproximetly 3.0th seconds of the earthquake record. It can be accepted that the minaret began to be damaged and collapsed after this time.

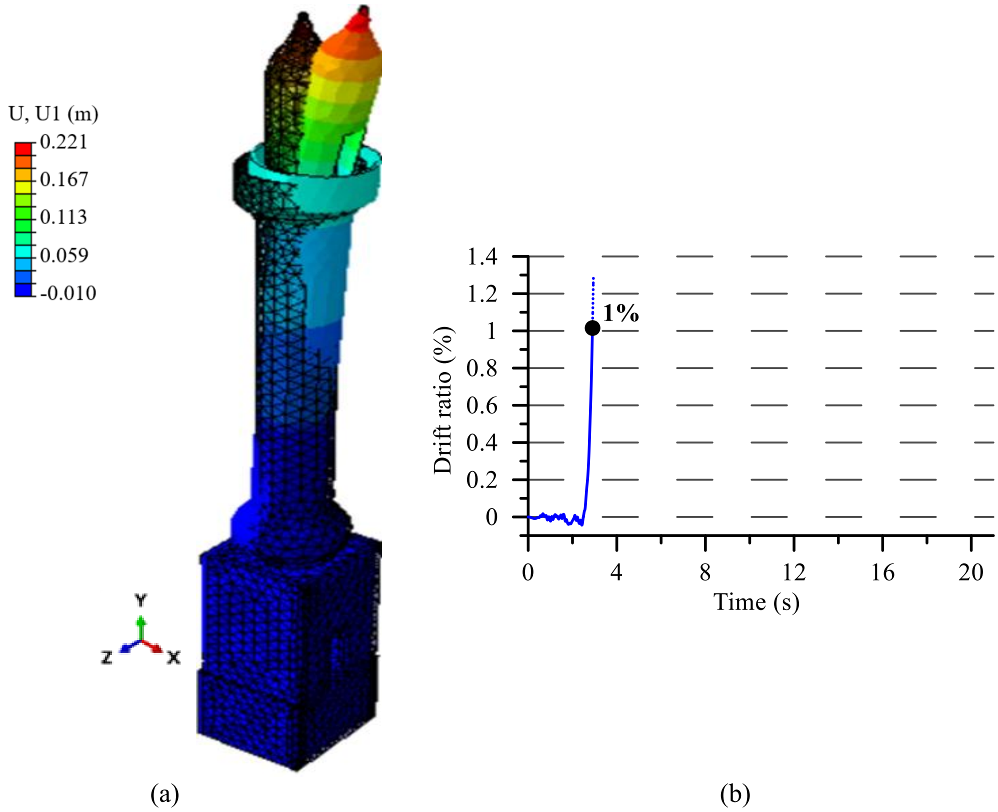

Fig. 6. (a) Displacement contour diagram and (b) time-history graphic of lateral drift ratio

The developing of DamageT contour diagrams under tensile stresses during the earthquake is given in Fig.7. As can be seen in Fig. 7, the transition segment between the pedestal and the cylindrical body of historical minaret started to be damaged at the aproximetly 3.0th second of the earthquake. In the transition segment where the square form of the pedestal transforms into a cylindrical body, damage resulting from horizontal loads such as earthquakes and wind is one of the most common types of damage. The reason for this is the tensile stresses concentration that occurs due to a decrease in cross-section and stiffness at the intersection between the transition segment and the cylindrical body of the minaret. This stiffness reduction results in uneven stress distribution and creates localized points of weakness. The damage mechanism observed in the 4th second of the earthquake is similar to the actual collapse mechanism of the historical minaret (Fig. 8). It was observed that in the following seconds of the earthquake, damage mechanisms also began to occur at the junction of the upper body and the balcony of the historical minaret.

4. Conclusions

This paper presents the evaluation the seismic performance and determinetion the collapse mechanisms of a historical masonry minaret, which is narreted to have collapsed in 1939 Erzincan Earthquake. The following conclusions are drawn from the paper:

- The first five mode shapes are defined as translational modes in x and y directions, bending modes in x and y directions, and torsional modes, respectively. In addition, the frequencies of the first five modes were obtained within 1.502-11.391Hz.
- It was observed that the damage caused by tensile stresses occurred primarily in the transition segment of the historical minaret. It can be stated that this situation arises from the difference in stiffness between the clindirical body and the more rigid In the transition segment where the square form of the pedestal transforms into a cylindrical body, damage resulting from horizontal loads such as earthquakes and wind is one of the most common types of damage. The reason for this is the tensile stresses concentration that occurs due to a decrease in cross-section and stiffness at the intersection between the transition segment

and the cylindrical body of the minaret. This stiffness reduction results in uneven stress distribution and creates localized points of weakness. Also, in this segment, insufficient connections and incorrect design are effective to tensile stress concentration. The geometry and cross-sectional ratios of the pedestal and cylindrical body must be compatible with tensile stresses to spread along the height of the minaret.. The damage mechanism observed in the 4th second of the earthquake is similar to the actual collapse mechanism of the historical minaret.

Minarets, which have long and thin in structural, are very sensitive to earthquake effects in segments where their cross-sections and stiffness differ, and collapse mechanisms generally occur in these regions. So, it can be stated that, it is of great importance to strengthen the minaret walls with rod bars in order to absorb the tensile stresses.

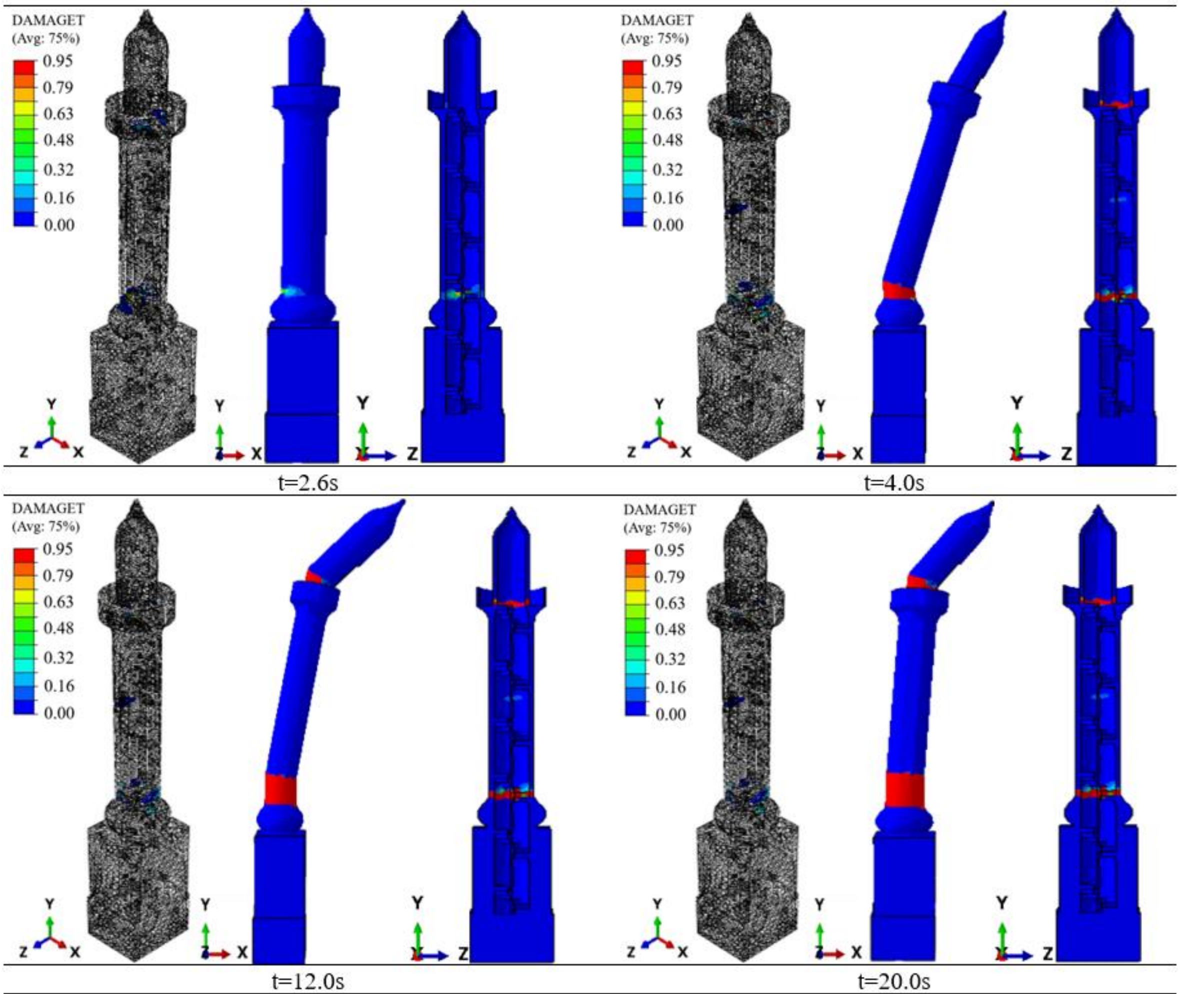

Fig. 7. The evolution of the tension damage during earthquake

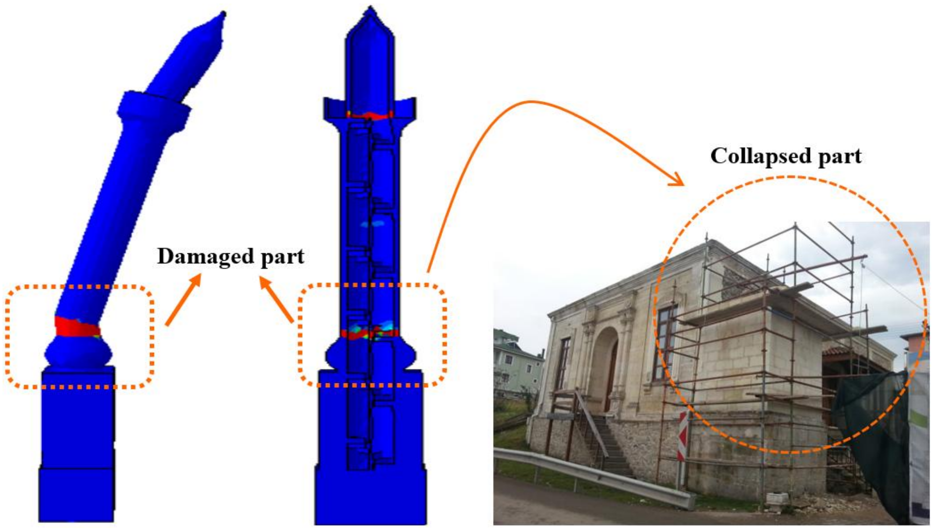

Fig. 8. Comparison of actual collapsed part of historical minaret and tensile damage at t=4th sec of earthquake

Selection of ground motion records considering near field effects for nonlinear time history analysis

Dilara Orhan*[1], Yasin Fahjan[1]

[1] *Istanbul Technical University, Department of Civil Engineering, Istanbul 34469, Turkey*

Abstract. Near-field records exhibit distinct ground motion characteristics compared to far-field records. Assuming these records to have identical characteristics may lead to the oversight of critical near-field effects, such as fling and velocity pulses, which are inherent to near-field records. These effects, however, must be considered during the design process to ensure safety, as they impose additional demands on structural systems. Various design codes propose different solutions to address this issue, with the most common approach involving the application of distinct coefficients to design spectra. Nevertheless, these assumptions often prove either insufficient or overly conservative for certain periods. Additionally, when Time History Analysis is conducted, the aforementioned effects require careful consideration. This is because they are prone to being eliminated during the spectral matching and scaling process or misrepresented in ground motion selection steps. This paper aims to evaluate the perception of near-field effects and compare current methods for selection and scaling of ground motion records for Nonlinear Time History Analysis. To achieve this, different approaches from design codes worldwide are applied within Nonlinear Time History Analysis to Single Degree of Freedom (SDOF) systems of different natural frequencies. The impact of near-field effects across different periods is assessed by examining changes in ductility demands. The results indicate that the inclusion of near-field effects is crucial for certain periods. Thus, these effects must be accurately represented without exaggerating their influence during less critical periods.

Keywords: Ground motion selection; Near-field effects; Nonlinear time history analysis; Ground motion scaling; Ductility

1. Introduction

Near-field ground motions require attention to the dynamics of occurring earthquake waves. Specifically, when rupture propagates toward a site at a velocity close to the shear wave speed, seismic energy concentrates into a single strong velocity pulse at the beginning of the record (Somerville et al., 1997). Besides the mentioned forward directivity, directionality of ground motion record changes the amplitude across periods and distance ranges. For sites at 5 km radius of causative fault maximum spectral accelerations tend to appear closer to 90 degrees (strike-normal orientation) (Shahi & Baker, 2013). These phenomena can significantly influence structural response, highlighting the need for accurate representation in seismic analysis.

However, existing Ground Motion Prediction Models (GMPEs) do not consider near-field effects explicitly and some available design codes only provide rough approximations. UBC-97 was the first design code in United States of America to incorporate near-field effects, applying coefficients to response spectra based on earthquake magnitude and source distance. ASCE introduced the near-fault concept for the first time in its 7.16 version, requiring ground motion record pairs to be rotated to fault-normal and fault-parallel directions while ensuring they are not lower than the maximum considered earthquake spectra. Additionally, ASCE 7-22 modifies the response spectra at longer periods by applying calculated coefficients to address the increased safety demands.

TBDY-2018 was the first design code from Turkiye to state that properly scaled near-field records should be used in nonlinear time history analysis for sites located within 15 km of an earthquake source in the section 5B.3.6(a). In addition to TBDY-2018, the Design of Highway and Railway Tunnels and Geotechnical Structures Under Seismic Effects Code (2020) also imposes restrictions on the selection and scaling of ground motion records for sites near active fault zones in Turkey.

As it is depicted in both ASCE-7-22 and TBDY-2018, selecting the ground motion records is as crucial as processing them. The ground motion records shall be selected to reflect the site conditions at best. Earthquake magnitude, causative source to site distance and site class being the most commonly used factors since they contain the significant information of frequency content, spectral amplitudes, spectral shape and event duration (Beyer &

* Corresponding author, E-mail: orhand19@itu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_031

Bommer, 2007). Additionally, the causative fault mechanism should be similar to the considered event, and the ground motions should contain sufficient energy to accumulate on-site while being recorded within a distance range close to it. Besides these main properties different design codes require certain details to be considered. Those selected ground motions have to be carefully handled in the amplitude scaling process. Since near-field ground motions respond differently at short and longer periods due to variations in spectrum level and magnitude, uniformly scaling a fixed response spectral shape fails to accurately represent them (Somerville, 2003).

Despite the developments in design codes, their coverage and efficiency remain vague. Thus, this study aims to assess ground motion selection methods from ASCE-22 and TBDY-2018 under near field effects. A sample site in Tuzla/Istanbul is selected, which is expected to be affected by the North Anatolian Fault. Ground Motion records are obtained from PEER NGA West2 Ground Motion Database. Nonlinear time history analysis will be performed on a SDOF system while aforementioned codes are applied. As ductility demand outputs of the analysis are compared for that particular site, sufficiency of the methods will be discussed.

2. Influence of near field effects on ground motion records

Prior to investigate the impact of near field effects, it would be more explanatory to show the change in the records themselves. As the most characteristic sign, the velocity pulse is present in the near field records. Even though the pulse can be seen without any procession, it can be clearly shown by extracting from the record itself. The Morgan Hill Earthquake (1984) record from Coyote Lake Dam-Southwest Abutment Station has been used in illustration. Ground motion record is Low-pass Butterworth filtered to get rid of the noise, thus the velocity pulse is more visible. It should be noted that; while filtering the near fault records, especially with high-pass filters, velocity pulses might get lost due to their high frequency characteristics. Filtered results have to be reviewed to avoid such mistakes. Fig. 1 demonstrates the velocity time histories of two perpendicular horizontal components of Morgan Hill Earthquake with properties given in Table 1. The velocity pulse is clearly visible as a full sine wave on both components' velocity time series as highlighted with magenta.

The primary properties of a near field record; magnitude, distance and directionality are examined as they consequentially create the variance in design spectra. To analyze their impact, 56 different near field ground motion records had been chosen from PEER NGA West2 Ground Motion Database which are listed in Table 2. Amplification factors were used to express the change of distance and magnitude caused over spectral period. Following subsections will discuss each factor in detail.

2.1. Effect of directionality and directivity

Directionality becomes an issue where directivity effects, mainly the velocity pulse, change the characteristic of the ground motion record. More specifically, the resultant pulse is directed towards the fault normal direction since surface horizontal shear waves align normal to the fault (Hayden et al., 2014, pp. 2). Consequently, forward directivity pulses typically exhibit the highest peak-to-peak velocity within a 30° range of the fault normal direction, despite considerable scatter (Hayden et al., 2014, pp. 13). Thus, near field records would be underestimated if directionality is not considered in the process.

ASCE 7-22 requires the near field records to be rotated to fault normal and fault parallel directions before applied to the building in the section 16.2.4. While TBDY-2018 does not mention rotation of near field records before application. Thus, assessing the amplification of rotated records would emphasize one of the points those codes differ. To evaluate how much of a difference directionality makes in near field, spectra of records form Table 2 will be rotated to fault normal and fault parallel. And the average ratio to geometric mean of two horizontal components will be plotted over time. Fig. 2 illustrates the average amplification factor of 56 near field records over time. It is clear in Figure 2 that, Fault Normal to Geometric Mean ratio gets even larger after 1.4-1.5 seconds reaching to 1.2 and exceeding 1.35 at longer periods. Which makes longer periods after 1.5 seconds more fragile about directionality of near field records. As expected, fault parallel rotations remain smaller than geometric means with amplification factor smaller than 1 at longer periods, proving velocity pulses concentrate on fault normal direction.

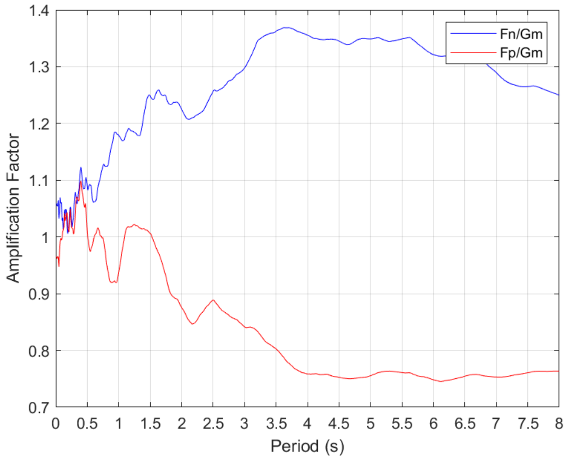

Fig.2. Amplification factor over period graph containing fault normal, fault parallel ratios

2.2. Effect of distance

Spectral acceleration amplitude differs across rotation angles as it is shown in the previous subsection. But it is not the only aspect that near field obliges the designer to be careful of. Meaning that, causative fault-to-site distance plays a crucial role as the spectral amplitude changes with both distance and time. To briefly explain significance over this concept, wave propagation characteristics must be pointed out. Since earthquake waves accumulate in a near field record, high frequency pulses dominate the response. Demanding higher ductility from the structures.

Before investigating the impact on ductility, the most amplificated distance and period couples are to be determined. To accomplish this, the near field events listed in Table 2 are categorized into groups based on Joyner & Boore distance (R_{jb}): less than 5 km, less than 10 km, and more than 10 km. Using the ratios between Fault Normal to Geometric mean and Fault Normal to Maximum Rotated spectra, amplification factors are plotted over period on Fig. 3. Fig. 3 shows that Fault Normal to Geometric Mean spectra ratio has the biggest amplitudes at longer periods for the first 10 km exceeding 1.4. Besides, the factor increases further, nearly reaching 1.5 after

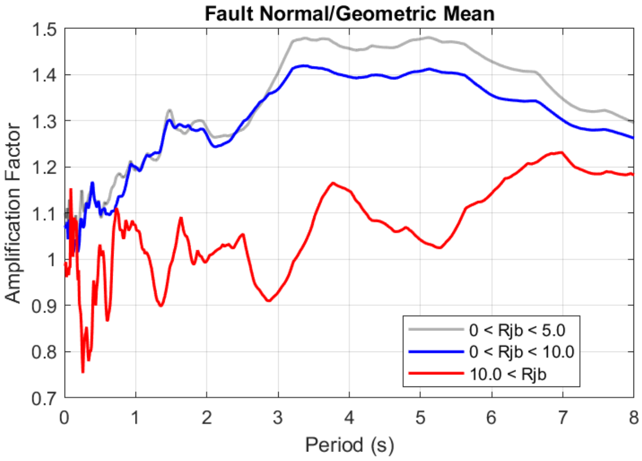

Fig. 3. Amplification factors depending on distance, fault normal to geometric mean spectra ratio over time

3 seconds in the first 5 km. As distance grows larger than 10 km, amplification factor decreases. Yet, Fault Normal spectra remain larger than Geometric Mean spectra for longer periods.

2.3. Effect of magnitude

Another aspect to consider in a possible near field event is the magnitude of the earthquake. Magnitude may seem less relevant in the design process, but a closer look at the components of Moment Magnitude, specifically the Seismic Moment, reveals its significant influence on wave propagation. Seismic Moment quantifies the energy released by a fault during an event, considering the rigidity of the soil, fault area, and slip. Since a fault does not rupture altogether instantaneously, seismic waves accumulate throughout the event. In cases of longer slip, more waves are generated, leading to formation of low-frequency waves. Therefore, smaller magnitude earthquakes lack the frequency content necessary to produce strong near-field effects. Additionally, as the fault area decreases, waves are released bearing less energy, making them easily get damped along the site.

The mentioned relations suggest that as earthquake magnitude increases, near-fault effects have a greater impact on the spectra. Thus, earthquake data from Table 2 are divided into two groups, those with less or more magnitude than Mw 6.5. Average of Fault Normal spectra to Geometric mean spectra ratio of each separate group is plotted over time in Fig. 4. It is clearly shown in Figure 4 that, as the period gets longer, the effect of magnitude on spectra becomes explicitly greater, verifying the suggested relation.

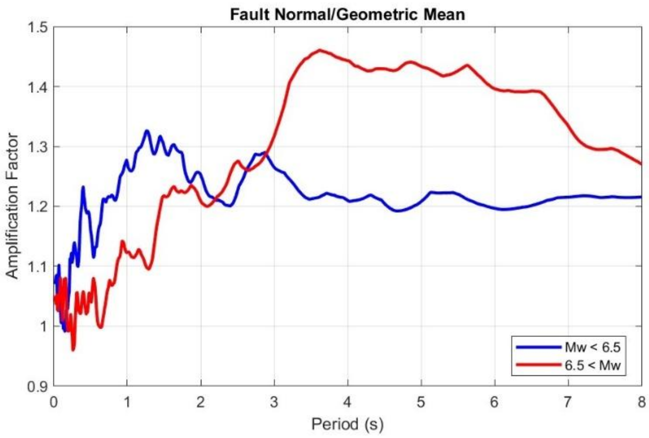

Fig. 4. Amplification factors depending on earthquake magnitude, fault normal to geometric mean spectra ratio over time

3. Ground motion selection

As it is emphasized in earlier sections; properties of ground motion records affect the acceleration spectra due to near field effects. Hence, before conducting a nonlinear time history analysis, selecting proper features to represent near field behavior is essential. The range of features must be defined similarly to the site of interest. These factors can become extensive when more data are available but optimum results can still be obtained with certain features. Mainly, distance to the fault, magnitude of event and Vs_{30} (shear wave velocity of soil) can describe the site conditions effectively. As it has been explained in Section 2, impact of defined range of distance diminishes significantly after 10 km thus, accurate range should be set. Likewise, before and after magnitude of 6.5 spectral amplitudes differ at longer periods making the spectra sensitive to magnitude increment. Also, source mechanism should be similar to the ones that potentially affect the site. Lastly, Vs_{30} of soil is crucial since soil amplifies or deamplifies certain periods. Thus, amplified periods might be amplified again due to soil conditions. Being accurate with these factors leads to a spectrum accounting near field effects decently and resulting in a non-overestimated or underestimated analysis results.

Current codes briefly mention ground motion selection for near fault sites. Besides the magnitude, source characteristics, distance and site conditions; ASCE 7-22 implies in the section 16.2.2 that, MCE_R (Risk based Maximum Considered Earthquake) shall also include the rupture directivity and impulsive characteristics. Although at least 11 records are required, since experiencing pulse-like motions is probabilistic, only a portion of the records (based on pulse probability) has to be pulse-like in the ground motions set. Current code in use in Turkey TBDY-2018, do not put any restrictions considering near fault selection but rather implies that ground motion records should have compatible source to site distance with the site under observation. But Design of Highway and Railway Tunnels and Geotechnical Structures Under Seismic Effects Code adopts a similar approach with ASCE 7-22, making the designer use at least 3 directivity possessing ground motion records with possibility of rupture directivity. Project location is given in Fig. 5 which has at least 10 km distance to the North Anatolian Fault shown with red lines. Considering the possibility of affection of sample site, a range is set for each feature. And the selected 11 ground motion data is given in the Table 3.

Fig. 5. Project location and the North Anatolian Fault

4. Ground motion scaling

For the last step of ground motion processing, amplitude scaling will be executed in accordance with the ASCE 7-22 and TBDY-2018 instructions. If those codes are to be compared upon their restrictions to amplitude scaling, they both do not put any restriction to preserve the near field characteristics of motions. But ASCE 7-22 forbids the usage of spectral matching unless pulse characteristics are preserved. ASCE 7-22 modifies the response spectra before scaling by coefficients to obtain maximum response spectra rather than geometric mean spectra. To achieve that seismic ground motion maps are increased %10 for short period and %30 for 1 second responses. This modification adequately compensates the growth that velocity pulses create in long period responses. Meanwhile, TBDY-2018 does not embrace such an approach regarding maximum response. But requires the design spectra to be multiplied by 1.3 to close the gap between the component combination methods SRSS and GM, often confused to replace the amplification ASCE 7-22 provides. Besides these coefficients, ASCE 7-22 and TBDY-2018 adopt different approaches with directionality of records. ASCE 7-22 demands the all earthquake records representing nearby causative faults to be rotated to fault normal and fault parallel directions before application. Whereas, TBDY-2018 only demands the seismic components to be orthogonal to the building, overlooking the amplification at fault normal direction.

To compare the differences between ASCE 7-22 and TBDY-2018's methods, selected earthquake records from Table 3 will be scaled to design spectrum that belongs to location in Figure 5. And to compare the difference that near fault makes in rotation of ground motions records, spectra will also be scaled after rotating to fault normal and maximum direction separately. Design spectra of seismic ground motion level with 2% possibility of exceedance in 50 years is obtained which corresponds to the MCE_R spectrum that ASCE 7-22 requires. Ground motion records are rotated by 1 degree to later sort out the maximum of the rotated records. Resultant values of maximum rotation and rotation to fault normal processes are scaled as a group to obtain the best fitting average spectra. Scaling factor of each earthquake record had been picked out as the optimum value as Fahjan (2008) states that in nonlinear analysis scaling factors should be limited between 0.5 and 2. And since, considerably large or small factors alter the physical content of records, excessive factors are intentionally avoided. And the exerted scaling factors are given in the Table 4. In Fig. 6 result of the mentioned processes according to ASCE 7-22 is presented. Fig. 6(a) represents the maximum rotation results. It is obvious that maximum rotated records are well comply with the MCE_R spectrum. Fig. 6(b) represents the fault normal spectrum, showing smaller acceleration values than maximum rotated spectrum. But scaled fault normal spectrum fits the MCE_R spectrum good as well. Figure 7 illustrates the scaling process rooting from TBDY-2018. And in 7(a), maximum rotation process results are presented. Design spectrum lies far below the maximum rotated spectrum after the corner periods, showing that actual ground motion records result in a larger spectrum after scaling. Lastly, Fig. 7(b), shows the resultant spectrum of fault normal records. Even though the spectrum remains smaller than 7(a) similar inference can be made, meaning that fault normal rotated records make a higher spectrum with near field effects. As it is obvious on both Fig. 6(a) and 7(a), maximum rotated spectra catch the amplification on longer periods better contrary to GM and SRSS spectra.

5. Nonlinear time history analysis

The low-frequency nature of velocity pulses increases the elastic demand due to the amplification observed at longer periods in the elastic design spectra. However, what truly ensures the safety of a structure is its ability to accommodate plastic deformation and ductility. Therefore, the changes in ductility demands caused by near-field effects will be investigated through nonlinear time history analysis. To compare different methods, the maximum rotated, fault-normal, and fault-parallel time series are scaled according to the factors provided in Table 4. Each pair of scale factors and time series is analyzed separately. The results are then plotted as the average ductility of the selected ground motion series over the period. Fig. 8(a) and 8(b) illustrate the average ductility demand results of the maximum rotated time series scaled according to ASCE 7-22 and TBDY-2018, respectively. Despite differences in the elastic spectrum, the ductility demands show no significant variations based on the dissimilar scale factors provided by ASCE 7-22 and TBDY-2018. Fig. 9(a) and 9(b) present the average ductility demand results of the fault-normal and fault-parallel rotated time series scaled according to ASCE 7-22, respectively. When comparing Fig. 9(a) and 9(b), the anticipated impact of near-field effects becomes evident in Fig. 9(a). It is clear that ductility demands increase significantly in the fault-normal direction compared to the fault-parallel direction, especially between 0.5 and 3 seconds. A similar conclusion can be drawn from Fig. 10(a) and 10(b), which show the fault-normal and fault-parallel ductility demands according to TBDY-2018. To further emphasize the increased ductility demand due to fault-normal rotation, non-rotated horizontal components are plotted in Fig. 11(a) and 11(b). It is clearly evident that near-field effects are overlooked when ground motion records are not rotated. The outcome of the nonlinear time history analysis demonstrates that, regardless of the method provided by the codes regarding spectra, ductility demands are most affected by the orientation and the high-frequency content of pulse-like ground motion records.

6. Conclusions

Near-field ground motion records inherently contain additional high- and low-frequency waves that differ from those in far-field records. Therefore, this study aims to evaluate the significance of these features, which might be overlooked in current practices. To briefly compare the methods, the impact of near-field motions was investigated through both spectral analysis and nonlinear time history analysis. The results indicate that selecting appropriate ground motions for analysis is crucial to simulate realistic structural responses. Simple scaling method was utilized in this study; however, during the selection and scaling processes, certain near field records resulted in extreme scaling factros. Therefore, acceptable scaling factors must be chosen. For advanced projects, sophisticated scaling methods should consider directivity when dealing with near-field records. The outcome of the spectral analysis shows that the TBDY-2018 design spectrum does not adequately capture the amplification effects caused by near-field motions, remaining approximately 25% to 50% lower than the obtained spectra at longer periods. In contrast, ASCE 7-22 manages to cover the scaled spectra with almost no disparity. However, regarding ductility analysis, both codes provide comparable results, regardless of the orientation of the time series.

- Near-field records tend to exhibit greater amplification within the first 5 km, with the amplification decreasing significantly after 10 km.
- Near-field effects require sufficient energy to become active; thus, as the event magnitude increases, near-field effects grow in intensity and influence the acceleration spectra, particularly after Mw 6.5 events.
- Although ASCE 7-22 addresses the necessary criteria for ground motion selection, TBDY-2018 lacks sufficient requirements beyond source-to-site distance considerations.
- Accumulated earthquake waves do not significantly impact the short-period range of the acceleration spectra; however, low-frequency velocity pulses increase the spectral acceleration at longer periods.
- TBDY-2018 overlooks the orientation of near field records, resulting in a underestimated design spectrum.
- Nonlinear time history analysis results indicate that regardless of the method suggested by design codes, average ductility demand increases and reaches maximum values along the fault-normal direction at short periods.

An investigation on the effect of rotational ground motion on seismic behavior precast RC single story industrial building

Yaman Khalbous*[1], Rafet Sisman[1]

[1] Yıldız Technical University, Department of Civil Engineering, 34220 Istanbul, Türkiye.

Abstract. In current engineering practice, seismic design of buildings is realized by considering translational ground motions only. However, for buildings with certain geometrical properties rotational ground motions can be effective. For instance, precast industrial buildings are generally low-rise structures with large plan dimensions. Due to the larger dimensions in the plan, precast industrial buildings can be susceptible to rotational ground motion components. Therefore, the contribution of the rotational ground motion components to the overall seismic behavior of the industrial buildings should be investigated. In this study, it is aimed to perform nonlinear time history analysis for precast industrial buildings by considering rotational ground motion components together with the translational ones. A set of ground motions from the past earthquakes that occurred in Türkiye are utilized in this study. The numerical model of the precast industrial building is developed using a commercial Finite Element Method (FEM) software. In the numerical model, nonlinear elements are modelled using line elements with fiber sections. Appropriate material models are utilized for concrete and reinforcing steel from the material library of the FEM software. The effects of rotational ground motions are evaluated based on the change in the drift ratios of the precast columns. Nonlinear time history analysis results indicate that the contribution of rotational ground motions to the overall seismic performance can be significant.

Keywords: Rotational ground motions; Nonlinear time history analysis; Precast industrial buildings; Seismic structural behavior

1. Introduction

A significant portion of Türkiye lies on active fault lines, making it one of the most seismically active countries in the world. This geographical reality puts millions of people and countless structures at risk, especially in major cities like Istanbul and Balıkesir, where dense populations and vital industrial facilities are concentrated. In these regions, the structural resilience of buildings is not just a matter of engineering it's a matter of public safety and economic stability.

To address this challenge, seismic design standards have been developed and continuously refined over the years. These regulations aim to ensure that buildings can withstand the destructive forces of earthquakes by taking into account the specific seismic characteristics of each region. Traditionally, these codes and engineering practices have focused on translational ground motions those that move the ground horizontally or vertically.

However, growing evidence from recent research suggests that this may not be the full picture. Earthquakes also produce rotational ground motions subtle but potentially influential twists around vertical and horizontal axes that have often been overlooked in conventional analysis. These rotational components can interact with a building's structural system in complex ways, especially in large or irregularly shaped structures like industrial precast buildings.

This study aims to explore this lesser-considered aspect of seismic activity. By using nonlinear time history analysis, which simulates the dynamic response of structures to real recorded ground motions, the research examines how rotational ground motion components influence the behavior of precast industrial buildings. The goal is to provide a deeper understanding of their impact and to highlight the importance of including rotational effects in performance based seismic design, especially for critical infrastructure.

2. Methodology

2.1. Description of the precast RC industrial building
The building analyzed in this study is a single-story precast reinforced concrete (RC) industrial structure located in Balıkesir, Türkiye. It has a floor plan of 18 by 37.5 meters and has a total height of 12 meters as shown in Fig.1 The structure includes 12 precast concrete columns that carry prefabricated roof beams, trusses, and girders, all designed in accordance with the building codes. The connections between the columns and beams are not rigid they're designed to release moments, so they act like pinned joints. This kind of connection is quite common in precast construction and allows the parts to move slightly without transferring bending forces.

The sandwich panels receive support from precast concrete purlins. Elastic diagonal braces, with pinned connections, were placed between purlins in the numerical model for simulation of the diaphragm effect that was provided by these sandwich panels according to guidelines specified in (TBDY-2018).

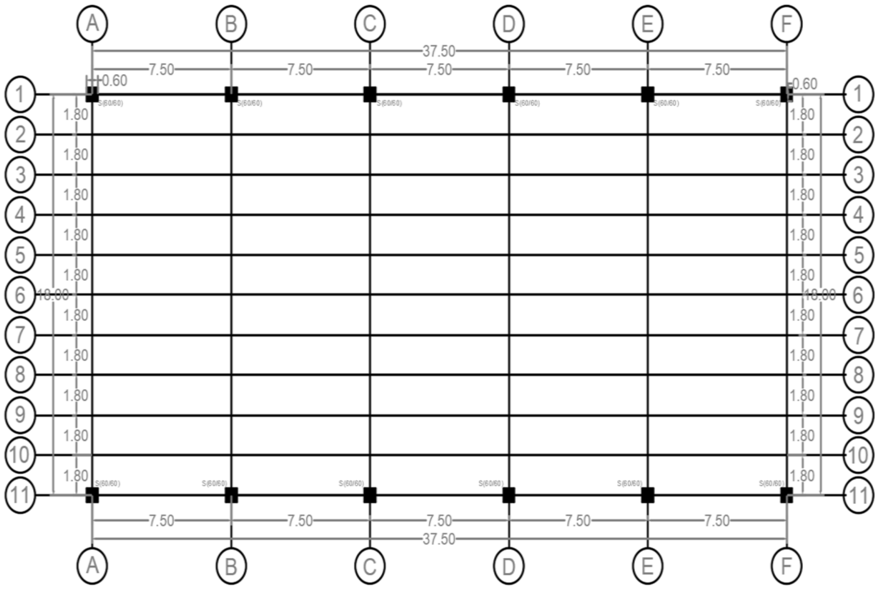

Fig. 1. Plan layout of the structure

$$(\mathrm{EA})_{\mathrm{e}} = 3.5\ \mathrm{t} \tag{1}$$

In this calculation (EA)e. t represents the overall thickness in millimeters of the sandwich panel sheets. As per code requirements, the spacing of purlins in addition to diagonal brace angle was modelled as $\alpha \approx 45°$.

2.2. Numerical modeling approach

2.2.1. Finite element modeling (FEM)
Fig. 2 shows detailed three-dimensional numerical model and it created using (SAP2000, 2025), a widely used software for finite element analysis in structural engineering. The model explicitly captures both translational and rotational seismic excitation responses. Structural columns were modeled with nonlinear frame elements that include plastic hinges defined at potential plastic hinge regions, in accordance with the Turkish Building Earthquake Code (TBDY 2018) requirements. Roof girders, beams, and trusses were idealised as elastic members with pinned connections at the supports.

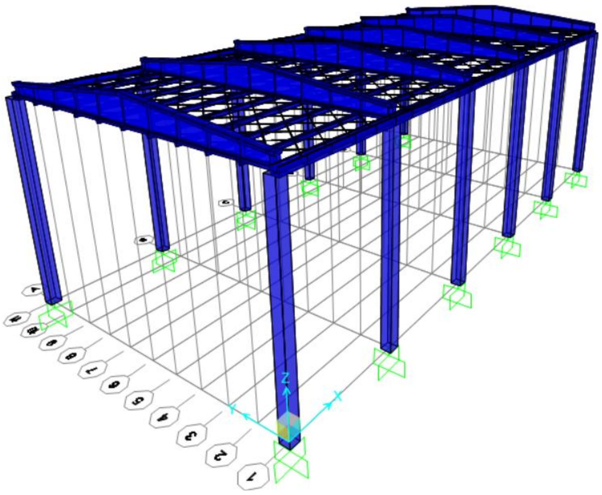

Fig. 2. Three-dimensional modeling of the structure (SAP2000)

2.2.2. Nonlinear material and section modelling

To account for material nonlinearity, fiber hinges are placed at the ends of the columns. These hinges represent the different parts of the cross-section confined concrete, unconfined concrete, and reinforcing steel using individual fibers defined through SAP2000's fiber modeling tool.

The concrete behavior is modeled using (Mander, 1988)'s stress-strain curves, with separate properties for confined and unconfined zones as shown in Fig. 3. In this study, C40 concrete is used, which offers good strength for industrial structures. The reinforcement is B420C grade steel, modeled with an elastoplastic approach to reflect yielding behavior.

The cross-section is divided based on the actual geometry and reinforcement layout, and the hinge length is taken as 10% of the clear column height, following the recommendation in TBDY 2018. This setup allows the model to realistically capture how columns respond during strong earthquakes, especially when they go beyond their elastic limits.

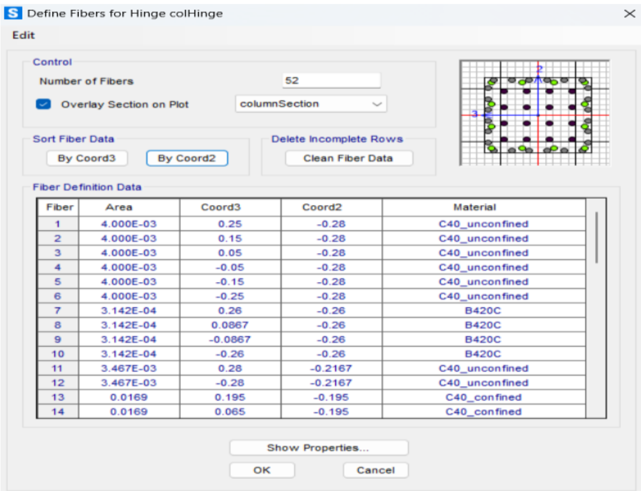

Fig. 3. Fiber section definition for bottom column hinge

2.3. Vertical loading conditions

The vertical loads applied in the structural analysis were determined according to the (TS-498) based on its use and condition of the building. The unit weights of structural elements such as precast concrete columns, roof beams, and roof purlins were directly incorporated into the numerical model through the material definitions transferred to SAP2000. Specifically, the unit weight of reinforced concrete elements was 25 kN/m³ and that of steel elements was 78.5 kN/m³. Table 1 shows the additionally applied dead load and live loads (snow). According to TBDY 2018/Table 4.3, the live load participation factor n=3 was used in the seismic analysis to consider the probability of live loads under seismic conditions.

Table 1. Vertical loads

Loads	Dead/Live	Load Intensity
Covering roof	Dead	0.12 kN/m^3
Snow	Live	0.75 kN/m^3

2.4. Ground motion selection

2.4.1. Translational ground motions

A set of seismic acceleration records of major earthquakes in Turkey was selected from the (AFAD, 2025) database. The criteria for selecting these records included earthquake magnitude, distance from the epicentre to the site, similarity of soil types. This careful selection helps ensure that the ground motions reflect realistic conditions for the area. As a result, the analysis outcomes are more reliable and relevant to the building's actual seismic risk.

The peak ground acceleration (PGA) values for the selected earthquakes in the X, Y, and Z directions are presented in Table 2. An example of the recorded motion, specifically for the 2023 Kahramanmaraş (Elbistan) earthquake, is shown in Fig. 4, which illustrates the translational acceleration time history in the X-direction.

Table 2. Transalational GMs PGA values

Earthquake	PGA_X (g)	PGA_Y (g)	PGA_Z (g)
Mw5.8 Izmit (Kocaeli) 1999	0.324	0.074	0.07
Mw7.1 Duzce (Bolu) 1999	0.523	0.408	0.321
Mw7.7 Kahramanmaras (Elbistan) 2023	0.5	0.549	0.692

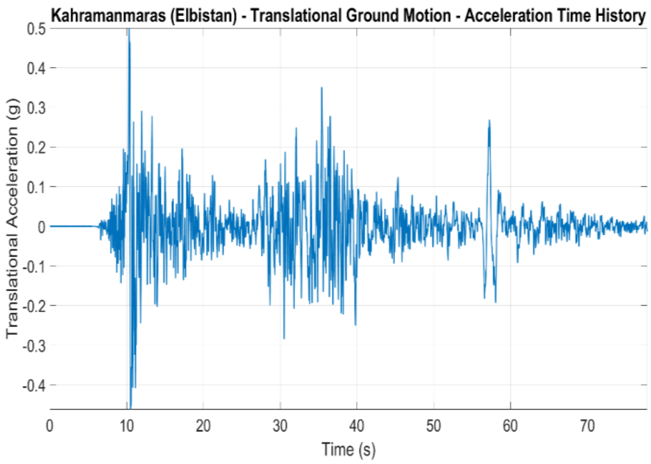

Fig. 4. Translational ground motion time history in X-direction

2.4.2. Rotational ground motion components

In this study, we did not just focus on the usual translational ground movements rotational ground motions also taken into account. These rotational components, which represent twisting around the vertical axis, were estimated using the Single Station Procedure (SSP), this method reconstructs the torsional acceleration histories from the recorded ground translational motions. This method allows the determination of the rotational components by analyzing the wave propagation characteristics of a single recording station.

The rotational motions corresponding to selected seismic events in Turkey are derived and used directly together with the translational motions for nonlinear time history analysis (based on the procedure described in (Şişman & Taciroglu, 2024) paper. When the rotational effects Included it gives us a more realistic picture of how an earthquake might impact large structures, especially those with wide floor plans, like the precast industrial building studied in this project.

The peak rotational acceleration values for the selected earthquakes around Z direction are presented in Table 3. An example of the recorded motion, specifically for the 2023 Kahramanmaraş (Elbistan) earthquake, is shown in Fig. 5.

Table 3. Roatational GMs PGA values

Earthquake	Peak Rotational Acceleration (rad/s²)
Mw5.8 Izmit (Kocaeli) 1999	0.007281837

Mw7.7 Kahramanmaras (Elbistan) 2023	0.100387171

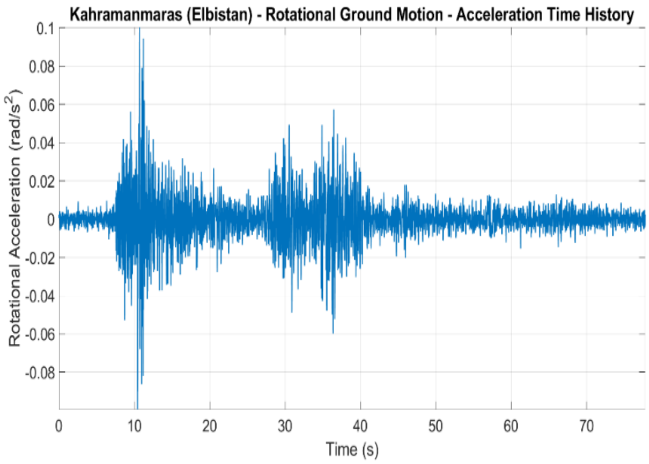

Fig. 5. Rotational ground motion time history

2.5. Nonlinear time history analysis

To better understand how the building will respond to earthquakes, the nonlinear time history analyses are performed. In these analyses, both horizontal (translational) and rotational ground motions applied to the building's finite element model as shown in Fig. 6. The analysis was performed using the Newmark-β method, as described in (Chopra, 2017). with a small time step, typically 0.01, to ensure the seismic input's high frequency content was accurately captured.

The main focus is on how the columns will behave in their drift ratios, and where plastic hinges (potential damage or failure) will form and spread during the earthquake. Two scenarios were examined:

- One where only horizontal and vertical ground motions were applied.
- Another example where both translational and rotational motions were included.

By comparing these two cases, it became clear how rotational ground motions can affect a building's seismic performance. The results of drift ratios and plastic hinge patterns were then evaluated using the performance limits and damage states set by the Turkish Earthquake Code (TBDY 2018), helping us judge whether the current structure meets safety requirements under realistic earthquake conditions.

In the nonlinear time history analysis, the Newmark-β method is used for numerical time integration. The parameters γ=0.5 and β = 0.25 are calculated according to the constant mean acceleration method and β=0.25 is chosen. This method is generally applicable to the analysis of nonlinear structures with large deformations and inelastic behavior.

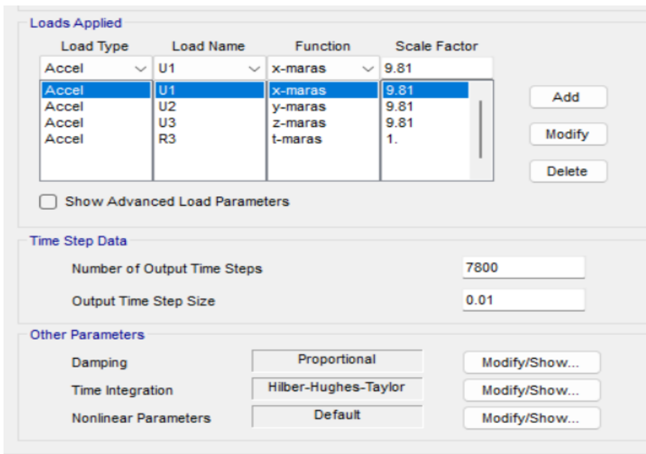

Fig. 6. Time history load case definition for translational and rotational ground motion

Classical proportional damping considered using Rayleigh damping. The damping matrix [c] is defined as the combination of the mass and stiffness matrices:

$$c = \alpha m + \beta k \tag{2}$$

where α and β are the Rayleigh damping coefficients. The modal damping ratio ζ_r for each mode r was calculated as:

$$\zeta_r = \frac{1}{2}\left(\alpha \frac{1}{\omega_r} + \beta \omega_r\right) \tag{3}$$

where ω_r is the circular natural frequency of mode r.

To define appropriate damping across critical vibration modes:

For combined translational and rotational ground motions, the first mode (T = 0.95 sec) and the third mode (T = 0.84 sec) were captured for torsional effects as shown in Fig. 7.

A 5% critical damping ratio (ζ = 0.05) was specified for both selected periods.

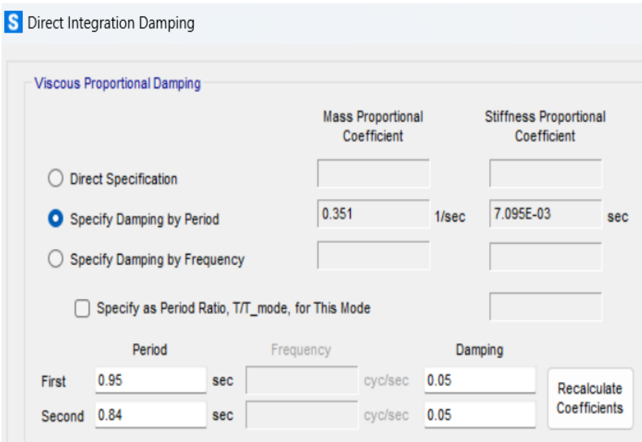

Fig. 7. Damping model

3. Results

The results from the nonlinear time history analysis show that rotational ground motion does not affect every part of the structure in the same way. For example, at Joint 13, as seen in Table 4, there's a slight increase in displacement when rotational ground motion is included—indicating a small rise in drift at this location. Meanwhile, at Joint 145, the opposite occurs: the displacement slightly decreases under rotational input. This pattern is also evident in the Duzce 1999 earthquake results (Table 5) and the Izmit 1999 earthquake results (Table 6). These differences suggest that the effect of rotational motion varies across the building, with certain areas experiencing increased drift while others experience reduced drift depending on the direction and location.

This variation in drift behavior is also illustrated in Fig. 8 and Fig. 9, which compare the X- and Y-axis drift values at Joints 13 and 145 under different ground motion cases.

Table 4. Mw7.7 Kahramanmaras (Elbistan) 2023 maximum drift ratio

4. Discussion

This study finds that rotational ground motions have relatively little effect on the overall seismic response of the precast industrial building. Rotational effects sometimes caused a drift reduction slightly, such as at Joint 145, but at others, like Joint 13, a slight increase was felt.

This implies that the torsional effect does not function equally and sometimes, aid in the redistribution of forces within to reduce lateral displacement. Despite their little magnitudes compared to translational accelerations, rotational components can even have a slight influence, mainly in large floor plan structures.

However, the findings suggest that for symmetric and regular precast buildings, rotational motion effect is negligible. Therefore, while it may not be necessary to consider rotational movements in all design scenarios, it can improve accuracy in performance analyses, particularly in sensitive or unconventional structural configurations.

5. Conclusions

The research on the influences of rotational ground motions on the seismic response of a single-story precast RC industrial building using nonlinear time history analysis was the object of this research. The study indicated that although the overall influence of rotational components is minor, they can affect structural response by the minimal change of drift values at specific points.

The analyses confirmed that the interaction between translational and rotational motions produces a non-uniform seismic demand, even in ordinary structural configurations. This emphasizes the necessity of considering more than a single component of motion to gain a more complete understanding of structural behavior under earthquake loading.

Lastly, although rotational motions are not critical for all designs, their inclusion provides a more realistic representation of seismic demands. The conclusion is especially beneficial for performance-based design and analysis of industrial facilities where safety and continuity of operations are of utmost importance.

Acknowledgments

I would like to sincerely thank my supervisor, Dr. Rafet Sisman, for his invaluable guidance and support throughout this research.

A rapid and hybrid prestressed seismic strengthening system for RC piers using Fe-SMA plates: Experimental breakthrough

Adel Al Ekkawi[1], Raafat El-Hacha[*1]

[1] University of Calgary, Department of Civil Engineering, 2500 University Drive NW, Calgary, Alberta, Canada

Abstract. This study evaluates the efficiency of a rapid and hybrid seismic strengthening technique using prestressed iron-based shape memory alloy (Fe-SMA) plates. Two 1/3-scale RC bridge piers were prepared for this study. The first column remained unstrengthened for baseline comparison. The second column was strengthened with external vertical prestressed Fe-SMA plates on both sides of the column to significantly enhance its flexural and seismic performance. In addition, circumferential Fe-SMA welded plates were utilized around the column for active confinement. All Fe-SMA plates were thermally activated above 250°C, inducing vertical prestressing and active confinement effects in the second column. Under quasi-static lateral cyclic loading, the vertical Fe-SMA plates alone improved the column's lateral strength, energy dissipation, and displacement ductility by 35.97%, 107.29%, and 55.16%, respectively. Thereby, the addition of vertical and lateral prestressed Fe-SMA significantly improved the lateral cyclic response of the second column, alongside with reducing its residual displacements, and effectively suppressing damage in its plastic hinge region. This study pioneers the application of novel prestressed flexural and active confining strengthening systems on RC piers, addressing a significant gap in the area of seismic strengthening. As the first experimental investigation of its kind, it marks a breakthrough in utilizing prestressed Fe-SMA plates as hybrid strengthening to enhance the seismic performance of RC piers. Additionally, the study provides a detailed methodology for the rapid implementation of the proposed hybrid strengthening system, making it highly suitable for scenarios requiring quick bridge rehabilitation and minimal service disruption.

1. Introduction

Previous pioneering studies (ChaiI, Priestley, & Seible 1991; Priestley & Seible 1995) have shown that reinforced concrete (RC) bridge columns built before the 1971 seismic code revisions have suffered from poor ductility and low lateral strength due to inadequate design practices. These issues included widely spaced transverse reinforcement that fails to provide sufficient concrete confinement and short lap splice lengths that prevent full yielding of the columns' longitudinal reinforcements. As a result, such deficiencies posed serious risks to the structural integrity and post-earthquake functionality of bridges. To address these problems, various strengthening systems have been explored, especially focusing on external confinement techniques, which can be classified into passive and active systems. Passive confinement engages only after the column witnesses damage and deforms circumferentially, while active confinement engages instantly after its utilization, thereby providing the deficient RC column with an early increase in strength and enhancement in its performance, even before damage occurs.

Traditional confinement methods like concrete or steel jacketing are labour-intensive, non-durable, and incapable of providing active confinement. Therefore, heavy attempts to use prestressed steel strands, like in (Saatcioglu & Yalcin 2003), or fiber-reinforced polymer (FRP) prestressed belts, like in (Nesheli & Meguro 2006), have been conducted to utilize the great benefits of active confinement and enhance the seismic performance of deficient RC bridge piers. However, such attempts required complex strengthening hardware and installation, and careful design due to challenges like creep rupture in FRP.

In the past three decades, Shape Memory Alloys (SMAs) have emerged as promising materials for seismic strengthening, owing to their unique thermo-mechanical properties (Lagoudas 2008). Notably, (Shin & Andrawes 2011) were the first to introduce Nickel-Titanium-Niobium (NiTiNb) SMA 0.58 mm spirals to apply active confinement around deficient RC columns. Their study showed that the NiTiNb-SMA active confinement

* Corresponding author, E-mail: relhacha@ucalgary.ca

https://doi.org/10.31462/icearc2025.ce.eqe054

https://doi.org/10.31462/icearc2025_ce_eqe_054

significantly increased the column's displacement ductility, energy dissipation, and drift capacity. Consequently, their findings demonstrated the SMA's high potential in enhancing the seismic performance of deficient RC piers.

However, while SMA-based active confinement significantly enhances the ductility and energy dissipation of deficient RC bridge piers (Shin & Andrawes 2011), it contributes little to the column's lateral strength, which is a common observation reported by many researchers (ElGawady, Endeshaw, McLean, & Sack 2010; Saeed, Aules, & Rad 2022; Sause, Harries, Walkup, Pessiki, & Ricles 2004; Shin & Andrawes 2011), whether for actively or passively confined RC columns. As such, flexural strengthening has become important in noticing a significant enhancement in the column's lateral strength and addressing strong-beam weak-column conditions. Countless studies have attempted to utilize flexural strengthening systems on deficient RC columns; however, prestressed flexural strengthening systems have never been attempted before due to its heavy practical challenges in applying prestress forces externally along the column's vertical plane. As a result, passive systems like externally bonded (EB) and near-surface mounted (NSM) reinforcements have gained traction due to their simplicity and ease of use.

In response to the limitations of prestressed flexural strengthening systems utilized on deficient RC bridge columns, the current study builds on prior research by (Al Ekkawi & El-Hacha 2025a) (same authors of this manuscript) who developed recently in 2025, a "*practical and innovative prestressed flexural strengthening technique using iron-based SMA (Fe-SMA) plates*." These plates were anchored on both sides of the column using a welded-bolted system to achieve robust prestressing. Therefore, this study further investigates the performance of this prestressed Fe-SMA flexural strengthening system on another RC column, combining it with active confinement techniques using the same Fe-SMA plates. Correspondingly, two seismically deficient RC columns, representing 1/3-to-scale RC bridge piers, were tested under lateral cyclic loading to assess their lateral cyclic performance in terms of the parameters mentioned in Section 2. The results confirmed the significant benefits of the proposed "active hybrid systems," which integrate flexural and confinement strengthening using prestressed Fe-SMA plates. The findings of this research fill a critical gap in the field of prestressed flexural strengthening and active confinement of RC columns, thereby offering an insightful and better approach for further enhancing the seismic performance of deficient RC bridge columns in the future.

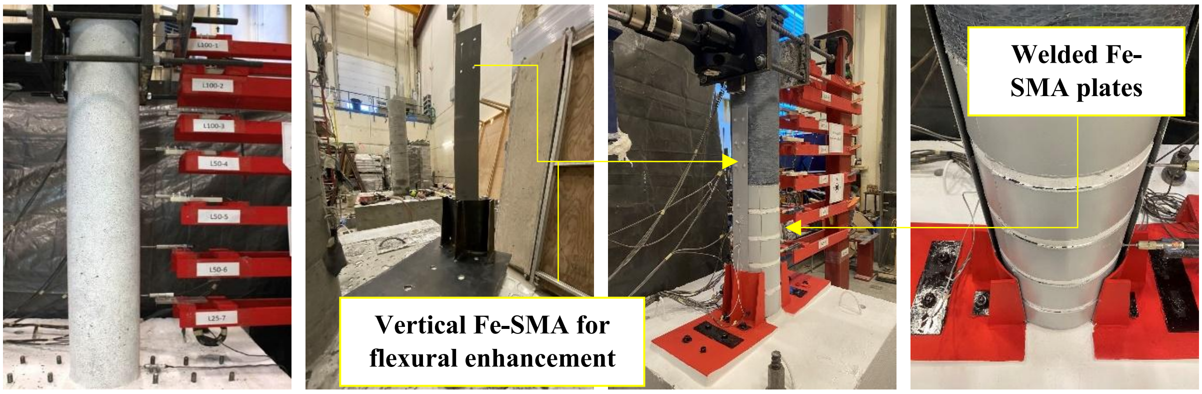
2. Research objective

This study investigates the effectiveness of a novel active hybrid strengthening system using iron-based Shape Memory Alloy (Fe-SMA) as a prestressed flexural external reinforcement and an active confining material to enhance the seismic performance of deficient RC columns. The key performance metrics studied in this research include lateral strength, hysteretic behaviour, displacement ductility, energy dissipation, recentering ability, and accumulated damage. It also explores the benefits of incorporating active confinement using Fe-SMA plates applied through a robust and quick welding approach, highlighting its convenience for emergency applications.

To achieve this, two circular RC columns with low transverse reinforcement – representing seismically vulnerable 1/3-to-scale RC bridge piers – were tested under quasi-static lateral cyclic loading. The two columns are shown in Fig. *1*. One column remained unstrengthened as a control (Fig. *1*a). The second column, named "FlexSMA-CSW," was strengthened and prestressed in flexure using prestressed Fe-SMA plates. In addition, welded Fe-SMA plates were utilized around the column for active confinement (Fig. *1*b). Notably, the aforementioned strengthening elements were applied along the columns' estimated plastic hinge length (determined later in another section). By comparing the performance of these columns, the study demonstrates the effectiveness of the Fe-SMA prestressed flexural strengthening system combined with the confining Fe-SMA welded plates in improving the column's lateral cyclic response.

3. SMA: brief overview

Shape Memory Alloys (SMAs) have gained significant attention in structural strengthening over the past decade due to their unique smart behaviour and superelasticity.



(a) As-built (b) FlexSMA-CSW

Fig. 1. Column testing matrix

These properties stem from a reversible crystallographic transformation between two phases: austenite (A) and martensite (M). Notably, temperature governs this transformation, with the alloy becoming martensitic upon cooling below the martensite start (M_s) and finish (M_f) temperatures and transforming back to austenite when heated above the austenite start (A_s) and finish (A_f) temperatures.

When fully austenitic, SMAs exhibit superelastic behaviour characterized by a flag-shaped stress-strain curve, shown in
Fig. 2, where deformations are fully recoverable upon unloading. In contrast, martensitic SMAs behave similarly to steel under loading but retain significant permanent deformations when unloaded, as presented in
Fig. 2. These deformations, however, can be reversed by heating the alloy above A_f, triggering the shape memory effect (SME). However, if the SMA is restrained during this transformation, it generates significant "recovery stresses," which are crucial for prestressing applications.

Noteworthy, an SMA with a wide thermal hysteresis ($A_s - M_s$) can maintain its recovery stresses even after cooling, making it highly effective for long-term structural use. These distinctive thermo-mechanical behaviours position SMAs as powerful materials in advanced prestressing and seismic strengthening strategies.

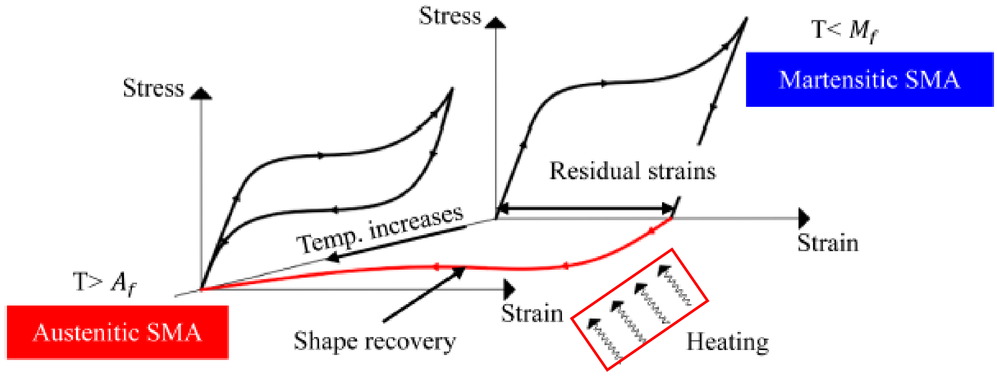


Fig. 2. Mechanical behaviour of SMA under different crystallographic structures

4. Research materials: mechanical characterization

4.1 Concrete

The foundations were cast first, with the columns poured a few months later to replicate a realistic construction timeline. The average compressive strength (f_c') of the columns was measured in accordance with ASTM C39/C39M, yielding values of 44.86 MPa at 28 days and 42.49 MPa at the time of testing. The 28-day strength was determined using 100×200 mm concrete cylinders cured in a humidity-controlled room at 95% humidity, while the strength at the testing age was obtained from uncured cylinders of the same dimensions.

4.2 Steel rebars

In both column specimens, 10M and 20M rebars are used as shear and longitudinal reinforcement, respectively. The 10M bars have a nominal diameter of 11.3 mm, while the 20M bars have a nominal diameter of 19.5 mm. Both types of reinforcement have a specified yield strength of 400 MPa. To determine the actual yield strength, four to six samples of each rebar type were tested under uniaxial tension in accordance with ASTM A370. The average yield strength obtained was 439 MPa for the 10M rebars and 404.4 MPa for the 20M rebars.

4.3 Fe-SMA plates

The Fe-SMA plates used in this study were previously characterized by (Shahverdi, Michels, Czaderski, & Motavalli 2018), who conducted extensive mechanical testing on the same material. Their results, summarized in Table 1, form the basis for this study's material properties. While Shahverdi et al. thoroughly assessed the mechanical behaviour of the Fe-SMA, they did not investigate its use in prestressed flexural or active confinement applications for RC columns, underscoring the novelty of the current research. The Fe-SMA, composed of Fe-17Mn-5Si-10Cr-4Ni-1(V,C) by mass, was supplied in plate form (1.5 mm thick, 120 mm wide) and pre-strained to 2% at room temperature, retaining 1.25% residual strain after unloading. Its transformation temperatures, reported by (Lee et al. 2013), are listed in Table 2. Notably, this research adopted the high-precision results from the aforementioned studies since advanced thermal monitoring, controlled heating systems, and Differential Scanning Calorimetry (DSC) were heavily used to ensure reliable and accurate material characterizations.

Table 1. Mechanical properties of the Fe-SMA plate

Austenitic elastic modulus (GPa)	Martensitic elastic modulus (GPa)	Yield strength (MPa)	Ultimate strength (MPa)	Rupture strain (%)	Recovery stress (MPa)	Stress losses (%)
75	160	534.58	981.32	42.92	386.71	9.6

Table 2. Transformation temperatures of the Fe-SMA plate

Martensitic finish temp. (M_f, °C)	Martensitic start temp. (Ms, °C)	Austenitic start temp. (As, °C)	Austenitic finish temp. (A_f, °C)
-64	-60	103	163

4.4 Carbon FRP wraps

Unidirectional CFRP wraps were applied as secondary confinement to the upper portions of the deficient RC column to strengthen specific anchorage regions and to conform with the strengthening confinement requirements of the CSA S6-19 standard. These wraps, identified as SikaWrap Hex-230 C®, have a thickness of 0.38 mm and manufacturer-reported properties of 801 MPa tensile strength, 74.70 GPa elastic modulus, and 1.01% rupture strain ("Sika Canada. SikaWrap Hex-230 C" 2018). Tensile tests conducted on CFRP coupons in accordance with ASTM D3039/D3039M, yielded average values of 710 MPa for tensile strength, 68.9 GPa for elastic modulus, and 1.29% for rupture strain, as tested by (Abdelrahman 2017).

5. Design of column specimens

The two circular RC columns, designed as 1/3-scale bridge piers, were constructed to evaluate the proposed seismic strengthening systems. Each column has a diameter of 300 mm and a clear height of 1600 mm, supported by a 600 mm thick RC foundation. To simulate realistic construction practices, the foundations were cast months before the columns, allowing the columns to be anchored through protruding reinforcement bars without using chemical bonding agents. This setup ensured load transfer occurred solely through mechanical interlock at the column-foundation interface. The cast is shown in Fig. *3*.

Both columns were built with seismic deficiencies, featuring widely spaced transverse reinforcements that were positioned at 150 mm spacing, thereby falling short of the 75 mm maximum spacing required by CSA S6-19 for ductile performance. The reinforcement detailing is presented in Fig. *3* as well. This low confinement level replicates outdated construction practices that have historically contributed to RC column failures during earthquakes. The columns were reinforced with 8-20M longitudinal bars evenly distributed around the perimeter, resulting in longitudinal and transverse reinforcement ratios of 3.40% and 1.16%, respectively. Concrete covers were 30 mm for columns and 50 mm for foundations.

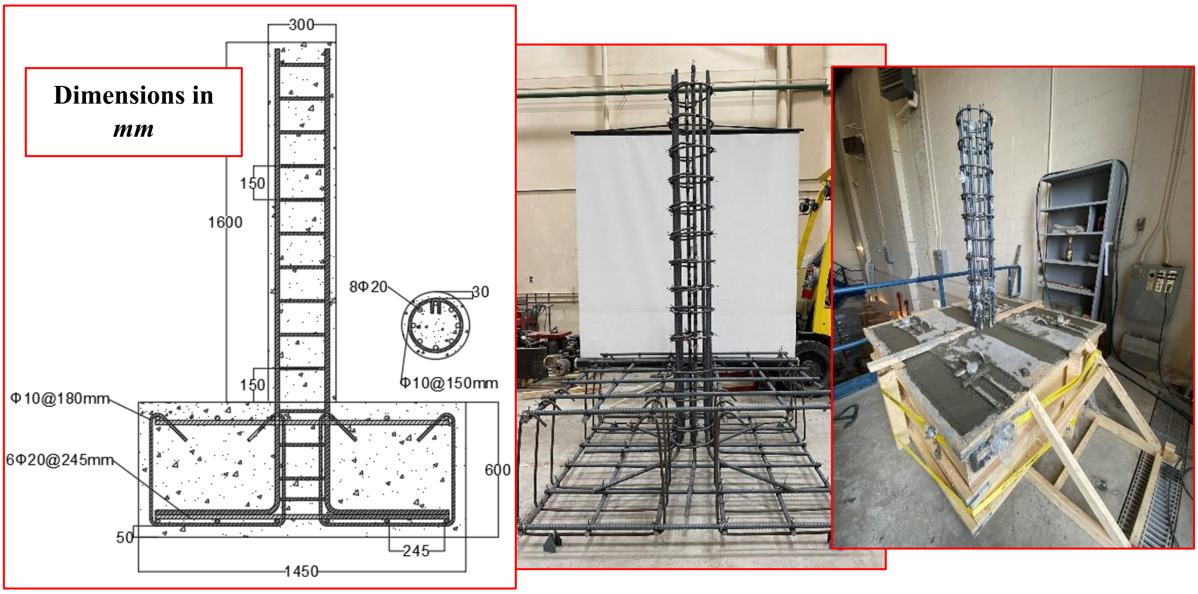

Fig. 3. Reinforcement detailing and columns' casting

6. Description of the lateral cyclic loading regime

Both RC columns were tested under quasi-static lateral cyclic loading applied at their tops using a 250 kN displacement-controlled actuator, with an effective height of 1425 mm, as shown in Fig. 4. The loading protocol, also illustrated in Fig. 4, followed the FEMA testing guidelines to capture key structural responses such as cracking, reinforcement yielding, and strength degradation. A total of 49 pull-push cycles were applied. Initial cycles were conducted at small displacements (0.5–3 mm) with a rate of 0.25 mm/sec. The displacement was then increased in stages − first by 3 mm up to 12 mm, then by 8 mm up to 68 mm, and finally by 15 mm up to 126 mm, with corresponding increases in loading rate, ending at 2 mm/sec. At the aforementioned rate, the columns were left to cycle until failure.

A constant axial load was also applied to simulate gravity effects, as presented in Fig. 4. It ramped from zero to -160 kN before lateral loading began. The axial load was equal to 5% of the column's gross concrete compressive strength, which falls within the axial load limits specified in CSA A23.3-19 for flexure-dominated columns. Consequently, this low axial load level helped isolating the lateral cyclic response of the columns.

7. Strengthening procedure

7.1 Determination of the columns' plastic hinge length (L_p)

The critical plastic hinge length (L_p) of the RC columns was determined using established equations from key studies on plastic hinge behaviour, with values ranging between 0.48h and 0.96h (ChaiI et al. 1991; Corley 1966; Priestley & Park 1987) (h is the column's diameter). However, the CSA S6-19 standard recommends a fixed L_p of $2h$ for such columns. Therefore, to simplify implementation and ensure safety, the authors adopted a conservative estimate of $2h$ (approximately 600 mm) for all specimens. This choice aligns with the code requirements and mirrors similar decisions in other studies (Miralami, Esfahani, & Tavakkolizadeh 2019; Shin & Andrawes 2011) that used L_p values between $1.5h$ and $2h$.

7.2 Utilization of the confining Fe-SMA welded plates

The FlexSMA-CSW column features lateral Fe-SMA plates designed to provide active confinement once activated. These plates are cut, bent, and tightly fastened around the column using hose clamps to eliminate any gaps and ensure a snug fit. The confining Fe-SMA welded plates are installed along the column's 600 mm plastic hinge region. For installation, only the overlap region − set to twice the plate width (2w), or 240 mm − is welded, as shown in Fig. 5.

Following the installation of the confining plates, vertical Fe-SMA plates are added to the FlexSMA-CSW column, following the procedure described subsequently in Section 7.3.

7.3 Utilization of the vertical Fe-SMA plates for prestressed flexural strengthening

In this study, 1100 mm long Fe-SMA plates were vertically installed on opposite sides of the FlexSMA-CSW column, aligned with the direction of the lateral loading. These plates were welded to stiffened steel base plates (Fig. 6a), which were anchored to the column foundations using six cast-in anchors per side (Fig. 6b). The anchors were 16 mm in diameter, Grade 36 steel, and embedded 210 mm deep. While cast-in anchors were used here for ease of testing, real-world applications would employ post-installed wedge anchors or concrete screws capable of withstanding the high tensile demands of the vertical Fe-SMA plates during seismic events.

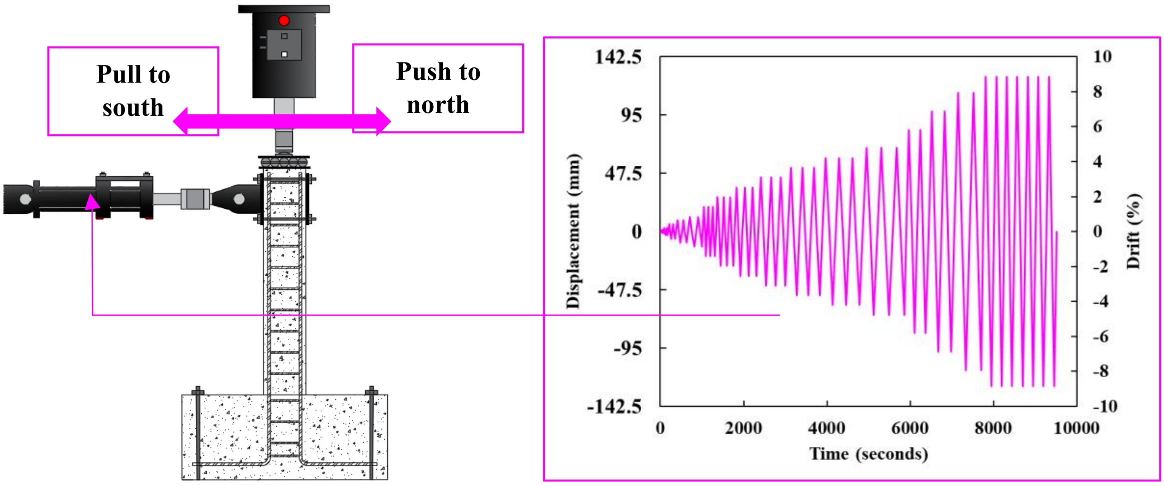

Fig. 4. Testing setup and loading protocol

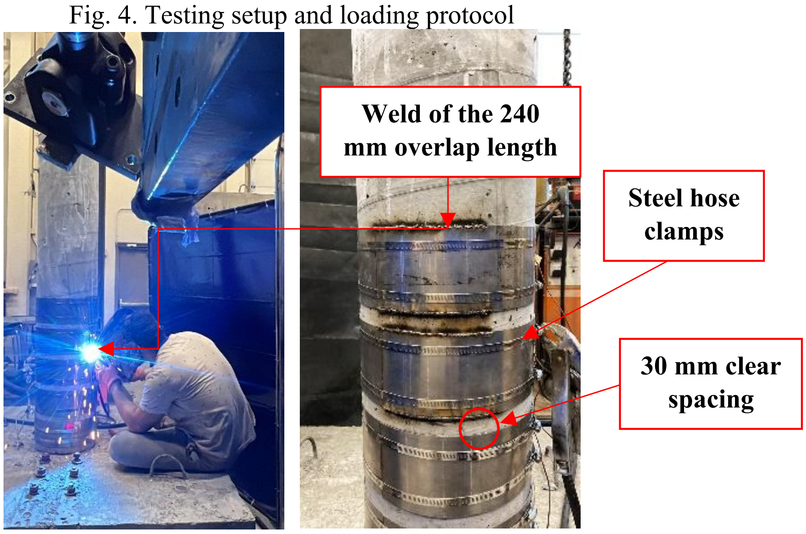

Fig. 5. Welding of the confining Fe-SMA plates

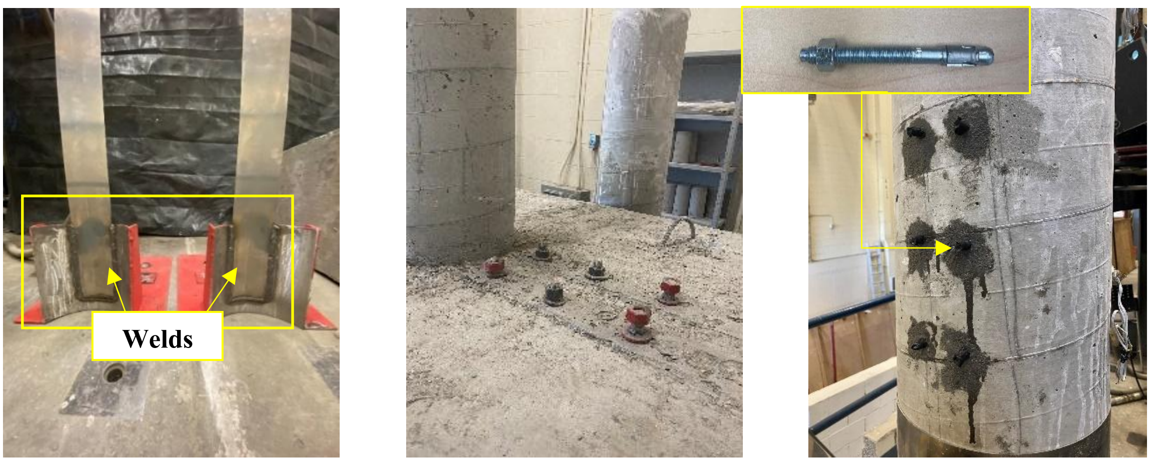
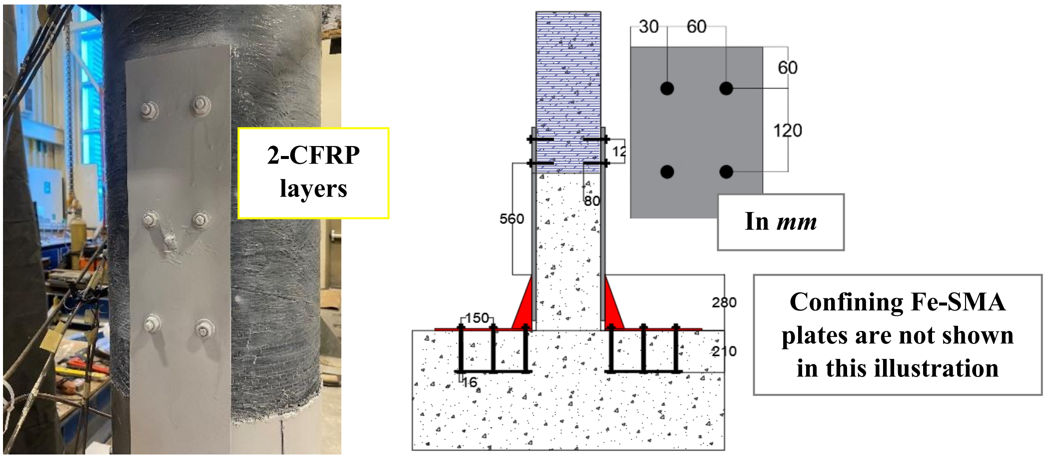
At the top, the plates were fixed to the FlexSMA-CSW column using six post-installed 9.5 mm wedge anchors (Fig. 6c). The effective plate length of the vertical Fe-SMA plates in the FlexSMA-CSW column was 560 mm to match the 600 mm expected plastic hinge length. To prevent anchorage failure in the wedge anchors at the top of the FlexSMA-CSW column due to shallow anchor embedment and moderate concrete strength, two CFRP layers were added (Fig. 6d). A schematic representation of the flexural strengthening system is shown in Fig. 6e.

Though the system may seem complex, it can be simplified for field use by replacing cast-in anchors in the foundation with threaded screw concrete anchors.



(a) Fe-SMA weld to steel plates (b) Cast-in anchors (c) Post-installed wedge anchors



(d) CFRP wrapping (e) Scheme of the flexural system

Fig. 6. Process of the utilization of the vertical Fe-SMA plates in the FlexSMA-CSW column

7.4 Estimation of the Fe-SMA active confinement pressure

The confining Fe-SMA welded plates are designed to achieve a target confinement pressure of 4.05 MPa. This value is determined based on the ductility requirements outlined in the CSA S6-19 standard for FRP-confined systems, specifically from Chapter 16. Other equations from (Mander, Priestley, & Park 1988) were also used to accurately estimate the confinement pressure exerted by the confining Fe-SMA welded plates. Notably, these equations are lengthy and cannot be presented herein for brevity purposes; however, some of the equations are detailed in the author's recent publication (Al Ekkawi & El-Hacha 2025b). As a result, a clear spacing of 30 mm between adjacent Fe-SMA plates was obtained to provide a 4.05 MPa confinement pressure, as shown in Fig. 5.

Additionally, a 50 mm gap is maintained between the lowest Fe-SMA plate and the column base to prevent dislocation and to align with similar spacing requirements found in FRP confinement practices.

Similarly, the two layers of CFRP added at the remaining height (800 mm) of the FlexSMA-CSW column also provide a 4.05 MPa confinement pressure, thus maintaining a uniform confinement pressure along the columns' entire effective height.

7.5 Activation of the Fe-SMA plates

The vertical and confining Fe-SMA plates were heated above 163 °C using a flame torch to activate their shape memory effect (SME), as shown inFig. 7. Since the plates were anchored at both ends, their shape recovery was restrained, inducing vertical prestressing and active confinement in the FlexSMA-CSW column. Two to three thermocouples were attached to each vertical plate to monitor temperatures during heating. An example of temperature results from the FlexSMA-CSW column's south plate is shown inFig. 7, which shows a consistent temperature measured by the two thermocouples, with occasional spikes caused by direct flame contact. Similar temperature behaviour was observed on the other Fe-SMA plates; however, these results are not presented here for brevity.

The peak temperatures reached were 334.9 °C for vertical plates and 500.38 °C for confining plates – which were well above the required activation threshold of 163 °C. This ensured temperatures remained elevated and higher than 163 °C for an average of 12.67 minutes post-heating, thereby enabling a full martensite-to-austenite transformation.

7.6 Estimation of the recovery stresses in the Fe-SMA plates: Brief explanation only

The recovery stress of the Fe-SMA plates was estimated at approximately 450 MPa based on the activation temperature–recovery stress relationship established by (Shahverdi et al. 2018). To evaluate prestress losses, strain gauges (SGs) were attached at the mid-length of the Fe-SMA plates. Using the strain data collected and applying the analytical approach developed by (Al Ekkawi & El-Hacha 2025a) – which allows for accurate estimation of recovery stress from measured strain – the effective recovery stresses were calculated. The results showed that the vertical and confining Fe-SMAs reached an average recovery stress of 264 MPa and 398 MPa, respectively.

8. Results

8.1 Lateral strength

The lateral strength of the tested columns was defined as the peak lateral load attained during the cyclic loading protocol.

Fig. *8* presents the lateral strengths measured in both the push and pull directions for each column.

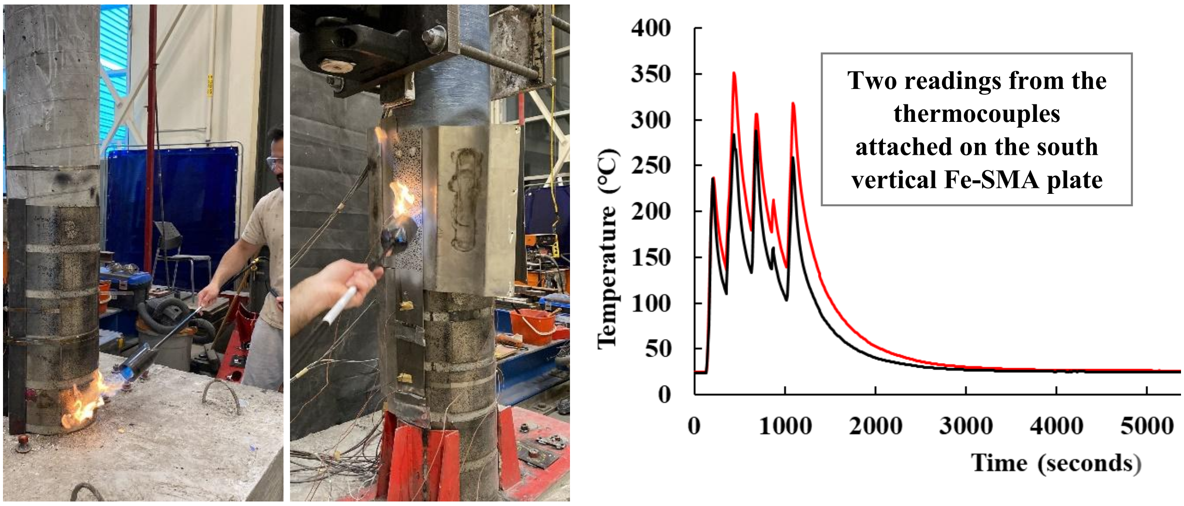


Fig. 7. Activation of the Fe-SMA plates and temperature versus time curves measured by thermocouples

The as-built column exhibited the lowest average lateral strength, reaching 91.53 kN at an average drift of 4.74%. As the drift demand increased beyond this point, a significant decline in strength was observed, driven primarily by severe crushing of the concrete and pronounced buckling of the longitudinal reinforcement. By the end of the test at 8.84% drift, the as-built column experienced a substantial 65.68% reduction in its lateral load capacity after sustaining 42 cycles.

In contrast, the FlexSMA-CSW column, which included both vertical and confining Fe-SMA welded plates, recorded a 35.97% increase in average lateral strength, peaking at 5.55% average drift. Despite the occurrence of a localized rupture in its vertical Fe-SMA plates (

Fig. *8*), the column maintained sufficient strength throughout the test, showing only a 19.69% drop at 8.84% drift and at the 49th cycle. This result illustrates the beneficial role of the vertical and confining Fe-SMA plates in enhancing both lateral resistance and damage resilience of seismically deficient RC columns. However, the authors suggest that adding welded Fe-SMA confinement had limited influence on the column's lateral load capacity, though it may have contributed to improved post-peak behaviour.

8.2 Hysteretic response

The full load-displacement and load-drift responses recorded during the lateral cyclic tests are presented in

Fig. *9*. All columns initially responded elastically until concrete cracking occurred, which was observed at an average lateral load of 12.24 kN and a corresponding drift of approximately 0.12%. As the drift increased, a consistent rise in lateral load was recorded for both specimens up to the point of longitudinal reinforcement yielding.

For the as-built column (

Fig. *9*a), the maximum lateral strength was reached at an average drift of 4.74%. Beyond this point, further increases in drift did not result in a significant gain in lateral capacity. Additionally, the hysteretic loops became increasingly pinched and unstable due to severe crushing of the concrete core and substantial buckling of the longitudinal steel bars. By the 42nd cycle, at 8.84% drift, the column exhibited global instability due to its extensive degradation in its lateral strength in both directions, thereby prompting an early termination of the test to prevent damage to the hydraulic loading system.

The FlexSMA-CSW column (

Fig. *9*c), which combined vertical Fe-SMA plates with confining Fe-SMA welded plates, similarly exhibited a stable and ductile hysteretic behaviour throughout the test. Although a temporary load drop was observed at 4.77% drift in the pull direction during the 34th cycle due to the rupture of the north vertical Fe-SMA plate, the load capacity recovered as the confining plates engaged more fully. Peak lateral strength was achieved at 5.55% average drift, and the column maintained its structural integrity until the onset of flexural cracking at 8.84% drift. The cyclic test was completed after the 49th cycle, with only a modest degradation in load response during the final loading stages.

Overall, the FlexSMA-CSW column maintained a well-defined and wide hysteretic envelope, highlighting the effectiveness of vertical and confining Fe-SMA plates in enhancing damage suppression and displacement capacity of the seismically deficient RC column. The hysteretic responses of the latter remained stable through the entire lateral cyclic test until reaching the maximum drift level of 8.84%. In contrast, the as-built column began to exhibit serious degradation beyond 4.74% drift. These results underscore the critical role of the vertical Fe-SMA plates in improving the displacement capacity, ductility, and cyclic stability of seismically deficient RC columns, particularly under large inelastic deformations. Moreover, the confining Fe-SMA welded plates acted as a second line of defense in enhancing the lateral cyclic response of the FlexSMA-CSW column, right after the rupture of the column's vertical Fe-SMA plates.

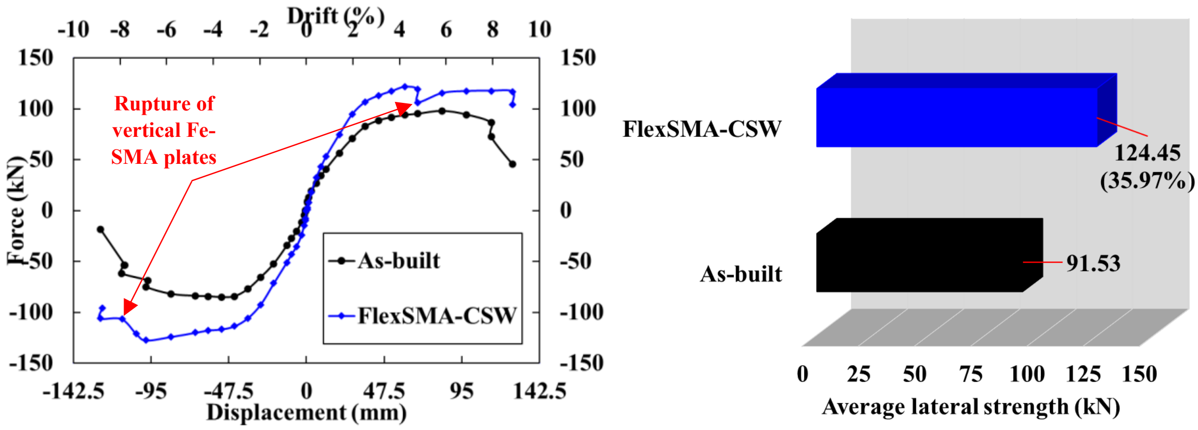

Fig. 8. Backbone curves and illustration of increase in the columns' lateral strength

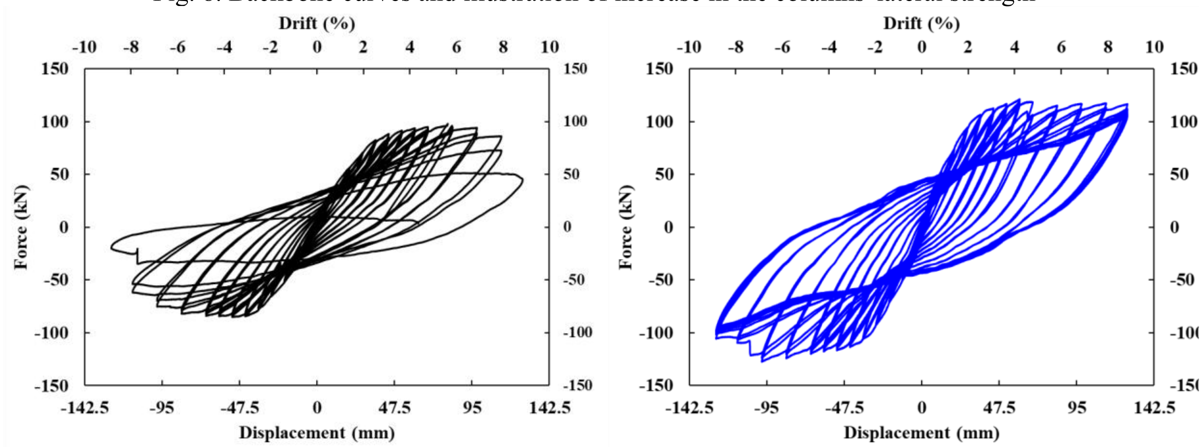

(a) As-built column

(b) FlexSMA-CSW column

Fig. 9. Lateral cyclic hysteretic response of the columns

8.3 Displacement ductility (μ_Δ)

The displacement ductility index (μ_Δ), defined as the ratio between the ultimate drift (Δ_u) and the yield drift (Δ_y), serves as a critical metric for evaluating the capacity of RC columns to undergo inelastic deformations without experiencing rapid strength degradation (Priestley & Park 1987).

In this study, Δ_u is defined as the drift level at which the lateral load declines to 85% of its peak, indicating a 15% loss in lateral strength. On the other hand, Δ_y is identified based on the onset of longitudinal bar yielding, determined from the strain gauge readings attached to the internal reinforcement. The calculated values of Δ_y, Δ_y, and μ_Δ for all tested specimens are summarized in Table 3.

Table 3. Δ_y, Δ_u, and μ_Δ of the tested columns

Column	Average Δ_y (%)	Average Δ_u (%)	Disp. ductility μ_Δ	% increase in μ_Δ
As-built	2.50	7.41	2.96	NA
FlexSMA-CSW	1.93	8.84	4.59	55.16

On the other hand, the FlexSMA-CSW column exhibited a significantly higher μ_Δ value compared to the as-built column, recording an outstanding increase of 55.16%, which corresponds to a value of 4.59. This enhancement is largely attributed to the reduction in the column's yield drift, facilitated by increasing the column's yield stiffness due to the Fe-SMA welded confinement.

As was shown in previous research (Al Ekkawi & El-Hacha 2025a), the utilization of vertical Fe-SMA plates alone did not significantly boost the column's displacement ductility due to absence of confinement. In contrast, the confining Fe-SMA welded plates promoted more uniform stress distribution inside the column's concrete core and delayed damage localization, thereby significantly improving the column's ductile performance.

Moreover, the FlexSMA-CSW column succeeded in surpassing the minimum displacement ductility requirement ($\mu_\Delta \geq 4.0$) stipulated by the CSA S6-19 standard for a single ductile column. This finding demonstrates that the combination of vertical and confining Fe-SMA welded plates offers a promising strategy to meet modern seismic performance standards by effectively improving both deformation capacity and structural resilience.

8.4 Cumulative energy dissipation capacity (E_{cum})

The energy dissipation capacity of the tested columns was evaluated to gain insight into their ability to absorb and dissipate the cyclic input energy through reinforcement yielding and damage mitigation mechanisms. The cumulative energy dissipation, denoted as E_{cum}, was computed by summing the area enclosed within each complete load-displacement hysteresis loop from the beginning of the test until failure, as per the method outlined in (Hwang 1982). The resulting E_{cum} values for all specimens are presented in Fig. 10.

Overall, the FlexSMA-CSW column demonstrated improved energy dissipation capacity compared to the as-built specimen, primarily due to its structural stability that remained up to 8.84% drift, allowing it to undergo more cycles and larger inelastic deformations. The FlexSMA-CSW column showed a significant enhancement in its cumulative energy dissipation − recording a remarkable increase of 107.29% relative to the as-built column. This notable improvement confirms the effectiveness of the hybrid active strengthening system, incorporating prestressed and confining Fe-SMA plates, in facilitating energy absorption and controlling damage progression, making them highly suitable for seismic strengthening applications.

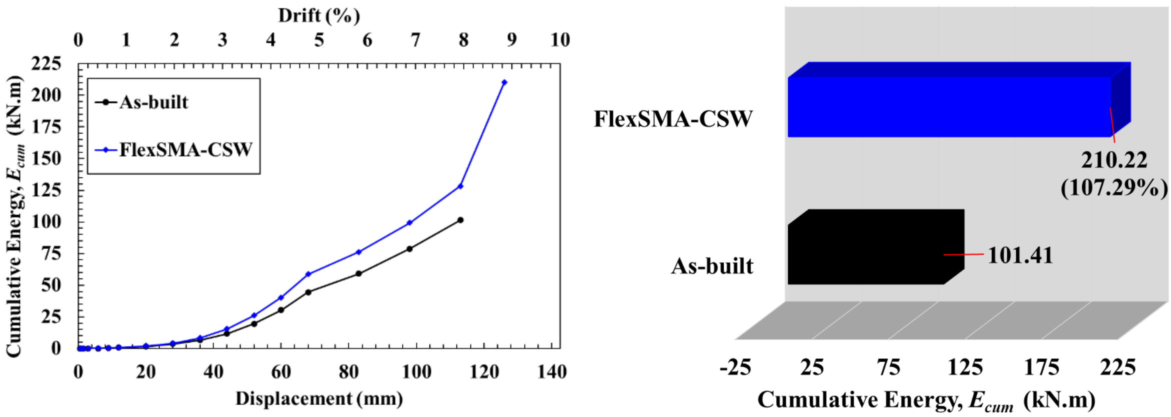

Fig. 10. Increase in columns' energy dissipation capacity with the increase in drift levels

The Fe-SMA welded plates likely provided sustained lateral pressure on the concrete core, thus minimizing premature cracking and enabling the column to retain its structural integrity throughout the inelastic deformation range and absorb further energy. As a result, it is concluded that the confining Fe-SMA welded plates promoted a stable and energy-efficient hysteretic behaviour. Consequently, this finding offer promising potential for advanced seismic retrofit strategies aimed at extending the service life and improving the post-yield performance and energy absorption of vulnerable RC columns.

8.5 Column's recentering ability (Δ_{res})

The elastic deformation capacity of Fe-SMA plates plays a critical role in improving the recentering capability of seismically deficient RC columns. This characteristic helps reduce permanent displacements after significant lateral deformation, thereby enhancing structural resilience under cyclic loading. To evaluate this, the progression of average residual displacements, Δ_{res}, with increasing drift levels, was tracked for all specimens and is illustrated in Fig. 11.

As seen in Fig. 11, both columns maintained relatively low Δ_{res} values up to approximately 2.53% drift, reflecting elastic structural behaviour in the early cycles. Beyond this point, residual displacements began to increase significantly, indicating the transition to an inelastic response and accumulating damage. With continued drift beyond 2.53%, the columns exhibited generally comparable recentering behaviour, as evidenced by similar trends in the average Δ_{res}. However, as the drift levels increased beyond 6.88%, the as-built column began to display a marked rise in residual displacement due to severe internal damage. At 8.84% drift, it reached a peak average residual displacement of 74.55 mm, indicating substantial permanent deformation resulting from concrete crushing and reinforcement buckling.

A greater improvement was observed in the FlexSMA-CSW column, which recorded an average residual displacement of 58.42 mm at 8.84% drift, representing a 21.63% reduction relative to the as-built column. This highlights the effectiveness of vertical Fe-SMA plates in the column's enhancing recentering ability through suppression of damages. Additionally, the notable improvement in recentering performance is also attributed to the active confinement provided by the confining Fe-SMA welded plates, which effectively restrained damage propagation and preserved the integrity of the concrete core throughout the cyclic loading.

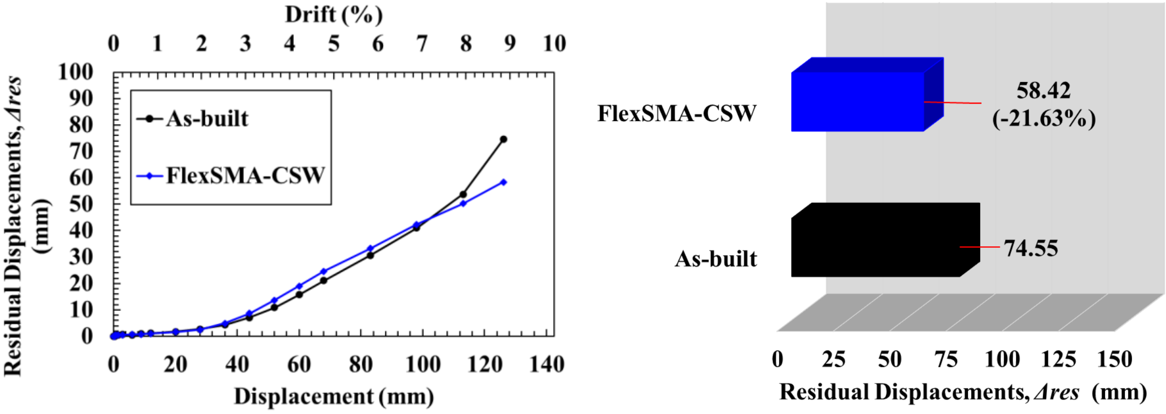

Fig. 11. Increase in columns' residual displacements with the increase in drift levels

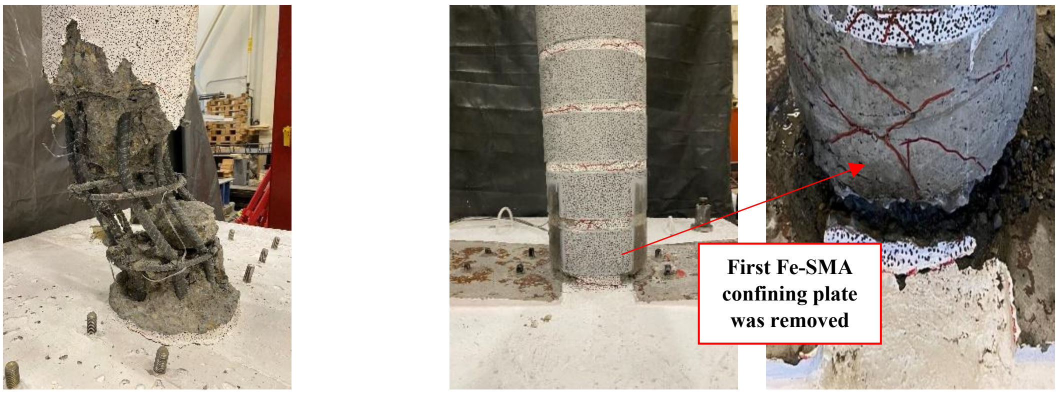
Moreover, no abrupt increase in residual displacement was observed despite the rupture of vertical Fe-SMA plates in the FlexSMA-CSW column at 4.77% and 7.93% drift levels in the pull and push directions, respectively (see

Fig. *8*). This further suggests that the primary enhancement in the column's recentering ability was driven by the confining Fe-SMA welded plates as the column approached high drift levels and its ultimate failure, in which the confining plates continued to mitigate damage and maintain column's stability even after the rupture of the vertical Fe-SMA plates.

8.6 Damages accumulated

Among all tested specimens, the as-built column experienced the most severe damage. Concrete crushing initiated at 5.82% drift, and at the maximum applied drift of 8.84%, the column exhibited significant crushing of the concrete core and visible buckling of the longitudinal reinforcements (Fig. 12a). However, no reinforcement rupture occurred by the end of the test.

The FlexSMA-CSW column exhibited much less damage. Both the concrete cover and core remained undisturbed throughout the test, with no reinforcement buckling observed (Fig. 12b). The additional confinement provided by the confining Fe-SMA welded plates further contributed to the column's superior protection, effectively suppressing damage even at high drift levels. Therefore, post-earthquake repair would be limited to replacing the Fe-SMA plates and sealing surface cracks only, making this system particularly attractive for rapid recovery applications.



(a) As-built (b) FlexSMA-CSW

Fig. 12. Columns' accumulated damage at the end of the lateral cyclic test

9. Conclusion

This experimental study yielded the following conclusions:

- The as-built column experienced rapid strength degradation, extensive concrete core damage, and reinforcement buckling at large drift levels, indicating limited ductility and poor energy dissipation.
- Strengthening with vertical and confining Fe-SMA plates significantly improved the lateral response, flexural strength, and ductility of the columns. These plates also effectively limited damage to the concrete core and prevented reinforcement buckling.
- Confining Fe-SMA welded plates played a major role in improving column's stability under cyclic loading, increasing energy dissipation, and reducing its residual displacements. This hybrid active system also demonstrated a robust recentering capability and met critical ductility criteria for seismic applications.
- The hybrid active strengthening system provided excellent control over inelastic deformations, allowing the columns to maintain structural integrity under high drift demands.
- Damage in the strengthened column was minimal and localized to the concrete cover. As a result, repairs would be straightforward, primarily involving replacing external strengthening components such as Fe-SMA plates and surface crack sealing.
- The proposed hybrid active system also support rapid post-earthquake repair and reuse, offering practical advantages for resilience-based design and emergency recovery strategies.

In summary, using vertical Fe-SMA plates and confining Fe-SMA welded plates proved to be an effective and reliable method for enhancing the seismic performance of vulnerable RC columns. Noteworthy, the proposed strengthening system can be utilized within a few hours, thereby promoting the system as an effective rehabilitating solution for bridges in emergency situations.

The effect of solar power panels on industrial structure's seismic performance

Samet Kılıç*[1], Turgay Çakmak[2]

[1] *Star Yazılım Mühendislik ve Danışmanlık, Ataşehir, Türkiye*
[2] *Protek Proje Tek.Müş.ve Kont. Hizm.Ltd.Şti., Ataşehir, Türkiye*

Abstract. In recent years, the use of solar panels has become quite widespread in our country. In particular, many factories want to meet some of their high electricity consumption with the electricity they produce within themselves. Additionally, solar panels are renewable energy sources. Significant damage was observed in many industrial structures in the Kahramanmaraş earthquake. Some of the damaged and destroyed factories had solar energy panels. Especially the effects of the presence of solar panels on roofs on the earthquake performance of buildings should be carefully examined. It is known that panels, in particular, affect seismic weight by increasing dead weight. In this study, solar panels were added to one of two existing buildings, while the other was left as is. In this way, it is aimed to measure the seismic effect of the panels. SAP2000® software is used for the study. In order to compare the effects of solar panels performance-based assessment is carried out with respect to Turkish Seismic Design Code. While analyzing structures, moving loads of cranes, snow loads, wind loads are also taken into account. Performance levels of structure with/without solar panels, drift ratios, base shear forces, steel elements capacities are checked. The finite element method used in the study is a valid way of seismic performance levels of structures. With this study, the impact of the solar power panels on seismic performance levels and the required precautions can be perceived.

Keywords: Performance based design; Solar energy panels; Seismic design of industrial structures; Retrofit of steel structures; Cranes design

1. Introduction

As businesses embrace renewable energy sources to lower operating costs and carbon footprints, the incorporation of solar panels into industrial buildings has become increasingly popular. Usually mounted on rooftops or other approved mounting locations, solar panel systems pose a special set of engineering difficulties, especially in seismically active areas. Solar energy has long been known to have positive effects on the environment and the economy, but in order to guarantee safety and resilience, a thorough analysis of how solar panel installations affect the seismic performance of industrial facilities is necessary.

Systems with solar panels add heft to the building, which may change how it responds to earthquakes. In addition to raising the dead load, the additional weight may shift the center of gravity of the structure, increasing its vulnerability to seismic forces. According to research, the distribution of mass might increase base shear and overturning moments, which can intensify seismic effects, especially when panels are concentrated in places (ASCE, 2022). Additionally, ill-planned installations may result in unequal loading, which could jeopardize structural integrity due to localized stress concentrations.

The dynamic implications of solar panel systems for the seismic performance of structures are crucial, even beyond static load considerations. Both solar panels and their mounting mechanisms have inherent frequencies. Resonance may arise when these frequencies coincide with the structure's inherent frequencies, intensifying vibrations and raising the risk of structural damage. In order to reduce such dangers, it is crucial to make sure that the dynamic characteristics of the solar panel system are compatible with the host structure, according to studies by Walters et al. (2012).

The seismic performance of industrial buildings is greatly impacted by the way solar panels are fastened to them. Mechanically anchored mounts, which are fixed directly to the structure, and ballasted mounts, which use weight to secure the panels, are examples of common mounting systems. Although ballasted systems are useful for reducing roof penetrations, instability may result from shifting during seismic activity. However, to prevent

*Corresponding author, E-mail: kilicsamet123@gmail.com

https://doi.org/10.31462/icearc2025_ce_eqe_060

water intrusion and guarantee long-term durability, mechanically anchored systems must be carefully designed, even though they offer higher seismic resilience (Baker et al., 2012).

Guidelines for incorporating solar panel systems into industrial facilities are provided by seismic design standards and building codes like ASCE 7 (2022) and Eurocode 8 (2003). With a focus on securing panels to prevent dislodgment and making sure their addition does not jeopardize structure safety; these standards address seismic loading considerations for rooftop solar installations. The new rules in the regulation (ASCE, 2022), provide precise criteria for wind and seismic loads on solar systems, emphasizing the importance of compliance to protect both the panels and the underlying structure (ASCE, 2022).

Retrofitting old industrial facilities with solar panel installations creates new obstacles. Older buildings may be unable to withstand the increased bulk and dynamic forces caused by the panels. Structural assessments are required to determine the building's load-carrying capacity and identify any necessary reinforcements. Advanced approaches, like as finite element modelling (FEM), are increasingly being utilized to predict the seismic performance of retrofitted structures, providing information on potential weaknesses and ideal remedies (Chopra, 2011).

While solar panel installations help to achieve sustainability goals, their impact on seismic resilience must be carefully monitored. Proper planning, material selection, and attention to design requirements can ensure that solar panels improve a structure's energy efficiency while maintaining its earthquake resistance. Innovative technologies, such as lightweight panel materials and vibration-damping systems, present intriguing opportunities for reducing earthquake risk.

The incorporation of solar power panels into industrial facilities represents a significant step toward sustainable energy solutions. However, it brings complications in seismic performance that must be carefully considered during the design, installation, and retrofitting phases. Engineers can ensure that solar panels are structurally safe in seismically prone areas by addressing added mass, dynamic impacts, and correct mounting solutions. Adhering to revised seismic design standards and utilizing advanced technical techniques will be key in attaining this balance and opening the road for safer, more environmentally friendly industrial infrastructure.

In this study, the same structure with and without solar panels were compared by considering the Turkish Regulations (TBDY, 2019; ÇYTHYE, 2016) drift ratios, base shear forces, steel element capacities, and structure performance levels with and without solar panels are examined as described in the relevant studies (Kılıç, 2024; Kılıç et al., 2022; Kılıç et al., 2021).

2. General Information about solar panels usage on roofs of buildings

In the Maraş earthquake in 2023, many residential, commercial and public buildings were destroyed, as well as industrial buildings. In some of the shared images of industrial buildings, as seen in Figure 1, it is noticed that buildings with solar panels were heavily damaged, which are very common today. In recent years, solar power plants have been subsidized by the state due to being a renewable energy source. However, especially when they are installed on existing buildings, their effects on the seismic behavior of the buildings must be examined in detail.

Fig. 1. Damaged Industrial Building with Solar Panels After Maraş Earthquake (Industrial Damage, 2024)

In practice, the static design of these solar panels is usually done by the supplier companies. The structural engineers are provided with layout drawings and distributed load values. Figure 2 shows a finite element model made by a solar energy supplier company. The constructions of solar panels can be manufactured from hot or cold rolled steel profiles as well as aluminium. The dead, live, seismic, snow and wind load of these structures are also made independently. While it is seen that many secondary situations such as the presence of panels or eaves on roofs are examined in the regulations (TS-EN 1991-1-4, 2007; TS-EN 1991-1-3, 2007), there is no special explanation regarding the presence of solar panels. Figure 3 shares a visual of wind analyses performed in the study (Hachem et al., 2024) on solar panels using the computational fluid dynamics method. For these reasons, the effects of newly designed panels with solar panels or panels added to an existing structure on the structural performance were evaluated within the scope of this study.

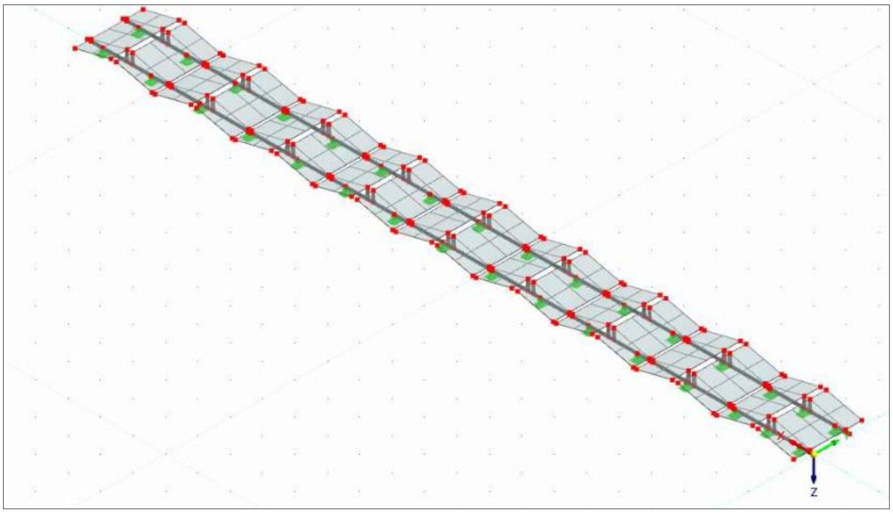

Fig. 2. Independent FEM Solution of Solar Panels (SAP2000, 2021)

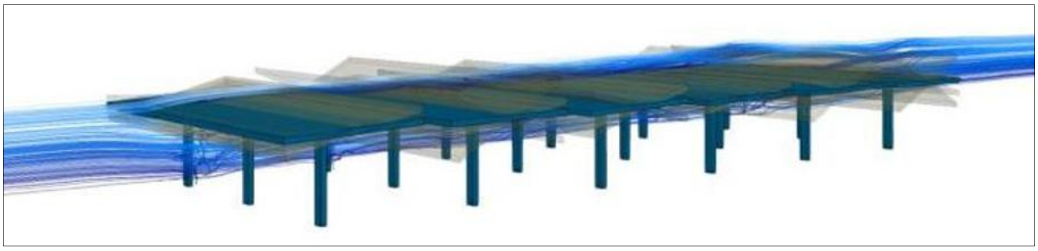

Fig. 3. Wind Loads for Solar Panels (Hachem et al., 2024)

2.1. Linear Models of Industrial Building with/without Solar Panels

In industrial structures consisting of steel trusses pinned on cantilever columns, a performance evaluation request was made due to the increase in crane capacity. In addition, it was planned to place solar panels on the existing structure during this process. For this reason, the seismic evaluation of the relevant structure was made separately for both cases.

Fig. 4. Snow Cleaning Method Views of Solar Panels (Cleaning Methods, 2024; Solar Panels, 2024)

It is very important to keep solar panels constantly clean in practice. Otherwise, electricity production will be interrupted. Therefore, manual and automatic snow cleaning methods are shown in Figure 4. The average loads of solar panels vary between 15-35 kg/m^2. The full snow load considered in this structure is 75 kg/m^2. Sometimes, the fact that snow is constantly cleaned, especially with automatic systems, leads to hesitations about whether the snow load is considered. Considering the coefficients in the loading combinations, it gives the impression that the distributed load of the solar panel is lower than the snow load and that it is on the safer side. However, while the snow load is calculated with a 0.3 live load participation coefficient when calculating the seismic weight, this coefficient is 1 when solar panels are evaluated as dead load. For this reason, seismic evaluation must be done. In addition, during the design, crane loadings as a moving load were renewed and wind and snow loads were revised according to the relevant standards and affected the structure (TS-EN 1991-1-4, 2007; TS-EN 1991-1-3, 2007). In Figure 5, Finite element components are presented. Solely, cantilever columns are for lateral seismic forces. Thus, only columns are evaluated under earthquake loads.

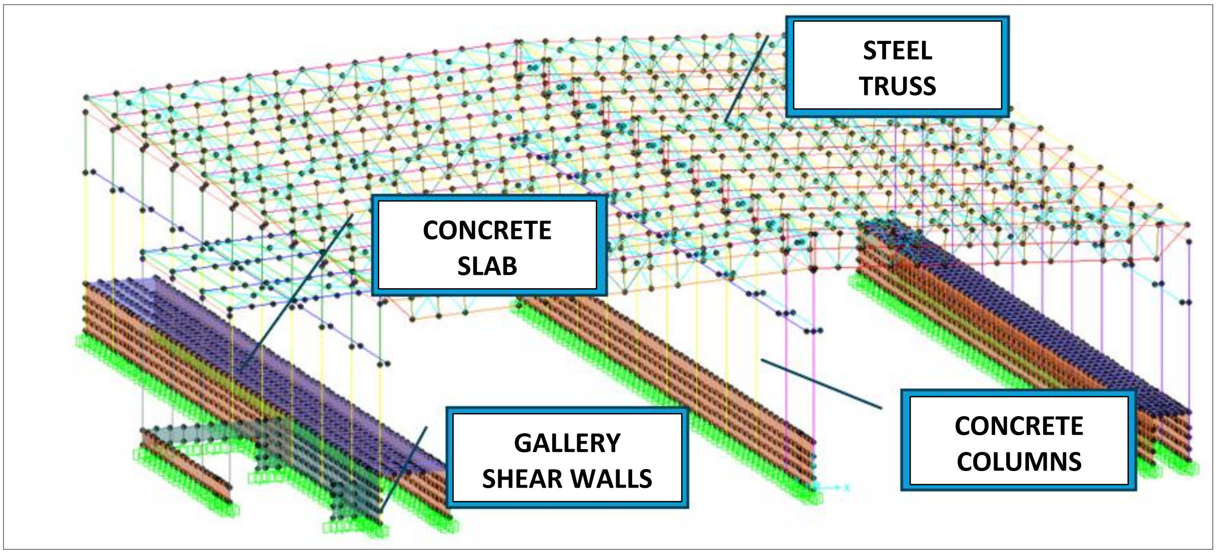

Fig. 5. Finite Element Model of Structure (SAP2000, 2021)

2.2. Result Review of Linear Finite Element Models

Table 1 shows the summary of certain results of the finite element model for two identical buildings with and without solar panels. Here, T_p indicates the dominant period in both directions, and drift indicates the maximum lateral relative displacements. While the addition of solar panels increases the seismic mass of a structure, it causes an increase in the base shear force and also causes a decrease in the base shear force due to the period shift. When Table 1 is examined, it is seen that the dominant period in the x direction does not change much with this addition, while the dominant period in the y direction is extended. For this reason, the base shear force in the x direction has increased, while it has decreased in the y direction. From here, it is expected that there will be very large changes in the base shear forces acting on the columns whose performance levels are important in buildings in which seismic loads are fully resisted by single-story frames with columns hinged at top. The decrease in the base shear force is not very important, but it is predicted that the increase in one direction may worsen the performance level of the elements located especially at the boundaries. When the lateral drift ratios are examined, a striking result emerges. When the base shear forces and dominant periods are close to each other, it is seen that the building with solar panels is shifted to the negative side in lateral drifts. The reason for this is that a very large mass is added to the weight of the roof with solar panels, which causes the upper end of the columns to displace more. This structure was evaluated with this method because it meets the performance analysis criteria with the linear calculation method defined in 15.5.3 of regulation (TBDY, 2019). The most important factor determining the performance of a column in this method is lateral drift. Therefore, due to the two determinations made at the end of this paragraph, in case a solar panel is added to the roof of an existing industrial structure, a performance analysis must be performed and if necessary, retrofit must be made.

Table 1. Summarized Information for Industrial Building’s Model with/without Solar Panels

Solar Panels	$T_p(x)$	$T_p(y)$	Base Shear-X	Base Shear-Y	Drift-X	Drift-Y	Average Steel PMM Ratio
With	0.8165s	0.7173s	5263 kN	5982 kN	1.75%	1.13%	0.44152
Without	0.8165s	0.6952s	5198 kN	6101 kN	1.19%	0.95%	0.42937

Figure 6 shows the Steel PMM Ratios of Roof Elements (SAP2000, 2021). According to the results, all roof elements in both structures meet the strength requirements and do not exceed the deflection limits. However, the 20 kg/m^2 increase in dead load caused small increases in the PMM ratios of many elements. According to Table 1, the average PMM ratio of the structure without solar panels is 0.42937, while the average PMM ratio of the structure with solar panels is 0.44152.

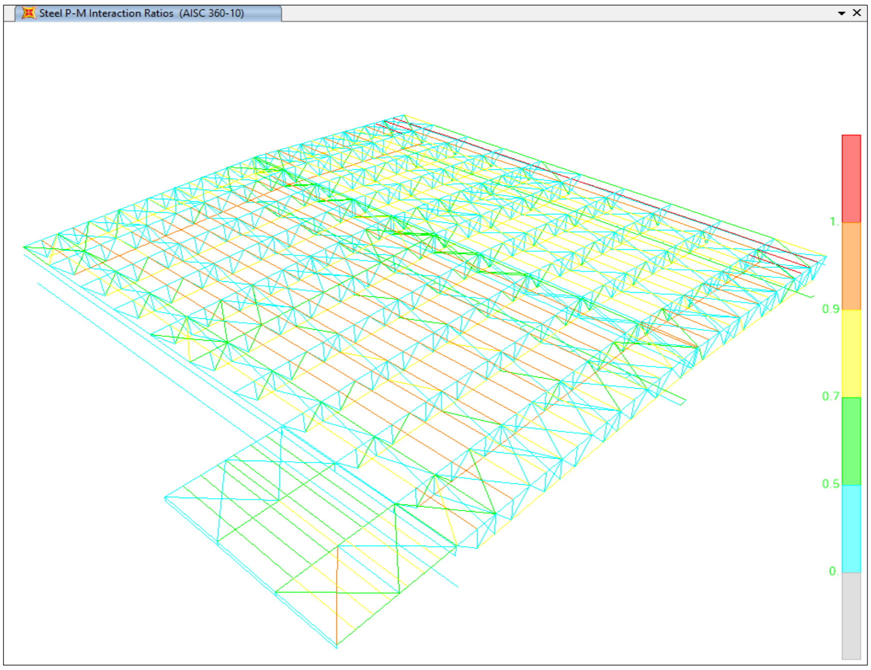

Fig. 6. Steel PMM Ratios of Roof Elements (SAP2000, 2021)

3. Performance based assessment of industrial building with/without solar panels

Since the structure is an existing building, all material research was carried out according to regulation (TBDY, 2019). Enough cores were taken, and the average concrete compressive strength was found to be 40.29 MPa. It was determined that the reinforcement realization rate was 1 with destructive and non-destructive examinations. In addition, it was seen in the stripping that the reinforcement was ribbed. The building's survey was checked, and it was seen that it was exactly compatible with the static project designed in 2014. Comprehensive knowledge level is accepted. Performance analyses of the structure were made by considering all the information.

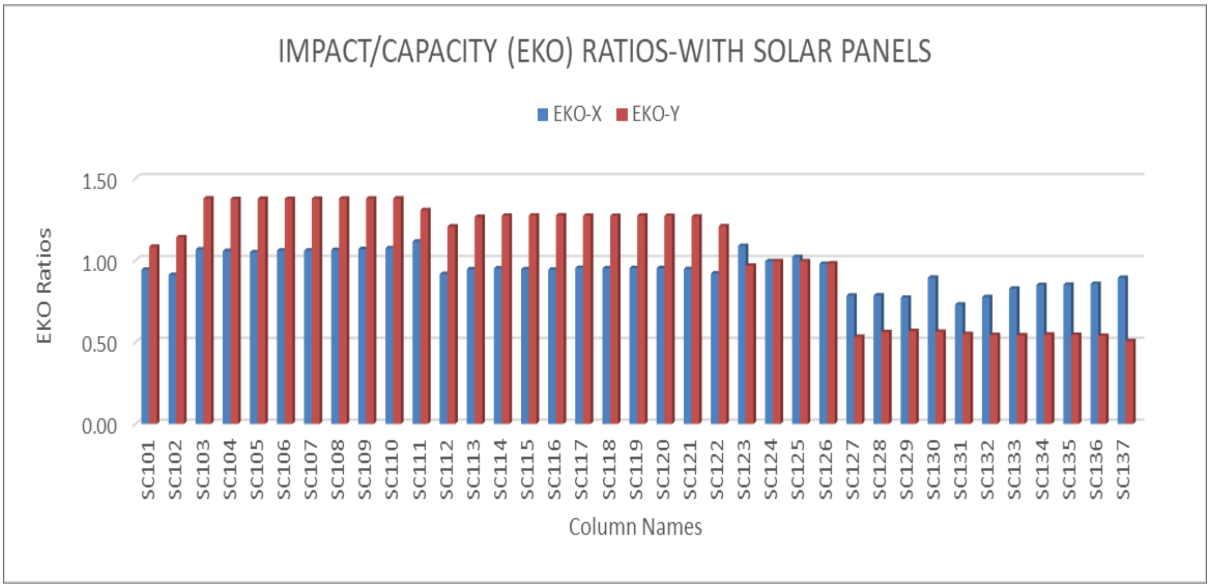

Fig. 7. EKO (Impact/Capacity) Ratios of Column Elements in Model with Solar Panels (Excel 2022)

The impact/capacity ratios, heights, and absence of B3 irregularity of the structures provided the linear performance analysis conditions. When the situation without solar panels was compared with the situation with them, it was seen that both structures provided the controlled damage performance level. In addition, no element was brittle in the shear force control. In this section, the EKO ratios of the elements were compared and presented in Figure 7 and 8 for both structures.

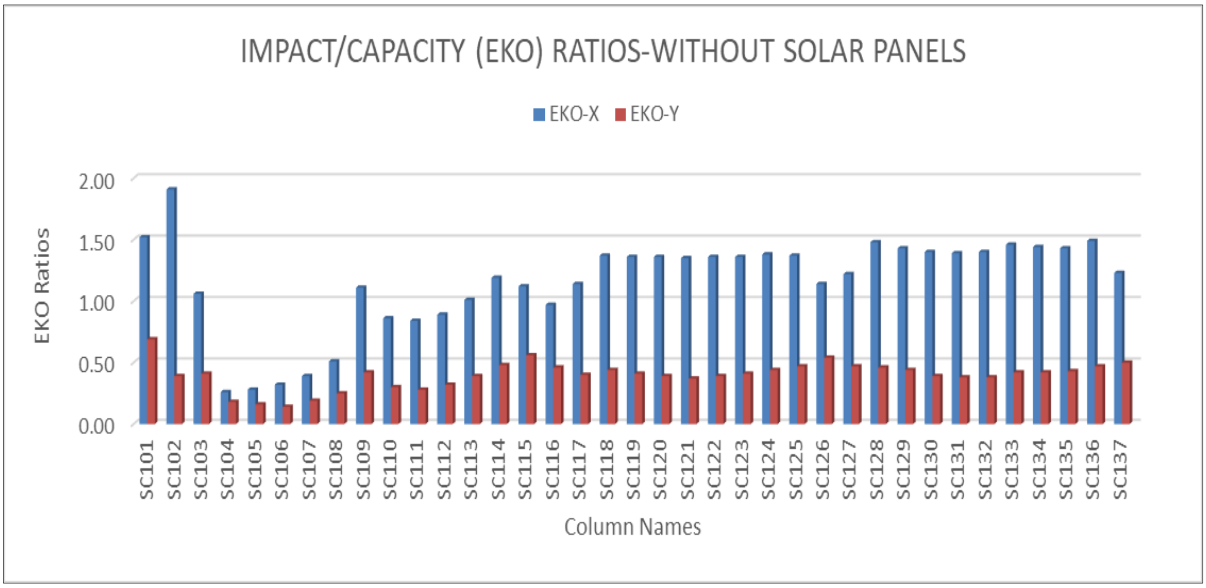

Fig. 8. EKO (Impact/Capacity) Ratios of Column Elements in Model without Solar Panels (Excel 2022)

Table 2 shows the summary of column damage levels where Table 3 illustrates the shear force ratio of columns passing into advanced damage zone to total shear force. In tables IO, LS, CP and CZ refer to immediate occupation, life safety, collapse prevention and collapse damage zones successively. Both structures satisfy the conditions for controlled damages performance level. According to regulation (TBDY, 2019) 15.8.4 (b), the total contribution of vertical elements in the collapse prevention zone to the total shear force carried by the vertical elements on each floor must be less than 20%. In the model without panels, there is no element in this damage zone, but in the model with panels, there are eleven columns in this zone in y direction. So, Table 3 is given below in order to show this limit which is 12.76% lower than 20%. In x direction all elements in both models are in the IO and LS zones.

Table 2. Summary of column damage levels

Solar Panels	Direction	Total Number	IO	LS	CP	CZ	Performance Level
With	X	37	11	26	0	0	Controlled Damage
	Y	37	11	15	11	0	Controlled Damage
Without	X	37	12	25	0	0	Controlled Damage
	Y	37	11	26	0	0	Controlled Damage

Table 3. Shear force ratio of columns passing into advanced damage zone to total shear force

Columns	Direction	V_i (kN)	SV_i (kN)	SV_{It} (kN)	SV_i/SV_{iT}
SC101	Y	533.287	2196.5	17222.0	%12.76
SC102	Y	57.979			
SC103	Y	137.227			
SC104	Y	147.124			
SC105	Y	148.667			
SC106	Y	148.879			
SC107	Y	148.855			
SC108	Y	147.618			
SC109	Y	137.639			
SC110	Y	56.613			
SC111	Y	532.614			

4. Conclusions

With respect to the results obtained from this study, the conclusions are summarized below:

- Average EKO ratios of columns in model without solar panels are 1.16 in the x direction, 0.41 in the y direction; are 0.91 in the x direction, 1.07 in the y direction in model with solar panels. They are lower than 3 which is defined as linear calculation method boundary in regulation (TBDY, 2019) 15.5.3 article. In x direction values are close to each other, however in y direction the values in the model containing solar panels are greater than the other model due to base shear increase as expected.
- When we look at the damage conditions in the columns, it is seen that 11-12 columns in both models in the x direction have IO damage, while the remaining columns remain in LS damage zone. In the y direction, the numbers are the same as in the x direction in the model without panels, while in the y direction with solar panels, it is seen that 11 columns are in IO damage level, 15 columns are in LS zone, and 11 columns are in CP level. Since this building is relatively new, it may have provided controlled damage performance levels, but in structures built in older years with low material quality, the desired performance level could not be achieved, and serious damages could have occurred.
- Changes in EKO values, element damage status obtained from performance analysis, and period, base shear force, drift and average PMM values obtained from linear analysis reveal the fact that structures where solar panels are placed must be subjected to a new seismic assessment. Retrofit work may be required to eliminate deficiencies that may occur after solar panel usage.

Critical evaluation of empirical and analytical models for predicting the behaviour of FRP-confined concrete

Nisreen Salameh[1], Raafat El-Hacha*[1]

[1] *University of Calgary, Department of Civil Engineering, 2500 University Drive NW, Calgary, Alberta, Canada*

Abstract. This paper presents a comprehensive evaluation of empirical and analytical models used to predict the compressive behaviour of Fibre Reinforced Polymer (FRP)-confined concrete cylinders subjected to uniaxial compression. The study compares theoretical predictions with experimental data, with particular emphasis on ultimate axial strength, ultimate axial strain, and the overall stress–strain behaviour of confined concrete. Seven widely recognized FRP confinement models are investigated, including the empirical models proposed by Fardis and Khalili (1982), Toutanji (1999), Lam and Teng (2003), Berthet et al. (2005), and Fahmy and Wu (2010), as well as the analytical models developed by Spoelstra and Monti (1999) and Teng et al. (2007). The findings reveal notable disparities in predictive accuracy across models, underscoring the importance of selecting confinement models that align with the specific material properties and confinement configurations in question. By identifying the strengths and limitations of each model, this study offers valuable guidance for their practical application in structural design and contributes to the broader understanding of the mechanical behaviour of FRP-confined concrete.

Keywords: FRP-confined concrete; Compressive behaviour; Empirical and analytical models; Ultimate axial strength; Ultimate axial strain

---

1. Introduction

The application of Fiber Reinforced Polymer (FRP) composites for the confinement of concrete has received considerable attention due to the significant improvements in compressive strength and ductility that it offers. Over the past few decades, various empirical and analytical models have been developed to predict the behaviour of FRP-confined concrete. These models aim to capture the complex interaction between the FRP jacket and the concrete core under axial loading, providing critical insights for structural design and analysis.

Empirical models, such as those developed by Fardis and Khalili (1982), Toutanji (1999), and Lam and Teng (2003), derive their predictive expressions from experimental data specific to their respective studies. On the other hand, analytical models, including those by Spoelstra and Monti (1999) and Teng, Yu and Wong (2007), incorporate theoretical frameworks to simulate the confinement effects. Despite their contributions, these models often exhibit varying degrees of accuracy, particularly when predicting the ultimate axial strength and strain of FRP-confined concrete.

This study focuses on evaluating the performance of these existing models by critically comparing their theoretical predictions against experimental results obtained from 12 sets of concrete cylinders confined with Carbon Fiber-Reinforced Polymer (CFRP) and Steel Fiber-Reinforced Polymer (SFRP). The analysis examines the ultimate axial strength, ultimate axial strain, and overall stress-strain response, aiming to identify the limitations of the current models and provide recommendations for their application in structural design.

2. Methodology

2.1. Review of existing confinement models

The performance of various empirical/analytical confinement models are analyzed in this section to assess their accuracy in predicting the ultimate axial strength, ultimate axial strain and the stress-strain behaviour of CFRP- and SFRP-confined concrete cylinders. The confinement models under consideration are summarized in Table 1. Each model is assigned a unique designation ID, as shown in the second column of Table 1 and will be used hereafter when referring to these models in any discussion that follows. The confinement effectiveness coefficient, k_l, adopted by each model is summarized in Table 2.

Table 1. Summary of empirical/ analytical confinement models

Models	Model Designation	Theoretical f'_{cu}	Theoretical ε_{cu}
Fardis and Khalili (1982),	FK-R	$f'_{cu} = f'_{co}\left[1 + 4.1\frac{f_{lu}}{f'_{co}}\right]$	$\varepsilon_{cu} = 0.002 + 0.001\frac{E_{frp}t_{frp}}{Df'_{co}}$
Fardis and Khalili (1982),	FK-N	$f'_{cu} = f'_{co}\left[1 + 3.7\left[\frac{f_{lu}}{f'_{co}}\right]^{0.86}\right]$	$\varepsilon_{cu} = 0.002 + 0.001\frac{E_{frp}t_{frp}}{Df'_{co}}$
Toutanji (1999)	TTJ	$f'_{cu} = f'_{co}\left[1 + 3.5\left(\frac{f_{lu}}{f'_{co}}\right)^{0.85}\right]$	$\varepsilon_{cu} = \varepsilon_{co}\left[1 + (310.57\varepsilon_{frp} + 1.9)\left(\frac{f'_{cu}}{f'_{co}} - 1\right)\right]$
Lam and Teng (2003)	LT	$\frac{f'_{cu}}{f'_{co}} = 1 + 3.3\frac{f_{lu,a}}{f'_{co}}$	$\frac{\varepsilon_{cu}}{\varepsilon_{co}} = 1.75 + 12\left[\frac{f_{lu,a}}{f'_{co}}\right]\left[\frac{\varepsilon_{frp,a}}{\varepsilon_{co}}\right]^{0.45}$
Berthet et al. (2005)	BFH	$f'_{cu} = f'_{co} + k_l f_{lu}$ $k_l = 3.45, 20 \le f'_{co} \le 50\ MPa$ $k_l = \frac{9.5}{(f'_{co})^{1/4}}, 50 \le f'_{co} \le 200\ MPa$	$\varepsilon_{cu} = \varepsilon_{co} + \frac{(\varepsilon_{frp} - v_c\varepsilon_{co})}{\gamma}$
Fahmy and Wu (2010)	FW	$f'_{cu} = f'_{co} + k_l f_{lu}$ $k_l = 4.5{f_{lu}}^{-0.3}, f'_{co} \le 40MPa$ $k_l = 3.75{f_{lu}}^{-0.3}, f'_{co} > 40MPa$	$\varepsilon_{cu} = \frac{f'_{co} - f_o}{E_2}$ $E_2 = m_2(245.61{f'_{co}}^{m_1} + 0.6728E_l)$ $m_1 = 0.5, m_2 = 0.83\ if\ f'_{co} \le 40\ MPa$ $m_1 = 0.2, m_2 = 1.73\ if\ f'_{co} > 40\ MPa$
Spoelstra and Monti, Exact (1999)	SM-E	$f'_{cu} = E_{sec,u}\varepsilon_{cu}$	$\varepsilon_{cu} = \varepsilon_{cc}\left[\frac{E_{sec}[E_{co} - E_{sec,u}]}{E_{sec,u}[E_{co} - E_{sec}]}\right]^{1-\frac{E_{sec}}{E_{co}}}$
Spoelstra and Monti, Approx. (1999)	SM-A	$\frac{f'_{cu}}{f'_{co}} = 0.2 + 3.0\left(\frac{f_{lu}}{f'_{co}}\right)^{0.5}$	$\frac{\varepsilon_{cuc}}{\varepsilon_{co}} = 2 + 1.25\frac{E_c}{f'_{co}}\left(\frac{f_{lu}}{f'_{co}}\right)\varepsilon_{lu}^{\ 0.5}$
Teng et al. (2007)	THY	$\frac{f'_{cuc}}{f'_{co}} = 1 + 3.5\frac{f_l}{f'_{co}}$	$\frac{\varepsilon_{cuc}}{\varepsilon_{co}} = 1 + 17.5\frac{f_l}{f'_{co}}$
CAN/CSA S806-12		$f'_{cu} = 0.85f'_{co} + k_l k_c f_{lu}$ $k_l = 6.7(k_c f_{lu})^{-0.17}$ $f_{lu} = \frac{2t_{frp}\phi_{frp}f_{frp}}{D} \le \frac{2t_{frp}0.006E_{frp}}{D}$	-
CAN/CSA S6-14		$f'_{cu} = f'_{co} + 2f_{lu}$ $f_{lu} = \frac{2\phi_{frp}t_{frp}f_{frp}}{D}$	-

For clarity and consistency in the notation and symbols used in this table, readers are encouraged to consult the original work, as referenced herein, for comprehensive definitions and context.

All the aforementioned confinement models, except SM and THY, are empirical models in which the ultimate axial strength and ultimate axial strain prediction expressions were derived based on their author's own experimental data sets. Furthermore, only four of these models have expressions to predict the entire axial stress-axial and lateral strain curve. These four models are TTJ, BFH, SM and THY models. The rest propose expressions for the axial stress-axial strain curve only.

The two models of FK are the only models, out of the nine, which was developed based on models developed for steel-confined concrete. SM and THY models were based on an actively-confined concrete model by Popovics.

TTJ and BFH utilized a model originally developed by Sargin and modified by Ahmad and Shah for concrete confined by steel spiral, while LT based their model on the four parameter curve by Richard and Abbot (1975).
Of the nine confinement models reviewed in this section, five models, namely, FK-R, LT, BFH, FW, and THY models, have an ultimate strength expression that is based on an expression originally proposed by Richart, Brandtzaeg, and Brown (1928). The strength enhancement coefficients,k_l ,used in the models are summarized in Table 2. The last two FRP confinement models in the table are adopted by the Canadian building code (CSA S806-12) and bridge code (CSA S6-14). Both models are based on a model originally developed by Richart, Brandtzaeg, and Brown (1928), however, CAN/CSA S806-12 adopts a modified version of the model that was proposed by Saatcioglu and Razvi (1992). Neither code has yet adopted any model for ultimate axial strain prediction.

Table 2. Strength enhancement coefficient, k_l, for FRP-confined concrete

Model	Confinement Effectiveness Coefficient k_l
Fardis and khalili (1982), (Richart)	4.1
Farids and Khalili (1982), (Newman)	$3.7\left(\frac{f_{lu}}{f'_{co}}\right)^{-0.14}$
Toutanji (1999)	$3.5\left(\frac{f_l}{f'_{co}}\right)^{-0.15}$
Lam and Teng (2003)	3.3
Berthet et al. (2005)	$k_l = 3.45, 20 \leq f'_{co} \leq 50\ MPa$ $k_l = \frac{9.5}{(f'_{co})^{1/4}}, 50 \leq f'_{co} \leq 200\ MPa$
Fahmy and Wu (2010)	$k_l = 4.5{f_{lu}}^{-0.3}, f'_{co} \leq 40MPa$ $k_l = 3.75{f_{lu}}^{-0.3}, f'_{co} > 40MPa$
Teng et al. (2007)	3.5

3. Results and discussions

3.1. Performance analysis of confinement models

The experimental results versus the theoretical predictions of the various confinement models are first summarized and tabulated for each confinement configuration. The performance of each of these models is then evaluated graphically by plotting the experimental results versus the corresponding theoretical values, with the 45˚ reference line representing the exact match between experiment and theory is also plotted for comparison. Points falling above the 45˚ line imply that the theoretical predictions are lower than the experimental values and, hence, indicate conservative predictions while points falling below the line imply that the theoretical predictions are higher than the experimental values and hence indicate unconservative predictions.

3.1.1. Models' performance in prediction of f'_{cu}

The experimental results versus the theoretical predictions of the ultimate axial strength, f'_{cu} for empirical and analytical confinement models are reported respectively in Table 3 and Table 4. The experimental results versus the theoretical predictions of the ultimate axial strength, f'_{cu} for building and bridge Canadian design codes are reported in Table 5.

Fig. 1. Empirical models' performance in predictingf'_{cu}/f'_{co}

The FK models generally overestimate the ultimate axial strength of FRP-confined concrete, with FK-R showing particularly poor accuracy for cylinders with higher lateral confinement pressure ratios due to its use of a high confinement effectiveness ratio more suited for actively confined concrete. In contrast, FK-N offers better predictions. Models such as TTJ, LT, BFH, and THY provide accurate predictions across different confinement levels, whereas FW and SM-A models significantly underestimate the ultimate axial strength. The SM-E model performs well for weakly and moderately confined cylinders but shows high prediction errors for highly confined ones, unlike the THY model, which accurately predicts the strength of highly confined cylinders but slightly overestimates it for weaker confinement levels.

The overall accuracy of the empirical, analytical and design codes confinement models in predicting the ultimate axial strength is summarized in Table 6 and plotted in Figure 4. The average, standard deviation (SD) and coefficient of variation (COV) of the absolute average error in the prediction are shown for the whole experimental set and for the two distinctive sets of CFRP- and SFRP-confined concrete cylinders, providing insights into the models' predictive performance across different confinement configurations.

Fig. 3. Canadian codes confinement Models' performance in predicting f'_{cu}/f'_{co}

Figures 4(a) and (b) illustrate the accuracy of various confinement models in predicting the ultimate axial strength of FRP-confined concrete cylinders. The models by BFH, LT, and TTJ demonstrate the highest accuracy for the whole set, with average absolute errors of 3.4%, 4.5%, and 5.6%, respectively. Notably, BFH, LT, TTJ, and THY models perform better for SFRP-confined cylinders, while FK-R, SM-E, SM-A, and FW excel in predicting CFRP-confined cylinders, highlighting the influence of lateral confinement ratio sensitivity. Both Canadian design codes, CAN/CSA S6-14 and CAN/CSA S806-12, underestimate the ultimate axial strength, with S6-14 slightly outperforming S806-12. However, S6-14 lacks provisions for SFRP sheets, limiting its applicability. The higher errors for SFRP-confined cylinders in S806-12 are attributed to its calibration based on CFRP, GFRP, and AFRP data. These findings emphasize the need for refinement in both codes to improve predictions for SFRP-confined concrete.

3.1.2. Models' Performance in Prediction of ε_{cu}

The experimental results versus the theoretical predictions of the ultimate axial strain, ε_{cu} for empirical and analytical confinement models are reported respectively in Table 7 and Table 8.

The experimental and theoretical ultimate axial strain are normalized by dividing them by the unconfined concrete strain at peak values and compared the results for various empirical and analytical models in Figure 5 and Figure 6, respectively. The analysis revealed that prediction errors for ultimate axial strain, ε_{cu} are significantly larger than those for ultimate axial strength, f'_{cu}, consistent with previous research. Among the nine models evaluated, the SM-E and THY models performed well for weakly and moderately confined concrete, with SM-E underestimating and THY overestimating the strain for highly confined cylinders. The TTJ model excelled for highly confined cylinders but underestimated strain for weaker confinement. Other models generally performed poorly, often underestimating the strain.

The overall accuracy of the models in predicting ultimate axial strain is summarized in Table 9, and shown in Figure 7 with the metrics including the average, SD, and COV of the absolute average error for both CFRP- and SFRP-confined concrete cylinders.

It can be concluded that the models that exhibit superior performance when it comes to ε_{cu} prediction are SM-E, TTJ and SM-A, which have average absolute errors respectively of 15.6%, 18.8% and 34%. All models seem to fail in predicting the ultimate axial strain with reasonable accuracy.

Figure 5. Empirical models' performance in predicting of $\varepsilon_{cu}/\varepsilon_{co}$

3.1.3 Axial stress-strain behaviour prediction

The performance of two empirical models, TTJ and BFH, and two analytical models, SM-E and THY, was assessed to predict the stress-strain behaviour of FRP-confined concrete cylinders. These four models were selected as they uniquely provide predictions for the entire axial stress-axial strain and axial stress-lateral strain responses. Other models under consideration were excluded from this evaluation as they only provide partial predictions.

The TTJ model, shown in Figure 8(a), demonstrated notable accuracy in predicting the transition point of the axial stress-lateral strain behaviour, particularly in terms of stress level and the radius of curvature at the transition. However, it exhibited significant limitations in predicting the axial stress-axial strain response. Specifically, it overestimated the radius of curvature at the kinking point and underestimated the ultimate axial strain, leading to inaccuracies in the overall response.

The BFH model, shown in Figure 8(b), effectively captured the experimentally observed upward-shift of the transition point as FRP lateral stiffness increased. Despite this, it tended to overestimate the axial stress-axial strain behaviour, particularly in highly confined cylinders, due to an overestimation of the stress at the transition point. Additionally, the model predicted the smallest radius of curvature at the kinking point, which aligned well with experimental data for weakly to moderately confined cylinders but was less accurate for highly confined cases.

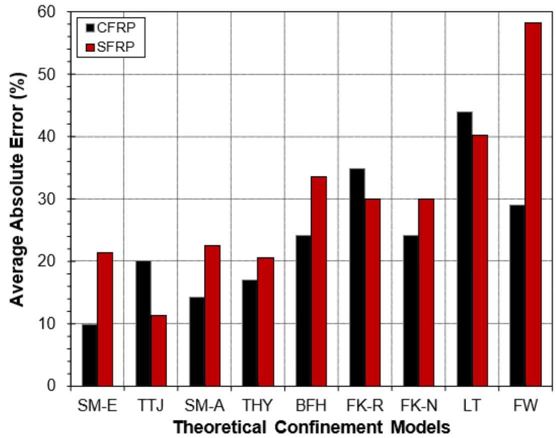
(a)



(b)

Fig. 7. Confinement models accuracy in εcu predictions for: (a) the whole experimental set (b) CFRP and SFRP experimental sets

Among the models evaluated, the SM-E model, shown in Figure 8(c), provided the most accurate predictions for weakly and moderately confined cylinders. It successfully captured key aspects of the stress-strain response, including the transition point, initial and final slopes, and ultimate stress and strain. However, the model significantly underestimated the overall stress-strain behaviour of highly confined concrete, highlighting its limitations under extreme confinement conditions.

The THY model, shown in Figure 8(d), while reasonably accurate overall, failed to capture the upward-shift of the transition point with increasing FRP jacket stiffness. It assumed the transition point occurred at stress levels close to unconfined concrete, which deviates from experimental observations. Nonetheless, the model accurately predicted the increase in the radius of curvature at the kinking point as lateral stiffness increased, contributing to its reasonable performance in predicting the overall stress-strain response.

This analysis underscores the variability in the predictive capabilities of empirical and analytical models across different confinement levels. While some models excel under specific conditions, others require refinement to improve their accuracy, particularly for highly confined concrete.

4. Conclusions

This study performed a comprehensive evaluation of widely used empirical and analytical models for predicting the compressive behaviour of FRP-confined concrete, including both CFRP and SFRP confinement systems. The models were assessed based on their ability to predict ultimate axial strength, axial strain, and full stress–strain behaviour. Comparative analysis with experimental data revealed significant variation in predictive accuracy among models and identified areas requiring refinement. The key conclusions are:

- Empirical models such as BFH, LT, and TTJ demonstrated the highest overall accuracy in predicting ultimate axial strength, with average absolute errors of 3.4%, 4.5%, and 5.6%, respectively.
- The TTJ and THY models provided reliable predictions across a range of confinement levels, particularly for SFRP-confined concrete, while FK-R and SM-A tended to over- or underestimate strength values significantly.
- The Canadian design codes (CAN/CSA S806-12 and S6-14) consistently underestimated ultimate axial strength, especially for SFRP-confined cylinders, due to a lack of calibration with SFRP data.
- Strain predictions showed higher variability than strength predictions across all models. While the SM-E and TTJ models achieved relatively lower average error (~15%), most models—including BFH and FW—underperformed for strain predictions, particularly under high confinement.
- Analytical models SM-E and THY showed better performance for moderately confined cylinders, but exhibited limitations in predicting the behaviour of highly confined concrete, especially in axial strain capacity.
- The TTJ and BFH models offered the best approximations for the stress–strain response of confined concrete, although each had limitations in capturing specific behaviours like curvature or transition points under high confinement.
- No single model demonstrated consistent accuracy across all performance metrics and confinement levels, reinforcing the need for model selection based on the specific type and level of confinement and for further refinement of existing models.
- This study highlights the necessity of refining design code provisions, particularly for SFRP confinement, and encourages the development of hybrid or adaptive models that can improve prediction accuracy for a broader range of FRP systems and concrete strengths.

Assessment of the effect of strengthening measures on seismic fragility curves in reinforced concrete structures

Yagmur Aras*[1], Rafet Sisman[1]

[1] *Yildiz Technical University, Department of Civil Engineering, 34420 Istanbul, Türkiye.*

Abstract. Earthquakes are among the most devastating natural disasters, causing substantial destruction to human life and the built environment. In recent years, the increasing frequency and intensity of seismic events worldwide have made it imperative to re-evaluate the seismic performance of existing building stock and to implement appropriate retrofitting measures where necessary. Structures located in high seismic risk zones are often found to be inadequate in terms of strength and ductility, particularly those constructed according to outdated design standards. In this context, performance-based seismic assessment methods play a vital role in ensuring life safety and minimizing economic losses in the event of an earthquake. This study investigates the seismic performance of an existing three-story reinforced concrete (RC) building using a two-dimensional (2D) frame model developed in SAP2000 software. The building's response to lateral loads was evaluated through a nonlinear static pushover analysis. Analysis results revealed that the original structure exhibited insufficient load-bearing capacity and deformation ability. To address these deficiencies, a retrofitting strategy involving column jacketing was proposed and implemented. Separate models were created for both the original and the retrofitted structure, and pushover analyses were conducted for each. Additionally, seismic fragility curves were developed to quantify the probability of damage at various limit states. The findings demonstrate a notable improvement in the seismic capacity of the retrofitted structure, with a significant reduction in damage probabilities, particularly at extensive and collapse-level damage states. This study highlights the effectiveness of column jacketing as a practical and efficient retrofitting technique for improving the seismic resilience of existing RC buildings.

Keywords: Seismic retrofit, Seismic vulnerability, Pushover analysis, Fragility curves, Seismic resilience.

1. Introduction

Earthquakes are among the most devastating natural disasters, causing sudden and widespread destruction. Due to its geographical location, Türkiye is situated on active fault lines and frequently experiences destructive earthquakes. Recent major events, such as the 2023 Kahramanmaraş earthquakes, have once again revealed the vulnerability of the country's existing building stock. The severe loss of life and property has underscored the critical importance of evaluating and improving the seismic safety of structures.

A significant portion of Turkey's building stock was constructed according to outdated seismic codes and often without adequate engineering supervision. Many of these structures exhibit poor construction quality, insufficient detailing, and inadequate material properties, making them highly susceptible to seismic damage. Particularly for older buildings, continuous evaluation is necessary due to factors such as the deterioration of material properties over time, exposure to environmental effects, engineering errors during design, deficiencies in inspection and control mechanisms, and evolving engineering standards (Avcı, 2025). Therefore, assessing the current performance of these buildings and implementing appropriate strengthening measures when necessary is of utmost importance for public safety.

One of the widely used methods for evaluating the seismic performance of existing structures is the pushover (static nonlinear) analysis. This method simulates the progressive nonlinear behavior of a structure under increasing lateral loads, revealing plastic hinge formations and performance levels. Based on the results of pushover analysis, fragility curves can be developed to estimate the probability of reaching various damage states under different levels of seismic intensity. This approach not only enables a detailed assessment of the current performance but also allows for evaluating the effectiveness of proposed strengthening strategies.

In this study, the seismic performance of a three-story reinforced concrete building with a two-dimensional frame system was analyzed using the SAP2000 software, and fragility curves were developed based on the obtained data. Subsequently, a strengthening strategy involving jacketing of columns was proposed, and the

* Corresponding author, E-mail: ygmurars@gmail.com

https://doi.org/10.31462/icearc2025_ce_eqe_090

building's performance was re-evaluated after the strengthening. Both conditions, before and after retrofitting, were compared to assess the improvements. The aim of this study is to contribute to the enhancement of seismic resilience in existing structures by proposing and evaluating practical strengthening methods.

This study seeks to contribute to the analytical evaluation of the seismic performance of existing buildings through the development of fragility curves. By comparing the structural behavior before and after retrofitting, it aims to provide objective data on the effectiveness of strengthening strategies. Thus, the study aspires to establish a scientific basis for improving the earthquake resilience of reinforced concrete structures and for mitigating potential seismic risks.

2. Materials and methods

In this study, the performance analysis of a 3-story reinforced concrete frame structure with a two-dimensional configuration is conducted using static pushover analysis. The analysis is performed using SAP2000, a widely used structural analysis software. The primary objective of this study is to investigate the behavior of the structure under lateral loads and to develop fragility curves for both pre- and post-strengthening conditions. The strengthening strategy involves the application of external insulation to the columns to improve the overall structural performance. All necessary models for the existing and strengthened conditions have been created and analyzed in SAP2000. Additionally, fragility curves have been developed to assess the structure's sensitivity under various loading conditions. The results obtained from these analyses will be compared to evaluate the effectiveness of the proposed strengthening method and to assess the extent to which the capacity of the existing structure can be increased.

2.1. Existing structure characteristics

In this section, the material properties and cross-sectional specifications of the modeled existing building are detailed. A three-story reinforced concrete structure with a two-dimensional frame system was modeled for the purposes of this study. Each story has a height of 3 meters, resulting in a total building height of 18 meters. The structure consists of three spans, with each span having a 6-meter bay width. The cross-sectional layout are presented in Fig. 1.

Given that the building is assumed to be an older structure, the material strengths and section dimensions were defined to reflect this condition. The concrete class was taken as C16/20. The material properties assigned to this concrete class are detailed in Table 1. The columns were modeled with cross-sectional dimensions of 30 cm × 30 cm, designed deliberately with a reinforcement ratio below the minimum code requirements to represent the deficiencies typical of aging structures. S220 grade reinforcing steel was used, with 6Ø12 mm longitudinal bars placed in each column. The stress-strain characteristics of concrete and reinforcing steel, intended for use in the structural behavior model, were obtained by modeling the beam and column cross-sections through the "Section Designer" tool in the SAP2000 (Computers and Structures, Inc., 2023) software. The cross-sectional and material properties of the columns are illustrated in Fig. 2 and Fig. 3. Additionally, the stress strain curve for C16/20 concrete is presented in Fig. 4.

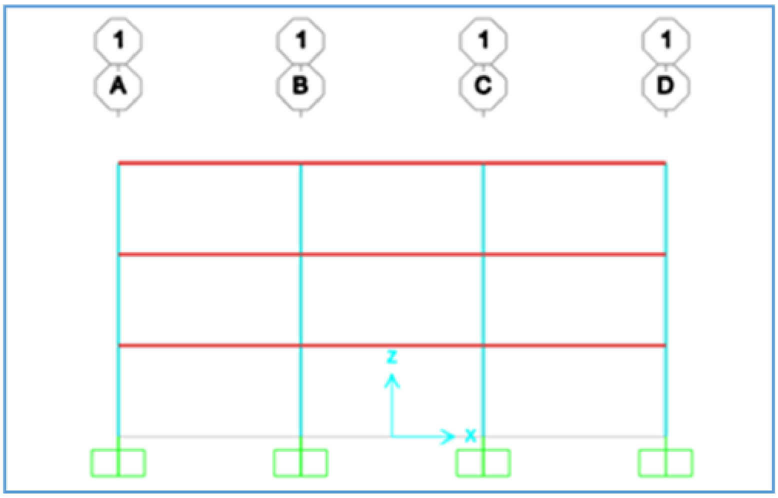

Fig. 1. The cross-sectional layout of the structure

Table 1. The material properties corresponding to C16/20 concrete and S220 reinforcement steel

Material	Parameter	Value
C16/20	Concrete Compressive Strength (f'$_c$)	16 Mpa
	Modulus of Elasticity	27000Mpa
S220	Minimum Yield Stress (F_y)	220 Mpa
	Minimum Tensile Stress (F_u)	340 Mpa

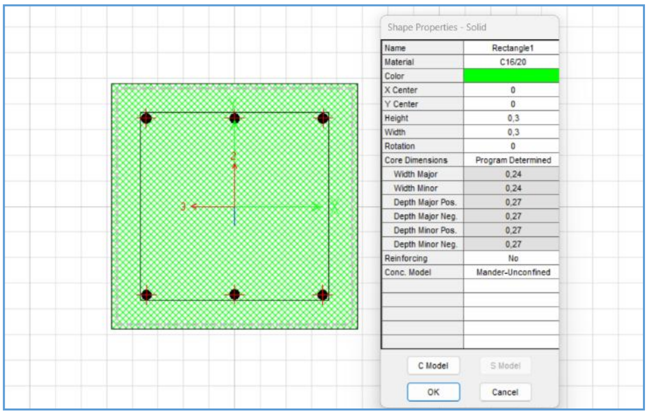

Fig. 2. Cross-sectional properties of the column

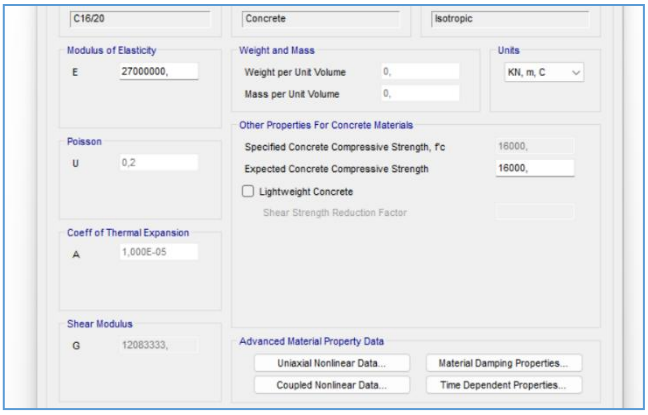

Fig. 3. Material properties of the column

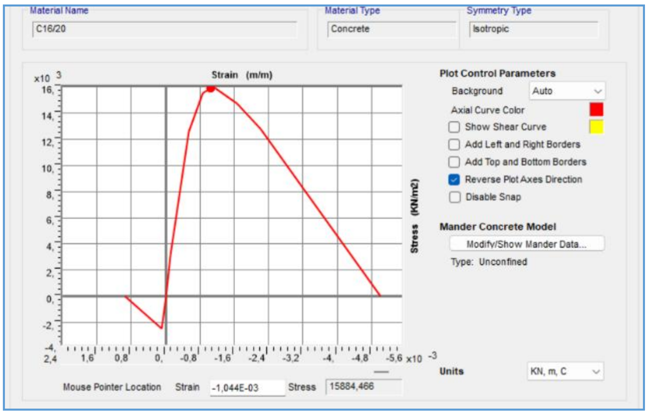

Fig. 4. The stress strain curve for C16/20

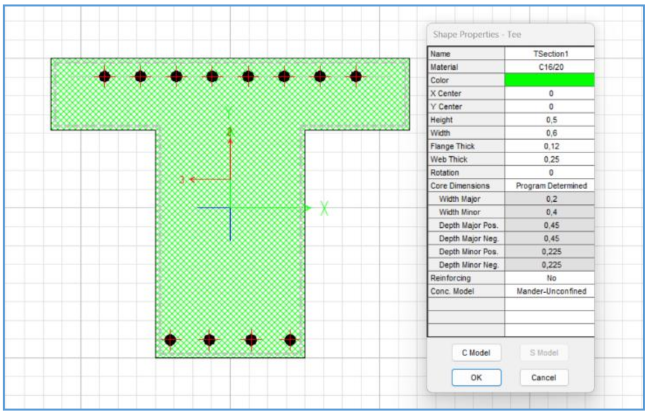

Fig. 5. Cross-sectional properties of the column

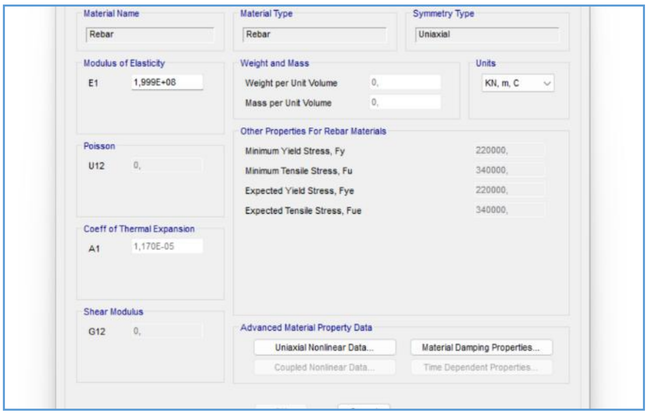

Fig. 6. Material properties of S220 stell

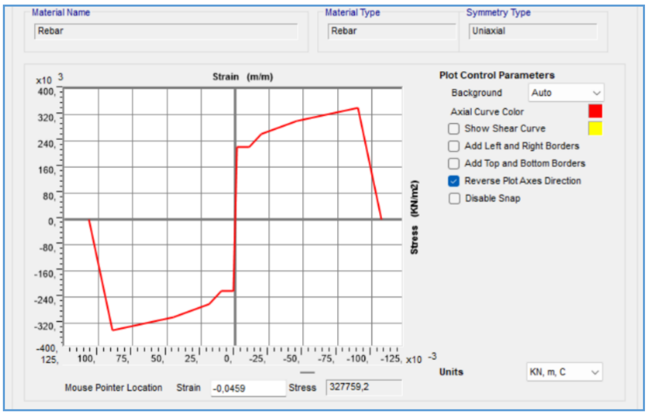

Fig. 7. The stress strain curve for S220

In the beam design, care was taken to ensure that the reinforcement ratio exceeded the minimum requirements. The beams were modeled as T-shaped sections, with an overall depth of 50 cm. The flange width was defined as 60 cm, and the web width as 25 cm. Similar to the columns, S220 grade steel was used for beam reinforcement, with twelve Ø18 mm longitudinal bars provided. Special attention was paid to avoiding a strong-beam weak-column configuration, and the beams were modeled accordingly. Furthermore, based on the assumption that each story carries an approximate total load of 360 kN, a uniformly distributed load of approximately 20 kN/m was applied to each beam element. The detailed cross-sectional and material properties of the beams are provided in Fig. 5. In addition, the material properties and the stress-strain curve for the S220 steel used as reinforcement are presented in Fig. 6 and Fig. 7, respectively.

2.2. Analysis of the existing structure

The existing structure was modeled in SAP2000 based on the properties described above, and its seismic behavior was assessed through a nonlinear pushover analysis. Furthermore, to simulate the nonlinear behavior of structural elements and to evaluate their responses when exceeding load-carrying capacities, plastic hinges were assigned to the load-bearing members. Since only flexural effects were considered in the beams, plasticity was assumed to occur solely around the bending moment axis (M3). In contrast, due to the combined effects of axial force and bending moments in the columns, P-M2-M3 plastic hinges were defined (Kırat, 2025). Considering these parameters, plastic hinges were assigned to the columns and beams in the SAP2000 program to model the plastic behavior of structural elements. The details of the hinge assignments are presented in Fig. 8 and Fig. 9.

After assigning hinges to the relevant sections, the necessary loadings for the pushover analysis have been established. For the nonlinear pushover analysis, a horizontal loading is applied in the X direction (PUSHX). In the first step, the pushover target was set to approximately 5% of the building's height. However, the pushover analysis was not completed up to this value. In such cases, as the value can be reduced to continue the analysis (Ekmen, 2005). In the pushover analysis, the target displacement was defined as approximately 0.45 m, corresponding to 5% of the total building height. However, the analysis terminated at a displacement level of approximately 0.20 m, indicating that the structure could not be pushed further due to numerical instability. This suggests that the structural system reached its collapse mechanism and lacked additional lateral load capacity. The pushover curve reveals a distinct peak followed by a sharp decline in base shear, demonstrating a significant reduction in lateral strength. This behavior is indicative of widespread plastic hinge formation and a subsequent loss of structural stability. The results clearly demonstrate the necessity for structural strengthening. Based on the analysis results, the necessity for structural strengthening was established. Additionally, the pushover curve obtained from the pushover analysis is presented in Fig. 10.

2.3. Properties of the retrofitted structure

In recent years, column jacketing has become a widely used strengthening technique for reinforced concrete buildings, especially those that do not meet current seismic design requirements. This method enhances both the axial and shear capacity of columns by increasing their cross-sectional area and improving confinement. According to studies in the literature, jacketed columns show significant improvements in ductility and energy dissipation capacity under seismic loading (Altun & Anıl, 2007; Sezen & Moehle, 2004). In this study, the retrofitting strategy involves reinforced concrete jacketing of the existing columns, aiming to improve the structural performance and ensure compliance with current code requirements.

According to the Turkish Earthquake Building Code (TBDY, 2018), the minimum confinement thickness for reinforced concrete columns should be 10 mm. All reinforced concrete column elements were jacketed with a 15 cm layer on all four sides. During the jacketing process, the plaster on the surface of the existing columns was removed and the surface was roughened to eliminate any remaining plaster residues. The surface was then cleaned using pressurized air to remove dust particles, and a bonding agent was applied between the existing and new concrete layers in order to enhance adherence. This procedure ensures monolithic behavior between the old and new concrete.

The retrofitted column model was developed using Section Designer. In older structures, the reinforcement in structural elements is often subjected to corrosion, leading to a reduction in cross-sectional area. Therefore, in strengthening calculations, the existing reinforcement in columns is typically not included in the analytical models. It is generally assumed that these reinforcements have lost their structural effectiveness (Karabacak, 2020). In this study, the existing column reinforcements were not included in the model, and C30/37 grade concrete was used for the jacketing. In addition, S420 grade reinforcing steel was utilized. The properties of these materials are summarized in Table 2. The columns, originally with cross-sectional dimensions of 30 cm × 30 cm, were enlarged to 60 cm × 60 cm through jacketing. Since no deficiencies were identified in the beam elements, no strengthening was deemed necessary. Therefore, the beams were modeled as shown in Fig. 5. In the retrofitted column elements, 32 reinforcing bars with a diameter of 16 mm were used. Furthermore, the cross-sectional and material properties of the retrofitted column is presented in Fig. 11 and Fig. 12. Additionally, the stress strain curve for C30/37 concrete is presented in Fig. 13.

Table 2. The material properties corresponding to C30/37 concrete and S420 reinforcement steel

Material	Parameter	Value
C30/37	Concrete Compressive Strength (f'_c)	30 Mpa
	Modulus of Elasticity	33000 Mpa
S420	Minimum Yield Stress (F_y)	420 Mpa
	Minimum Tensile Stress (F_u)	540 Mpa

2.4 Analysis of the retrofitted structure

In this section, the nonlinear pushover analysis of the retrofitted building was conducted and the results were evaluated. The retrofitted structural model was created by assigning the previously mentioned material properties to the relevant cross-sections. To simulate the nonlinear behavior of structural elements, plastic hinges were assigned to columns and beams. The details of the hinge assignments are presented in Fig. 15 and Fig. 16. As in the analysis of the existing structure, a lateral load was applied in the X-direction, and the analysis was completed. The resulting pushover curve is presented in Figure 17.

Fig. 15. Retrofitted column hinge detail

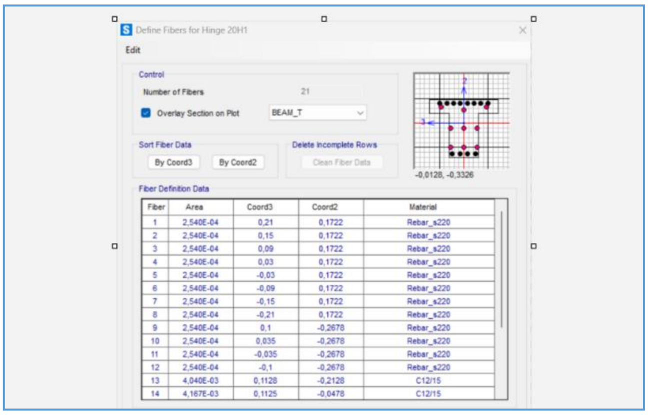

Fig. 16. Beam hinge detail

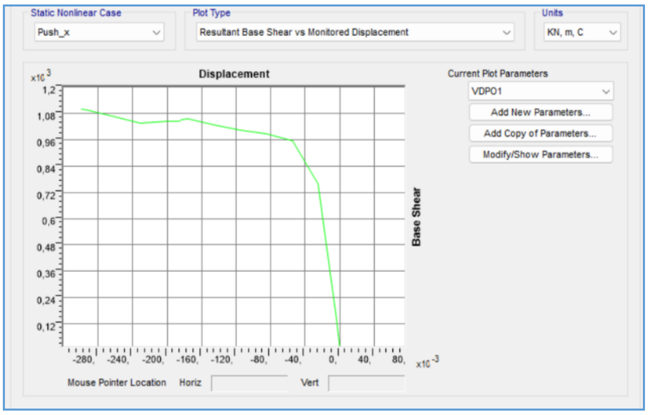

Fig. 17. Pushover curve of retrofitted structure

As illustrated in the pushover curve, the retrofitted structure demonstrates a significant increase in base shear capacity, indicating improved lateral load resistance. Furthermore, the structure exhibits enhanced deformation capacity, reflecting an increase in overall ductility. These results confirm that the applied strengthening strategy effectively improves the seismic performance of the building.

3. Comparison of fragility curves for existing and retrofitted structures

Fragility curves are widely used in seismic risk assessment to represent the probability of a structure reaching or exceeding a specific damage state under varying levels of ground motion intensity. These curves provide a quantitative basis for evaluating the vulnerability of structures and comparing the seismic performance of different structural configurations (Cornell et al., 2002; FEMA, 2009). In this study, fragility curves were developed for both the existing and the retrofitted building models using pushover analysis results. The comparison aims to highlight the improvements in seismic resilience achieved through the column jacketing technique.

3.1. Development of fragility curve for the existing structure

In this section, the process of deriving the fragility curves of the existing structure based on the results of the pushover analysis is explained. The roof displacements corresponding to the yield and ultimate points of the structure were obtained from the SAP2000 model and converted into spectral displacements as yielding displacement D_y and ultimate displacement D_u using Equation (1). For the determination of the fragility curves, four distinct damage states have been considered: slight damage, moderate damage, extensive damage, and complete damage. The standard deviations of the Sd values for these damage states, categorized by building height, have been determined (HAZUS, 2003). Using these values, the mean of the Sd values is obtained. All of these data are summarized in Table 2 and 3. The obtained spectral displacement values are substituted into Equation (2), thereby creating the fragility curves for the structure and the fragility curves for different damage states are illustrated in Fig. 18.

$$S_d = \frac{Roof\ displacement\ in\ first\ mode}{1st\ mode\ participation\ factor\ x\ 1st\ modemodal\ displacement\ roof} \tag{1}$$

$$P\left(\frac{DS}{Sd}\right) = \emptyset\left(\frac{Ln(Sd)-Ln(\lambda)}{\beta}\right) \tag{2}$$

Table 2. Values of the D_y and D_u

	Roof Displacement (m)	D
Yield point	0,0164	0,020676
Ultimate Point	0,2	0,054007

Number	Damage State	Displacement	Mean of S_d (in)	Standart Deviation of S_d (in)
1	Slight	$0.7D_y$	0.569811024	0.81
2	Moderate	D_y	0.814015748	0.84
3	Extensive	$D_y + 0.25\ (D_u - D_y)$	1.142076772	0.86
4	Complete	D_u	2.126259843	0.81

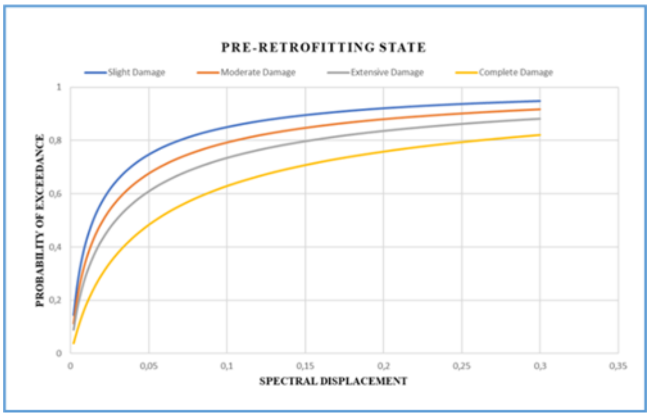

Fig. 18. Fragility curve of existing structure

3.2. Development of fragility curve for the retrofitted structure
In this section, the fragility curves for the strengthened structure have been derived using Equation (1) and Equation (2). The procedures for obtaining these curves are the same as those described in the previous section. Since the yield and ultimate displacements change after strengthening, the spectral displacements have been recalculated. The calculated displacement values are summarized in Table 4 and 5. The obtained spectral displacement values are substituted into Equation (2), thereby creating the fragility curves for the structure and the fragility curves for different damage states are illustrated in Fig 19.

Table 4. Values of the D_y and D_u

	Roof Displacement (m)	D
Yield point	0.0215	0.034858

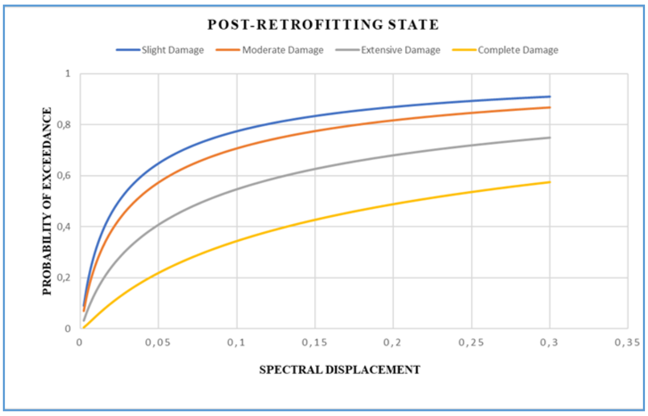

Fig. 19. Fragility curve of retrofitted structure

4. Conclusion

This study aimed to evaluate the impact of retrofitting interventions on the seismic fragility of a reinforced concrete frame structure. A comparative analysis was conducted by comparing the fragility curves of the structure before and after retrofitting. As an illustrative example, the spectral displacement level of 0.15 m was selected to observe how the probability of exceeding various damage states changed due to retrofitting. The results regarding the damage probabilities at this displacement level are as follows:

- The probability of exceeding the slight damage state was approximately 90% before retrofitting and reduced to around 85% after retrofitting. This minor decrease suggests that the retrofitting intervention had limited influence on mitigating low-level damage.
- For the moderate damage state, the probability of exceedance decreased from about 85% in the pre-retrofitting condition to approximately 78% post-retrofitting. This result indicates a modest improvement, implying that the retrofitting provided some level of reduction in the likelihood of moderate damage.
- In the case of extensive damage, a more noticeable change was observed, as the exceedance probability dropped from nearly 80% before retrofitting to around 65% after retrofitting. This reflects the effectiveness of the intervention in significantly reducing the probability of severe structural damage.
- The most significant improvement was observed in the complete (collapse) damage state, where the probability of exceedance at 0.15 m spectral displacement fell from approximately 70% before retrofitting to about 45% afterward. This substantial reduction demonstrates the critical role of retrofitting in enhancing the structural resilience and minimizing the risk of collapse under seismic excitation.
- Overall, these results demonstrate that retrofitting, applied via jacketing, significantly reduces the likelihood of severe damage and collapse, thereby greatly improving the seismic performance and durability of the structure.

Investigation of the non-linear design parameters of steel moment frames at different seismic sites in Turkey

Salah Eddine Hamadi *[1], Serkan Bekiroğlu [1]

[1] Yıldız Technical University, Department of Civil Engineering, İstanbul, Türkiye

Abstract. Turkey has a high seismicity and a considerable number of densely populated cities that are located along active faults. This paper investigates the nonlinear design parameters of steel moment frames at different sites in Turkey to evaluate the proportionality between the design parameters of the structure and those of the spectrum with the aim of enhancing the building design. For this purpose, steel moment frames are modeled using SAP2000; all the systems have the same characteristics except the span to height ratio. Then, the capacity spectrum method based on the ATC-40 procedure is performed to calculate the nonlinear behavior parameters for each system, including the effective damping ratio, stiffness ratio, ductility and reduction factor. Additionally, four different demand spectra that include different elastic design spectrum characteristics are used, precisely, the horizontal elastic design acceleration spectrum corner period T_B and the peak ground acceleration (PGA). Afterward, the comparison of the results yields substantial findings regarding the nonlinear behavior of the steel moment frame and the overall building design. This paper provides significant information to the designers about the structural behavior in terms of design parameters. In addition, it offers very important recommendations for researchers to conduct more relevant studies to develop new practical approaches to optimize the building design.

Keywords: Nonlinear behavior parameters; Steel moment frame; Design spectrum parameters; Capacity spectrum method; Reduction factor

1. Introduction

Turkey has a high seismicity rate and a considerable number of densely populated cities that are located along active faults. On February 6, 2023, a series of earthquakes occurred in the Eastern Anatolia region, resulting in varying degrees of damage to various types of buildings and significant human victims. It is worth noticing that the Northwestern region of Turkey is particularly vulnerable to large-scale seismic events(Vuran et al., 2024; Aydin et al., 2025). In this regard, enhancing the design process of the building is imperative to avoid the undesirable drawbacks from both the life safety and economic perspectives.

There are several methods of analyzing the building for the purpose of design. Among them, nonlinear time history analysis has been demonstrated to produce the most accurate results. However, conducting this type of analysis takes a long time and requires precise modeling and interpretation of results, which can present challenges in practical design(Izadinia et al., 2012; Loulelis et al., 2018). In response to these challenges, various simplified methods are used in the codes to design buildings through linear analysis, where the nonlinear behavior of the building is taken in consideration through constant value known as the reduction factor (Loulelis et al., 2018; Boussa et al., 2022). The reduction factor reduces the elastic design spectrum to inelastic design spectrum, in other words, reducing the base shear in the building (Loulelis et al., 2018; Hassan, 2022). In general, the value of the reduction factor is determined based on the resistant system type and certain code specifications (Hassan, 2022; Loulelis et al., 2018). In reality, the value of the reduction factor is proportional to several conditions, making its determination a significant challenge(Boussa et al., 2022). Since the 1960s, a substantial volume of experimental and numerical studies has been conducted to ascertain the values of the reduction factor employed in the design. These studies have considered the site conditions, the level of ground motion, the characteristics of structural systems (Hassan, 2022).

The structure has several types of resisting systems used to withstand seismic forces. The steel moment frames are widely used due to the advantages of the high ductility capacity, their architectural flexibility, and simple applied construction (Özkula, 2023; Yılmaz & Bekiroğlu, 2023). However, the steel moment frames can be exposed to significant damage in cases of severe earthquakes, as was observed in the 1994 Northridge and 1995 Kobe earthquakes (Miller, 1998; Mahin, 1998; Nakashima et al., 1998; Watanabe et al., 1998). This event

encourages a rigorous investigation of the behavior of steel moment frames. The seismic resistant steel frame has been studied by several researchers, Özhendekci et Özhendekci, 2012 mentioned that the span to height approximately 2 is suitable for both the steel moment frames capacity and economy considerations, On the other hand, using a long span to height greater than 2.5 can lead to damage in the lower stories (Özhendekci & Özhendekci, 2012). In addition, the performance of the steel moment frame can be evaluated through the reduction factor value. Ferraioli et al., 2012 concluded that the average of the reduction factor for irregular steel moment frames is 5.2 and 6.5 for regular steel moment system(Ferraioli et al., 2012). Other studies reported that the reduction factor reduces as number of stories or span length increases and discussed that the effect of number of spans on the reduction factor is related to the number of stories(Hassan, 2022). In most seismic codes, the reduction factor for steel moment frames is specified based on the level of ductility or the type of steel moment frame. In Turkish Building Seismic Code (Code, 2018), the reduction factor (R) value is 8 for steel moment frame with high ductility level, and 4 for the steel moment frame with limited ductility level. Based on previous research, this constant value can be overestimated or underestimated, which significantly affects the design of buildings.

This paper investigates the nonlinear design parameters of steel moment frames at different sites in Turkey to evaluate the proportionality between the design parameters of the structure and those of the spectrum with the aim of enhancing the building design. For this purpose, steel moment frames are modelled using SAP2000; all the systems have the same characteristics except the span to height ratio. Then, the capacity spectrum method based on the ATC-40 procedure is performed to calculate the nonlinear behavior parameters for each system, including the effective damping ratio, stiffness ratio, ductility and reduction factor. Additionally, four different demand spectra that include different elastic design spectrum characteristics are used, precisely, the horizontal elastic design acceleration spectrum corner period T_B and the peak ground acceleration PGA. Afterward, the comparison of the results yields substantial findings regarding the nonlinear behavior of the steel moment frame and the overall building design.

2. Methodology

2.1. Analysis of the nonlinear behavior of steel moment frame using the capacity spectrum method

Fig.1 illustrates the steps to analyze the nonlinear behavior of structures using the Capacity Spectrum Method. A nonlinear static procedure, known as the Capacity Spectrum Method, is employed based on the ATC-40 procedure(Council, 1996) to analyze the nonlinear behavior of the steel moment frame.

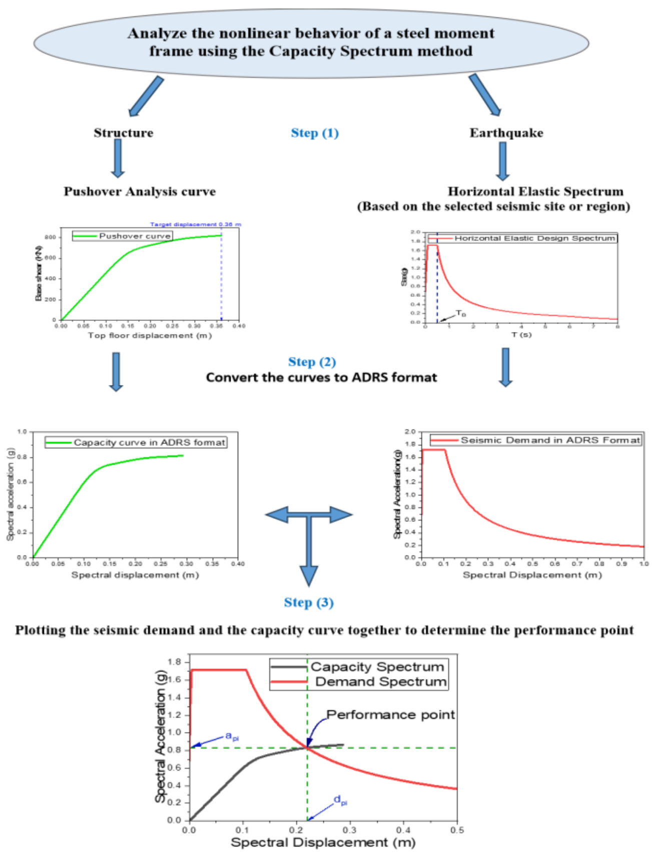

Fig. 1. Steps of the capacity spectrum procedure used to analyze the nonlinear behavior of steel moment frames

The system is pushed according to the first mode pattern up to the target displacement of 0.36 m (4% of the total height of the structure) to obtain the inelastic capacity curve, also known as the pushover curve. It should be noted that this pushover curve characterises the performance of the structure independently of any specific seismic demand (Council, 1996). In this regard, to evaluate the system's performance based on seismic demand, the capacity curve and the specified horizontal elastic design spectrum are transformed into the spectral acceleration–displacement domain (ADRS format). In this way, the capacity curve and the demand curve in spectral acceleration displacement can be plotted together. The intersection of these curves is the performance point of the structure that represents the maximum displacement demand from the system for a specified earthquake. The procedure described in Fig.1 is performed in this study using the SAP2000 software (*Computers and Structures Inc. SAP2000 Basic Analysis Reference Manual*, n.d.).

2.2. Estimating the nonlinear behavior parameters of a steel moment frame

In this study, the following nonlinear parameters are investigated:

- Effective damping ratio; serves as an index of the amount of energy dissipated by the system.
- Stiffness ratio; representing the degradation in the system's strength.
- Ductility; defined as the capacity of a structure to undergo plastic deformation without collapsing.
- Reduction factor; a critical parameter used to reduce the elastic design spectrum to account for the inelastic behavior of the system in the design process.

The bilinear representation has been used to facilitate the calculation of nonlinear parameters of interest in a simplified manner. To achieve this, the capacity curve extended up to the performance point is approximated by a bilinear representation. Based on Chapter 8 of the ATC-40 document (Council, 1996), the flowchart in Fig. 2 illustrates the procedure for converting the nonlinear capacity curve into a bilinear curve, along with the equations used to estimate the aforementioned parameters. It should be noted that, according to the Turkish Building Seismic Code (Code, 2018), the overstrength factor D is taken as 3 (used in this study) for steel moment frames with high ductility and 2.5 for those with limited ductility.

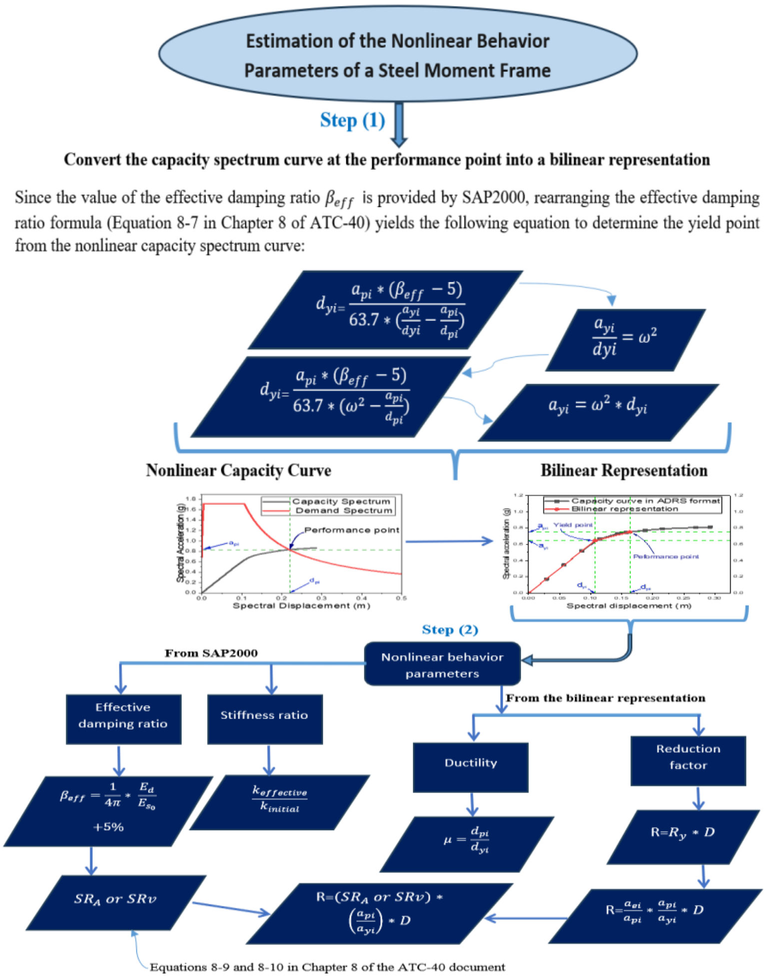

Fig. 2. Flowchart illustrating the calculation of nonlinear behavior parameters

2.3. Numerical study

2.3.1 Benchmark model

A steel moment frame is modeled using SAP2000 (*Computers and Structures Inc. SAP2000 Basic Analysis Reference Manual*, n.d.) and is taken as the benchmark for this study (Fig. 3). The system consists of three spans and three stories, with HE240B columns and IPE300O beams with each section meshed into eight parts. To achieve the objectives of the study, 15 frames are modeled based on this benchmark. The span length of these frames is incrementally increased by 0.3 meters, starting from 3.3 meters and extending to 7.5 meters. This procedure results in a series of steel moment frames that are identical in all properties except for the span-to-height ratio.

Table 1. Presentation of additional characteristics of the steel moment frames

Characteristics	Dead load(kN/m)	Live load(kN/m)	Hinges	Material type
For all systems	13.2	9	Fiber model	Steel material

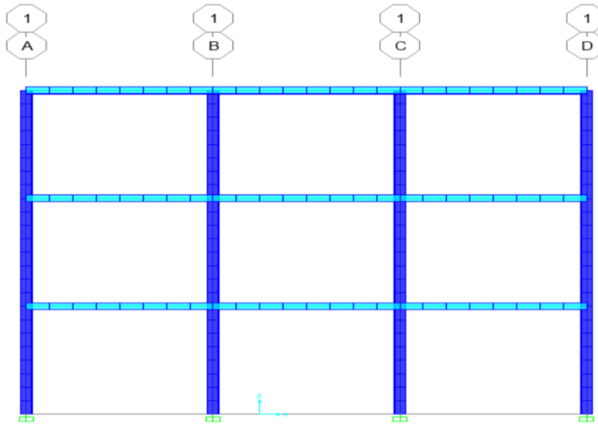

Fig. 3. Two-dimensional model of the steel moment frame

2.3.2 Seismic demands

As illustrated in Fig. 4, the four seismic demands have been selected to represent earthquake loads. The selected horizontal elastic design spectra are obtained from the AFAD seismic hazard map for different seismic regions in Turkey (Database. & Https://deprem.afad.gov.tr/, n.d.). The demand spectra used correspond to an earthquake ground motion level with a 10% probability of exceedance in 50 years (recurrence period of 475 years), specifically Earthquake Ground Motion Level DD-2. The spectra are defined by a variety of characteristics, including peak ground acceleration (PGA), the corner period of the horizontal elastic design spectrum(T_B), and the soil type. It is evident that the seismic demands exhibit variation with respect to high spectral acceleration and earthquake duration. These distinctions enable the investigation of the effect of the external loads on the nonlinear behavior parameters of the system.

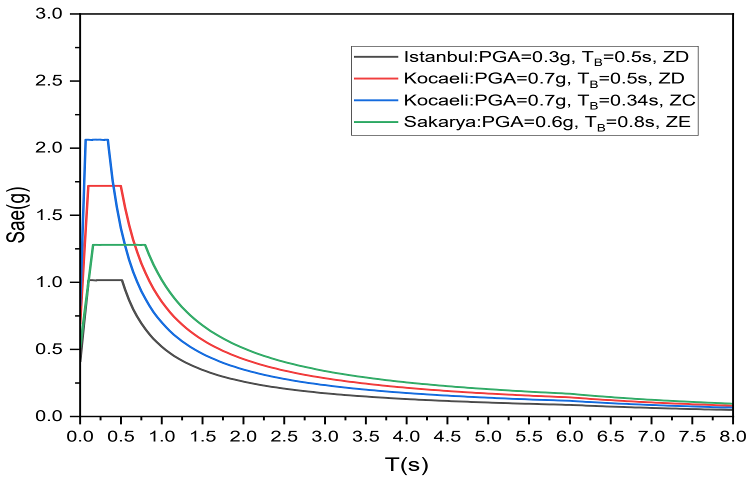

Fig. 4. Horizontal elastic design spectra for different seismic regions in Turkey

3. Results and discussion

3.1. Effect of the span to height ratio on the nonlinear behavior of steel moment frames under different seismic demands

The effective damping ratio values of the different steel moment frames subjected to four seismic demands are illustrated in Fig. 5. Then, it's clear that the increase in span to height ratio increases the initial period of the system, in this manner, the effective damping ratio is getting higher. In addition, the increment degree of the effective damping ratio is affected by the characteristics of seismic demand, more precisely, when we compare the cases of Kocaeli (ZD), Kocaeli (ZC) that have the same PGA and different T_B, it's observed that the systems have high damping when T_B is longer and significantly with large span to height ratio. On the other side, in the Istanbul and Kocaeli ZD cases, we observe that for the same T_B period (Same soil type) and different PGA, the systems have high damping level with the high PGA. Moreover, for the span to height ratio less or equal 1.9, there are no observations of plastic hinges in the columns in all the cases. On the other hand, when the span to height ratio exceeds the value 1.9, the plastic hinges are observed in the columns in the Sakarya case. It is worth noticing that in the Sakarya case, the increment in the effective damping ratio is dramatically compared to other cases. From periods insight, in the Sakarya case, the initial period of the system is less then T_B, the increase of the span to height ratio results to increase in the initial period, in this manner, the initial period of the structure goes more close to T_B of seismic demand, that results to high effective damping ratio due to long vibration term with the formation of the plastic hinges in columns, this is the crucial case where the column sway mechanism can be happen. In other cases, most of the initial periods are greater than T_B, the increase of the span to height ratio increases the initial period, that makes the later far from T_B and provide more effective damping without observation of plastic hinges in the columns.

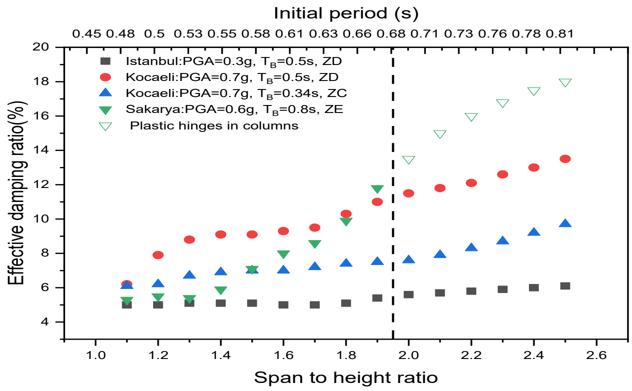

Fig. 5. Effective damping ratio with respect to the span to height ratio and initial period of steel moment frames under different seismic demand cases

Fig. 6 presents the stiffness ratio of the systems in terms of span to height ratio and initial period under different seismic demands. The degradation of the stiffness is increased with the increase of the span to height ratio and initial period, significantly, when T_B and PGA of seismic demand are larger. Furthermore, the degradation of the stiffness is significant and dramatic in the Sakarya case compared to other cases, where after the span to height ratio 1.9, the degradation of stiffness exceeds 15% with the formation of the plastic hinges in the columns, this is due to the increase of the initial period of the structure results from the increase of the span ratio make it close to T_B. In contrast, the plastic hinges in columns are not observed in the other cases. This due to the increase of span to height ratio that increases the initial period, but makes it more greater than T_B, this makes the system in safe zone and reduce the external load effect, the comparison of the Kocaeli cases confirm that, we observed for same PGA and initial period, the degradation of the stiffness of Kocaeli ZD ($T_B = 0.5s$) is greater than the case of Kocaeli ZC($T_B = 0.34s$); the initial period is more closer to T_B. In general, the results of the stiffness ratio confirm the comments of the effective damping ratio.

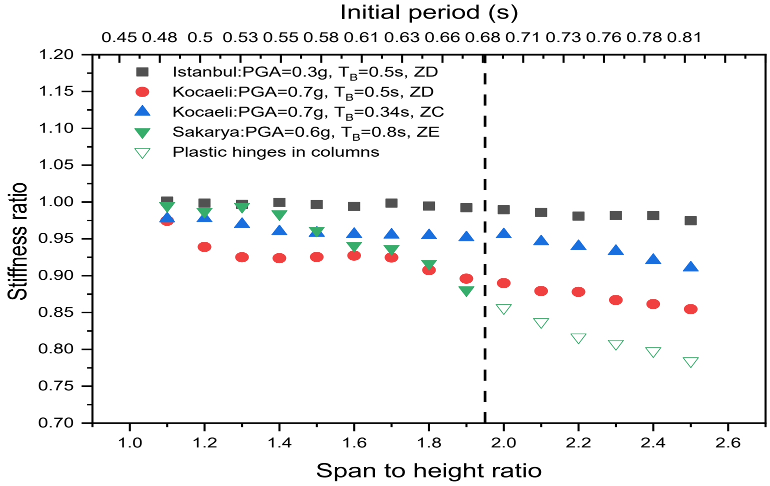

Fig. 6. Stiffness ratio with respect to the span to height ratio and initial period of the steel moment frames under different seismic sites

The ductility of the studied systems presented in Fig. 7 in terms of span to height ratio and initial period of the systems for four seismic regions. The trend of change of the ductility with the variation of the studied parameters is not so clear in this curve; however, in general, it's observed that the ductility value is changed with the variation of the span to height ratio, initial period, and the seismic demand type. The ductility value varies approximately from 1.2 to 2 for the systems that experienced nonlinear behavior, perhaps, we can classified the systems in the same level, but from other insight, if we compare the results of ductility with effective damping ratio and stiffness, we observe that small variation in ductility value has significant effect in the amount of energy dissipation of the systems and also the plastic hinges at the column can be occurred despite the systems have so close ductility level. This observation suggests that the concept of ductility deserves a more precise classification.

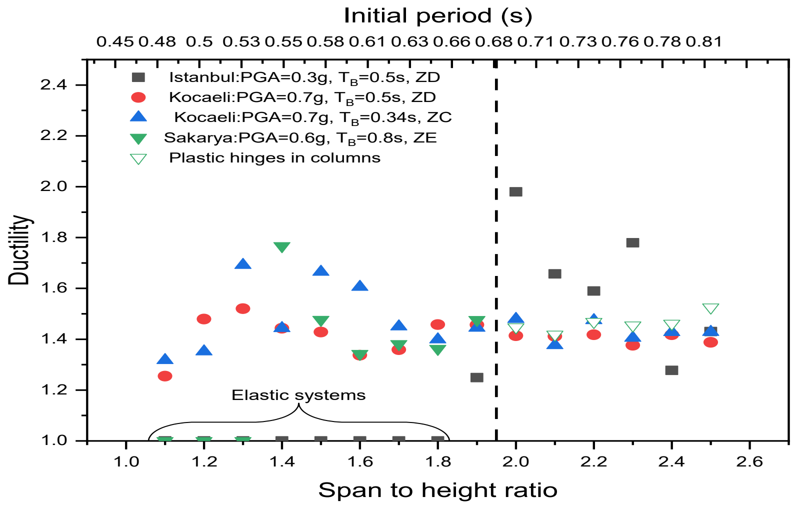

Fig. 7. Ductility with respect to the span to height ratio and initial period of steel moment frames under different seismic demand cases

Fig. 8 illustrates the modal participation mass ratio with respect to the span to height ratio and the initial period of the first mode of the different steel moment frames under four seismic demands. It's visible that the modal participation mass ratio is decreased with the increase of the span to height ratio and the initial period. The use of the long span increases initial period of the system and significantly leads to the occurrence of the plastic hinges in columns in earthquakes with long duration, this is clear in the case of Sakarya ($T_B = 0.8s$) after the span to height ratio exceeds 1.9.

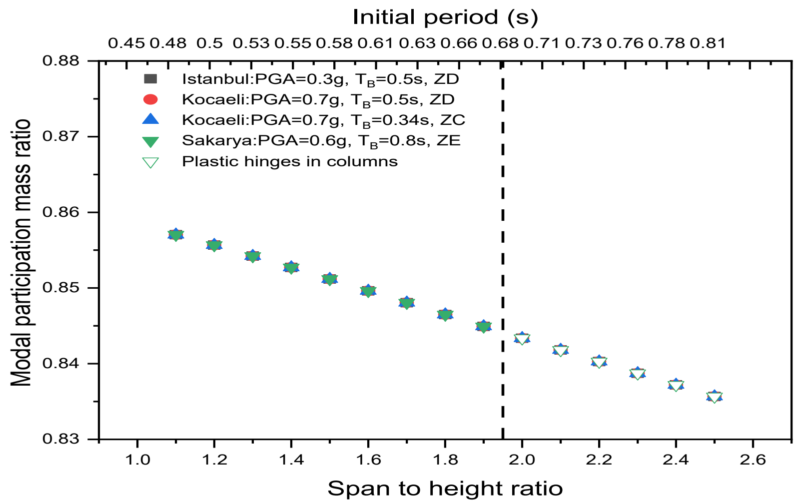

Fig. 8. Modal participation mass ratio of the first mode of the systems with respect to the span to height ratio and initial period of the different seismic cases

The effective damping ratio with respect to ductility of the steel moment frames considered in this study is shown in Fig. 9. It's visible that the effective damping ratio is changed significantly under short range of ductility values. Furthermore, it's clear that the high effective damping ratio can be result from the plastic hinges in the columns. The results of Fig. 9 indicate that the same system type can provide significantly different level of effective damping ratio although there is a small variation in the ductility value. In addition, the high effective damping ratio can not be always acceptable, since it can be provided through the formation of the plastic hinges in the columns.

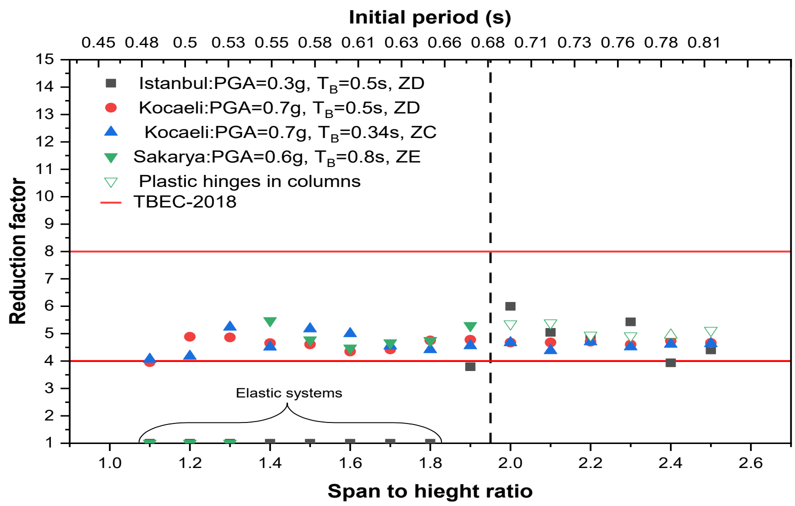

Fig. 9. Effective damping ratio with respect to ductility of the systems in different seismic sites

3.2. Assessment over the reduction factor value within the design with TBEC-2018

Fig. 10 shows the reduction factor of the steel moment frames studied in this paper in terms of the span to height ratio and the initial period. The results in Fig. 10 show that the reduction factor of the studied cases varied in range from approximately 4 to 6. The reduction factor is influenced by the span to height ratio and initial period of structure, additionally, the seismic region. In contrast, TBEC-2018 considers the reduction factor for the steel moment frame type as constants values based on ductility level, the results of Fig. 10 indicate that the reduction factor can take different values for the same system type based on several conditions.

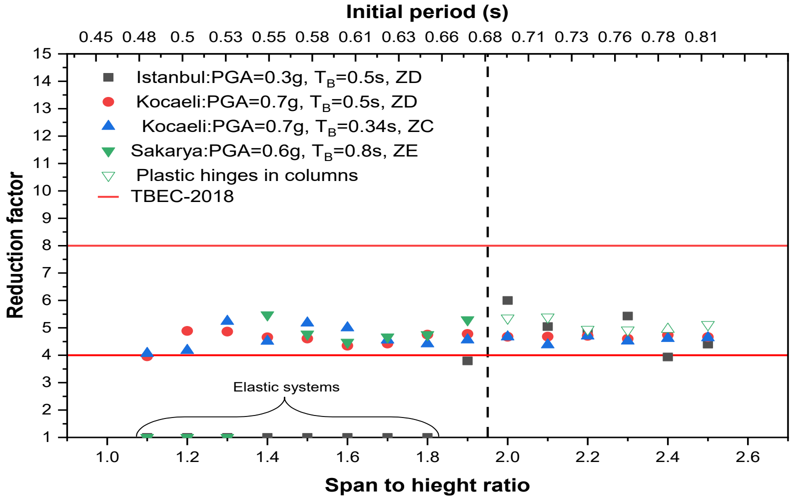

Fig. 10. Reduction factor values with respect to span to height ratio and initial period of the steel moment frames under different seismic demands

The reduction factor values with respect to the period ratio (T_B/T_i) of the different cases of the steel moment frames are illustrated in Fig. 11. In the range where the period ratio (T_B/T_i) is greater than one, the reduction factor value varies with both the span to height ratio and the period ratio (T_B/T_i). It ranges approximately from a minimum value of 4 to a maximum of 5.5. In addition, the plastic hinges are observed in the columns when the long span to height ratios are used, as mentioned earlier, this is the crucial case that's observed in this study, in fact, this case represents the column sway mechanism in real world scenario and can lead to the total collapse of the building. In the other range, the reduction factor value varied between approximately 4 to 6, without any observation of plastic hinges in the columns. Further, we observe some systems have the same period ratio (T_B/T_i) but different reduction factor, it should be mentioned that those cases have different span to height ratio, most straightforward, the span to height ratio increases the initial period T_i and with the change of T_B, we obtained some system with the same period ratio (T_B/T_i) and different span to height ratio. Overall, when we compare the cases with the same period ratio (T_B/T_i) and different span to height ratio as highlighted in Fig. 11, the reduction factor is affected by the span to height ratio.

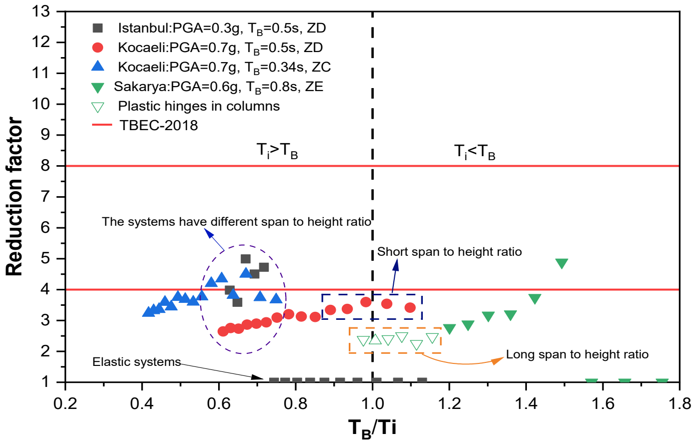

Fig. 11. Reduction factor with respect to the period ratio(T_B/T_i) of the systems in different seismic regions

4. Conclusions

This paper investigates the nonlinear behavior of the steel moment frames that have the same characteristics and different span to height ratios subjected to four different seismic demands. For this purpose, the capacity spectrum method was used to obtain the nonlinear parameters of the systems. The comparisons and the investigations of the results can reach to the following points:

- The long T_B period value of the soil demands a large damping from the system, the later can lead to the formation of the plastic hinges in columns when the long span to height ratio is used, consequently, the structure can collapse due to the column sway mechanism.

- The nonlinear behavior of the steel moment frame is so proportional with the span to height ratio, in addition, the span to height ratio changes the distribution of the plastic hinges, in this regard, the span to height ratio should be optimized to reach high performance of the steel moment frame.
- Increasing the span to height ratio increases high deformation of base floor in the first mode. This is because the plastic hinges can occur in the columns in long period earthquakes when the span to height ratio is more than 1.9 for steel moment frames.
- The reduction factor value is affected by the span to height ratio and the period ratio (T_B/T_i). The variation of those parameters can change the reduction factor value.
- For the same system type and similar level of ductility, the reduction factor value can be significantly different, as a result, assuming a constant value of the reduction factor base on the system type and level of ductility in TBEC-2018 (Code, 2018) can be overestimated or underestimated, which significantly affect the design. In response to these challenges, the reduction factor value should be checked at the end of the design process.

This paper provides significant information to the designers about the structural behavior in terms of design parameters. In addition, it offers very important recommendations for researchers to conduct more relevant studies to develop new practical approaches to optimize the building design.

Abstract. Earthquakes have been one of the greatest threats in human history due to the devastating effects of movements in the Earth's crust. The Kahramanmaraş earthquakes that occurred in 2023, with their large scale and destructiveness, have led us to question the seismic performance of not only modern structures but also historical artifacts. Such disasters have once again revealed the importance of protecting our cultural heritage as well as increasing the resistance of structures to earthquakes. Historical structures require a special approach in terms of engineering as well as their architectural and aesthetic values. Slender and tall structures such as minarets are more vulnerable to earthquakes; therefore, a detailed evaluation of their seismic performance is necessary. Analyses performed for historical masonry structures provide critical information in terms of understanding the current durability of structures and developing the right reinforcement solutions. Ensuring the safety of minarets is not only an engineering problem, but also a necessity for carrying cultural heritage into the future. This study aims to determine the seismic assessment of the historical minaret of Nebi Mosque. For this purpose, a finite element model and seismic analysis of the minaret were carried out using the ANSYS finite element software with the macro modeling technique. The nonlinear analysis method in the time history was applied to the minaret using the of the February 6, 2023 Pazarcık-Kahramanmaraş earthquake (M_w = 7.7). The dynamic response of the minaret was evaluated. The maximum tensile and compressive stresses in the minaret were determined, and the possible locations of the first damage were investigated.

Keywords: Masonry structure; Minaret; Numerical analysis; Finite Element Method

1. Introduction

On 6 February 2023, two major earthquakes with M_w = 7.7 and M_w = 7.6 struck the Pazarcık and Elbistan districts of Kahramanmaraş, Türkiye, causing widespread damage in eleven cities and affecting approximately 15 million people. The earthquakes severely damaged more than 230,000 buildings, including historical structures (Özmen et al., 2024; İnce, 2024; Atar et al., 2024). Mosques are particularly vulnerable to earthquakes due to their structural characteristics, such as slender minarets and massive masonry walls (Eronat et al., 2024). Protecting these unique and irreplaceable buildings and other structures for future generations is a key responsibility. In this context, numerical studies play an important role in the preservation, maintenance, and rehabilitation of historical structures.

Historical mosques are among the most important religious monuments in the world's cultural and architectural heritage. Over time, these structures are subject to various forms of deterioration due to natural disasters, strong ground movements, aging of materials, and adverse environmental conditions. These factors often lead to structural deficiencies that eventually cause partial or total collapse. Protecting these unique and irreplaceable buildings for future generations is a key responsibility. In this context, numerical studies play an important role in preserving, maintaining, and rehabilitating historical structures (Bayraktar et al. 2018). Türkiye is home to many historic mosques, many of which are located in seismically active regions. These structures typically consist of massive masonry walls, central domes, semi-domes, and slender minarets that form an integrated architectural system. The domes are typically constructed of materials such as brick, timber, or stone bonded with mortar, and the minarets - tall and slender masonry towers - are particularly vulnerable during seismic events due to their geometric slenderness and height. One of the primary objectives of structural engineering is to understand and evaluate the behavior of historic mosques under different loading conditions. There has been a growing interest in such structures conservation and seismic assessment in recent years, with numerous numerical studies focusing on

*Corresponding author, E-mail: oftas@firat.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_137

their dynamic characteristics and potential vulnerabilities. The literature provides various examples of structural assessments of historic mosques and their minarets, emphasizing the importance of preserving these heritage assets architectural and structural integrity (Lourenço et al., 1995; Mangia et al., 2016; Karaton & Aksoy, 2018). Sezen et al. After the 1999 earthquakes in Düzce and Kocaeli, the damage and vulnerability of 64 reinforced concrete and masonry minarets were assessed (Sezen et al. 2008). Altunışık investigated the dynamic behaviour of a masonry minaret before and after strengthening with FRP (fibre reinforced polymer) composite. For this aim, the 1992 Erzincan earthquake was used to analyse and investigate the analytical model of the minaret. (Altunışık 2011). Yurdakul et al. conducted a study to investigate the seismic performance of a historic minaret in Bayburt, Türkiye. Three acceleration records (1992 Erzincan, 1999 Kocaeli-Duzce and 2011 Van-Ercis) were used to evaluate the seismic behaviour of the historic minaret (Yurdakul et al. 2021). Çubuk et al. focus on the seismic evaluation of the historical Murat Bey Bridge in Kütahya, which was built in 1460. The bridge was evaluated using numerical methods and time-history analysis. The highest displacement and stress values were obtained from the acceleration records of the 2011 Van earthquake, which were used to evaluate the dynamic behaviour of the bridge (Çubuk et al.2022). Taş et al. aimed to determine the seismic assessment of the historical Nebi Mosque (Taş et al., 2024).

This research aims to evaluate the seismic characterization of the historic minaret of the Nebi Mosque. In order to achieve this objective, a finite element model and seismic analysis of the minaret were carried out using ANSYS finite element software with macro modeling methodology. The nonlinear time history analysis technique was applied to the minaret using the recordings of the 2023 Pazarcık-Kahramanmaraş earthquake (M_w = 7.7). The dynamic behavior of the minaret was evaluated. The maximum tensile and compressive stresses within the minaret were identified, and the potential location of initial damage was investigated.

2. The minaret of the Nebi Mosque

The Nebi Mosque is one of the oldest and most remarkable mosques in the Mesopotamian region still in active use in Diyarbakır, a city in southeastern Türkiye (Fig. 1). Constructed during the Akkoyunlu period in the early 15th century, the architect of the mosque remains unknown (Diyarbakır Provincial Directorate of Culture and Tourism, 2025). The minaret of the Nebi Mosque is located in the northeastern part of the structure.

Fig. 1. Location map of Nebi Mosque and minaret location map of Nebi Mosque and minaret (Google Maps)

The historic minaret and mosque were built using basalt stone and mortar for the walls, while the vault, dome, and arches of the Nebi Mosque were built using stone and brick. Stone was used as the primary building material in the construction of the Nebi Mosque. The properties of the structural masonry and mortar used in the mosque were evaluated. The mechanical properties of these materials, such as Young's modulus (E=25000 MPa), Poisson's ratio (v=0.2), and material density (p=1600 kg/m^3), were taken into account for the seismic analyses. The north and south views of the mosque are shown in Fig. 2 and Fig. 3, respectively. A plan view of the mosque is also shown in Fig. 4. The minaret has a square prismatic shaft, which is alternately clad with black and white basalt stones up to the balcony. Above the balcony, a cylindrical shaft has been added.

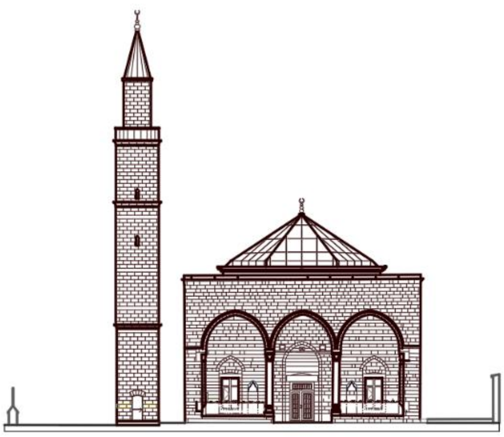

Fig. 2. North view of Nebi Mosque and Minaret

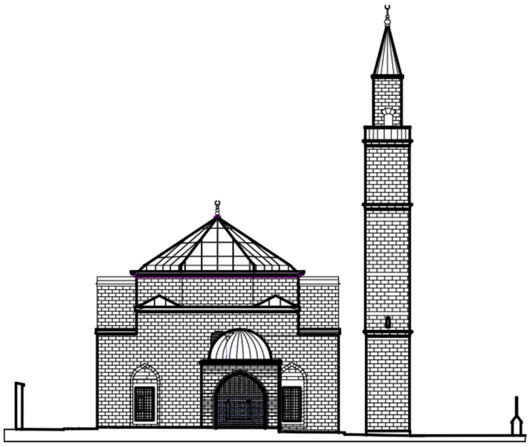

Fig. 3. South view of Nebi Mosque and Minaret

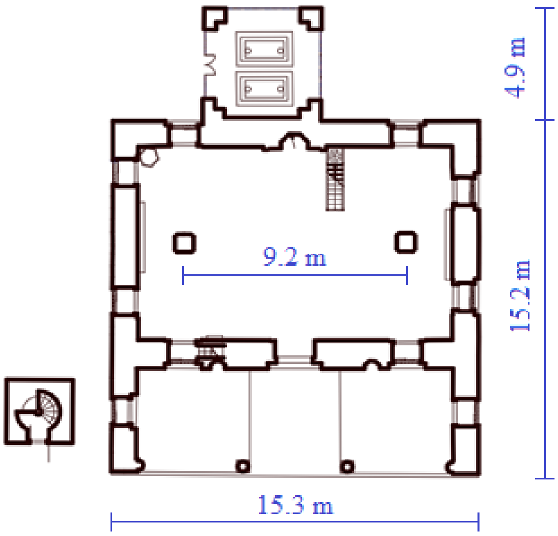

Fig. 4. Plan view of Nebi Mosque and Minaret (Taş et al., 2024)

3. Finite element modelling and analysis

Studying the structural behavior of historical structures using analytical methods requires many assumptions and methods. There are three primary modeling techniques for masonry structures: micro modeling, simplified micro modeling, and macro modeling. The detailed micro-modeling approach represents brick and mortar as separate materials. For the finite element modeling of the mosque minaret, the SOLID65 element, a three-dimensional solid element available in the ANSYS software (Fig. 5), was used (ANSYS, 2015). The SOLID65 element consists of eight nodes with three degrees of translational freedom. This element can be used for linear and non-linear static and dynamic structural analyses. The three-dimensional (3D) solid model of the minaret is shown in Fig. 6.

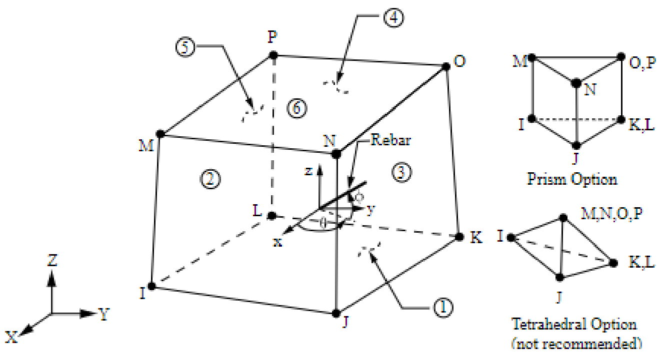

Fig. 5. Geometry of SOLID65 element (ANSYS, 2015)

Fig. 6. a) Three-dimensional geometric representation, b) finite element mesh, and c) internal staircase model of the Nebi Mosque Minaret

According to the literature review, the macro modeling technique is more advantageous for large-scale structural models because of the results' low computational effort and accuracy. It has been used in many studies (Carpinteri, Invernizzi, & Lacidogna, 2005; Sayın, 2016; Erdil, Tapan, Akkaya, & Korkut, 2018). In this study, the macro modeling technique was selected to model the historical minaret. Three-dimensional geometric representation, finite element mesh, and internal staircase model of the Nebi Mosque Minaret are shown in Fig. 6. A 3D finite element model of the minaret was created using the ANSYS finite element software, which included 81,949 nodes and 449,845 elements. All degrees of freedom were also assumed to be fixed at the foundation level.

4. Modal analysis

A modal analysis was conducted to comprehensively understand the dynamic behavior of the minaret and to identify its principal vibration modes, the corresponding mass participation ratios, and the associated periods. This study selected the macro modeling technique to model the minaret. Modal analysis of the minaret's first three mode shapes and their frequencies is shown in Figure 7. The first 20 frequencies of the minaret of the Nebi Mosque are shown in Table 1. A 3D finite element model of the mosque was created using the ANSYS finite element software, which included 26680 nodes and 116445 elements in the three-dimensional finite element model of the Nebi Mosque. All degrees of freedom were also assumed to be fixed at the foundation level.

Table 1. Modes and frequencies of the Nebi Mosque Minaret

Mode no	Frequency (Hz)	Mode no	Frequency (Hz)
1	1.62	11	28.25
2	1.65	12	33.44
3	7.90	13	38.26
4	7.94	14	38.58

5. Linear dynamic time history analysis

In this study, the acceleration records of the 6 February 2023 Pazarcık-Kahramanmaraş earthquake (Mw=7.7) were used for dynamic analyses to evaluate the seismic performance of the minaret. The most effective 20 seconds of the earthquake were used for time-history analyses of the minaret (Fig. 8 - Fig. 9). In the dynamic analyses, the north-south (N-S) and east-west (E-W) acceleration records of the earthquake were applied to the x and y directions of the minaret, respectively. The principal tensile and principal compressive stresses obtained from the time history analyses are shown in Fig. 10. The time-displacement graphs of the top point of the minaret are also presented in Fig. 11 and Fig. 12.

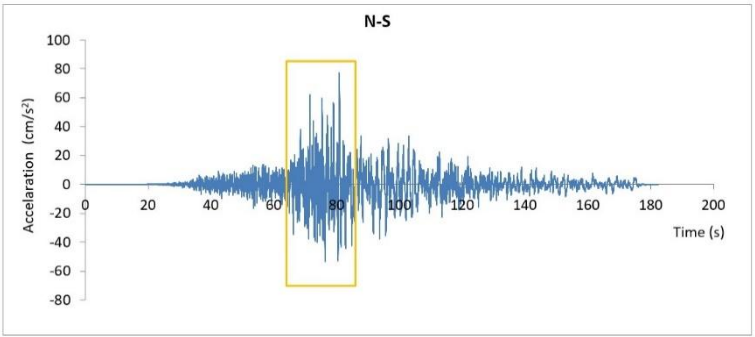

Fig. 8. Pazarcık-Kahramanmaraş North-South component (acceleration station 2101)

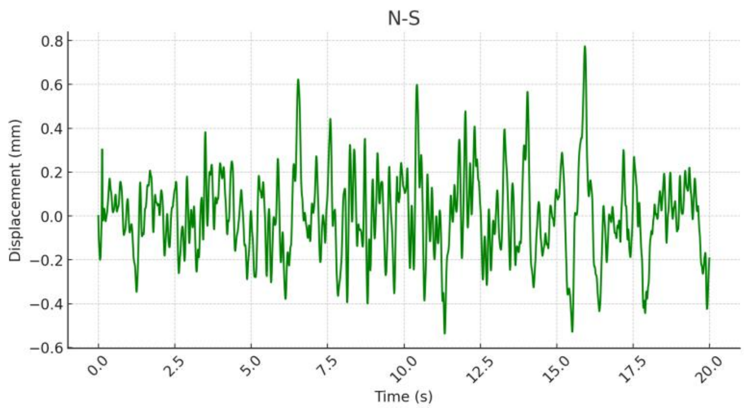

Fig. 12. Time-displacement graphs of the top point of the Nebi Mosque Minaret for N-S direction

Conclusions

This study aims to determine the seismic assessment of the historical minaret of Nebi Mosque. For this objective, a finite element model and seismic analysis of the minaret were executed utilizing the ANSYS finite element software with macro modeling methodology. A linear time history analysis method was employed for the minaret, and the 2023 Pazarcık-Kahramanmaraş earthquake records (M_w = 7.7) were selected. The dynamic response of the minaret was evaluated. The maximum tensile and compressive stresses that developed in the structure were assessed, and potential areas for initial damage were investigated.

- When the analysis results are examined, it is observed that compressive and tensile stresses are concentrated in the bottom parts of the minaret.
- Although the structural system of the minaret is predominantly subjected to compressive forces, the base regions where tensile stresses occur are critical in terms of structural damage risk.
- It is planned to make experimental measurements of the minaret in future studies. Experimental and numerical results will be compared.
- In this study, linear analysis of the minaret was performed. In future studies, it is aimed to determine the damage formation and progression with non-linear analysis.

Dynamic vibration control through tuned liquid damper under different excitation angle: shaking table tests study

Brahım A. Idriss*[1], Murat Günaydın[1], Fezayil Sunca[1], Fatih Y. Okur[1], Cihat Şahin [1], Algıhan K. Karahasan [2], Ahmet C. Altunışık[1], Yunus E. Akbulut[1]

Abstract. This study investigates the performance of a building model equipped with a tuned liquid damper through a series of shaking table tests under varying excitation directions. To assess directional effects, the model was rotated in 15-degree increments from 0° to 180°, while the excitation direction remained fixed. Acceleration and displacement time histories were recorded for each orientation to evaluate the damper's effectiveness. The results demonstrate that the TLD effectively reduced both accelerations and displacements of the structure. However, its efficiency declined progressively as the excitation angle increased from 0° to 90°.

Keywords: Different excitation direction; Shake table test; Tuned liquid damper; Vibration control

1. Introduction

Tuned Liquid Dampers (TLDs) are passive control devices widely used in structural and mechanical engineering to mitigate vibrations and enhance the dynamic performance of structures. These systems typically consist of a fluid-filled container and a tuned mass connected to the structure through a spring mechanism. The fluid provides damping through motion or viscosity, while the mass-spring assembly introduces stiffness, allowing the system to be tuned to specific frequencies. By carefully adjusting these parameters, TLDs can effectively reduce structural responses to dynamic loads such as wind or seismic activity. Two primary types of TLDs are commonly employed in buildings: sloshing TLDs, which dissipate energy through fluid motion, and viscous TLDs, which rely on the fluid's viscosity for damping. Depending on design considerations such as fluid depth, container geometry, and function, TLD systems are further categorized into Tuned Liquid Dampers (TLD or TSD-rectangular section), Tuned Liquid Column Dampers (TLCD), Hybrid TLCDs (HTLCD), and Double TLCDs (DTLCD), each offering unique performance characteristics for vibration control.

TLDs offer several notable advantages over other passive damping systems, making them an attractive solution for structural vibration control. Their design is inherently simple, involving no complex mechanical components, which contributes to lower installation and maintenance costs. Furthermore, TLDs are highly adaptable and can be tuned to target a broad spectrum of frequencies, allowing them to perform effectively under various dynamic loading conditions. This versatility makes them suitable for a wide range of applications, including tall buildings, long-span bridges, and offshore structures exposed to wind, wave, or seismic forces. Despite these strengths, the performance of TLDs can be limited in environments characterized by extremely large-amplitude vibrations, where nonlinear effects may reduce damping efficiency. Additionally, in regions with low seismic or dynamic excitation, the benefits of TLDs may be marginal, potentially making them less justifiable compared to other control systems. Nonetheless, their cost-effectiveness, simplicity, and adaptability continue to make TLDs a valuable option in modern structural engineering.

The concept of using fluid-based systems for structural vibration control dates back to the mid-20th century. One of the earliest theoretical foundations was laid by Housner (1954), who explored the influence of earthquake incidence angles on structural seismic response-paving the way for passive control systems such as TLDs. During the late 1950s to early 1970s, researchers began to systematically investigate the use of liquid-filled containers as damping devices to mitigate vibrations in buildings and other structures. Significant advancements occurred in the late 1980s (Miyata et al.,1989; Sakai & Takeda 1989; Sakai et al., 1989; Sun et al.,1989). In the mid-1990s, numerical analysis became prominent (Zhao & Fujino, 1993; Balendra et al.,1995). Subsequent studies further explored adjustable and tunable fluid damping systems. Researchers such as Sun et al.,1992; Gao et al., 1997; and others (Reed et al., 1998; Kanok-Nukulchai & Tam, 1999; Yamamoto & Kawahara, 1999; Yu et al., 1999; Jin et

*Corresponding author, E-mail: idrissfils88@yahoo.fr

https://doi.org/10.31462/icearc2025_ce_eqe_164

al., 2007; Tait, 2008; Colwell & Base, 2009; Tait & Deng, 2010; Behbahani et al., 2016; Sonmez, 2016; Altunışık et al., 2018) expanded the application scope and refined the analytical models of fluid-based dampers. Konar & (Dey) Ghosh (2023) have contributed significantly to the field of structural vibration control by reviewing the performance and development of TLDs. Their studies emphasize the dynamic behavior of TLDs under various excitations, such as wind and seismic loads, and critically analyze the evolution of TLD design, including sloshing mechanisms, hybrid configurations, and optimization techniques for improved efficiency. Similarly, Greciano et. al., (2024) have conducted an in-depth review focused on the integration of passive control systems like TLDs in civil structures. Their work highlights recent experimental advances, modeling techniques, and practical implementation in tall buildings and bridges, with special attention to sustainability and adaptive damping strategies. Collectively, these authors offer a valuable synthesis of current trends and future challenges in the application of TLDs for structural vibration mitigation.

Although extensive research has been conducted on TLDs for mitigating structural vibrations under dynamic loads, studies focusing on their performance under seismic excitations occurring at varying angles of incidence remain limited. Most existing works consider idealized or unidirectional loading conditions, which may not accurately reflect the complex nature of real earthquake events. To address this gap, the present study experimentally investigates the effectiveness of TLDs in controlling structural responses when buildings are subjected to earthquakes impacting from different directions. The findings aim to enhance the understanding of TLD behavior under multi-directional seismic inputs and contribute valuable insights to the existing body of literature on passive vibration control.

2. Building model and design of TLD

A single span three-story steel building model (0.90 x0.90 x 3.0 m, width x depth x height) was built in the laboratory to simulate a dynamic response of a building (Fig. 1). The wight of the model was 172 kg. The model building is designed to represent the behaviour of a mid-rise or relatively high-rise building. This was effective in selecting the dimensions of the carrier elements. The model structure includes columns with dimensions of 20 × 20 × 1.5 mm, beams with a diameter of 8 mm (Ø8). The floor slab and base slab was constructed with 900 × 900 × 25 mm steel plate. To simulate the effect of an earthquake from different angles, the model was mounted on a steel plate with holes drilled at 15-degree intervals. The model was also fixed to uniaxial shaking table using these holes (Fig. 2). In this way, the building was rotated to angles of 0°, 15°, 30°, 45°, 60°, 75°, 90°, 105°, 120°, 135°, 150°, and 165°.

Fig. 1. Building model constructed in the laboratory

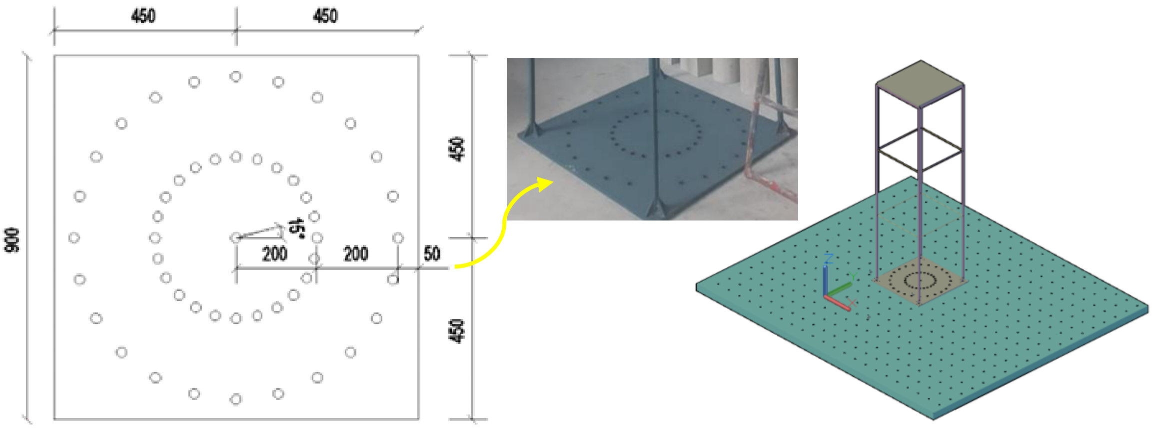

Fig. 2. Base plate with holes drilled at 15-degree intervals and a representative photo of the model on the shaking table

The dynamic characteristics of the building (mode shapes and natural frequencies) were obtained both numerical and experimental. A Finite Element (FE) model of the building was constituted using SAP2000 software (SAP2000, 2015). The experimental dynamic characteristics was detailed using ambient vibration test method. During the test, a B&K 3560 data acquisition system with 17 channels and B&K 4506 type, 9 uni-axial accelerometers having 0.5V/g sensitivity, uni-axial signal cables, PULSE and OMA software were used as the test equipment. Enhanced Frequency Domain Decomposition (EFDD) was employed to extract the dynamic characteristics Fig. 3 shows FE model, the accelerometer layout on the OMA model of the building and Singular Values of Spectral Density Matrices (SVSDM) of the dataset. Fig. 4 present the numerical and experimental mode shapes and corresponding natural frequency values. The mode shapes obtained for both cases included translational and torsional modes. The first three natural frequencies were calculated as 0.59 Hz, 0.59 Hz, and 1.41 Hz for the numerical model, and 0.52 Hz, 0.54 Hz, and 1.35 Hz for the experimental model. These results indicate that the natural frequencies of the numerical and experimental models are in close agreement. It should be noted that the first natural frequency of the building was used in the design of the TLD.

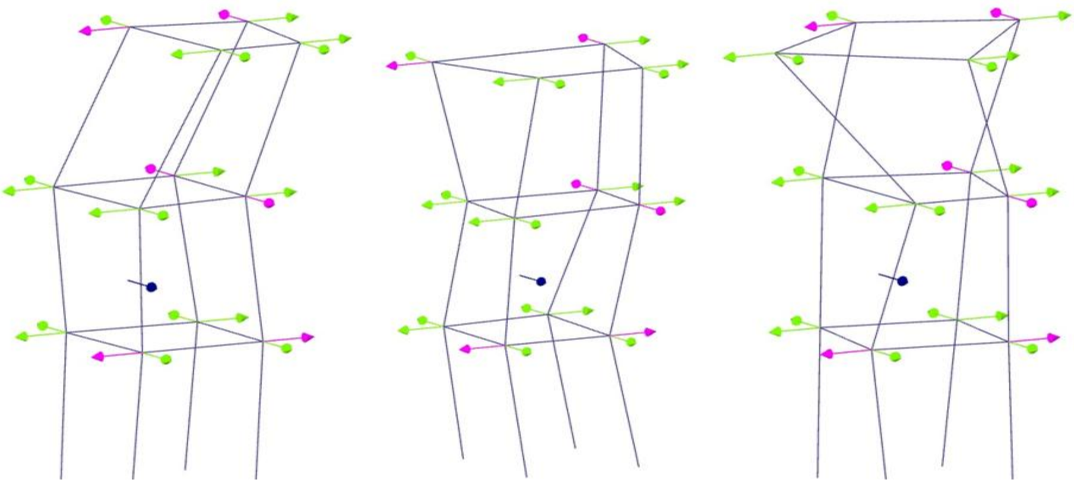
(a)



f_1=0.52Hz f_2=0.54Hz f_3=1.35Hz

(b)

Fig. 4. Numerical (a) and experimental (b) mode shapes and corresponding natural frequencies

According to linear wave theory (Lamb, 1932), the fundamental natural frequency of liquid sloshing motion, f_w is given by:

$$f_w = \frac{1}{2\pi}\sqrt{\frac{\pi \times g}{L} tanh(\frac{\pi \times h}{L})} \tag{1}$$

where g is the acceleration due to gravity, L is the length of the tank, h is the depth of the liquid.

During the TLD design process, the sloshing frequency *fw* (sloshing frequency was set equal to the first natural frequency of the building.

$$f_w = \frac{1}{2\pi}\sqrt{\frac{\pi \times g}{L} tanh(\frac{\pi \times h}{L})} = 0{,}59 = f_s \tag{2}$$

In the TLD design, the ratio of water depth to tank length (h/L was taken as 0.1, which is within the typical range of 0.1 to 5 for TLD applications. Based on this ratio and a tank length (L) of 0.67m, and the water depth (h) was calculated as 0.067m (Fig.5). The required liquid mass was calculated as 13.47 kg, based on an 8% mass ratio (range between 1% and 10%) relative to the total structural mass. The tank was constructed using 2.0mm thick plexiglass sheets (Fig. 6).

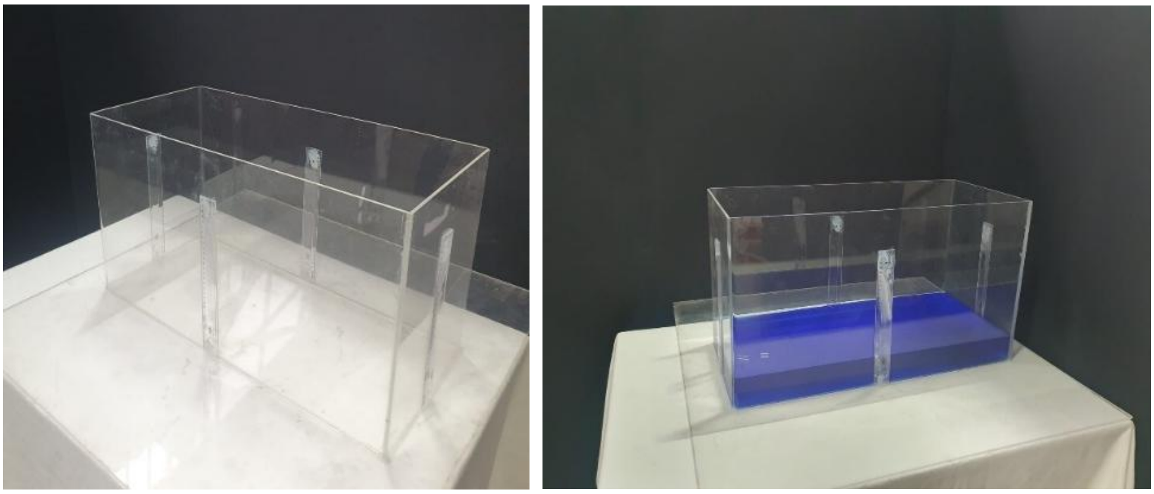

Fig. 6. Views of the TLD constructed using plexiglass.

3. Shaking table tests

A uniaxial shaking table (4.0m by 4.0m, 30tons capacity with accelerations up to 2g) was used to obtain seismic excitations. Three sinusoidal waves with amplitudes of 3mm, 6mm and 9mm each consisting of 5 cycles (Fig. 7), were selected as seismic excitations. During the shaking table tests (Fig. 8), the building was instrumented with four accelerometers in both the X and Y directions-two placed at the base and two at the top of the structure-to measure its dynamic response. To assess the effectiveness of the TLD at various orientations, the model structure was rotated to angles of 0°, 15°, 30°, 45°, 60°, 75°, 90°, 105°, 120°, 135°, 150°, and 165°, and tested on a shake table under three different dynamic excitation scenarios. For each configuration, acceleration responses were recorded at both the base and the top of the building. To analyze the structural response under varying seismic orientations, the acceleration input for each test was resolved into components along the X and Y axes using trigonometric transformations. At each rotation angle of the structure (ranging from 0° to 165° at 15° intervals), the effective acceleration in the direction of shaking was computed using the formula, as can be seen in Fig. 9.

4. Results and discussion

This section presents the acceleration values measured at the top of the building, both with and without the TLD system, for each excitation angle. The acceleration time histories recorded at the top of the structure under various excitation angles (ranging from 0° to 165° at 15° intervals) are presented for three different dynamic input scenarios (Fig.10). It should be noted that when the TLD is positioned at 0 degrees, the direction of earthquake excitation aligns with the natural sloshing direction of the water. In each case, comparisons are made between the responses of the building with and without the TLD system. It is evident from the graphs that the presence of the TLD leads to a noticeable reduction in peak acceleration amplitudes and a faster decay in oscillation amplitude over time. This damping effect is particularly prominent during the initial response period and remains consistent across all orientation angles. The results demonstrate that the TLD is effective in mitigating structural vibrations regardless of the direction of seismic input, confirming its contribution to enhanced dynamic performance and energy dissipation. The effectiveness is more distinguishable in excitation cases with stronger input amplitudes, where the gap between the with-TLD and without-TLD curves becomes more pronounced. In addition, it can be concluded that the TLD remains effective across all excitation angles. However, its efficiency slightly decreases as the excitation angle increases from 0° to 90°, and then gradually improves from 90° to 180°. This behaviour is also illustrated in Fig. 11. As can be seen in Fig. 11a, the displacement responses remain relatively high and consistent across all angles, showing limited variation with changing direction of excitation. Fig. 11b demonstrates that the structure equipped with a TLD exhibits a direction-dependent displacement response. The damping effectiveness decreases as the excitation angle approaches 90°, where the motion is perpendicular to the sloshing direction, and improves again as it approaches 180°. This pattern confirms that the TLD provides maximum efficiency when aligned with the excitation direction, effectively reducing structural displacement through directional energy dissipation.

5. Conclusion

This study investigated the effectiveness of a Tuned Liquid Damper (TLD) in reducing structural responses under varying excitation angles using shake table experiments. A scaled model structure was tested with and without the TLD at twelve different orientations ranging from 0° to 180°, under three levels of dynamic excitation. Acceleration responses were recorded at both the base and the top of the structure, allowing for a detailed comparison across configurations.

The results clearly demonstrate that the TLD significantly reduces acceleration responses, particularly when the excitation direction aligns with the natural sloshing direction of the liquid (0° and 180°). While the damping performance marginally decreased as the excitation angle approached 90°, it improved again beyond that, confirming the directional dependency of the TLD system. This behavior was consistently observed across different excitation amplitudes and was especially evident in the peak displacement data, where directional effectiveness was most pronounced.

Overall, the findings highlight that even under varying seismic input directions, the TLD maintains its capacity to mitigate structural vibrations, with optimal performance achieved when aligned with the excitation axis. These results affirm the potential of TLDs as a practical and efficient passive control solution for enhancing the seismic resilience of structures.

As a recommendation for future work, the study can be expanded by investigating the performance of alternative TLD configurations, such as multiple tanks with varying orientations or dimensions. Incorporating additional TLDs positioned along different axes may improve damping efficiency across a wider range of excitation angles, thereby enhancing the overall seismic performance of the structure.

Abstract. Arch dams, due to their complex geometry and interaction with reservoir water, are highly sensitive to dynamic effects and long-term environmental influences. The Yusufeli Arch Dam, one of the highest dams in Turkey, are equipped with Structural Health Monitoring (SHM) systems to assess their dynamic behavior and ensure operational safety. Yusufeli Dam, with a height of 275 meters, was recently completed and began reservoir impoundment. Its SHM system includes high-sensitivity accelerometers, temperature sensors, and displacement measurement instruments to track changes in modal characteristics as the water level rises. These data are crucial for understanding how hydrostatic pressure, temperature fluctuations, and external loads affect the dam's stability. The SHM system deployed on the dam provides long-term records of seismic response, structural displacements, and potential material degradation. Previous studies indicate that reservoir filling leads to a decrease in the natural frequencies of the dam, confirming the influence of the added mass effect and changing boundary conditions. Monitoring dam over time offers valuable insights into the structural integrity of high arch dams under real environmental conditions. The collected data contribute to the development of numerical models that improve the reliability of dam safety assessments. These case studies highlight the necessity of integrating SHM techniques into large-scale infrastructure projects to mitigate risks associated with environmental and operational factors.

Keywords: Arch dam; Operational modal analysis; Structural health monitoring; Yusufeli arch dam

1. Introduction

Archaeological discoveries and prehistoric engineering studies show that dam construction dates back to the early periods of human history. The Jawa Dam in Jordan, built around 3000 BCE, is recorded as the oldest known dam. In Ancient Egypt, the Sadd el-Kafara Dam (Dam of the Infidels), built around 2650 BCE on the northern banks of the Nile River, and the Hittite Dam (Alaca Höyük) in Anatolia, still functional and dating back approximately 3,200 years, are testaments to the ancient human effort to control and manage water (Üzen & Çetin, 2012). These structures represent a significant milestone in the storage and management of water, enhancing humanity's ability to intervene in the natural water cycle. The evolutionary journey of dams throughout history has led to an increased appreciation of water's value and more efficient use of water resources.

Over time, the design and functionality of dams have significantly improved. In the Middle Ages, the use of water power increased in Europe, leading to the widespread construction of dams. Notably, the arch dam, discovered by the Mongols in the 13th century, made it possible to build stronger dams with less material (Matthew, 2005). With the evolution of dam construction technology in the early 20th century, dams became more complex structures and an important resource for hydroelectric power generation. The use of materials such as concrete and steel enabled the construction of larger and more robust dams. Structures like the Hoover Dam and Aswan Dam, built during this period, are regarded as significant milestones in the field of engineering (Novokshchenov, 1997; Scott & Molyneux, 2001; Giroux, 2010).

The type and design of a dam to be constructed are determined by various factors such as geographical location, geological conditions, the intended use of water, and environmental impacts. Each type of dam offers specific advantages tailored to particular geological and environmental conditions. Arch dams are water retention structures that effectively utilize the strength of concrete with their curved design. The primary working principle of these dams is to transfer the hydrostatic pressure created by the water to the abutments and foundation through their curved shape. Therefore, the bearing capacity of the foundation and abutments where the dam will be located must be high. These characteristics make arch dams particularly preferred in narrow and steep valleys, providing a more effective and economical solution compared to other dam types in such geographical conditions.

Today, the role of dams is not limited to water storage and energy production; they also serve various purposes such as recreational use, water sports, and wildlife conservation. However, the environmental impacts and social consequences of dams are also heavily debated. These discussions have made it necessary to integrate sustainability and environmental protection measures into the design and operation of dams. Considering that structures storing such large volumes of water could lose functionality if damaged, causing harm to the national economy, and in the event of more significant damage, the collapse of a dam could result in the loss of many lives, accurately determining the static and dynamic behavior of these structures during the design and planning stages is of utmost importance.

The natural frequencies, mode shapes, and damping ratios, which describe the current structural condition of arch dams and all other structures, are referred to as dynamic characteristics and are directly influential in determining static and dynamic effects. The dynamic characteristics of such structures can be determined through numerical and experimental methods. Experimental methods take into account factors directly affecting the structures and test the accuracy of the data obtained from numerical methods, providing a realistic structural assessment. Today, the Experimental Modal Analysis Method is used to experimentally determine the dynamic characteristics of structures, such as their natural frequencies, mode shapes, and damping ratios, by placing sensitive accelerometers at various points on the structure. Since the vibration signals collected via accelerometers include signals from both the structure and the surrounding environment, they are separated using filtering techniques, and the signals belonging to the structure are processed to determine the experimental dynamic characteristics of the structures (Freyman et al., 1996).

Dams are critical infrastructure that serve various functions, such as water storage, energy production, and flood control. As such, maintaining the safety and functionality of these structures is paramount. Structural Health Monitoring (SHM) plays an essential role in ensuring the integrity of dams over time, enabling early detection of potential issues before they evolve into critical failures. By continuously monitoring key parameters such as vibrations, deformations, and crack growth, SHM systems facilitate the assessment of a dam's static and dynamic behavior. This data is invaluable in identifying early signs of damage, deterioration, or unexpected behavior, which might otherwise go unnoticed until they pose significant risks. Moreover, the use of advanced SHM technologies allows for the remote monitoring of dams in real-time, providing a cost-effective alternative to traditional manual inspections. The monitoring of dynamic characteristics, including natural frequencies and damping ratios, allows engineers to evaluate how the dam responds to environmental factors such as water level changes, temperature fluctuations, and seismic activity. Understanding these responses is crucial for predicting the dam's performance under various loading conditions and ensuring its continued safety and functionality. The implementation of SHM systems also aligns with modern engineering practices focused on sustainability, as it minimizes the need for inspections and repairs, reducing both operational costs and environmental impact. SHM represents an essential component of modern dam management, providing vital insights into the health and safety of these critical structures. For this purpose, within the scope of the literature, researchers carry out studies on dams, including operational and laboratory experiments (Darbre et al., 2000; Okuma et al., 2008; Sevim et al., 2012; Lew & Loh, 2013; Oliveira & Alegre, 2022; Hassan et al., 2024)

Within the scope of this study, long-term Structural Health Monitoring (SHM) efforts are aimed at determining the structural behavior of the Yusufeli Arch Dam, which has a height of 275 meters, through experimental methods, considering the effects of reservoir water and changing ambient temperatures. Sensitive accelerometers installed on the dam, whose construction was completed in 2022, have been used to obtain long-term signal data, including the condition where the reservoir is empty. This study is significant in terms of determining the changing dynamic characteristics of a 275-meter-high arch dam as the reservoir begins to fill with water.

2. Yusufeli arch dam

The Yusufeli Dam, situated on the Çoruh River in the Yusufeli district of Artvin, Turkey, stands as a remarkable feat of modern engineering. Construction began in 2013, and the dam was officially completed in 2022, with the reservoir impoundment commencing in November 2022. By November 2023, the dam's power generation activities were underway, and the water level reached a height of +701 meters, with the crest elevation at +715 meters. With a total height of 275 meters, it is the tallest dam in Turkey and ranks as the third-tallest double-curvature concrete arch dam type worldwide.

Boasting an installed capacity of 540 MW, the Yusufeli Dam contributes significantly, with an annual energy output of 1.8 billion kWh. In addition to its energy-generating capabilities, the dam plays a vital role in irrigation, water storage, and flood mitigation, with a reservoir that can hold up to 270 million cubic meters of water. The Yusufeli Dam, through its sophisticated engineering design and technological advancements, delivers long-term benefits, including energy production, environmental conservation, and disaster management. Some images of the dam are shown in Fig. 1.

Fig. 1. Views of Yusufeli Dam

2.1. Sensor installed and operational tests in the Yusufeli dam

Since environmental conditions can lead to structural changes over time in large engineering projects, it is crucial to monitor these changes. To monitor these changes and assess the dynamic characteristics of the dam, ambient vibration tests are employed. These tests use accelerometers placed at strategic points on the dam to capture natural vibrations caused by factors such as water level changes, wind, ground motions, and the passage of heavy vehicles.

Upon the completion of the Yusufeli Dam in 2022, ambient vibration tests were conducted to assess the dam's modal behavior with the reservoir empty. Seven accelerometers were used for each reference measurement along the dam crest to capture vibration data, which was then processed using the OMA (2023) software to determine the dam's dynamic characteristics (Fig. 2). The tests employed Sara SL06 three-axis accelerometers, which have a dynamic range of 156 dB and a frequency range from 0 to 1500 Hz. These accelerometers were positioned along the upstream-downstream axis of the dam crest to measure vibrations during the test. The results showed the first six natural frequency values ranging from 1.881 Hz to 5.191 Hz, with corresponding mode shapes provided.

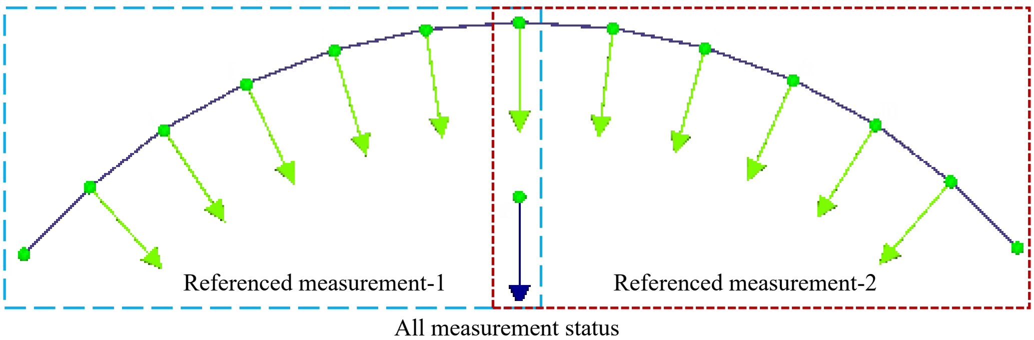

Fig. 2. Accelerometer placement for reference measurements at Yusufeli dam

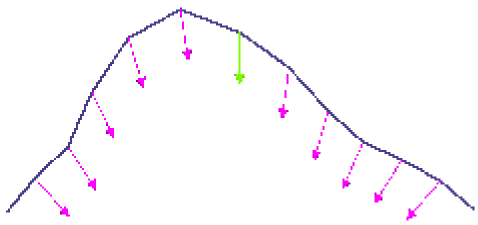
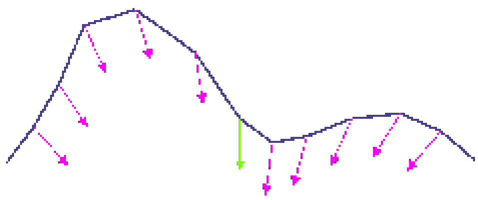
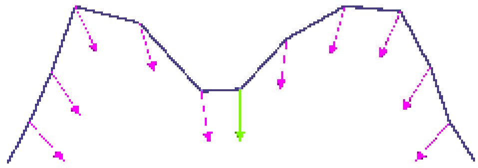
In Fig. 3, the frequency values of the first six modes are given for the case when the dam reservoir is empty, and the mode shapes corresponding to these modes are given.



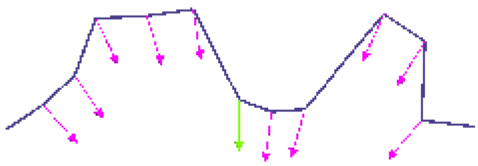
a) 1^{st} mode (1.881 Hz)



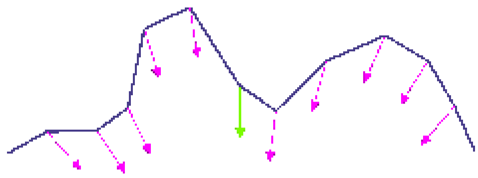
b) 2^{nd} mode (2.095 Hz)



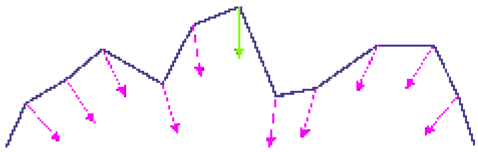
c) 3^{rd} mode (3.105 Hz)



d) 4^{th} mode (3.584 Hz)



e) 5^{th} mode (3.936 Hz)



f) 6^{th} mode (5.191 Hz)

Fig. 3. The first six mode shapes and corresponding natural frequencies

As the water level began to rise in the reservoir, the monitoring process continued with three accelerometers installed on the dam crest for long-term monitoring (Fig. 4). These accelerometers provided valuable data on the dam's dynamic behavior at different water levels, using the baseline measurements taken with the seven accelerometers as reference. The data from the three accelerometers, while sufficient for determining frequency values, were not enough to fully characterize the mode shapes. Therefore, the initial detailed data set, obtained when the reservoir was empty, was used to enhance the accuracy of ongoing measurements.

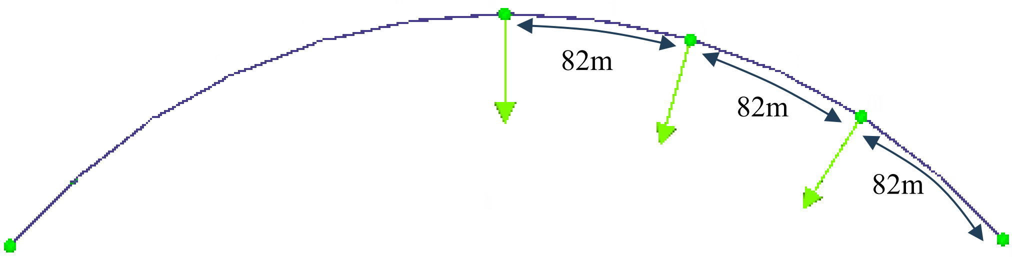


Fig. 4. Accelerometers layout plan

For continuous monitoring, a sensor setup was designed with three accelerometers spaced at equal intervals along the dam crest. These accelerometers were integrated into a system with an industrial modem for real-time online data transmission. The accelerometers were powered by an uninterrupted power supply and equipped with a signal management kit for periodic activation. This setup ensures reliable data collection and monitoring of the dam's dynamic properties, contributing to the long-term assessment of its structural health. Figure 5 shows visuals of the accelerometer installation at the dam crest for continuous monitoring.

Fig. 5. Accelerometers Instrumentation for continuous monitoring

2.2. Structural health monitoring in the Yusufeli dam

A comprehensive Structural Health Monitoring (SHM) study was carried out to evaluate the condition of the Yusufeli Dam, a towering structure, during the process of filling the reservoir and under varying seasonal conditions. The data collected from three accelerometers mounted on the dam were transmitted through an internet connection to an online SHM system developed by Okur (2023) as part of a thesis. An image of the system's interface, customized for Yusufeli Dam, is shown in Fig. 6. This web-based SHM system, together with its integrated software, automatically processes the raw data from the accelerometers and computes the frequency values corresponding to the identified modes. Additionally, the system can access regional air temperature data in real-time. Time-dependent frequency variations for the first six modes, stored in the system's database, are shown in Fig. 7. When Figure 7 is examined, the trends of frequency values belonging to all modes are similar. It first decreases in approximately the same date ranges, then increases, reaches the peak level and then decreases again. In order to observe the effect of environmental parameters on this change, the frequency change of the 1st mode is given in Fig. 8 together with the changes in reservoir water level and ambient temperature.

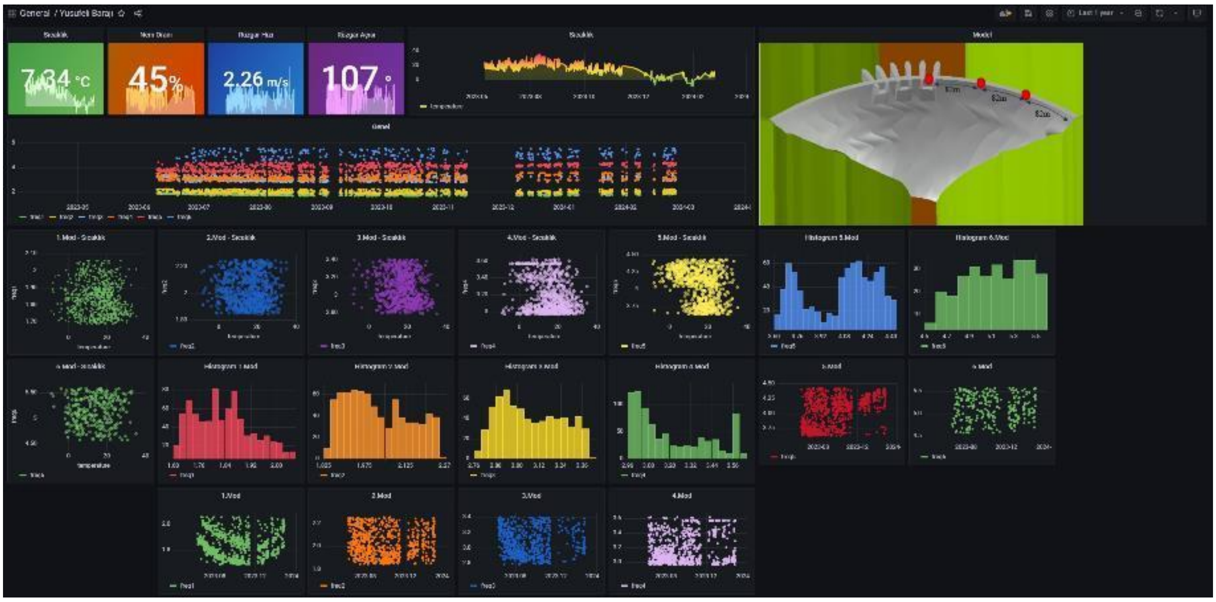

Fig. 6. Web-based structural health monitoring platform

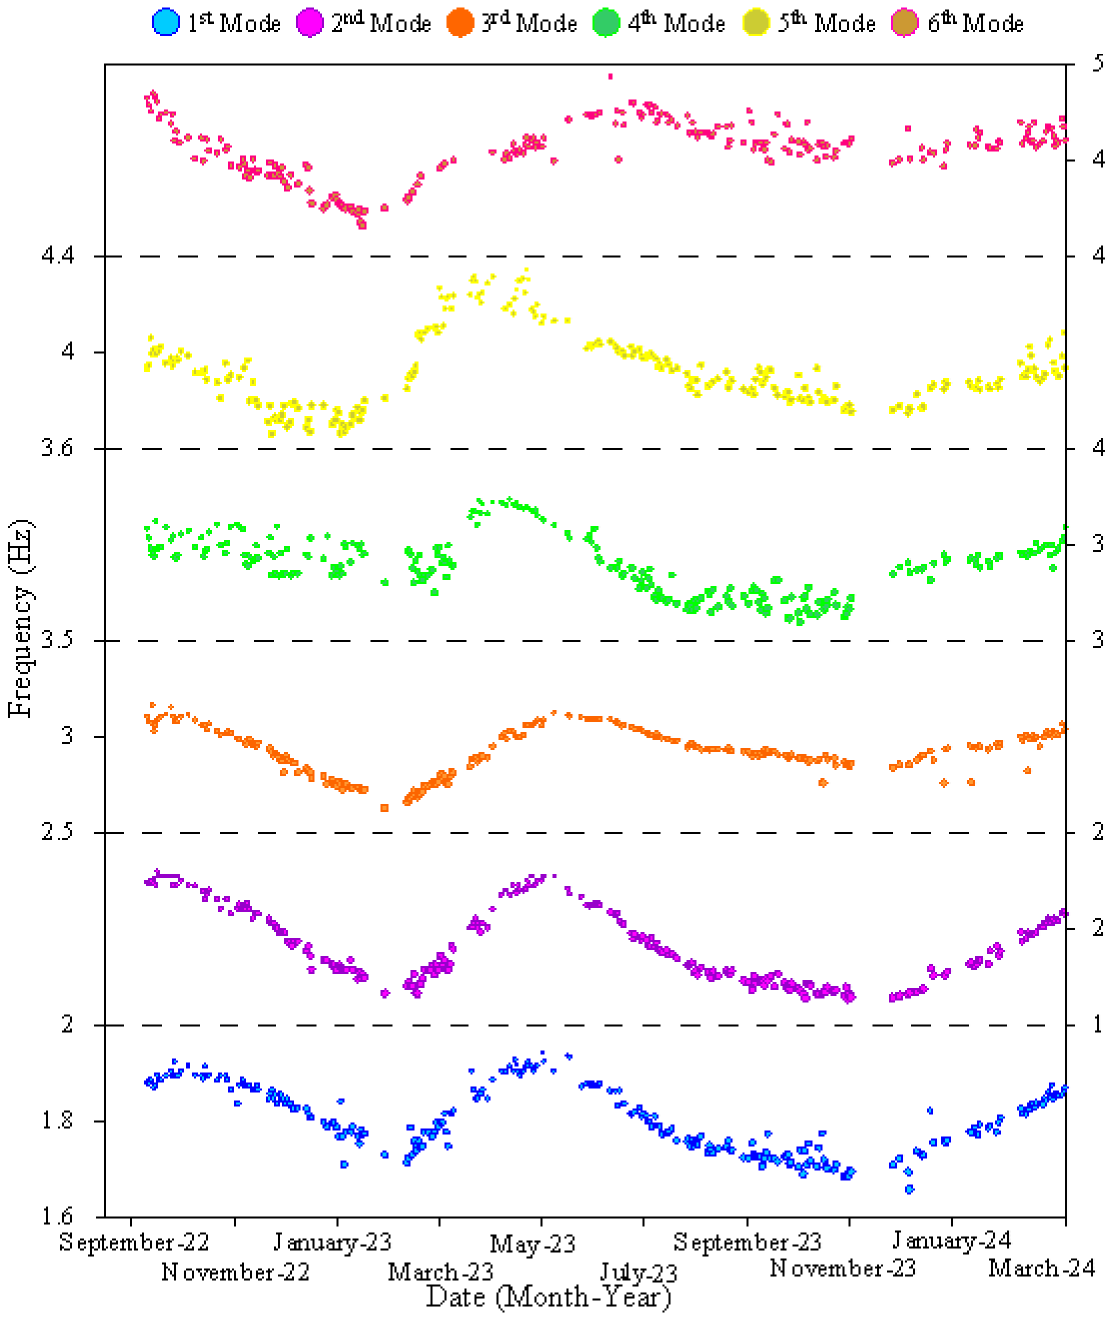

Fig. 7. First six frequency changes during the SHM

As depicted in Fig. 8, temperature data exhibited periodic fluctuations, while the water level steadily increased due to the dam's ongoing water retention process. A direct comparison of frequencies and temperature is challenging, as the thermal conditions change continuously over time with the fluctuation in water level. It is clear that the primary factor influencing the frequency changes is the amount of water in the reservoir. However, other contributing factors also influence the frequency variations over time. One of these factors is the dam's curved structure and daily temperature variations. The dam's vertical construction joints are well known, and these joints can open or close under loading. Literature commonly supports the idea that when the joints open, the dam's stiffness decreases, which in turn reduces the frequency. Conversely, as the joints compress and close, the stiffness increases, leading to higher frequency values.

Frequency values generally decreased until March, after which an upward trend began, continuing through June. This increase in frequency values, despite the rising water levels, is likely attributed to the compression and closing of the contraction joints, which enhances the stiffness of the dam. In March, the water level was at 68 meters, and by June, it had risen to 150 meters. This suggests that the compression of the joints in the double-curved dam body, caused by the increasing water level between 68 and 150 meters, contributed to the rise in stiffness. Beyond 150 meters, as the water level continued to increase, the frequency values began to decrease, which is consistent with the expected trend. It's also worth noting that the rise in water levels in January was much slower and almost stable, so the subsequent increase in frequency after this period may have been influenced by the drop in temperature.

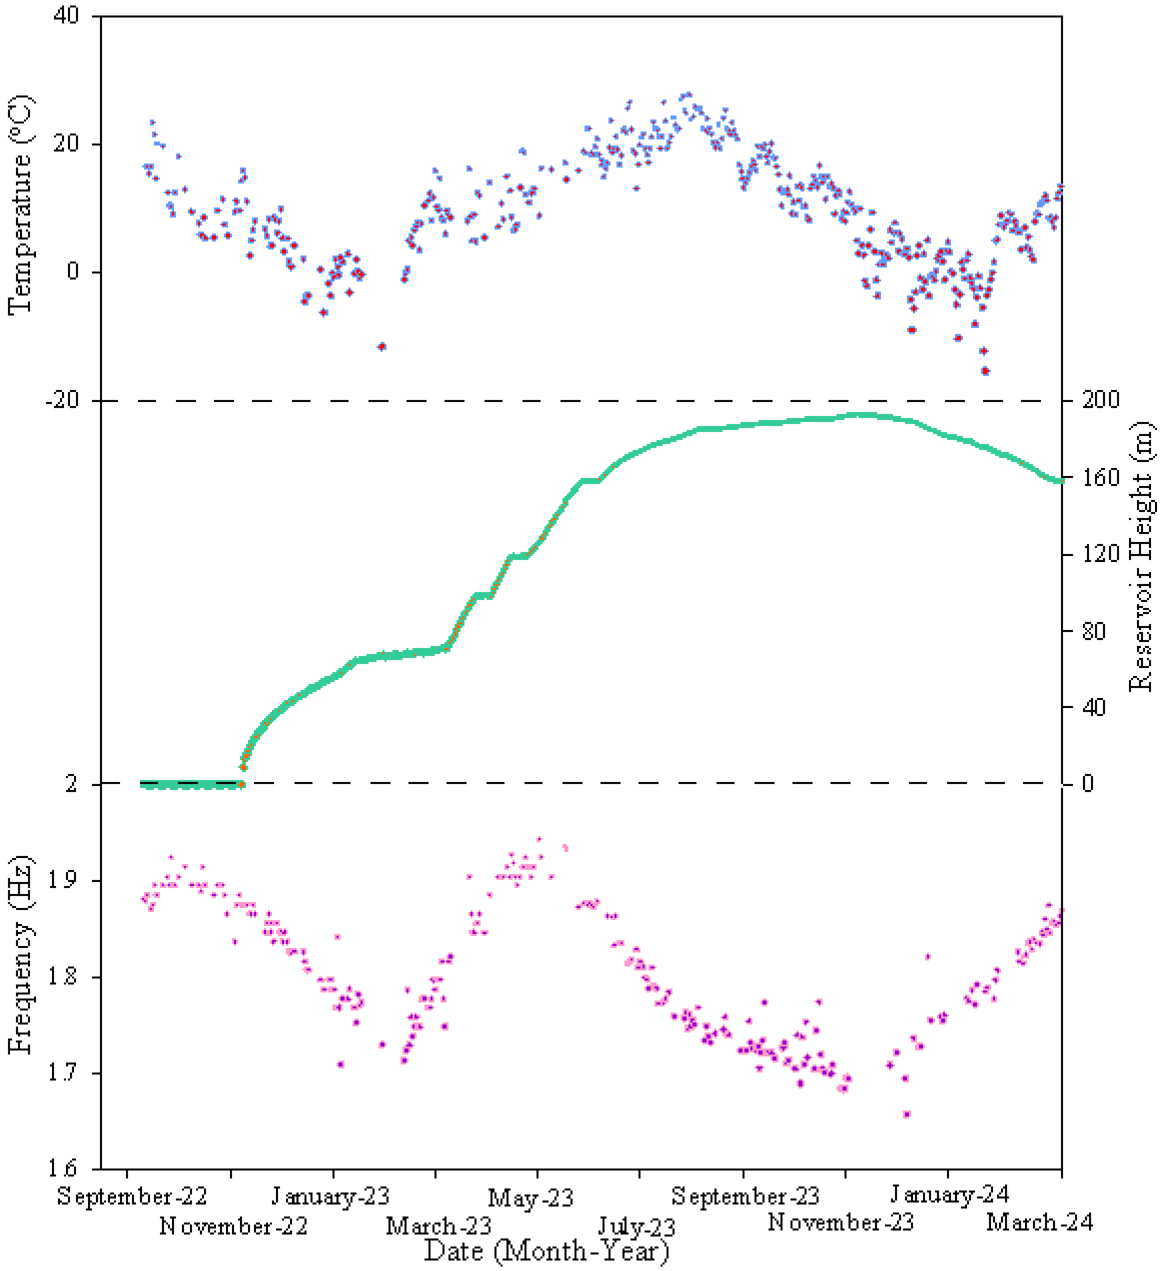

Fig. 8. Changes in ambient temperature, water height and frequency values obtained from the long-term Structural Health Monitoring of Yusufeli Dam

3. Conclusions

This study presents a comprehensive Structural Health Monitoring (SHM) approach to assess the dynamic characteristics and structural integrity of the Yusufeli Arch Dam, which stands as one of the tallest dams in Turkey. The SHM system implemented on the dam includes high-sensitivity accelerometers measurement sensors, providing crucial data on the dam's behavior as the reservoir fills and under varying seasonal conditions. The results obtained within the scope of the study can be listed as;

- The frequency values obtained when the empty reservoir indicated that the dam's initial natural frequencies ranged between 1.881 Hz and 5.191 Hz.
- The natural frequencies of the dam decrease as the reservoir fills, mainly due to the added mass of water.

- Additional factors, such as the dam's curved shape and daily temperature fluctuations, also affect frequency changes.
- The increase in frequency, despite the increase in water level, is due to the increase in hardness of the dam as a result of the compression and closure of the contraction joints.

Overall, the SHM system provides valuable insights into the dam's dynamic properties and allows for real-time monitoring, contributing to the development of more accurate numerical models. These models, in turn, enhance the reliability of dam safety assessments, ensuring the long-term stability and functionality of the structure. This case study underscores the importance of integrating SHM systems into large-scale infrastructure projects, not only for structural assessment but also for mitigating risks associated with environmental and operational factors.

Acknowledgments
The authors would like to extend their sincere gratitude to the General Directorate of State Hydraulic Works for granting the necessary permits for field studies at the Yusufeli Dam. Special thanks are also due to the 26th Regional DSI Branch Directorate for their invaluable support and assistance throughout the experimental studies.

This work was supported by the Karadeniz Technical University Scientific Research Project titled "Establishment of a Structural Health Monitoring Network and Development of Innovative Methods for Engineering Structures of Strategic Importance in the Eastern Black Sea Region" (Project No. FAY-2021-9635). The authors extend their thanks to Karadeniz Technical University for their invaluable support.

Abstract. This article focuses on the seismic performance analyzes of 5 reinforced concrete buildings located in different districts of Tunceli province and built during the period when the Türkiye Building Earthquake Code 1975 (TBEC, 1975) was in force. For the numerical study, core samples were taken from the buildings whose plans were prepared and the reinforcement in the structural elements were determined. Ground survey reports were used to determine the ground conditions of the buildings. According to the samples taken from the buildings, it was determined that the concrete strength of all buildings was below 10 MPa. In addition, it was determined that the reinforcements in the structural elements had smooth surfaces and the stirrup spacing was more than 250 mm. In the light of the data obtained, performance evaluation was made by performing nonlinear static pushover analyzes of the buildings. According to the analysis results, it was determined that no building met the adequate performance conditions defined in Türkiye Building Earthquake Code 2018 (TBEC, 2018).

Keywords: RC buildings; Seismic performance; Concrete strenght; Türkiye Building Earthquake Code 1975; Ground servey

1. Introduction

In countries situated on active tectonic faults, such as Türkiye, it is crucial that both new and existing structures are capable of withstanding potential earthquakes at the requisite performance level. However, the loss of life and property resulting from the earthquakes has been an indication that the earthquake performance is inadequate. Research conducted post-earthquakes identified the primary causes of damage in reinforced concrete structures as soil effects, inadequate material strength, irregular design, errors in architectural planning, and non-compliance of reinforcement with seismic codes. (Bayraktar et al., 2013; Demirel et al., 2022; Ertürk et al., 2022; Ivanov and Chow, 2023; Kocakaplan Sezgin et al., 2024; Onat et al., 2022; Sayın et al., 2021; Yön et al., 2024). Damages and losses of life occurring in earthquakes show the importance of earthquake-resistant and adequately safe building design. To do this, it is possible to accurately determine the nonlinear behavior of building systems during earthquakes with selection of accurate method. Reinforced concrete is a building material that is heterogeneous and its behavior is inelastic. However, the change in behavior depending on time and load invalidates the calculation methods developed with the assumption of ideal material in determining the behavior of this material. It uses various models and analysis methods to determine nonlinear behavior.

The static pushover analysis method is an effective approach that facilitates the assessment of existing buildings, the design of retrofitted structures, and offers insights to engineers in the design of new edifices (Hassan and Reyes, 2020; Kimeze and Kyakula, 2023; Kuria and Kegyes-Brassai, 2023; Pierre and Hidayat, 2020; Zebua and Koespiadi, 2022). Analysis: It is an estimated approach for exposing the structure to lateral forces that incrementally grow with a uniform height distribution until the desired displacement is achieved. In nonlinear static pushover analysis, structural systems are depicted using two- or three-dimensional analytical models. This method the horizontal load-peak displacement relationship, which signifies the structural strength under earthquake loads, in accordance with nonlinear theory concerning material and geometric alterations. In this method, the structure is subjected to horizontal loads at the floor levels to simulate dynamic inertia forces. While horizontal loads are applied, vertical loads concurrently exist within the structure. Static horizontal loads are incrementally raised at each stage, maintaining a consistent ratio, until the structure attains a specific displacement or collapse condition, so establishing the link between horizontal load and peak displacement of the structure. With the effect of increased horizontal loads, one or more of the sections reach their carrying capacity and plastic hinges

*Corresponding author, E-mail: burakyon@munzur.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_189

form in these sections. Sections formed by plastic hinges continue to rotate without any change in their bearing capacity. The system behaves linearly-elastic between plastic hinges. By continuing to increase the horizontal loads, the collapse load (limit load) is reached, which turns part or all of the structure into a mechanism. By evaluating the plastic hinge distribution under this load and displacement, the damage status of the building and whether the performance target is met are determined.

In this study, seismic performance analyzes of 5 reinforced concrete buildings located in different districts of Tunceli province and built during the period when the TBEC 1975 was in force were performed using the static pushover analysis method. For the numerical study, core samples were taken from the buildings and the reinforcement in the building elements were determined. Ground survey reports were used to determine the ground condition. In the light of the data obtained, non-linear analyzes of the buildings were solved in the STA4CAD building analysis program and performance evaluation was made.

2. Materials and method

The locations of the buildings used in the numerical analysis are shown in Fig. 1. Looking at the location of the buildings, it can be seen that they are very close to the faults. In addition, three-dimensional views of the buildings and destructive tests performed on the buildings are presented in Figs. 2-6, respectively. When the structures are examined, it is seen that the buildings were built with a reinforced concrete frame system and there are few or no reinforced concrete shear walls.

Also, building information, materials properties, horizontal and vertical elastic spectrum of buildings are given in Table 1 and Fig. 7, respecitvely. In this table, B, PB and GF define the Basement, Partial Basement and Ground Floor, respectively. Also, the rightmost number shows the normal floor number. Upon this table was investigated, it can be seen the compressive concrete strength of buildings under the 10 MPa. This value does not meet the TBEC 2018 nor does it meet the TBEC 1975 in which the lowest concrete compressive strength is B225 (C18). Also, transverse reinforcement spacings are well above the Code requirements. Upon Fig. 7 was investigated, it can be seen the Model 5 has the largest spectral acceleration. However, the others models are unders effective ground movements, too.

3. Results

Structural performances of the models were determined by performing nonlinear static pushover analyses. The capacity spectra and performance results obtained for the x and y directions are presented in Figs. 8-12, respectively. Upon these results were examined, it was determined that all buildings could not provide the desired performance level and collapsed because the capacity spectrum of the buildings was well below the demand spectrum. The lack of reinforced concrete walls in buildings, very low concrete strength, and insufficient transverse reinforcement spacing are the most important reasons for the decrease in the performance of these structures. In addition, the proximity of the structures to active faults caused the structures to experience large earthquake accelerations.

4. Conclusions

In this study, 5 different reinforced concrete buildings built in Tunceli during the period when the TBEC 1975 was in force were examined and the condition of the building stock of this period in Tunceli was evaluated. Core samples were taken from 5 buildings selected for the numerical study and the reinforcement in the building elements was determined. In addition, since there were no plans of the buildings, survey studies were carried out and ground conditions were determined by ground surveys. Then, the buildings were modeled with the STA4CAD building analysis program and nonlinear static pushover analyzes were performed. The results obtained from the study are written below.

- The buildings examined do not even meet the requirements of the TBEC 1975.
- There are not enough reinforced concrete walls in buildings to restrict horizontal drift.
- One of the most important reasons for low structural performance is low concrete strength. Since ready-mixed concrete was not used in the construction of the buildings, casting was done by hand. In the concrete samples examined, river aggregate was used instead of crushed stone as aggregate and not enough cement was used, which caused the concrete strength to be low.
- In the examination carried out in terms of reinforcement, it was determined that smooth surface reinforcement was used in the structural elements. In addition, the large stirrup spacing caused the shear stress resistance of these elements to decrease.

As a result, it is thought that the performance of similar buildings in Tunceli will not be sufficient in the evaluation made on these buildings. In order to prevent loss of life and destruction, performance inspections of buildings with inadequate engineering control and low concrete strength must be carried out. As a result of the evaluation, it is recommended that the relevant buildings be strengthened or demolished and rebuilt.

Influence of location of tuned mass damper in reducing vibrations of a building subjected to ground motions

Onur Araz*[1], Mohammed M. A. Saif[1]

[1] *Gumushane University, Department of Civil Engineering, 29100 Gumushane, Türkiye*

Abstract. The loss of life and property caused by earthquakes has led researchers to work more intensively on earthquake-resistant building design. One of the most effective methods used to reduce vibrations in structures subjected to earthquake excitations is the tuned mass damper (TMD). The TMD is a single degree of freedom (SDOF) system consisting of a mass, a stiffness, and a damping element. In order for the TMD to provide adequate control performance, its mechanical properties must be properly determined. Therefore, the majority of studies conducted on TMD are aimed at determining the optimum values of its mechanical properties. Another factor that affects the effectiveness of TMD is the location of TMD. TMD is generally placed on the top floor of buildings under dynamic loads (i.e., wind and seismic loads). Thus, the effect of TMD's location on the effectiveness and optimum design of TMD is investigated in this study. For this purpose, TMD is placed on three different floors (i.e., 1st floor, 2nd floor, and 3rd floor) in a 3-story shear building. The optimum parameters of TMD (i.e., the optimum frequency ratio and damping ratio) are obtained using the genetic algortihm (GA). The optimum parameters obtained in the frequency domain are then tested using twelve earthquake records in time domain analyses. Numerical results show that TMD's location is important in reducing displacement and acceleration responses of the structure affected by ground motions.

Keywords: Earthquake; Seismic response; Tuned mass damper; Vibration control

1. Introduction

Globally, over one million seismic events occur annually. Earthquakes in urban areas can cause structural shaking, deformations, and harm to people (Ras, 2014). High levels of such vibrations may lead to discomfort for individuals or disrupt certain systems. To address these dynamic effects on civil engineering structures, mitigation measures are essential. Researchers have explored various damping systems, including active, semi-active, and passive types (Kahya & Araz, 2019). Active and semi-active systems require external energy to function (Kaveh et al., 2015), unlike passive systems. Among passive devices used in practice, the Tuned Mass Damper (TMD) stands out (Fahimi Farzam et al., 2020).

The primary goal of integrating a TMD into a structure, like other passive systems, is to reduce the structural elements' demand by dissipating part of the input energy (Araz & Kahya, 2021). This is achieved by transferring vibrational energy from the structure to the damper. The concept of the TMD in contemporary applications traces back to dynamic vibration absorbers studied by Frahm in 1909 (Araz, 2021a). In its simplest configuration, a TMD comprises a solid mass and a spring connected to the structure (Araz, 2021b), as shown in Fig. 1. While proposed for seismic design, TMDs have primarily been applied to mitigate wind-induced vibrations.

Several review papers discuss their practical applications, as well as linear and nonlinear theories (Mariantonieta & Hojjat, 2013; Rahimi et al., 2020; Sgobba & Marano, 2010). Numerous studies have analyzed the performance of these systems (Garcí et al., 2021; Takeshi et al., 2019), while others have focused on their enhancement (Khatibinia et al., 2018; Lavan, 2017). Some research has proposed mathematical algorithms to improve structural responses to seismic and wind loads (Gino & Marcus, 2019; Mohtasham et al., 2013). Kaveh and Ardebili (2021) performed a comparative analysis of an optimal tuned mass damper for tall structures, accounting for soil-structure interaction. The effect of different support conditions on the effectiveness of TMD also has been addressed by many researchers (Zhao et al., 2019; Zhao et al., 2024; De Domenico et al., 2018; Araz & Elias, 2024; Araz, 2024, Araz, 2025; Araz et al., 2023).

In this study, the effect of TMD in reducing the dynamic effects of a 3-storey building under earthquake effect will be investigated. In this context, TMD will be placed on the 1st, 2nd and 3rd floors respectively. The dynamic

* Corresponding author, E-mail: onuraraz29@hotmail.com

https://doi.org/10.31462/icearc2025_ce_eqe_217

responses obtained for each case will be compared with the dynamic responses in the uncontrolled case. Finally, the control performance of TMD is compared for different situations.

2. Governing equations of motion

The structural model of a 3-story shear building with TMD is shown in Fig. 1. With the addition of TMD, the degrees of freedom of the building increases from 3 to 4. Here, TMD is placed on the 1st, 2nd and 3rd floors of the building, respectively. In the study, these are named as Case-1, Case2, and Case-3, respectively.

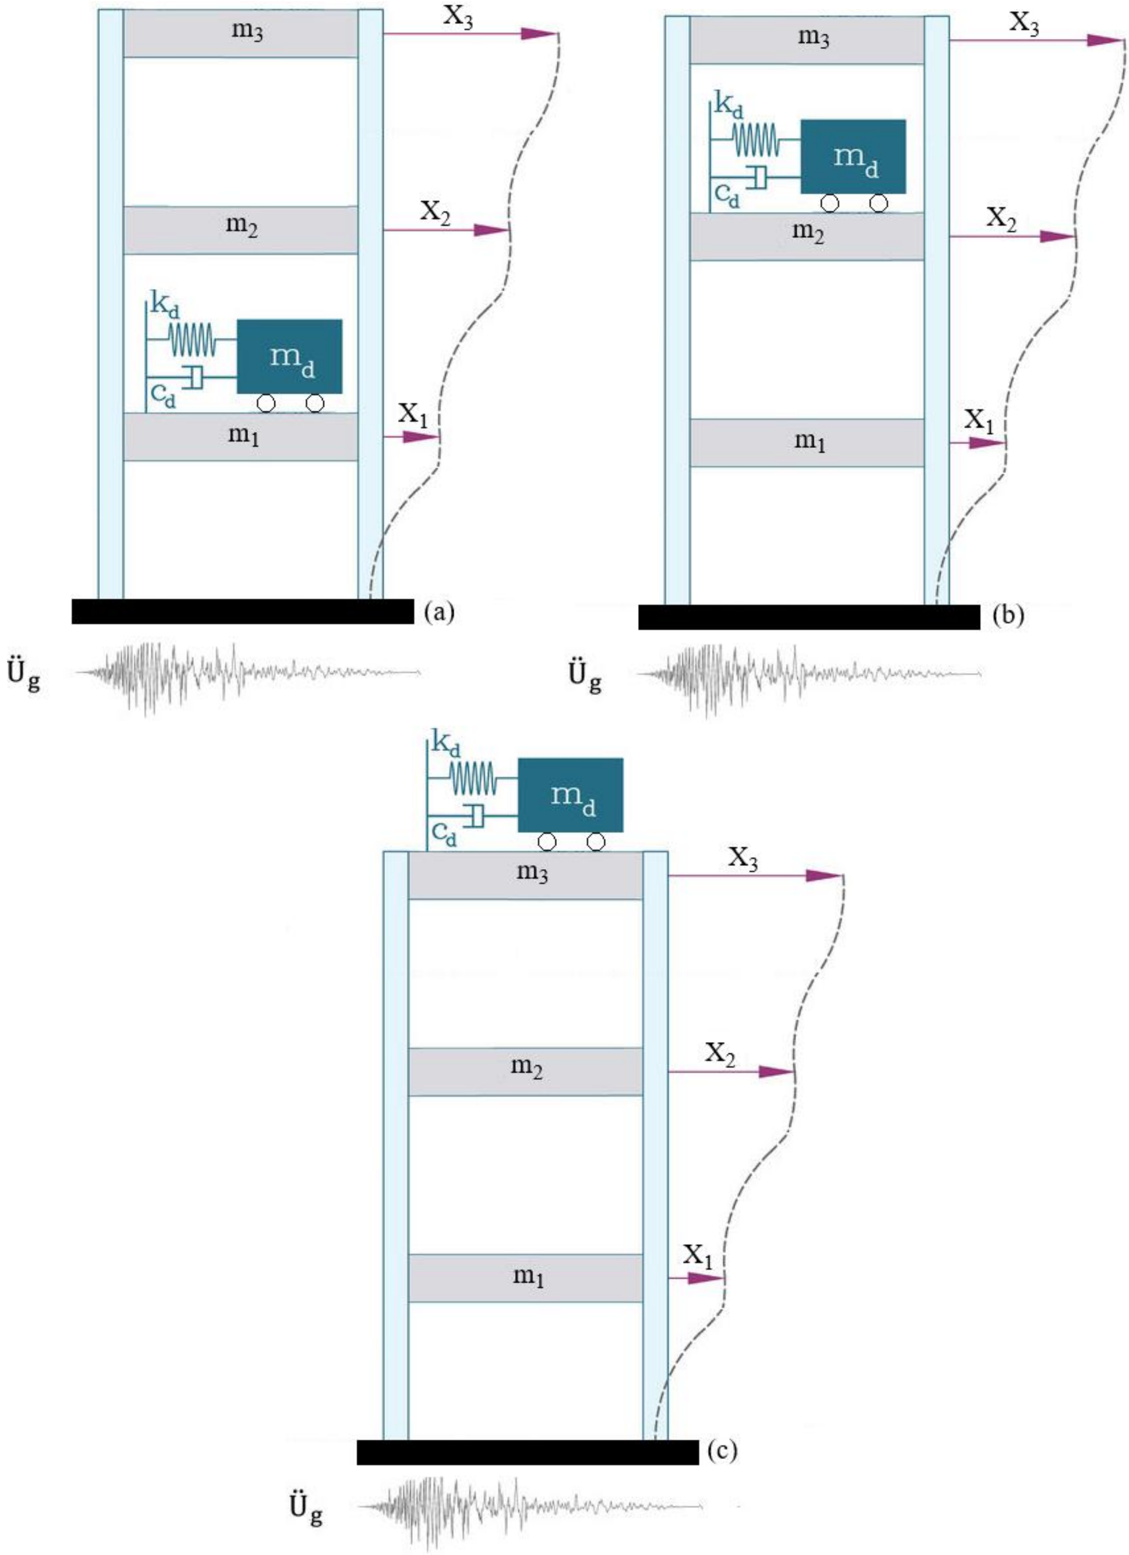

Fig. 1. 3-story building equipped with TMD. a) TMD added to the 1st floor (i.e., Case-1); b) TMD added to the 2nd floor (i.e., Case-2); c) TMD added to the 3rd floor (i.e., Case-3), respectively

The equations governing the motion of the building model with a TMD (i.e., Case-3) are represented by

$$\mathbf{M}\ddot{\mathbf{x}}(t)+\mathbf{C}\dot{\mathbf{x}}(t)+\mathbf{K}\mathbf{x}(t)=-Z\ddot{\mathbf{U}}_g(t) \tag{1}$$

Here, **M**, **C** and **K** are the (*4*×*4*) mass, damping and stiffness matrices, respectively. x denotes the (4×1) horizontal displacement vector. The equations of motion for Case-1 and Case-2 can be derived by taking into account the location of the TMD.

$$\mathbf{M}=\begin{bmatrix} m_1 & & & \\ & m_2 & & \\ & & m_3 & \\ & & & m_d \end{bmatrix} \tag{2}$$

$$\mathbf{C}=\begin{bmatrix} c_1+c_2 & -c_2 & & \\ -c_2 & c_2+c_3 & -c_3 & \\ & -c_3 & c_3+c_d & -c_d \\ & & -c_d & c_d \end{bmatrix} \tag{3}$$

$$\mathbf{K}=\begin{bmatrix} k_1+k_2 & -k_2 & & \\ -k_2 & k_2+k_3 & -k_3 & \\ & -k_3 & k_3+k_d & -k_d \\ & & -k_d & k_d \end{bmatrix} \tag{4}$$

$$\boldsymbol{Z}=\begin{bmatrix} m_1 & m_2 & m_3 & m_d \end{bmatrix}^T \tag{5}$$

$$x(t)=\begin{bmatrix} x_1 & x_2 & x_3 & x_d \end{bmatrix}^T \tag{6}$$

The floor masses, stiffness and damping values are represented as m_i, k_i, and c_i, respectively. m_d, k_d, and c_d are the TMD mass, stiffness, damping coefficients, respectively.

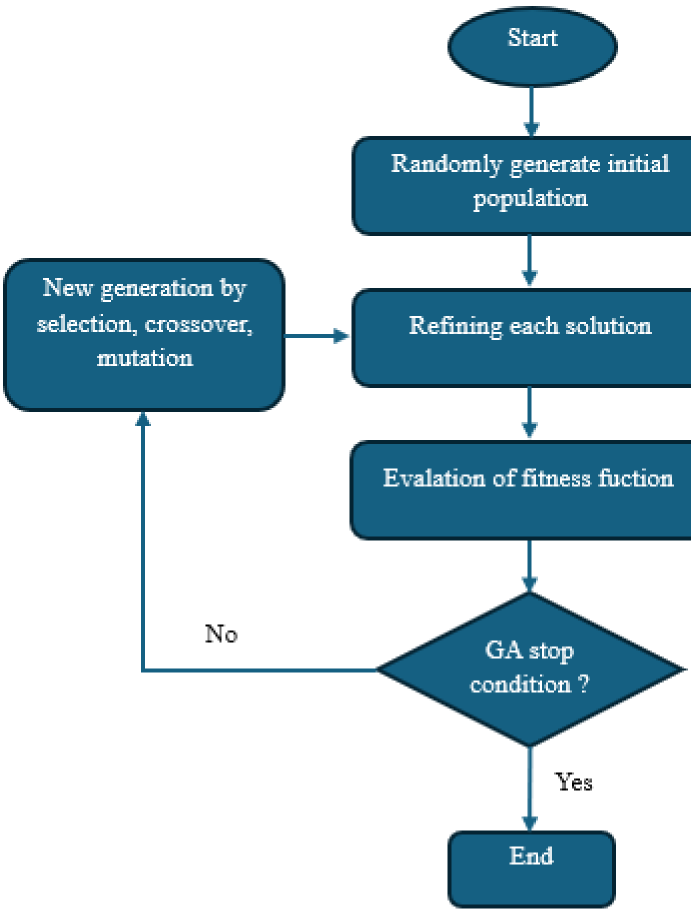

Fig. 2. Flowchart of GA

The design parameters of TMD are obtained by using genetic algorithm (GA) in frequency domain. GA is powerful optimization techniques inspired by the principles of natural selection and evolution, widely applied in engineering to solve complex, non-linear problems. By iteratively evolving a population of candidate solutions through selection, crossover, and mutation operations, GA efficiently explore large search spaces to identify optimal or near-optimal solutions. Their robustness and adaptability make them suitable for diverse applications, including structural design, control systems, and scheduling, where traditional methods may struggle. The aim of the optimization is to minimize the amplitude value of the displacement at the top floor of the building. The flow chart for the genetic algorithm is shown in Fig. 2.

The design parameters of TMD are expressed as follows

$$\xi_d = \frac{c_d}{2m_d\omega_d}; \quad \gamma = \frac{\omega_d}{\omega_1}; \quad \mu = \frac{m_d}{m_1 + m_2 + m_3} \tag{7}$$

Here, ξ_d, γ, and μ are the damping ratio, frequency ratio, and mass ratio of the TMD, respectively. Assuming that the mass ratio of the TMD is known at the beginning, the optimum values of ξ_d and γ are investigated.

3. Numerical study

The proporties of the three-story building considered in the study are given in Table 1. The natural frequencies corresponding to the first three modes of the building are given in Table 2. As can be seen, the obtained values are in agreement with the literature.

The optimum values of TMD for each case considered are summarized in Table 3. In obtaining these values, the mass ratio (μ) is taken as 0.05. As can be seen, from Case-1 to Case-3, the damping values increase while the stiffness values decrease. This situation causes a decrease in frequency ratio (γ) and an increase in the damping ratio (ξ_d). Optimization results obtained for each case are also presented in Fig. 3.

Table 1. Properties of 3-story building

Floor number	Mass (t)	Stiffness (MN/m)	Damping (kNs/m)
1	20	3.5	21.98
2	15	2.5	15.67
3	10	1.0	6.28

Table 2. Natural frequencies (ω_i) of 3-story building (rad/s)

Mode	Present	Marian and Giaralis (2014)
1	6.38	6.37
2	13.02	13.02
3	20.57	20.57

Table 3. Optimum values of the TMD

Case	m_d (kg)	k_d (N/m)	c_d (kNs/m)
Case-1	2250	88.736	1.913
Case-2	2250	81.502	3.719
Case-3	2250	66.935	5.552

In order to examine in detail the changes that occur on the dynamic responses of the building when the TMD is placed on different floors, 90 earthquake records are taken into account in the time history analysis. The features of the selected earthquakes are given in Fig. 4.

Figs. 5 and 6 show the maximum displacements and accelerations obtained at the top floor of the building, respectively. From these figures, it is seen that the responses in the uncontrolled condition are lower than the responses in the controlled condition. When compared to Case-1 and Case-2, it is observed that the responses obtained for Case-3 are lower.

The reductions obtained in displacement and acceleration reactions for the controlled cases are shown in Figs. 7 and 8, respectively. From these figures, it is seen that TMD is ineffective under some ground motions and even causes an increase in dynamic responses. However, the number of these earthquakes is quite low. This is due to the fact that the optimum parameters of TMD are obtained independently from earthquake records.

The average reduction ratios obtained for the displacement and acceleration responses are shown in Fig. 9. It can be seen that the highest control performance is obtained for Case-3, Case-2, and Case-1, respectively. Also, it is seen that TMD is more effective in reducing the displacement responses. This is because the goal of the optimization is to reduce the displacements at the top floor.

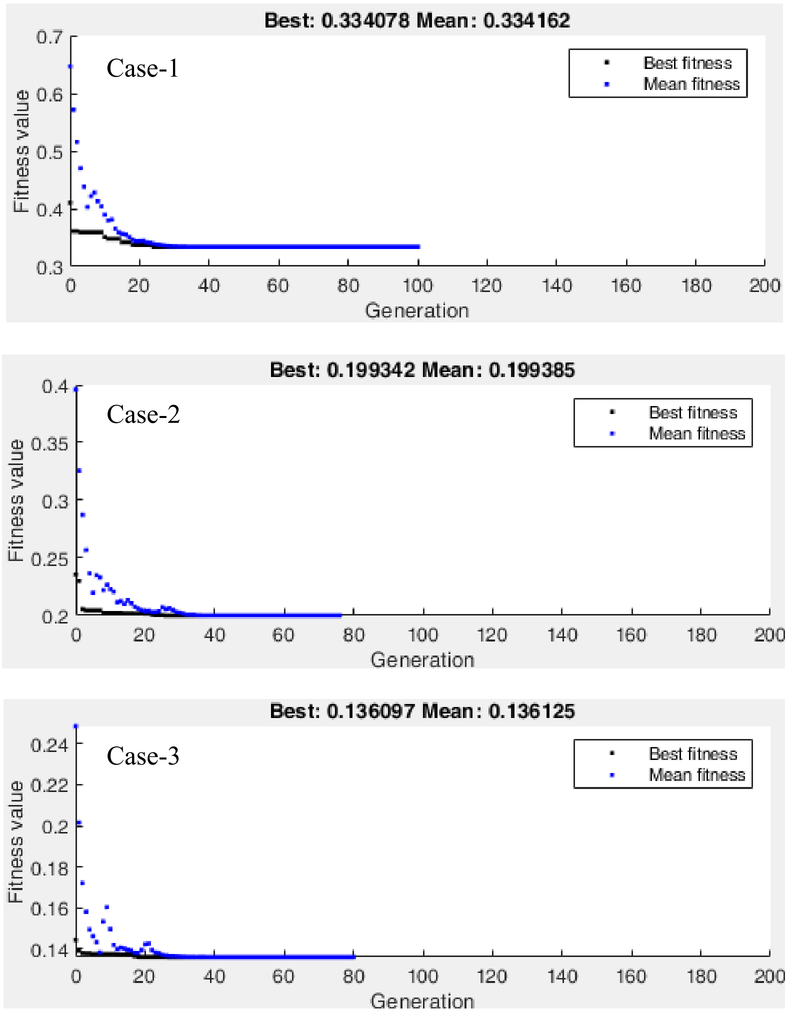

Fig. 3. Optimization results obtained for each case

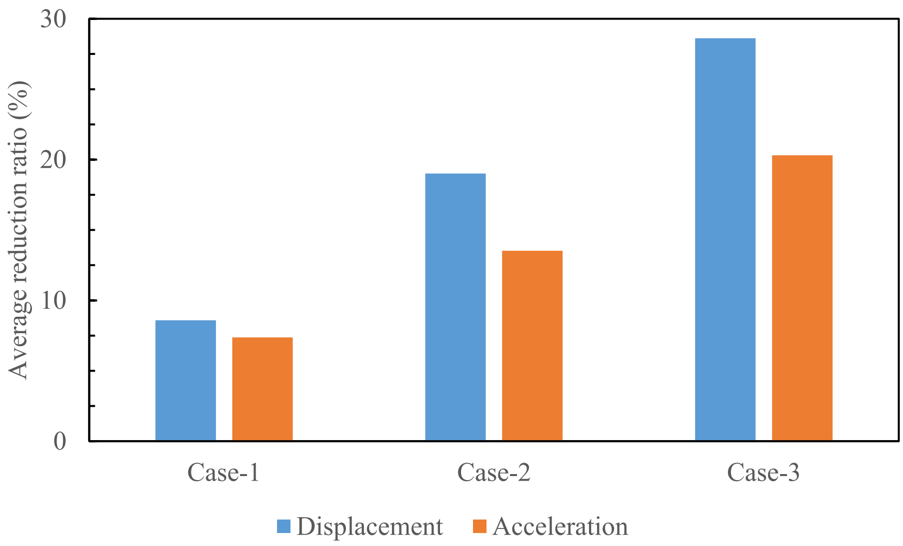

Fig. 9. Average reduction ratios of the maximum dynamic responses

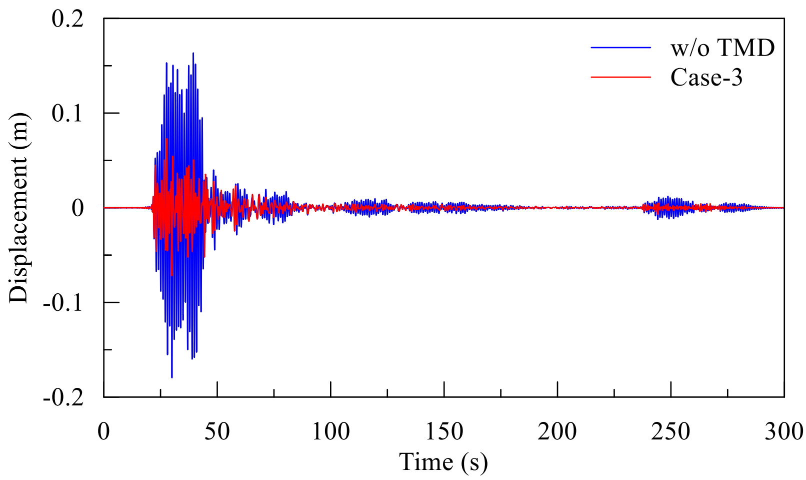

Fig. 10. Displacement time history of the building at the top story

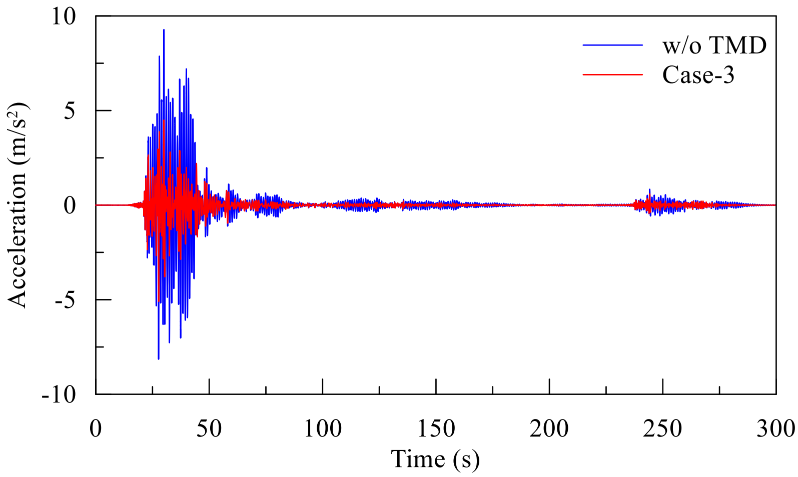

Fig. 11. Acceleration time history of the building at the top story

Figs. 10 and 11 show the time-dependent variation of displacement and acceleration at the top floor of the building under a benchmark earthquake record (i.e., $M_w = 6.63$, $R_{jb} = 25.14$ km, and PGA = 0.12g), respectively. The peak displacement and acceleration are reduced by 59.29% and 45.14%, respectively.

4. Conclusions

In this study, TMD was placed on the 1st, 2nd and 3rd floors of a 3-storey building, respectively, and the optimum values of TMD for these locations are obtained. Then, the accuracy of the obtained optimum parameters is investigated using 90 ground motions in the time domain. The main findings of the study are summarized below.

- Placing the TMD on different floors of the building causes significant changes in the design parameters of the TMD. The highest stiffness value is obtained when the TMD is placed on the 1st floor (i.e., Case-1), while the highest damping value is obtained for the 3rd floor (i.e., Case-3).
- The control performance of the TMD is significantly affected by the placement of the TMD on different floors. The largest reduction ratio in dynamic response values is obtained when the TMD is placed on the third floor (i.e., Case-3).
- When the TMD is placed on the 3rd floor of the building, the displacement and acceleration responses are reduced by approximately 30% and 20%, respectively.

Abstract. Finite element methods are widely recognized as reliable tools for evaluating the seismic performance of historical structures. However, the accurate definition of parameters such as material properties, which often involve significant uncertainties, is crucial for the validity of these analyses. In this study, the seismic behavior of Malatya Yeni Mosque, which completely collapsed during the 2023 Kahramanmaraş earthquakes, was investigated by examining the impact of different material properties. A finite element model of the mosque was developed, and two distinct sets of material properties recommended in the literature were assigned to the model. The first model (Model-1) utilized material properties derived from previous studies on the structure. The second model (Model-2) incorporated general material properties proposed in the literature for historical masonry mosques. Both models were subjected to dynamic analyses using a ground motion record obtained in Malatya during the Kahramanmaraş earthquakes. The results of the dynamic analyses revealed that material properties significantly influence the seismic performance of the structure. In Model-1, the structure exhibited no signs of damage. However, in Model-2, considerable damage was observed in structural elements, closely resembling the actual collapse mechanisms of the mosque during the earthquake. These findings highlight the critical importance of accurately defining material properties in the seismic performance assessment of historical structures to predict their behavior under seismic loading. Moreover, the study offers valuable insights into the calibration of analyses and the planning of effective retrofitting strategies for such structures.

1. Introduction

In recent years, devastating earthquakes have made the preservation of cultural heritage structures a priority research topic (Kocaman, 2023a; Mercimek, 2023; Yilmaz et al., 2024; Atmaca et al., 2024). These structures, which reflect the craftsmanship, technical knowledge, and cultural fabric of past generations, hold critical importance not only for their architectural and aesthetic value but also for preserving the collective memory of societies. Turkey, with its rich cultural diversity and heritage from various historical periods, stands out as a prominent representative of this legacy. According to data from the Turkish Ministry of Culture and Tourism, approximately 120,000 immovable cultural assets with diverse functions have been registered. Of these, around 9% consist of historical mosques and churches. Furthermore, 19 sites in Turkey are listed as UNESCO World Heritage Sites, with an additional 84 sites on the tentative list (KVMGM, 2005).

Turkey's location within the Alpine-Himalayan seismic belt presents a significant challenge to the preservation of its cultural heritage. Historical masonry mosques are particularly vulnerable to seismic events due to factors such as low tensile strength, limited energy dissipation capacity, weak connections between structural elements, insufficient out-of-plane resistance, and material deterioration (Kocaman & Kazaz, 2023; Aşıkoğlu et al., 2019). In this context, seismic performance assessments of historical structures have become increasingly important for developing effective retrofitting strategies to enhance their earthquake resilience (Şentürk et al., 2022).

Finite element modeling, commonly used to investigate the seismic behavior of historical masonry structures, employs micro- and macro-modeling techniques depending on the desired level of accuracy and the scale of the structure. These methods provide valuable insights into potential collapse mechanisms and help improve the earthquake resistance of such structures (Valente, 2023; Valente & Milani, 2018; Aghabeigi & Farahmand-Tabar,

* Corresponding author, E-mail: irfan.kocaman@erzurum.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_241

2021). These analyses contribute to the development of scientifically grounded strategies for preserving cultural heritage.

In structural modeling studies, one of the most critical steps in the finite element method is the accurate characterization of material properties. The non-homogeneous behavior of stone units, their prolonged exposure to environmental effects, and the influence of stone dimensions on the mechanical properties of entire walls present various challenges in this process. National and international codes propose different mechanical properties for stone masonry walls; however, the literature reveals a wide range of compressive strength (fc), tensile strength (ft), and modulus of elasticity (E) values. This wide variability complicates the determination of realistic parameters.

This study presents analyses conducted on Malatya Yeni Mosque, which completely collapsed during the 2023 Kahramanmaraş earthquakes. The mosque had sustained significant damage during the 2020 Elazığ-Sivrice earthquake and subsequently underwent extensive retrofitting and restoration efforts to repair the damage. During the restoration, material properties were determined from samples taken from the mosque and incorporated into finite element models. Two distinct models were utilized in the study: Model-1 employed mosque-specific material properties proposed in previous studies, while Model-2 utilized generic material parameters for masonry stone walls recommended in the literature and codes.

Nonlinear dynamic analyses were performed on both models using ground motion records from the 2023 Kahramanmaraş earthquakes observed in Malatya. The analysis results indicated that Model-1 experienced minimal damage, whereas Model-2 sustained significant damage and eventually collapsed. Additionally, the observed damage mechanisms in Model-2 closely aligned with those identified in post-earthquake field studies. These findings underscore the critical importance of accurately defining material properties for the seismic performance of historical masonry structures.

2. Determining material properties in historical structures

Determining the material properties of historical masonry structures requires more complex and specialized approaches compared to modern construction materials. The properties of the stones and mortars used in masonry structures vary significantly from one building to another, making it difficult to accurately define material parameters (Lourenço, 2002). One of the main challenges is the heterogeneous nature of the structures. The types of stones used, the mortar compositions, and environmental effects directly influence the mechanical properties of the material. Additionally, the limitations in testing historical structures significantly restrict sampling processes and the reliability of these samples. In particular, samples taken from deteriorated or damaged areas may not provide representative information about the overall structure.

Different methods for determining material properties are proposed in the literature and regulations. These methods are generally divided into two categories: non-destructive methods and destructive methods. Non-destructive methods allow for determining material properties while preserving the integrity of the structure. Techniques such as ultrasonic velocity measurements, surface hardness tests, and vibration analysis are among these methods. However, these methods may be insufficient for determining the exact mechanical properties of the material (Pantò et al., 2024). Destructive methods usually require sample collection and laboratory testing. These methods are used to measure compressive strength, tensile strength, and elasticity modulus (Banjo et al., 2024). However, the limitations in the sampling process and the risk of damaging the structure restrict the use of these methods.

Researchers often refer to national and international regulations when determining material properties. These regulations include parameters such as compressive strength (fc), tensile strength (ft), elasticity modulus (E), density (γ), and Poisson's ratio (v) (GERMHS, 2017; TEC-07, 2007; TBEC, 2018; FEMA 356, 2000; Eurocode-6, 2005). However, since historical structures are generally built with local materials, it is more appropriate to rely on national regulations. Nonetheless, the diversity of regulations and uncertainties in the properties of local materials create additional challenges in seismic performance analysis.

Differences between regulations become particularly evident when parameterizing material properties. For example, the GERMHS (2017) regulation defines the relationship between fc and E as 460fc, while TEC-07 (2007) specifies it as 200fc. TBEC-18 (2018) suggests 750fc, FEMA356 (2000) proposes 550fc, and Eurocode-6 (2005) recommends 1000fc. This wide range highlights the lack of standardization in determining material properties and the variability of results in analyses based on regulations.

To overcome these challenges, researchers utilize studies and recommendations found in the literature. Similar building types, wall typologies, and construction techniques provide important references for evaluating material properties. For instance, if buildings constructed in the same region contain similar stone and mortar types, the test results from these structures can serve as guidance for other similar buildings. The impact of construction techniques, stone types, and mortar compositions on material properties is considered to determine parameters that are consistent with local building practices (Kocaman, 2024).

In the literature, material properties used in historical masonry structures are presented over a broad range. For example, compressive strength may vary between 2 MPa and 27 MPa, and elasticity modulus may range from 600

MPa to 5000 MPa. This diversity depends on the geographical location of the structures, the types of materials used, and environmental effects. Therefore, to accurately determine material properties, tests on similar structures and recommendations from the literature are carefully evaluated.

Table 1 summarizes the material properties accepted in the literature for historical masonry structures. This table can serve as a guide for determining material parameters based on the uniqueness of the structures and local conditions. This diversity allows for the accurate analysis of a structure's seismic resilience and the achievement of reliable results.

Table 1. Material properties for historical masonry Structures - recommendations from various studies

Study	Material Properties					Structure type

2.1. Malatya Yeni Mosque

Malatya Yeni Mosque, also known by the public as "Teze Mosque" and "Ulu Mosque," is a significant structure located in the city center of Malatya. Initially built in 1843 by Hacı Yusuf, this mosque was rendered unusable after fires in 1889 and 1890. Following these fires, no restoration work was carried out, and the mosque was completely destroyed in the 7.1 magnitude earthquake that struck the region in 1893 (Selahattin, 2016). The mosque was rebuilt in 1913 at the same location, retaining its original design; however, only one minaret from the original structure has survived to this day.

The Malatya Yeni Mosque, which was damaged in the 2020 Elazığ-Sivrice Earthquake (Mw 6.8), underwent a comprehensive restoration process and was reopened for prayer in 2022. However, the earthquake centered in Kahramanmaraş on February 6, 2023, caused the complete destruction of the mosque.

Designed with a square plan and a central dome, Malatya Yeni Mosque reflects the characteristics of the late Ottoman architecture. The mosque is approximately 26 meters by 29 meters in size, with wall thickness around 1.2 meters. The load-bearing walls are constructed in a three-leaf arrangement, and there are two minarets located at the northeast and northwest corners of the structure. Between these minarets, the prayer hall is surrounded by five small domes.

The central dome is supported by four octagonal supporting columns (pendentives), which are connected to the walls with an arch system. The diameter of the central dome is approximately 11 meters, and its height has been measured as 21 meters. The appearance and details of the mosque before its destruction are shown in Fig. 1. For more detailed information about Malatya Yeni Mosque, see (Kocaman et al., 2024b).

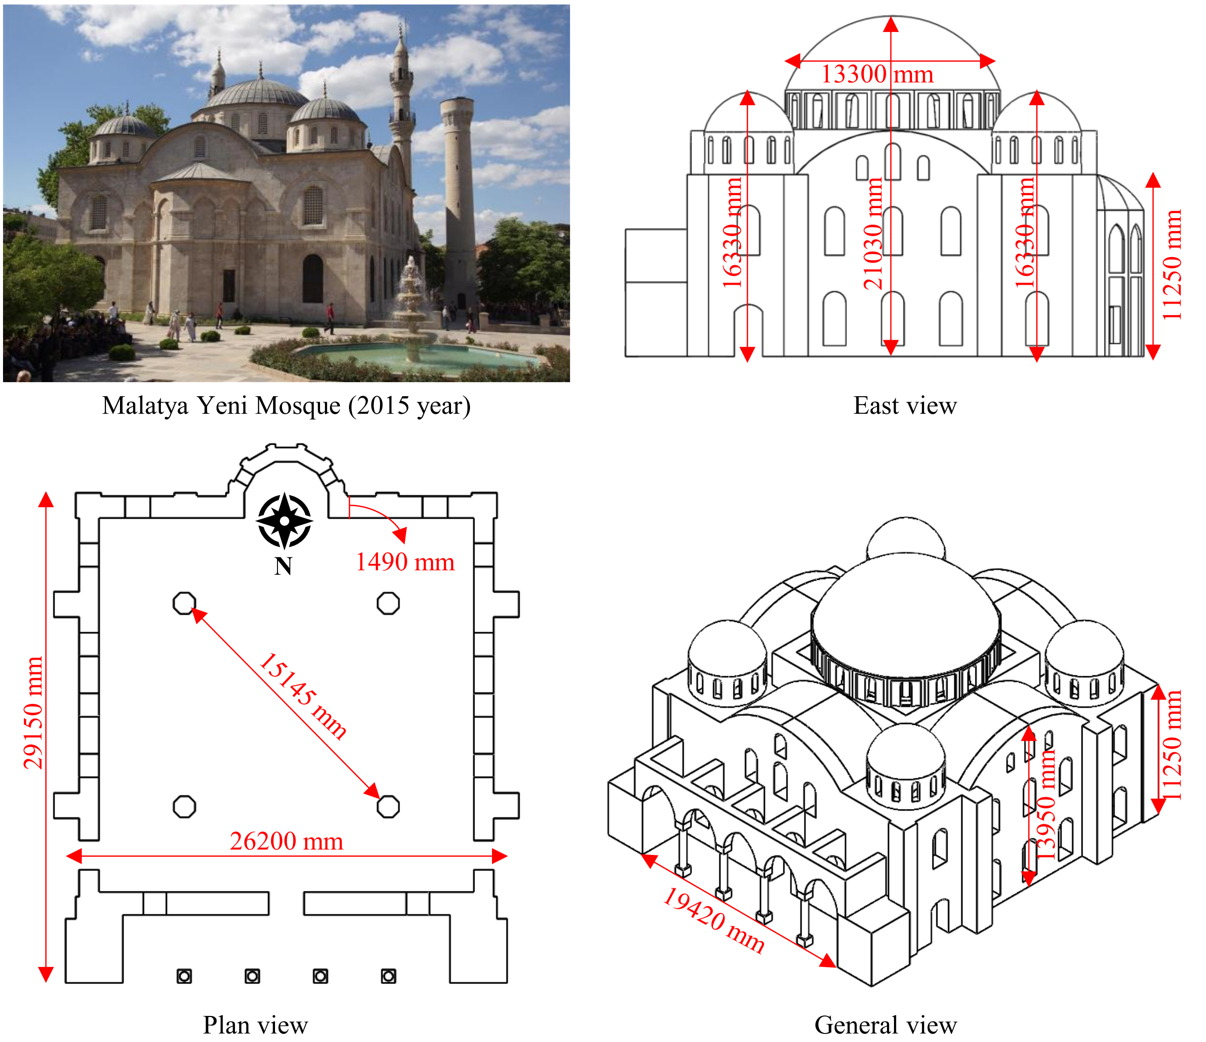

Fig. 1. Historical Malatya Yeni Mosque (Kocaman et al., 2024b)

2.2 Finite element model

The Finite Element Method (FEM) is a commonly used tool for examining the seismic performance of historical masonry mosques. Micro and macro modeling approaches are preferred based on model accuracy and computational efficiency. Micro modeling focuses on the behavior of individual units and mortar, while macro modeling treats the structure as a homogeneous entity, making it more suitable for the analysis of large structures (Valente, 2021). This study uses macro modeling and nonlinear dynamic analysis to understand the seismic behavior of the mosque's walls.

The three-dimensional model of the mosque was created using SolidWorks and transferred to ANSYS APDL for analysis. In the analyses, the SOLID65 element was preferred. This element is particularly notable for its ability to model nonlinear material behavior in masonry structures. The cracking conditions at each integration point and the corresponding material properties were modeled using SOLID65. However, factors such as element mesh density and skewness values are important. In the study, a mesh structure consisting of 286305 elements and 67687 nodes was used, with the element skewness value calculated as 0.16.

The masonry material behavior was analyzed using the Willam-Warnke material model. This model comprehensively defines the failure behavior of masonry materials by considering key parameters such as tensile and compressive strengths. In the analyses, shear transfer coefficients for tensile and compressive strengths were assigned as 0.05 and 0.8, respectively (Kocaman, 2023a).

Structural analysis of historical mosques is influenced by factors such as boundary conditions, material uncertainties, and geometric complexities. These factors require the use of advanced and reliable methods in the analyses. In this study, the mosque's foundational supports were assumed to be fixed, and soil-structure interaction was not considered due to a lack of soil information. Fig. 2 shows the finite element model of the mosque.

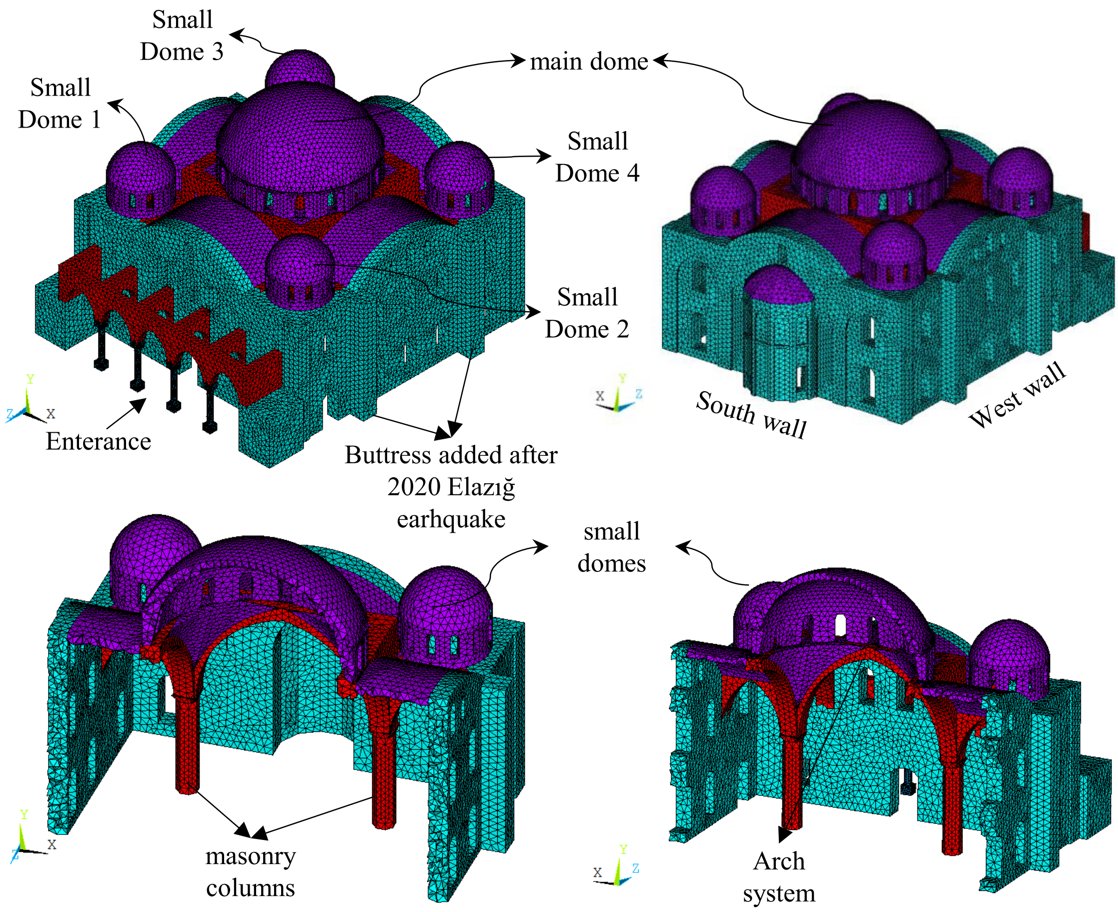

Fig. 2. Finite element model of Malatya Yeni Mosque (Kocaman et al., 2024b)

2.3 Material properties

Historical mosques present significant challenges in determining material properties due to their complex structures and the environmental impacts they have been exposed to over the years. In the literature, destructive and non-destructive tests have been conducted on both damaged and undamaged samples to understand the material properties of these structures. The unique characteristics of natural stones, in particular, reveal a distinctive structural profile for each mosque.

In this study, material properties were first determined through literature and regulatory recommendations. These material properties are used in Model-2 (M2). Demir (2012) conducted comprehensive compression tests on three-leaf walls. The study revealed an average compression strength of 3 MPa. Similarly, various studies in the literature have examined mosques with similar architecture in the region. Aşıkoğlu et al. (2019) used non-destructive methods to determine the material properties of Kurşunlu Mosque and recommended a compression strength of 2.1 MPa for the walls. Additionally, Kocaman and Gürbüz (2023b) performed finite element analyses to identify the collapse mechanisms of the narthex sections in mosques. In their models, they suggested a compression strength of 5.5 MPa for arches and 10 MPa for stone columns. Regarding compression strength values, the Italian Code (2009) recommends a range of 2.6-3.8 MPa for cut stone masonry. Therefore, for this study, the compression strength of the walls was accepted as 3 MPa. It is noteworthy that historical structures have low compression stresses and very low tensile strength. Experimental and analytical studies on historical mosques (Kocaman & Gürbüz, 2024; Gürbüz & Kocaman, 2024) have observed that the tensile strength is approximately 10% of the compression strength, and the Poisson's ratio varies between 0.17 and 0.2.

The second approach involves using material properties determined during restoration and strengthening works carried out after the 2020 Elazığ-Sivrice earthquake. These material properties are used in Model-1 (M1). In a study by Fırat et al. (2022), compression strengths of stone samples taken from the mosque were determined. The average compression strength of three samples was found to be 75.69 MPa, and their densities were 2458.4 kg/m³. The compression strength of the building's walls was calculated using the formula specified in TS EN 1996-1-1 (2005), under the heading "Characteristic compression strength of unreinforced masonry buildings made with general-purpose mortar."

$$f_k = K f_b^{0.65} f_m^{0.25} \tag{1}$$

In this context, fk represents the characteristic compression strength of the wall, fb is the compression strength of the stone, and fm is the compression strength of the mortar. K is a coefficient specified in the relevant regulations (TS EN 1996-1-1, 2005). In this case, the value of K has been determined as 0.40. The formula does not provide a value for the compression strength of the mortar. The compression strength of the mortar has been considered as 1 MPa. Accordingly, the characteristic compression strength of the building's wall body is approximately 6.65 MPa. In the literature, the tensile strength of such materials is approximately 1/10th of the compression strength. Therefore, the tensile strength of the building's wall body has been estimated to be approximately 0.66 MPa. The authors have assumed the value of the modulus of elasticity using the approach 1000fc, resulting in an elasticity modulus of 6650 MPa. Details of the material properties obtained with both approaches are provided in Table 2.

Table 2. Mechanical properties of the materials for M1 and M2

Mosque Part	Tensile strength f_t (MPa)		Compressive strength f_c (MPa)		Specific weight γ (kN/m^3)		Poisson ratio		Modulus of elasticity E (MPa)	
	M1	*M2*	*M1*	*M2*	*M1*	*M2*	*M1*	*M2*	*M1*	*M2*
Walls	0.30	0.66	3.00	6.65	24.5	24.5	0.18	0.30	600	6650
Dome and vaults	0.30	0.66	3.00	3.00	24.5	24.5	0.18	0.30	500	3375
Columns and Arches	0.55	0.66	5.50	6.65	24.5	24.5	0.18	0.30	1100	6650
Stone columns	1.00	1.00	10.00	10.00	29.0	29.0	0.20	0.30	10000	10000

3. Numerical analyses and results

The numerical analyses were conducted using two different models. The first model (Model-1) uses material properties determined based on literature recommendations, while the second model (Model-2) employs material properties obtained from samples taken from the structure and different approaches.

3.1 Modal analyses

In both finite element models of Malatya Yeni Mosque, vibration frequencies and mass participation ratios were determined using the modal analysis method. The analysis focused primarily on the first three modes, with a total of 20 modes evaluated. Table 3 provides the frequency values and mass participation ratios for these modes, offering significant data regarding the horizontal and vertical dynamic behavior of the mosque. In both models, the first mode represents movement in the north-south plane (Z direction), the second mode represents movement in the east-west plane (X direction), and the third mode represents torsional motion (rotation in the Y direction).

Fig. 3 presents graphical representations of the first three mode shapes obtained from both models. These visuals detail how the structure responds to different vibration modes and reveal its modal behavior. In both models, the total mass of the structure was calculated to be approximately 6080 tons. This mass is a key parameter that significantly affects the dynamic behavior of the mosque.

The modal analysis results provide a comprehensive overview of the fundamental vibration characteristics of Malatya Yeni Mosque and lay the groundwork for evaluating its structural performance and potential improvements. The differences between Model-1 and Model-2, particularly regarding changes in material properties, show that the frequency values were affected as expected. However, no significant changes were observed in the mode shapes or mass participation ratios.

Table 3. Frequencies and mass participation ratios (MPR) for the Model-1 and Model-2

Mod	Frequency (Hz)		MPR (X dir. vertical)		MPR (Z dir. vertical)		MPR (Y torsional)	
	M1	M2	M1	M2	M1	M2	M1	M2
1	2.11	6.28	0.66	0.62	0.21E-03	0.61E-04	0.46E-03	0.51E-03
2	2.13	6.37	0.20E-03	0.58E-04	0.70	0.67	0.16E-02	0.15E-02
3	2.66	6.97	0.27E-06	0.97E-06	0.16E-02	0.12E-02	0.32	0.30

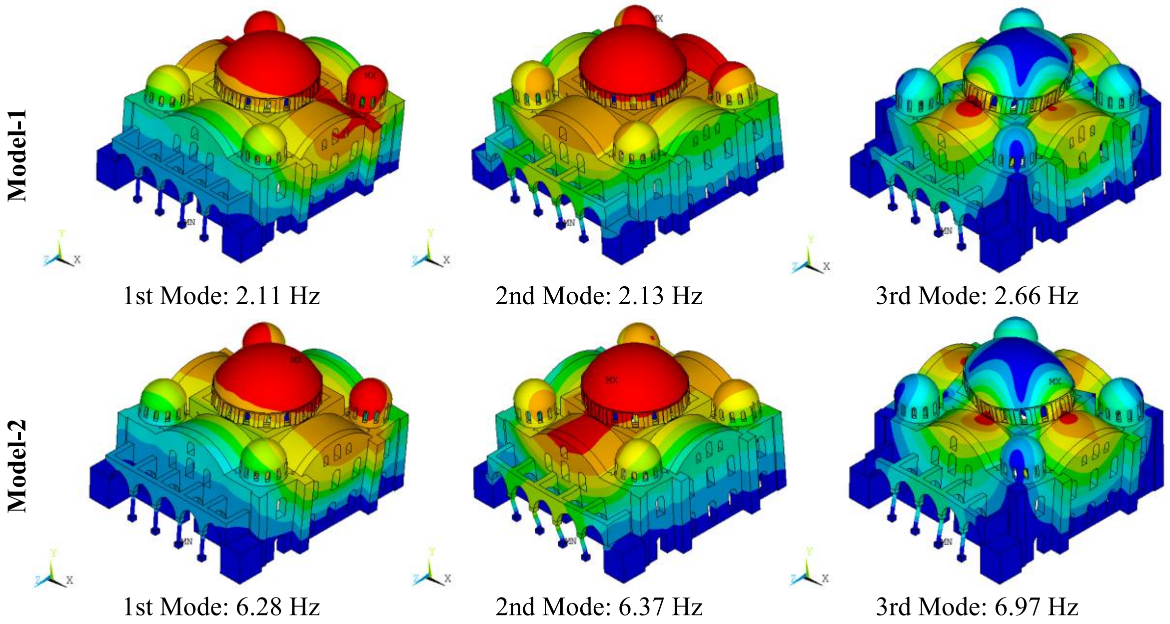

Fig. 3. Model-1 and Model-2 modal shapes of the first three modes

Material property changes result in significant differences in frequency values. Çalık et al. (2020) propose Equation 2 for the frequency value of the first mode of masonry domed mosques.

$$f_1 = 25.230 - 0.715E + 0.518B - 1.706S - 17.690D - 0.447H + 10.554KK + 0.352TA \quad (2)$$

In this equation, f1 represents the frequency value of the first mode (Hz), E is the mosque's short side length, B is the mosque's long side length, S is the length of the vestibule, D is the wall thickness, H is the wall height, KK is the dome thickness, and Ta is the footprint area of all the walls. When these values for Malatya Yeni Mosque are substituted into Equation 2, the frequency value of the first mode is determined to be 2.40 Hz. This result is clearly more suitable when compared to the frequency value of the first mode obtained from Model-1.

3.2. Nonlinear time-history analyses

The dynamic analysis of the mosque in the time domain involved applying the two horizontal components of the selected acceleration record in two orthogonal directions (X-Z). The vertical component was ignored in this analysis. Fig. 4 shows the acceleration-time graphs of the earthquake recorded in the Malatya city center during the Pazarcık-Kahramanmaraş earthquake (04:17 GMT+3, Mw 7.7) on February 6, 2023. Additionally, Fig. 4 presents the response spectra for the East-West (E-W) and North-South (N-S) components. The ground motion data were obtained from the Disaster and Emergency Management Authority (AFAD) database of Turkey (AFAD, 2023), and the dynamic analysis of the mosque was conducted using this recorded ground motion. This analysis allows for the evaluation of how the mosque responds to specific seismic forces produced by the earthquake.

Çalık et al. (2020) conducted experimental modal analysis tests on several historical masonry mosques, revealing damping ratios ranging from 1% to 4%. Additionally, in the literature (Kocaman & Gürbüz, 2024; Gürbüz & Kocaman, 2024; Kocaman, 2023b), a damping ratio of 3% has been proposed by researchers for nonlinear time-history analyses of historical masonry mosques.

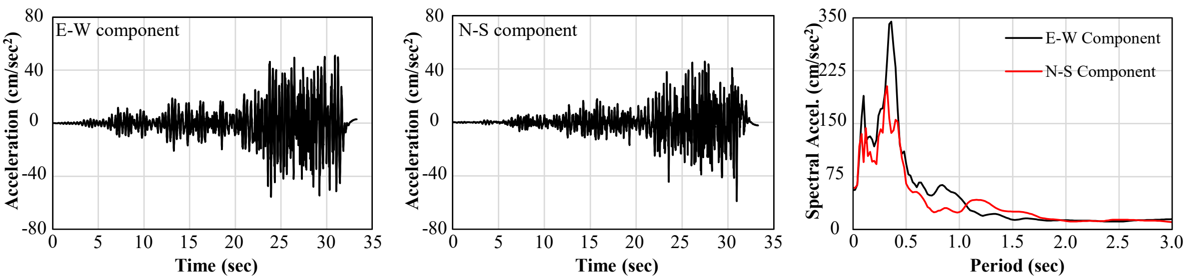

Fig. 4. Malatya city center (station 4414) record of the Pazarcık-Kahramanmaraş earthquake

Fig. 5 shows the peak displacement-time graph obtained from dynamic analyses for two different structural models (Model-1 and Model-2) of the Malatya Yeni Mosque, modeled with different material properties. This analysis, conducted by considering the top of the main dome, compares how the displacement values change over time and the behavior of the structure under dynamic loads. It was observed that Model-2 exhibited limited displacement, around ±5 mm, and remained within elastic limits throughout the analysis. This indicates that the material properties used in Model-2 are consistent with the structure having a high elasticity modulus and compressive strength.

On the other hand, in Model-1, the displacement values exceeded the ±50 mm limit starting from the 16th second and exhibited a sudden collapse behavior by going beyond the elastic limits. This shows that the material properties used in Model-1 represent a structure with a low elasticity modulus and weaker mechanical properties. Once the elastic limits were exceeded, local collapse mechanisms were triggered, and the load-bearing capacity of the main dome's supporting system rapidly decreased. This difference clearly highlights the critical role of material parameters in structural behavior.

The graphical presentation of Fig. 5 emphasizes both the elastic and plastic deformation stages, visualizing the impact of displacement trends on damage mechanisms. Particularly in Model-1, a rapid and uncontrolled displacement process was observed after exceeding the elastic limits, leading to the loss of the structure's overall stability. The analysis results once again emphasize the critical importance of accurately determining the material parameters of historical masonry structures in structural safety assessments and seismic resilience analyses.

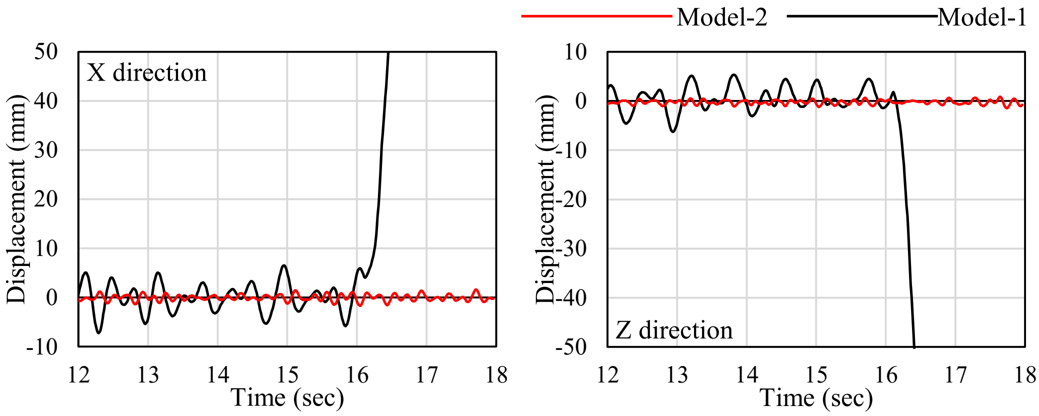

Fig. 5. Displacement-time graphs obtained from Model-1 and Model-2 dynamic analyses

Fig. 6 shows the force-displacement curves obtained from nonlinear dynamic analyses for Model-1 and Model-2 of the Malatya Yeni Mosque. These graphs provide a detailed analysis of the behavior exhibited by the structural components during the elastic and plastic deformation phases. Model-2 demonstrated limited deformation without exceeding the elastic limits under horizontal forces and was observed to have a lateral load-bearing capacity of approximately 5000 kN. This confirms the strength and rigidity provided by the material parameters defined in Model-2. The fact that the elastic limits were not exceeded suggests that no significant damage would occur in the structure and that it could maintain its stability.

The force-displacement curves obtained for Model-1, on the other hand, exhibited a different behavior. In Model-1, the elastic limits were clearly exceeded, and it was observed that the load-bearing capacity of the structure gradually decreased, ultimately resulting in collapse. The loops in the curves indicate that the structure lost its capacity to dissipate energy and that plastic deformations progressed in the structural elements. Particularly, the rapid reduction in the structural capacity was influenced by the damage at the arch-column joints. This collapse behavior is associated with the low strength and rigidity parameters of the materials used in Model-1.

A detailed analysis of the graphs clearly demonstrates how the material differences between the two models affect structural performance. In Model-1, after exceeding the elastic limits, the load-bearing capacity rapidly decreased, indicating that damage progressed quickly. In contrast, the curve for Model-2 shows that the material parameters provided higher strength and allowed the structure to maintain its stability under lateral loads. This analysis once again highlights the critical importance of the accuracy and calibration of material parameters in seismic performance evaluations.

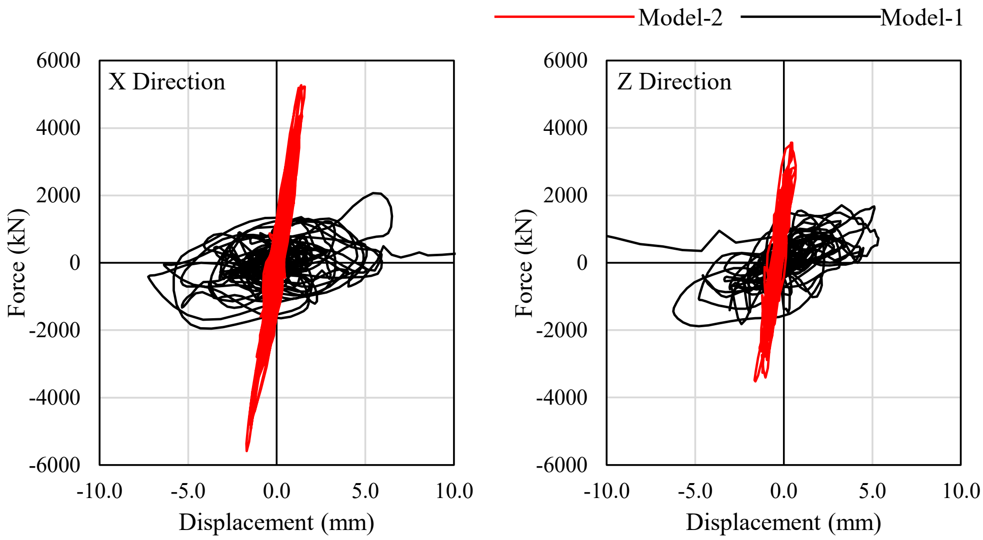

Fig. 6. Force-displacement graphs obtained from Model-1 and Model-2 dynamic analyses

Fig. 7 compares the damage distributions and mechanisms obtained from the finite element analyses of Model-1 and Model-2 of the Malatya Yeni Mosque. In Model-2, the cracks formed in the mosque's domes and some critical areas remained limited to a width of 1-1.5 mm, indicating light damage levels that did not exceed the elastic limits. It was observed that the dome and arch elements maintained their load-bearing capacities, and no collapse mechanism occurred. The high elasticity modulus and strength provided by the material properties of Model-2 helped the structure maintain its integrity under dynamic loads and minimized damage formation.

In contrast, a completely different damage scenario was observed in Model-1. A global collapse mechanism developed in the structure, particularly with severe damage to the arch and column elements that support the main dome. The damage spread from the feet of the arches along the arch system, ultimately leading to the collapse of the main dome. During this collapse, significant damage was also observed in the wall elements. The damage distribution is directly related to the inability of the structural elements in Model-1 to provide adequate rigidity and strength due to the low-pressure strength and elasticity modulus.

The damage distribution in Fig. 7 clearly demonstrates the critical effect of the material properties of both models on the seismic performance of the structure. The damage mechanism observed in Model-1 aligns closely with the actual damage mechanisms identified in field studies. This suggests that the material parameters used in Model-1 better reflect the actual behavior of the structure. Model-2, on the other hand, presents a scenario where the structure is more resistant to earthquakes, based on high strength parameters derived from literature recommendations. However, these parameters did not represent a realistic damage mechanism. These results once again emphasize the importance of carefully calibrating material properties and comparing them with field data.

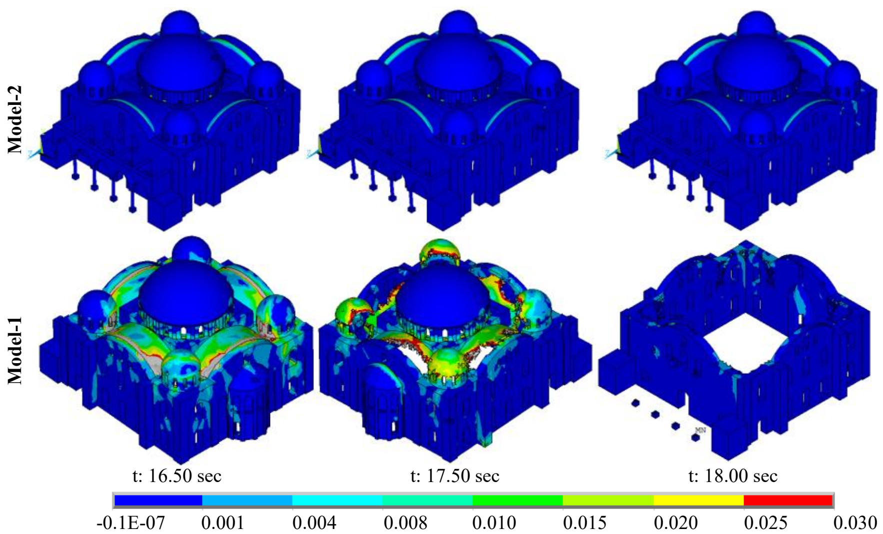

Fig. 7. Damage mechanisms obtained from Model-1 and Model-2 dynamic analyses

Fig. 8 compares the damage distributions obtained from Model-1 and Model-2 with the field observations conducted at Malatya Yeni Mosque following the 2023 Kahramanmaraş earthquakes. The field observations revealed that the structure, particularly the arch-column system, piers, and domes, sustained significant damage, with the collapse mechanism originating from these areas. It was determined that the main dome and side domes had collapsed, and significant cracks had formed in the walls during dynamic loading. The field observations in Fig. 8 show a high degree of agreement with the results from Model-1, while the results from Model-2 present a more optimistic scenario compared to the field damage.

In Model-1, similar damage mechanisms emerged due to the material parameters reflecting low strength and rigidity characteristics. Notably, the loss of stability in the piers supporting the main dome initiated a cascading damage process in the load transfer system. The loss of the arch's load-bearing capacity led to the collapse of the domes and the formation of large cracks in the walls. This analysis, which aligns with the field observations, demonstrates that the literature-based parameters represent the structure's real behavior more accurately.

In Model-2, only minor cracks were observed throughout the structure, with no collapse occurring in critical elements. The limited damage mechanism in Model-2 can be attributed to the high strength and elasticity modulus values used in the model. However, this does not align with the field observations and indicates that the material properties calculated based on literature recommendations fail to reflect the actual structural behavior.

Fig. 8 plays a critical role in the comparison of field observations and analysis results. The visuals demonstrate that Model-1 is more consistent with the field data, while Model-2 underrepresents the severity of the damage mechanisms. These analyses further emphasize the importance of calibration based on local material properties to accurately predict the seismic behavior of historic structures. Additionally, they highlight the necessity of constructing the geometric and material models in a manner consistent with field realities to obtain reliable results in finite element analyses.

Fig. 8. Damage mechanisms of Malatya Yeni Mosque obtained field study

4. Conclusions

This study was conducted to understand the seismic behavior and damage mechanisms of Malatya Yeni Mosque, which completely collapsed during the 6th February 2023 Kahramanmaraş earthquakes. Considering the challenges in determining material parameters specific to historical masonry structures, two different finite element models of the mosque (Model-1 and Model-2) were created. In Model-1, material parameters based on literature recommendations were used, while in Model-2, parameters derived from field samples and general parameters from regulations were adopted. Both models underwent nonlinear dynamic analyses using the actual earthquake acceleration-time records recorded in Malatya, and the modal properties and seismic performance of the structure were thoroughly investigated. The following key findings were obtained from the analyses:

- Significant differences were observed in the fundamental frequency values between Model-1 and Model-2. Due to Model-1's low elasticity modulus and compressive strength, its natural frequency was lower, while Model-2 exhibited a more rigid structural behavior, reaching higher frequency values. This difference highlights the critical impact of material properties on structural dynamics.
- It was observed that Model-1 exhibited a severe collapse behavior beyond the elastic limit, while Model-2 remained within elastic limits, maintaining the stability of the structure. However, comparisons with field observations revealed that the damage mechanisms in Model-1 better reflected the actual situation, while Model-2 represented the real damage less severely.
- In Model-1, damage resulted in a global collapse that spread from the piers and arch system to the main dome and load-bearing walls. This mechanism closely matched the field observations. In contrast, in Model-2, only minor cracks were observed, which presented a result that was far from a realistic damage representation. This suggests that the material parameters used in Model-2 did not adequately reflect the structural behavior.
- The accuracy of material properties is one of the most critical parameters in seismic performance analysis of historical masonry structures. The Model-1 analysis, based on field observation-derived parameters, was found to more successfully reflect the actual behavior of the structure. On the other hand, Model-2, created using general parameters from literature or regulatory recommendations, was insufficient in representing real damage mechanisms due to its high strength and rigidity values.
- In conclusion, this study emphasizes once again the importance of calibration based on local material properties in seismic performance analysis of historical structures. To understand the dynamic behavior of historical structures and obtain reliable results, it is necessary to combine field data, literature recommendations, and regulatory guidelines. Additionally, using modal analysis results to verify the accuracy of material properties is an important approach that enhances the reliability of analyses. These findings make significant contributions to engineering studies planned for the preservation and strengthening of historical structures.
- Suggestions for future studies may focus on detailing field observations, applying a broader range of material testing, and comparing the results of different analysis methods. This will allow for a more accurate assessment of the seismic performance of historical structures and the development of effective strengthening strategies.

Investigation of the effects of direct integration methods and their parameters on pounding in different impact models

Birkan Dag*[1], Muzaffer Borekci[1]

[1] *Yildiz Technical University, Department of Civil Engineering, 34220 İstanbul, Türkiye*

Abstract. The pounding of adjacent buildings during earthquakes is a significant concern, particularly in densely populated metropolitan areas where maximizing land use is crucial. Insufficient spacing between adjacent buildings often leads to repeated pounding impacts during seismic events which can result in severe damages, even collapse. Therefore, an accurate modeling to predict the pounding phenomena is highly important. Notably, pounding remains a challenging problem characterized by uncertainties and complexities that are difficult to capture in analytical models. This study investigates the pounding effect by comparing different impact models and direct integration methods available in the literature. For this purpose, two adjacent single-degree-of-freedom systems with different natural periods and inadequate gap distances were modeled analytically in SAP2000. Pounding was represented using link elements defined by linear and Hertz models without damping, employing the distinct elements available in SAP2000. Additionally, nonlinear time-history analyses were conducted using various direct integration methods provided in SAP2000, with carefully selected parameters for each method. The study evaluates the effects of the chosen impact models and integration methods, along with their solution parameters, on the estimated pounding forces. This ensures a consistent and precise simulation of the pounding effect and its impact on structural behavior.

Keywords: Pounding; Impact problem; Nonlinear time history analysis; Time integration methods; Single-degree-of-freedom systems

1. Introduction

Reinforced concrete (RC) buildings are generally designed without considering the pounding effect even when they are adjacent to other buildings with insufficient separation gaps. The pounding effect is a critical problem, particularly in metropolitan areas, where limited space leads to closely spaced structures and damage due to pounding is more pronounced in buildings with different vibration periods. In all circumstances, it would be unconservative to design a building without accounting for pounding and numerous studies in the literature have proved this outcome (Rosenblueth and Meli, 1986; Kasai and Maison, 1991; Karayannis and Favvata, 2005).

There are two types of pounding described in the literature: floor-to-floor (story-to-story) pounding and floor-to-column (inter-story) pounding. If the story levels of adjacent buildings are equal, the pounding scenario is classified as floor-to-floor; otherwise, it is floor-to-column. The literature suggests that floor-to-column pounding causes more damage to buildings than floor-to-floor pounding because it generates significant shear forces in the pounded columns due to the impact from adjacent building slabs (Brown and Elshaer, 2022).

A study conducted by Anagnostopoulos (1988) investigated the effects of seismic pounding on single and multi-degree-of-freedom systems. Their findings revealed that variations in mass, stiffness, and period of the modeled buildings lead to notable differences in pounding effects, significantly affecting relative story displacements, shear forces, and dynamic properties. Favvata et al. (2013) analyzed the impact of adjacent buildings on steel and RC structures. Their study found that in RC buildings, upper-story columns are more affected by bending and ductility demands, while lower-story columns are primarily influenced by shear and ductility demands. Conversely, in steel buildings, upper-story columns experience higher shear and ductility demands, whereas lower-story columns are more affected by bending and ductility. Akköse and Sunca (2016) modeled adjacent buildings of equal height but with different dynamic characteristics. They performed nonlinear time-history analyses (NLTHA) using both near-fault and far-fault earthquake records. The results showed that pounding forces under near-fault ground motion are higher than those under far-fault motion, indicating that the gap requirements are insufficient. Raheem et al. (2019) studied the impact of eccentric seismic pounding on

*Corresponding author, E-mail: bdag@yildiz.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_259

adjacent symmetric buildings, finding that pounding severity depends on building vibrations and ground motion characteristics. Their analysis showed that pounding increases acceleration and shear force demands, with torsional oscillations playing a significant role in the buildings' seismic response. Mavronicola et al. (2020) analyzed seismic pounding in base-isolated buildings using NLTHA, assessing impacts with adjacent structures. Key factors included seismic directionality, clearance, neighboring structures, and accidental torsion effects. Jiang et al. (2022) conducted experimental shaking table tests on scaled multi-story buildings to investigate seismic pounding, including story-to-story, inter-story, and eccentric pounding. A validated 3D finite element model was used to analyze mass eccentricity effects. The results showed that pounding increases structural response frequencies, with larger impact forces in story-to-story cases. Additionally, mass eccentricity significantly influences base shear and displacement. Taleshian et al. (2022) studied the effectiveness of viscoelastic links in mitigating seismic pounding between adjacent asymmetric-plan buildings. Using white-noise analysis and earthquake simulations, they found that plan asymmetries do not necessarily increase seismic responses. Viscoelastic links significantly reduce relative displacements, with damping effects improving as link stiffness decreases. The results showed up to an 80% reduction in displacement, with a dominant modal damping ratio twice as high in certain eccentric configurations. Miari and Jankowski (2022a) investigated seismic pounding effects between buildings on different soil types. Analyzing 3D models with varying heights, they found that pounding increases peak accelerations and shear forces, while its effect on displacements varies. Buildings on soft clay soil experience the highest displacements and forces, whereas those on rock and hard rock have the lowest. They (2022b) also analyzed floor-to-column pounding effects on buildings with different soil types during earthquakes. Studying various pounding scenarios, they found that pounding significantly increases shear demands, exceeding shear strength in all cases. The highest shear demands occur on soft clay soil, decreasing progressively for stiffer soils, with the lowest on rock and hard rock. Flenga and Favvata (2023) introduced a risk-targeted decision model to assess the seismic performance of RC structures against pounding and determine the minimum required separation gap distance. Using probabilistic seismic demand models and engineering demand parameter (EDP) hazard curves, they defined new performance objectives for pounding risk. The model was demonstrated through a case study, revealing a critical separation gap distance linked to structural pounding risk. Their findings suggest that while pounding risk increases, the required separation gap can be reduced with careful consideration of the pounding risk level. They (2021) also assessed various methodologies for developing fragility curves, concluding that the choice of methodology has minimal effect on risk assessments for highly vulnerable structures. Özer (2024) evaluated pounding effects in fixed-base models considering torsional irregularity, using 3D 5- and 9-story adjacent building combinations. NLTHAs were performed on 176 scenarios with spectrum-compatible ground motions. Results showed that pounding and torsion generally increase displacement demand, interstory drift, damage ratios, and torsional irregularity. The most critical values were found in irregular structures with building eccentricity in the same direction. The large standard deviation across ground motion records highlighted the importance of selecting an appropriate number of records. Börekçi et al. (2024) investigated the seismic behavior of buildings subjected to inter-story pounding, focusing on buildings with different story heights and adjacent on one or both sides. Using NLTHA, they assessed plastic rotations and shear forces in 3-, 6-, and 10-story buildings. The study found that inter-story pounding has a negligible effect on plastic rotations. However, the impacted columns experience increased shear forces, potentially leading to shear failure, particularly when adjacent on both sides. Manoukas and Karayannis (2025) examined floor-to-column pounding between multi-story RC buildings, focusing on the impact point location and gap width. They found that while the impact point affects external columns, the overall building behavior is less influenced. Inadequate seismic joints were found to be more detrimental than no separation, highlighting the importance of adhering to code provisions. They also confirmed that damage to external columns from pounding is usually limited to a small area (about 1 meter).

Accurate modeling of the pounding phenomenon is critical, as significant challenges arise due to inherent uncertainties and complexities that are difficult to fully capture in analytical models. Additionally, the direct integration methods used are of utmost importance for the accurate estimation of responses in pounded structures. This study evaluates different impact models and direct integration methods to predict the pounding effect in adjacent single-degree-of-freedom (SDOF) systems with varying natural periods and insufficient gap distances. The aim is to estimate the effects of different direct integration methods on various impact models and to evaluate the relationships between the considered parameters. Different SDOF systems modelled in SAP2000 with linear and Hertz contact models, and NLTHAs were conducted using 11 pairs of earthquake records with various integration methods. The effects of model choice, direct integration methods, and their parameters on pounding force estimates were assessed.

2. Materials and methodology

2.1. Impact models

Impact models are typically classified as stereomechanical or force-based (Miari et al.,2019). The stereomechanical approach derives pounding forces from momentum and energy laws, while the force-based (penalty) model uses impact stiffness-representing springs. This study adopts the force-based approach due to its modeling clarity and compatibility with the analysis software.

The force-based approach defines impact elements using linear spring, Kelvin-Voigt (linear viscoelastic), Hertz, and Hertz damp (nonlinear viscoelastic) models. Fig. 1 illustrates these models, where m_1 and m_2 are the colliding masses, k and K represent stiffness for linear and nonlinear models, c is the damping coefficient, and d is the gap distance. In this study, linear and Hertz models were used as impact models in the representation of the pounding of adjacent SDOF systems.

2.2. Adjacent SDOF systems

In this study, three different SDOF systems were considered which are equivalent to hypothetical buildings with 5, 8, and 10 stories. Two distinct pounding scenarios were investigated within the scope of this study as pounding between 5 story-10 story buildings and 8 story-10 story buildings. As illustrated in Fig. 2, both pounding scenarios were modeled under the assumption of a 2 cm separation gap between the structures. The impact effect is represented by link elements available in SAP2000.

In these equations, ω is the angular frequency, T is the structural period, m is the mass of the building and k is the stiffness.

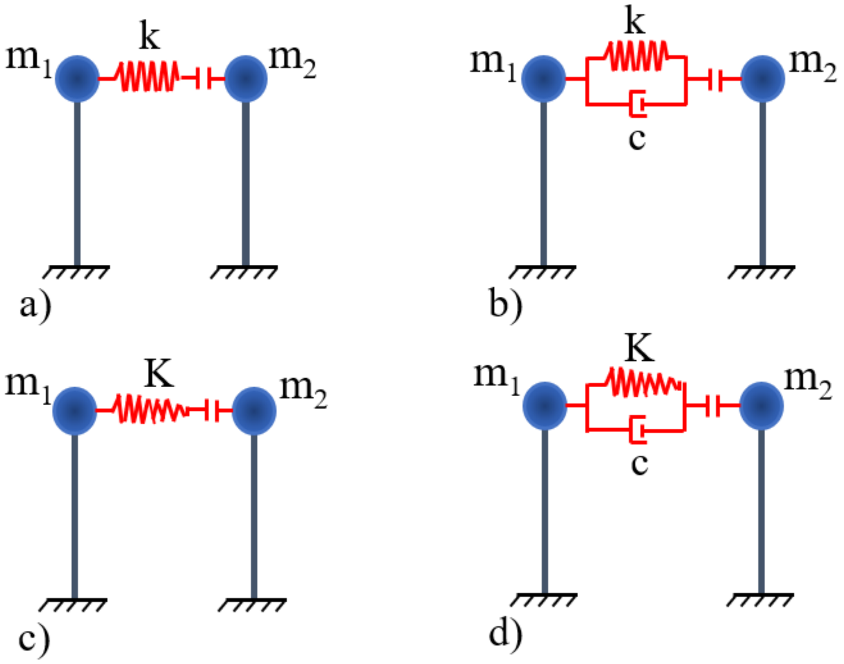

Fig 1. Impact models for pounding: a) Linear, b) Kelvin-Voigt (viscoelastic), c) Hertz, d) Hertz damped (Borekci et al, 2024).

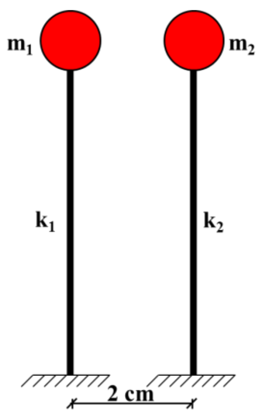

Fig. 2. Reprerantation of two adjacent SDOF systems with different natural period.

Given the known masses and estimated periods of the hypothetical buildings, their stiffness values were calculated using Equation (1–3) to match the target periods. The structural period of a 5-story building is assumed to be 0.5 seconds, the structural period of an 8-story building is assumed to be 0.8 seconds, and the structural period of a 10-story building is assumed to be 1 second. The mass and stiffness values of the corresponding SDOF systems are presented in Table 1.

$$\omega = \frac{2\pi}{T} \tag{1}$$

$$T = 2\pi\sqrt{\frac{m}{k}} \tag{2}$$

$$k = \frac{4\pi^2 m}{T^2} \tag{3}$$

A gap element was used as a linear impact model and multilinear plastic element was used as Hertz impact model. The study utilized impact stiffness values recommended in literature. An impact stiffness of $k=10^9$ N/m was used for the linear spring model, as recommended by Farahani et al. (2019). For the Hertz model, the impact stiffness of $K=1.13\times10^9$ $N/m^{3/2}$ was adopted, following the suggestion given in the study of Jankowski (2005).

2.3. Ground motions

In this study, 11 ground motion record pairs were selected from the Pacific Earthquake Engineering Research Center (PEER) database following the criteria defined in Turkish Seismic Code for Buildings (TSCB) 2018. These criteria consider factors such as soil class, faulting mechanism, magnitude, and distance to rupture. The records used in this study correspond to the ZC soil class, with shear-wave velocities ($V_{s,30}$) ranging from 360–760 m/s at a 30-meter depth. The fault type is strike-slip, with magnitudes ranging from 6.19 to 7.68. Detailed characteristics of the records are listed in Table 2.

The horizontal components of all ground motion records were scaled using the Spectral Matching Method in SeismoMatch to match the 5%-damped design earthquake spectrum from TSCB 2018. Fig. 3 shows the scaled pseudo-acceleration spectra and their average.

Table 1. Properties of SDOF systems.

	5-10 Story Pounding	8-10 Story Pounding
m_1 (kN.s^2/m)	1250	2000
m_2 (kN.s^2/m)	2500	2500
k_1 (kN/m)	197392	123370

2.4. Direct integration methods

Direct integration methods are widely used and effective for solving equations of motion in structural dynamics. These methods compute a system's time-dependent response by directly integrating the equations of motion. By advancing through discrete time steps, they can be applied to both linear and nonlinear systems. In this study, direct integration methods available in SAP2000 will be evaluated to estimate the effects of different integration methods on the pounding analyses.

The Newmark (1959) method is a popular time-stepping integration technique that offers a balance between accuracy and stability. It utilizes two parameters, β and γ, to approximate displacement and velocity at each time step. When $\beta = 0.25$ and $\gamma = 0.5$, the method is unconditionally stable and is known as the constant average acceleration method. The linear acceleration method ($\beta = 1/6$, $\gamma = 0.5$) provides higher accuracy but exhibits conditional stability.

The Wilson (1972) method builds upon the Newmark (1959) method, providing enhanced accuracy and a wider stability range. This approach predicts the solution by extending it forward in time. The stability of the method is governed by the parameter θ, which is commonly set to 1.4. Being unconditionally stable, the Wilson (1972) method is especially well-suited for dynamic analyses that involve high-frequency responses.

The method developed by Hilber et al. (1978) builds upon the Newmark (1959) approach, aiming to improve accuracy in low-frequency modes while enhancing the damping of high-frequency modes. The parameter α governs the level of numerical damping and is typically selected within the range of $-1/3$ to 0. This method offers unconditional stability and remains effective even when large time steps are used.

Collocation-based direct integration is a numerical method used to solve equations of motion (Hilber and Hughes, 1978). Unlike traditional direct integration techniques, it seeks to express the solution as a continuous function of time. This approach enhances accuracy, especially in the dynamic analysis of complex structures.

The method developed by Chung and Hulbert (1993) serves as the basis for the widely adopted Generalized Alpha method used in direct integration for structural dynamics. It aims to minimize undesired numerical oscillations in high-frequency modes while providing accurate results in low-frequency modes. Viewed as a generalized version of the classic Newmark (1959) method, the Chung-Hulbert (1993) method is unconditionally stable with proper parameter selection and can be effectively used with large time steps.

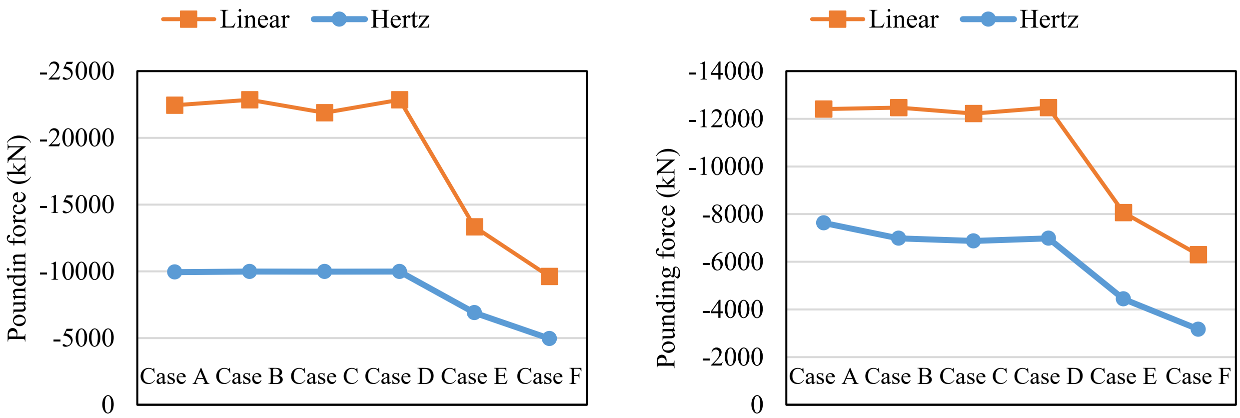
The parameters of considered direct integration methods are represented in Table 3. These integration methods are, respectively, Newmark constant acceleration, Newmark average acceleration, Wilson, Hilber-Hughes-Taylor, Collocation, and Chung and Hulbert. The analyses conducted using these direct integration methods are named Case A, Case B, Case C, Case D, Case E, and Case F, respectively.

3. Analysis results

The forces generated in both impact elements, as a result of the pounding of SDOF systems representing 5- and 10-story and 8- and 10-story buildings, are shown in Fig. 4.

Table 3. Different direct integration methods and their relevant parameters.

	Newmark-Constant	Newmark-Average	Wilson	Hilber-Hughes-Taylor	Collocation	Chung and Hulbert
Gamma	0.5	0.5	-	0.83	0.5	0.82
Beta	0.25	0.17	-	0.44	0.17	0.44
Theta	-	-	1.4	-0.33	1	-
Alpha	-	-	-	-	-	-0.33
Alpha-m	-	-	-	-	-	0.5



a) Pounding between 5-and 10- story

b) Pounding between 8-and 10- story

Fig. 4. Peak average pounding force of the systems with linear and Hertz impact models over the time history duration.

As seen in Fig. 4, the pounding forces obtained vary depending on the direct integration method and the impact model used. When the Hertz model is selected as the impact model, the resulting pounding forces are consistently smaller compared to the linear model. Regardless of the impact model, the highest force is obtained from Case A, while the lowest force comes from Case F. However, it should be noted that the acceleration records of the earthquakes used do not have the same time step. Some earthquake records have a time step of 0.005 seconds, others 0.01 seconds, and some 0.02 seconds. Authors anticipate that the time step might influence the effects of direct integration methods on the estimated response. Table 4 presents the time steps for the corresponding earthquakes.

Figs. 5 and 6 illustrate the pounding force for the 5- and 10-story buildings and the 8- and 10-story buildings, respectively, considering earthquakes analyzed with different time steps separately. These graphs represent the ratio of the average pounding force obtained for each direct integration method, considering earthquakes with the same time step, to the average pounding force from Case A for both the linear and Hertz impact models.

Table 4. Time intervals (step) of eathquakes.

NGA#	Earthquake	Time Step (s)
552	Chalfant Valley-02	0.005
838	Landers	0.02
897	Landers	0.02

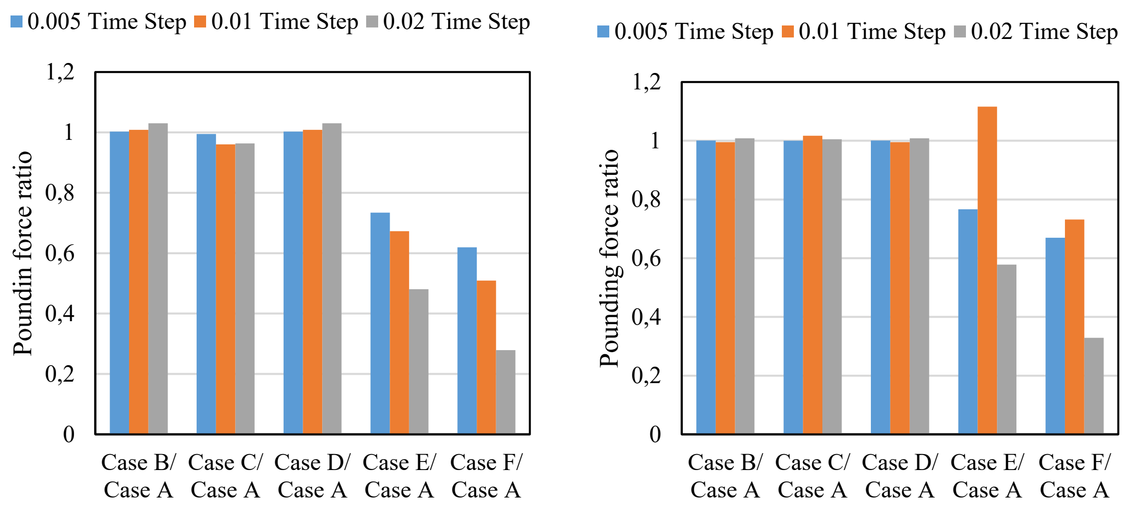
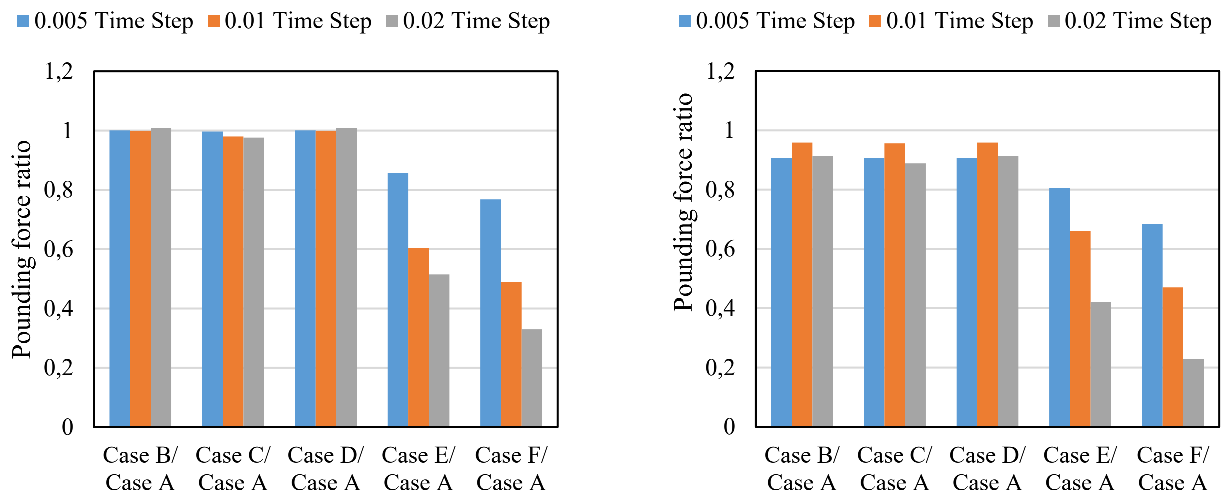
1164	Kocaeli, Turkey	0.01
1166	Kocaeli, Turkey	0.005
910	Big Bear-01	0.02
1762	Hector Mine	0.02
3757	Landers	0.02
1626	Sitka, Alaska	0.005
5830	El Mayor-Cucapah, Mexico	0.02



a) Linear model b) Hertz model

Fig. 5. The ratio of avarage pounding forces of each direct integration method to the average of Case A with respect to time step for 5- and 10- story building collision.



a) Linear model b) Hertz model

Fig. 6. The ratio of avarage pounding forces of each direct integration method to the average of Case A with respect to time step for 8- and 10- story building collision.

4. Conclusions

The study shows that the pounding forces vary depending on the integration method and impact model. The Hertz model consistently yields lower forces than the linear model, with the Newmark constant acceleration method producing the highest forces and the Chung and Hulbert method yielding the lowest. Additionally, the Collocation and Chung and Hulbert integration methods are highly sensitive to the time step of the earthquake's acceleration record. As the time step decreases, the results converge with those from other direct integration methods. To accurately analyze the impact effect, the time step of the earthquake acceleration recordings should either be chosen according to the integration method used or the most optimal integration method should be preferred when using an acceleration recording with a known time step.

Abstract. In the aftermath of major seismic events, performance-based design principles have exerted a substantial influence on the development of seismic design codes, culminating in the integration of capacity design concepts. A pivotal consideration in the evolution of seismic design over the past five decades has been the necessity of ensuring that vertical load-bearing elements, such as columns, exhibit greater strength compared to beams. This approach has been incorporated into various codes employing distinct criteria, with the objective of enhancing the seismic performance of structures. By prioritising the strong-column/weak-beam behaviour, the overall seismic response of structures is significantly improved, thereby reducing the likelihood of premature collapse due to insufficient ductility.This study examines a reinforced concrete structure affected by the Kahramanmaraş-centred earthquakes on 6 February 2023 in Turkey. Field observations revealed cases where the intended strong-column/weak-beam mechanism was not achieved, leading to damage in vertical load-bearing elements despite the design appearing to be compliant. The present study provides an in-depth examination of the theoretical underpinnings of the observed failures and their impact on the energy dissipation mechanisms of structures subjected to seismic loads. Furthermore, it offers a comparative analysis of the anticipated damage mechanisms, as outlined by capacity-design principles, with the observed damage, thereby providing valuable insights into the effects of compromised energy dissipation capacity. This research endeavors to enhance the comprehension of how deviations from capacity-based principles affect structural performance, thereby offering valuable insights for the enhancement of seismic resilience in future designs.

Keywords: Strong-colum/weak-beam; Frame damage mechanisms; Performance analysis; Energy dissipation

1.Introduction

In recent years, performance-based design approaches have gained prominence as a more accurate means of predicting the seismic behavior of structures and enhancing their safety during earthquakes. These approaches aim not only to ensure the structural strength of buildings but also to prevent collapse mechanisms by enabling controlled dissipation of the energy generated during seismic events. A cornerstone of performance-based seismic design is the capacity design principle, which prescribes that inelastic deformations and damage should be concentrated in the horizontal load-bearing elements namely beams while preserving the integrity of vertical elements such as columns. This concept, widely known as the strong column–weak beam principle, is explicitly defined in numerous international codes and standards, including the Turkish Building Earthquake Code (TBEC-2018). By ensuring that plastic hinges form preferentially in beams rather than columns, this principle facilitates a more ductile response, enhances energy dissipation capacity, and promotes life safety. Equation (1) provides the quantitative criterion used to assess compliance with this principle.

$$(M_{ra} + M_{r\ddot{u}}) \geq 1.2\ (M_{ri} + M_{rj}) \qquad (1)$$

However, field observations have revealed that the seismic behavior anticipated in theoretical design is not always realized in practice. A representative example, examined in detail in this study, was observed following the devastating earthquakes that struck the Southeastern Anatolia Region on February 6, 2023, with epicenters near Kahramanmaraş. While numerous buildings appeared to conform to seismic design principles, including the strong-column/weak-beam concept, significant damage and even total collapse were observed foften attributable to shortcomings in the overall lateral load-resisting system rather than isolated component failure.

* Corresponding author, E-mail: muhammetyilmaz061@gmail.com

https://doi.org/10.31462/icearc2025_ce_eqe_263

Post-earthquake site investigations identified recurring issues, particularly associated with vertical irregularities and discontinuities in structural stiffness. In many cases, shear walls were concentrated in lower-story configurations (such as basements), but were abruptly discontinued in the upper stories, leading to a sudden reduction in lateral stiffness and strength. This configuration resulted in excessive inter-story drift demands, ultimately compromising the structural system's ability to dissipate energy and maintain lateral stability even though the well-known strength ratio equation for achieving the strong-column/weak-beam condition at the beam-column joints was satisfied. These failures highlight the importance of continuous and well-distributed lateral support throughout the height of the structure. Moreover, such damage cannot be attributed solely to construction quality or detailing errors but also stems from insufficient evaluation of global structural behavior during the analysis and design process. For example, as noted in experimental studies by Ning et al. (2016), the contribution of floor slabs to beam stiffness can significantly influence the distribution of internal forces and the location of plastic hinge formations. In systems with discontinuous lateral resistance, this can exacerbate unexpected failure mechanisms, undermining the intended performance goals of modern seismic design.

Another critical factor influencing seismic performance is the axial load acting on columns. While moderate axial loads can enhance a column's load-bearing capacity by increasing compressive strength, excessive axial loading is well known to reduce ductility an essential attribute for energy dissipation during earthquakes. Türker and Gültekin (2023) emphasized that such ductility loss significantly limits the plastic rotational capacity of columns. When axial forces increase unexpectedly, columns may behave in a brittle manner and fail before the beams, resulting in a premature and uncontrolled collapse mechanism that contradicts the strong-column/weak-beam design objective.

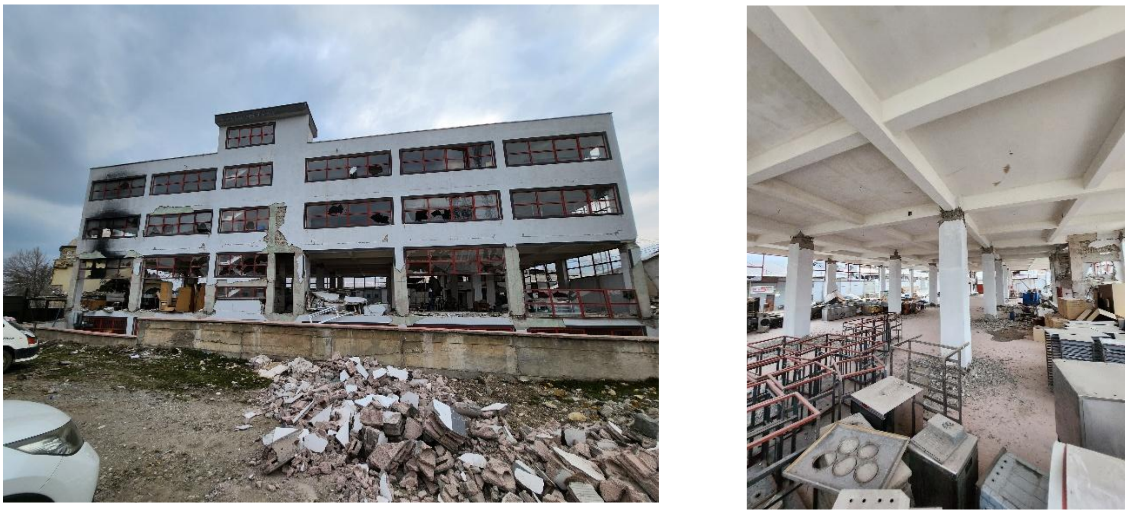
According to the Turkish Building Earthquake Code (TBEC-2018), if the axial load acting on a column is less than 10% of the product of its gross cross-sectional area and the characteristic compressive strength of concrete (Equation 2), the strong-column/weak-beam strength verification (Equation 1) is not required. However, if this limit is exceeded under any load combination that includes the effects of dead, live, and earthquake loads, the verification becomes mandatory. TBEC-2018 permits axial loads on columns up to 40% of the gross section capacity under such combinations still below the critical threshold of approximately 60%, beyond which a sharp decline in ductility is typically observed in experimental studies.

$$N_d \leq 0.10 \times Ac \; x \; fck \tag{2}$$

It is also important to highlight that during the February 6, 2023 Kahramanmaraş earthquakes, unusually high vertical ground motion components were recorded in several regions. These vertical accelerations may have temporarily increased axial loads beyond their design values, even in buildings nominally within code compliance. Such transient but severe vertical loading could have triggered brittle column failures in some structures, underscoring the need to more thoroughly account for vertical seismic effects particularly in regions susceptible to pulse-like or near-fault ground motions.

While numerous structures conceptualised in accordance with the strong column–weak beam principle formally almost comply with stipulated code requirements, the seismic events centred in Kahramanmaraş on 6 February 2023 exposed substantial discrepancies between anticipated and observed performance outcomes. In particular, buildings where nonlinear behaviour was accounted for solely through the use of a high seismic reduction factor (R = 8) as selected by practitioners while employing only linear analysis methods, exhibited damage mechanisms inconsistent with this principle. This discrepancy was especially pronounced in workshop-type structures, which are typically characterised by a small number of stories, basements enclosed by rigid shear wall elements, ground floors with greater story heights than upper floors, long structural spans, and heavily reinforced beams designed primarily for gravity loads.

The primary objective of this study is to perform a detailed structural analysis of a reinforced concrete building that experienced damage inconsistent with the strong column–weak beam philosophy during the February 6, 2023 Kahramanmaraş earthquakes. The analysis is conducted in accordance with the deformation-controlled design approach stipulated in the Turkish Building Earthquake Code (TBDY-2018). Moreover, the objective of the present study is twofold: firstly, to identify and evaluate the underlying causes of the observed damage, and secondly, to establish a methodology for the future prevention of such occurrences. The condition of the building, as documented during post-earthquake field investigations, is illustrated in Fig. 1.



(a) (b)

Fig. 1. (a) General view of the building and (b) Columns damages

2. Numerical modeling

In this study, a structural analysis was conducted by developing a representative model of a four-story reinforced concrete building that was identified, based on field investigations, as having sustained damage during the Kahramanmaraş-centered earthquakes on February 6, 2023. The model was designed to approximately reflect the actual structural characteristics of the original building, including its overall geometry and load-bearing elements (Fig. 2).

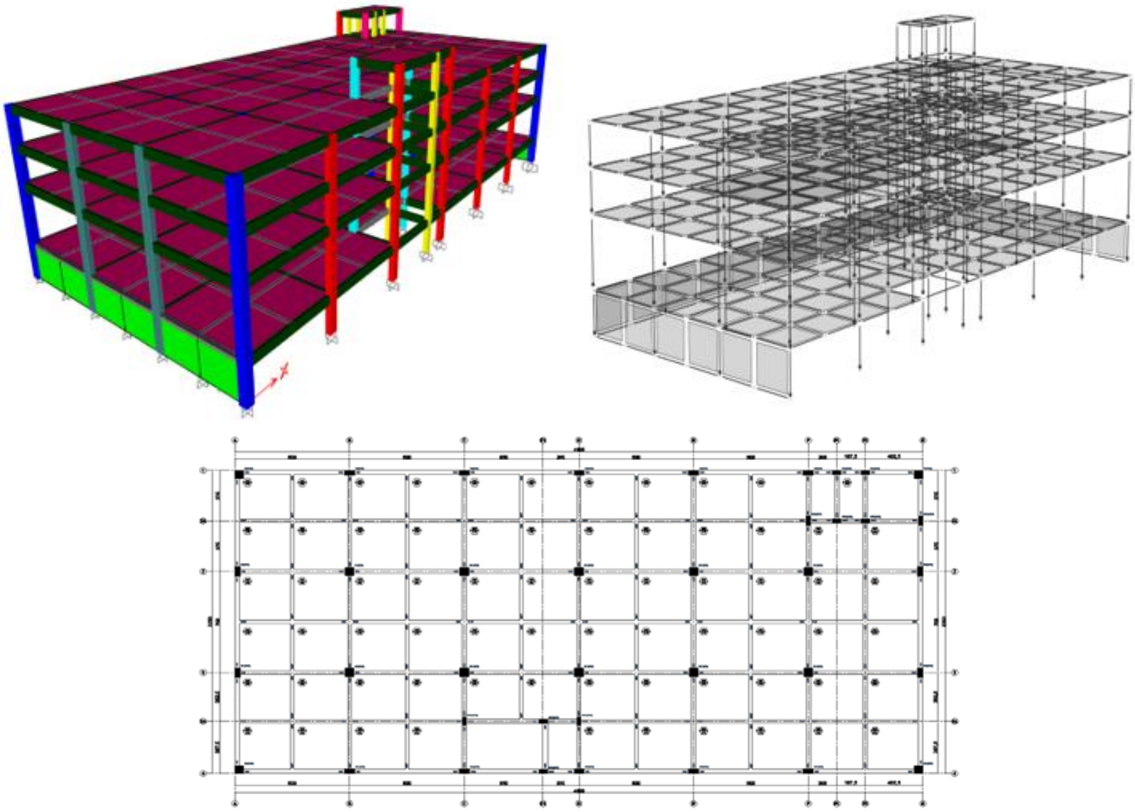


Fig. 2. Generated 3D soil model, formwork

Regarding material properties, the characteristic compressive strength of the concrete used in the reinforced concrete elements was defined as C25 (fck = 25 MPa), while the reinforcement steel was specified as S420 with a yield strength of 420 MPa. For loading conditions, the floor slabs in the basement and typical floors were subjected to a finishing dead load of 2.50 kN/m² and a live load of 3.50 kN/m², while for the roof slab, the finishing dead load and live load were taken as 1.00 kN/m² each).

The nonlinear behavior of the column and beam elements was incorporated into the analysis model using a distributed (fiber) plasticity model. The fiber modeling approach was implemented in accordance with the modeling guidelines specified by NIST (2017), along with the methodology presented by Padalu and Surana (2024) (Fig. 3). To represent the nonlinear material behavior, the material models for concrete and reinforcing steel were defined as shown in Figure 4.

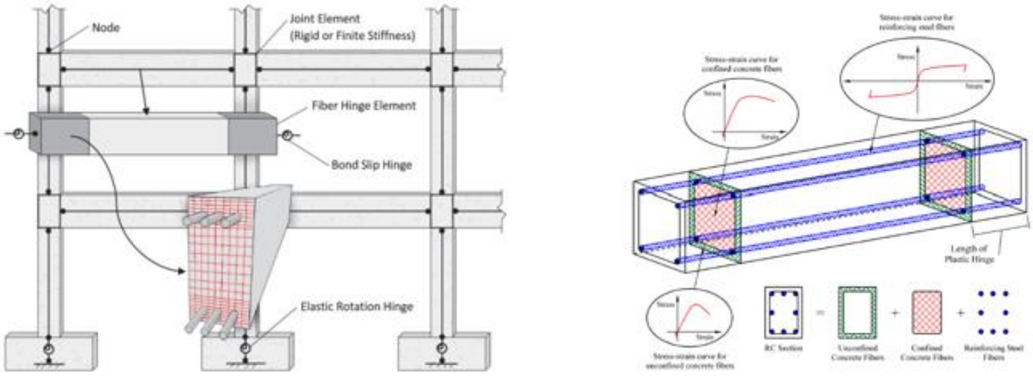

Fig. 3. Schematic representation of the definition of the distributed (fiber) plasticity behavior model

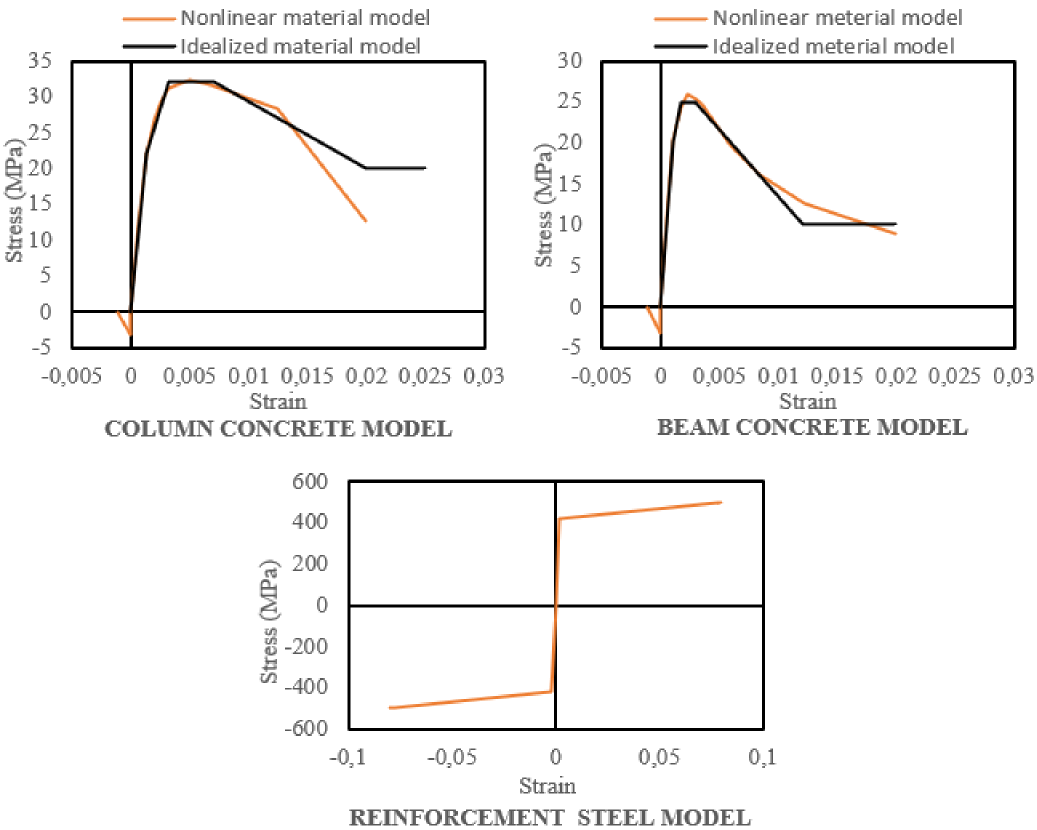

Fig. 4. Nonlinear material models

3. Selection of earthquake ground motion

In accordance with the provisions of the Turkish Building Earthquake Code (TBEC, 2018) and based on the local site-specific conditions, the earthquake that occurred on February 6, 2023 with a moment magnitude of Mw = 7.7 and an epicenter located in Kahramanmaraş was selected to represent the Design Earthquake Level 2 (DD-2) ground motion for the structural analyses. This selection was made using the geographical coordinates of the building under study to ensure consistency with seismic hazard mapping criteria defined in TBEC-2018.

For the analyses, ground motion records in the East–West and North–South directions were obtained from the nearest strong motion station to the damaged structure, identified as Station No. 4625. These records were used to simulate realistic seismic excitation corresponding to the structural location. Additionally, in order to assess the potential impact of regional variation in seismic demand, a second set of ground motion data was incorporated from Strong Motion Station No. 3129, located in Hatay one of the cities severely affected by the same earthquake sequence (Fig. 5). This comparative assessment aims to explore how different local site effects and ground motion intensities may influence structural response.

The selected acceleration records were applied simultaneously in the two horizontal directions (East–West and North–South) during the time history analyses to accurately capture bidirectional seismic effects. The acceleration time histories obtained from both recording stations are shown in Fig. 5. Furthermore, to evaluate the compatibility and intensity of these records, their corresponding response spectra were computed and compared against the elastic DD-2 design spectrum specified in TBEC-2018 for each respective location. These comparisons are presented in Fig. 6, illustrating how the recorded motions relate to code-defined expectations and providing insight into the severity of the ground shaking experienced during the Kahramanmaraş earthquakes.

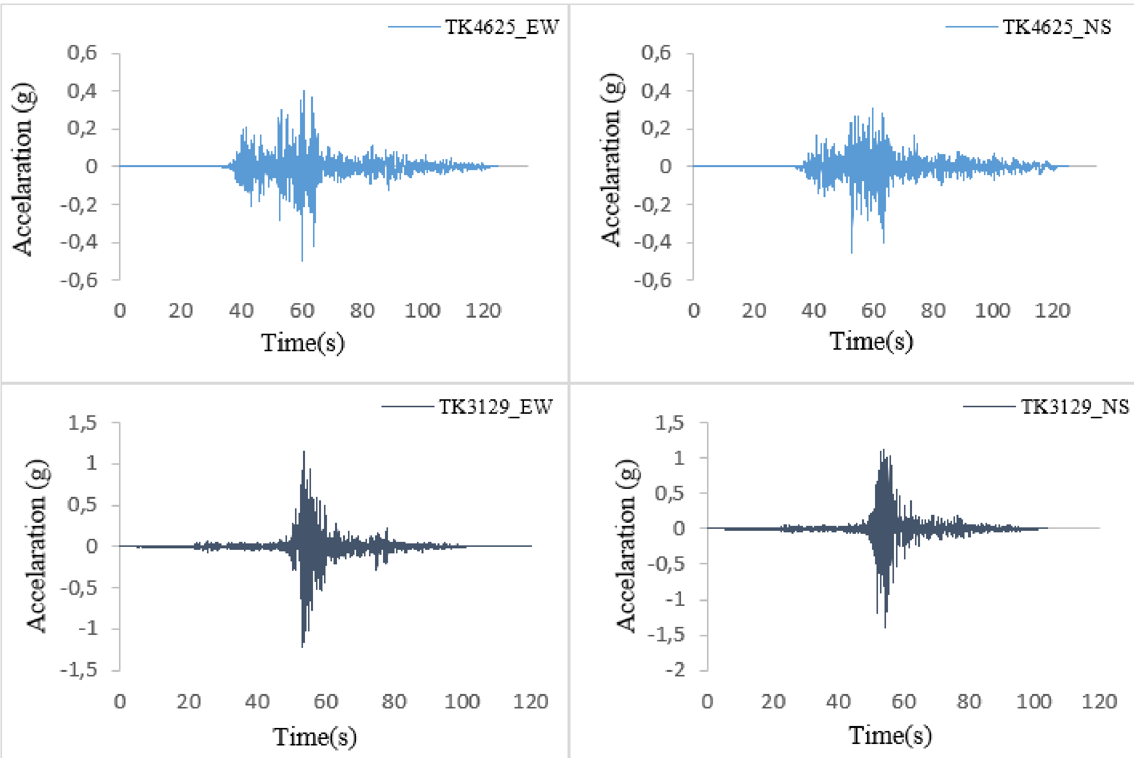

Fig. 5. Acceleration time histories of used earthquake data

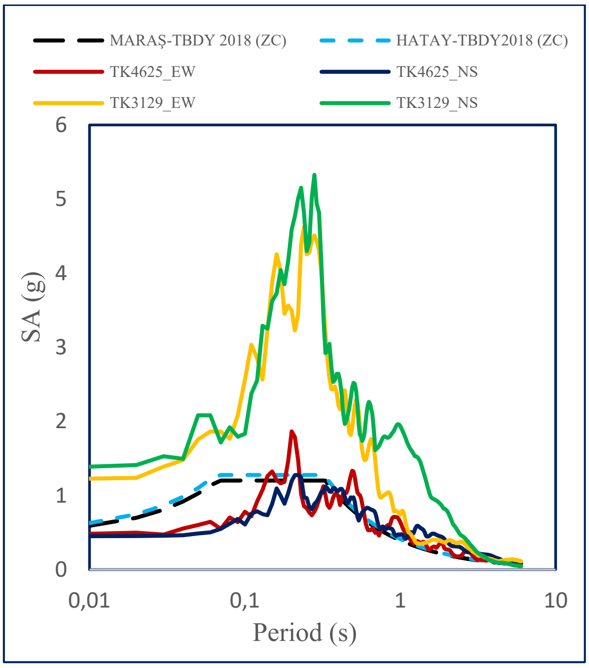

Fig. 6. Response Spectrum of considered records and elastic spekctrum fiven in TBEC-2018 for the site of recods.

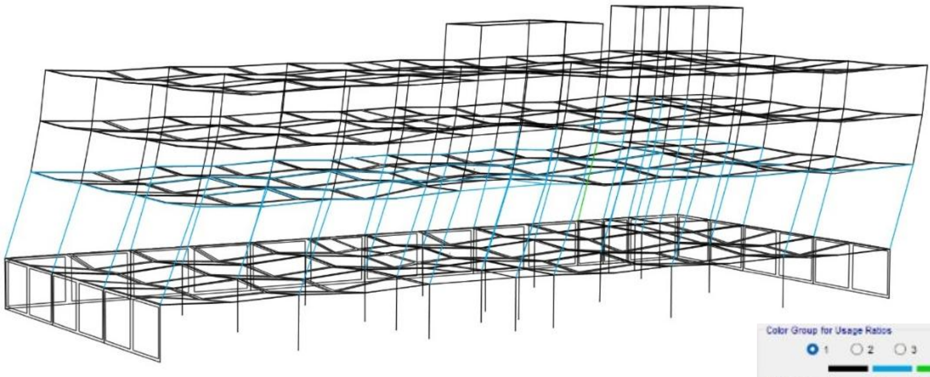
4. Analysis and results

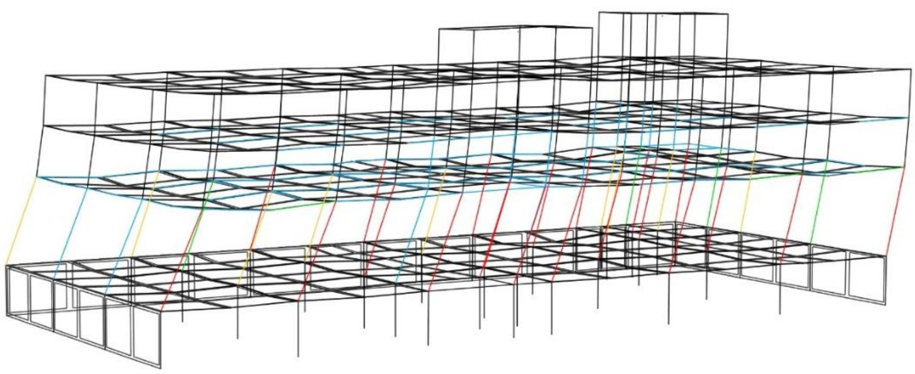
The structure assessed in this study was first documented during detailed post-earthquake field investigations. These observations served as the foundation for the development of a numerical model, which accurately incorporated the original geometric characteristics and the longitudinal reinforcement detailing of the building. The reinforcement quantities and layout derived from linear analysis were found to be largely consistent with those observed in the field, lending credibility to the assumptions made in the modeling phase. However, a key discrepancy was noted in the beam–column joint detailing. While the numerical model was constructed in accordance with TBEC-2018 provisions assuming compliant joint confinement and detailing the actual implementation in the field did not fully meet these code requirements. As a result, the model likely overestimates the real structural capacity and ductility, particularly at the critical connections. To evaluate the building's performance under realistic seismic loading, nonlinear time-history analyses were conducted. Material-specific strain limits corresponding to the collapse prevention (CP) performance level were adopted, with values of 0.013 for reinforced concrete column elements, 0.0065 for beams, and 0.032 for reinforcing steel. The analytical results closely matched the damage patterns observed during on-site inspections particularly the premature failure of second-story columns providing strong validation of the model and confirming the inadequacy of relying solely on linear analysis in such cases.

To further illustrate the damage progression captured in the nonlinear time-history analysis, Fig. 6 presents the distribution of plastic hinge formation in the column elements at the instance when yielding is first initiated. As shown, plastic deformation initially localizes in the second-story columns, indicating the onset of nonlinear behavior in vertical load-bearing elements. This finding aligns with field observations, where early signs of cracking and distress were also concentrated in the same story.

Subsequently, as the seismic excitation intensifies, additional plastic rotation demands accumulate, particularly in the same second-story columns. Fig. 7 shows the damage state of the structure when the strain values in these columns exceed the Collapse Prevention (CP) threshold. At this stage, the analytical results indicate that the columns have experienced severe nonlinear deformations beyond acceptable performance limits, while the adjacent beam elements remain in a comparatively lower damage state. This confirms that the failure mechanism is governed by column failure, rather than the intended strong column–weak beam behavior. These visualizations emphasize the critical role of column detailing and system-level stiffness discontinuities in driving collapse mechanisms during strong ground motion.



(a) t=52.95 s first yielding



(b) t=53.08 s most of columns pass the CP level (red)

Figure 7. Development of plastic hinges in column elements at two critical time steps during the seismic response of Kahramanmaraş records.

To further demonstrate the damage progression observed in the nonlinear time-history analysis, Fig. 7 illustrates the development of plastic hinges in column elements at two critical time steps during the seismic response. Fig. 7(a) shows the state of the structure at t = 52.95 s, corresponding to the onset of yielding in the second-story columns. At this stage, plastic deformations begin to develop in the vertical elements, marking the initiation of nonlinear behavior. This early yielding in the columns is consistent with the localized damage observed during field investigations and highlights a deviation from the expected strong column–weak beam mechanism.

Fig. 7(b) presents the structural response at t = 53.08 s, where a significant portion of the second-story columns exceed the Collapse Prevention (CP) strain threshold. The accumulation of plastic demands in a short time interval leads to severe damage in the column elements, while the beam elements remain below critical damage levels. This condition indicates the emergence of a soft-story mechanism and confirms that the collapse potential was primarily governed by column failure.

An in-depth evaluation of the nonlinear time-history analysis results under the Maraş (TK4625) and Hatay (TK3129) earthquake records reveals clear differences in the structural response and damage distribution across the building's floors (Table 1 and Table 2). For the Maraş ground motion, all column elements on the second story exceeded the Collapse Prevention (CP) performance level, while no such exceedance was recorded in beams. Most beams remained within the Immediate Occupancy (IO) range, with a few on the second floor reaching up to the IO–Life Safety (LS) transition range. The first, third, and fourth floors exhibited predominantly elastic behavior in both beams and columns, with all elements remaining below the IO threshold except for moderate IO–LS level damage in some third-story columns.

In contrast, under the Hatay ground motion, the demand on structural elements was more severe and widespread. Again, all columns on the second story surpassed the CP level, similar to the Maraş case. However, unlike the previous scenario, beam elements on the second floor also exhibited more advanced damage, with 18 beams exceeding the CP limit, 12 in the IO–LS range, and 31 remaining below IO. This suggests that the Hatay record induced higher energy input into the structural system, pushing some beams beyond critical damage states. Still, beam and column elements on the first, third, and fourth stories mostly stayed within elastic limits, apart from a few minor exceedances in the IO–LS range.

Table 1. Damage levels of load-bearing elements

	MARAŞ-TK4625				
	Story	<IO	IO to LS	LS to CP	>CP

	2	-	-	-	38
	3	27	11	-	-
	4	38	-	-	-

Table 2. Damage levels of load-bearing elements

	HATAY-TK3129				
	Story	<IO	IO to LS	LS to CP	>CP
BEAM	1(Basement)	45	-	-	-
	2	31	12	-	18
	3	55	6	-	-
	4	60	1	-	-
COLUMN	1(Basement)	38	-	-	-
	2	-	-	-	38
	3	27	11	-	-
	4	38	-	-	-

These findings underscore two significant points. First, the second floor consistently emerged as the most vulnerable story, reflecting a concentration of seismic demands and potential soft-story behavior due to stiffness discontinuity or inadequate lateral resistance. Second, the choice of ground motion record significantly influenced the structural performance, with the Hatay earthquake inducing higher damage levels in beam elements compared to the Maraş earthquake. This variability demonstrates the importance of selecting multiple representative ground motions in nonlinear performance-based evaluations to fully capture potential collapse mechanisms and inform retrofitting or design decisions accordingly.

The maximum interstory drift values obtained from the nonlinear time-history analyses were evaluated for both earthquake records to assess the overall deformation demand imposed on the structure. The results indicate that the maximum interstory drift reached approximately 2.92% for the Maraş (TK4625) record, whereas it escalated to 10.06% under the Hatay (TK3129) record (Fig. 8) . According to the deformation-based design limitations prescribed by TBEC-2018, the drift demand under the Maraş record slightly not exceeds the allowable threshold for collapse prevention performance but could still be considered marginally tolerable in practical terms, suggesting the possibility that the structure might survive this level of seismic excitation albeit with severe damage and residual deformations.

In contrast, the extreme drift value induced by the Hatay record far exceeds the permissible limits, pushing the structure into a state of global instability. Despite both records leading to collapse-level damage in the second-story columns, a key distinction lies in the damage progression of the beam elements, as well as the significantly different demand-to-capacity (D/C) ratios, which indicate a more severe overstress condition in the case of the Hatay record. The Hatay excitation not only triggers excessive deformation but also initiates widespread failure mechanisms that are incompatible with the structural system's ductility capacity.

Therefore, while collapse may be avoidable under the Maraş record, the structural response observed under the Hatay record clearly indicates that collapse is inevitable due to the compounded effects of drift exceedance, loss of stiffness in critical elements, and a failure to maintain structural integrity under large lateral displacement demands.

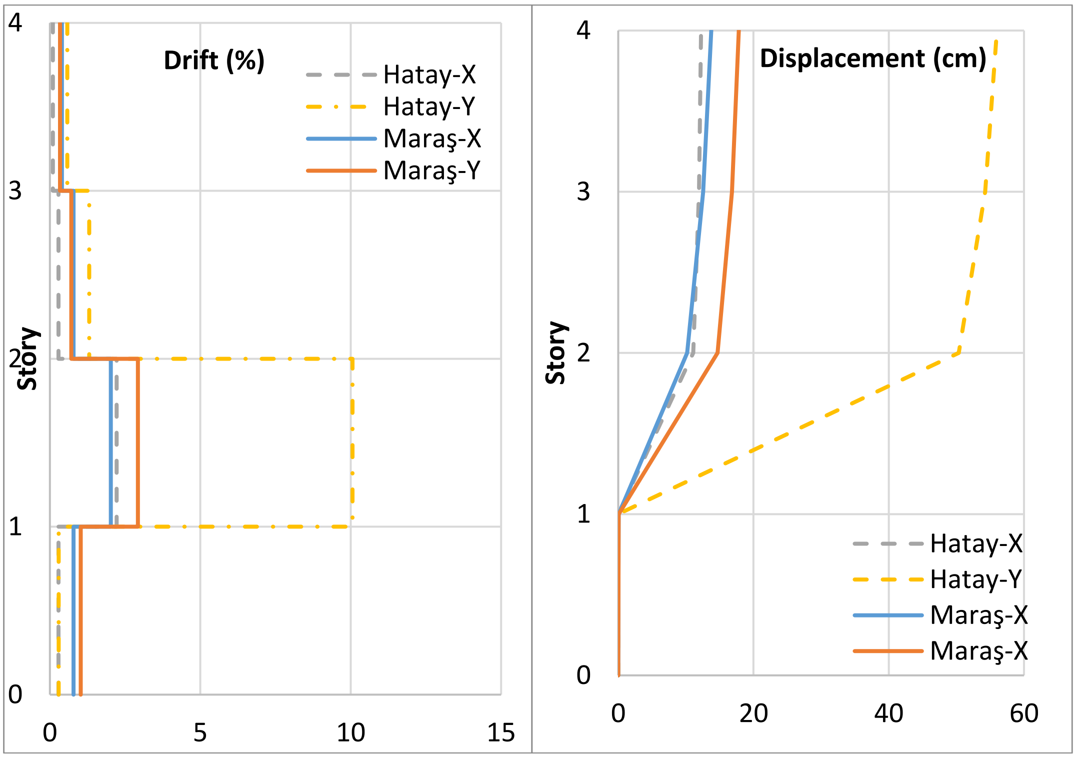

Fig. 8. Calculated displacement and drift variation with height.

The standard check for verifying the strong column–weak beam (SCWB) condition, as illustrated in Fig. 9, is based on the requirement that the inequality defined in Equation 1 must be satisfied for beam moments acting in both directions within the vertical plane of the frame. This check implicitly assumes that the flexural demands on the beams and columns connected to a joint develop in the same direction under lateral loading. This fundamental assumption underpins the moment capacity ratio control prescribed in seismic design codes, including TBEC-2018, and forms the basis of the conventional capacity design approach.

However, field observations from recent earthquakes—particularly the February 6, 2023 Kahramanmaraş events—have demonstrated that this assumption does not hold in many real-world structures. Specifically, in buildings where lower stories are rigidly confined with shear walls (e.g., basement levels), and upper stories consist of moment-resisting frames, the actual behavior deviates significantly from the idealized model. In such cases, columns connected to the beam–column joints being evaluated often develop opposing moments, effectively balancing each other out, resulting in a very low residual moment at the joint. This undermines the intended premise of the SCWB check, which assumes an unbalanced condition favoring beam yielding.

Additionally, analytical results indicate that in buildings with long-span beams subjected to high dead and live loads, the internal moments in these beams—governed primarily by gravity loading—do not significantly change during seismic excitation. As a result, these elements retain large internal moments regardless of lateral load reversals, and the assumption that beam moments will increase significantly under earthquake effects becomes invalid. Consequently, the practical relevance of the SCWB check—as traditionally formulated—diminishes in such systems, and its enforcement does not guarantee the intended energy dissipation mechanism. In such cases, the conventional SCWB verification loses meaning, and a more realistic approach to seismic design and detailing is required—one that considers actual deformation demands and stiffness irregularities in the vertical direction.

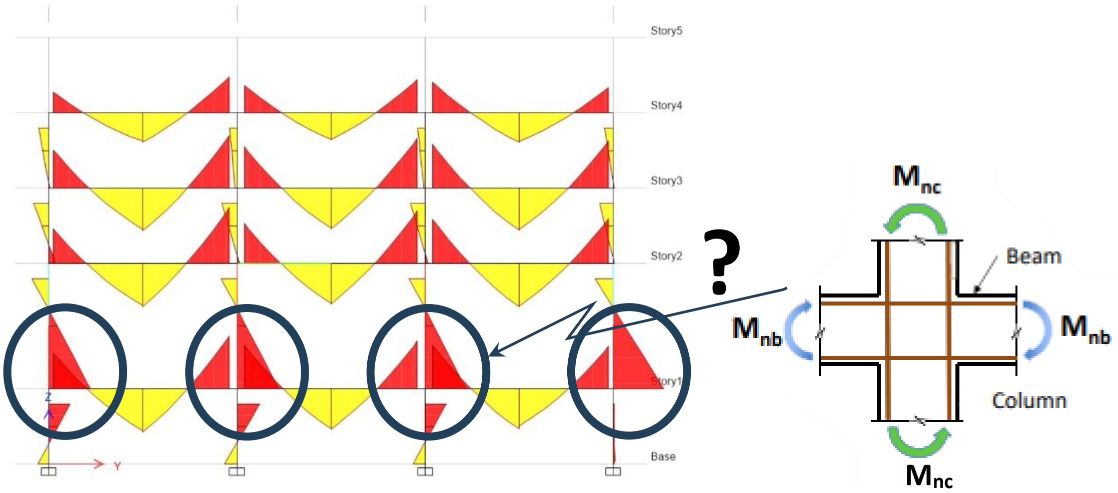

Fig. 9. Typical column moment diagram for investigated structure and assumption for the strong colum weak beam

In such configurations, the building's global behavior deviates from a typical shear-frame mechanism, especially just in the rigid basement level, and instead develops an alternative moment distribution pattern. In these cases, the actual seismic demands on the columns significantly exceed those on the beams, particularly at the interface between the rigid lower stories and the more flexible upper frames. This mismatch leads to concentration of inelastic demands in the columns, initiating damage mechanisms that violate the intended SCWB philosophy and often trigger premature failure at these critical story levels.

As a result, and in light of the preceding discussion, it becomes evident that relying solely on a high behavior factor such as R = 8, which is commonly adopted in design practice, is inadequate for ensuring seismic safety in structural systems exhibiting vertical irregularities. In such configurations—characterized by stiffness discontinuities, unbalanced deformation demands, and concentrated damage zones—the global energy dissipation capacity is significantly reduced, and the assumptions underlying the use of high R-factors are no longer valid. When more realistic values are adopted for ductility, the effective behavior factors must be considerably lower to reflect the actual deformation and failure mechanisms. For example, by adjusting for the material coefficients typically used in design, the effective R-factor can be approximated as R = 3.5 (≈1.5 × 2.38) for the Hatay ground motion and R = 4.0 (≈1.5 × 2.8) for the Maraş ground motion. These adjusted values provide a more accurate representation of the structure's true performance capacity and the level of seismic demand it can safely sustain.

Ultimately, adjusted R-values can provide a rough estimate of the reduced capacity, these values do not fully capture the complex nonlinear behavior of such irregular systems. Therefore, a deformation-based analysis approach is essential to realistically assess the structural response and to provide engineers with a more reliable understanding of how the building will perform under strong ground motion. Only through such advanced analysis techniques can the true inelastic demands, potential damage mechanisms, and collapse risks be identified, allowing for safer and more informed seismic design decisions—especially in structures with pronounced vertical irregularities.and long span only with such revised assumptions and a more performance-consistent evaluation of behavior factors can a realistic and reliable seismic design be achieved—particularly for buildings with significant vertical stiffness irregularities, where conventional code-based simplifications may lead to unsafe design outcomes.

5. Conclusions

This study critically examined the seismic behavior of a reinforced concrete building that suffered significant damage during the February 6, 2023 Kahramanmaraş earthquakes, with a particular focus on the applicability of the strong column–weak beam (SCWB) design principle. The building, which exhibited a vertically irregular configuration characterized by a rigid basement with shear walls supporting a flexible frame system above, was found to deviate substantially from the expected frame behavior under strong ground motions.

Field observations, reinforced by detailed nonlinear time-history analyses, revealed that all second-story columns exceeded the Collapse Prevention (CP) limit under both the Maraş and Hatay earthquake records. Although linear analysis indicated compliance with SCWB criteria, nonlinear analysis uncovered failure mechanisms that contradicted the intended ductile hierarchy. In particular, high demands were concentrated in the second-story columns—primarily due to vertical stiffness discontinuities—which undermined the SCWB mechanism and triggered premature column failure. These results underscore the critical limitations of relying solely on linear analysis and prescriptive R-factors, especially in irregular structures.

The study further highlighted the limitations of the standard SCWB verification method, which assumes that beam and column moments act in the same direction. In the examined case, and many similar configurations observed in earthquake-prone regions, columns connected to the beam-column joints often developed opposing moment demands, reducing residual joint moments and invalidating the assumptions behind the capacity design check. Moreover, long-span beams carrying substantial gravity loads retained large internal moments even during lateral loading, resulting in minimal seismic contribution and rendering the traditional SCWB control ineffective. In this context, nonlinear analysis methods proved essential for realistically evaluating the inelastic demand distribution and accurately capturing the failure mechanisms—particularly in columns situated between stiff and flexible regions. Linear methods, by contrast, failed to predict these critical behaviors, highlighting the risk of underestimating vulnerabilities when such approaches are used exclusively in design. In conclusion, accurate seismic performance assessment of irregular buildings demands an integrated approach—combining detailed nonlinear analysis with realistic design coefficients—to ensure safety, robustness, and code compliance. By adopting such strategies, engineers can deliver more resilient structures capable of withstanding severe seismic demands while minimizing the risk of unexpected failure.

Effect of vertical earthquake components on the base displacement response of seismically isolated buildings

Abstract. Seismic isolation is a widely implemented strategy for mitigating earthquake-induced demands on structures by incorporating isolator units at the foundation or other appropriate substructure levels. This approach effectively lengthens the natural period of the structure through horizontally flexible isolation elements, allowing the superstructure to respond in a near-rigid-body manner relative to the ground. As a result, interstory drift ratios and floor accelerations are significantly reduced, thereby preserving structural integrity and minimizing damage to non-structural components. Nevertheless, the performance of seismic isolation systems can be adversely affected under near-fault ground motions, which are characterized by high-amplitude velocity pulses and significant vertical ground motion components. These characteristics can notably increase seismic demands on the isolation system, necessitating a detailed evaluation of their effects. Prior studies have emphasized the critical role of such components in the seismic behavior of base-isolated structures. In this study, three-story and six-story three-dimensional reinforced concrete moment-resisting frame structures equipped with lead-rubber bearings (LRBs) were modeled using SAP2000. Two pulse-like ground motion records containing both horizontal and vertical components were selected in accordance with the Turkish Building Earthquake Code (TBEC-2018) and scaled to match the target design spectra for the relevant site classes. Nonlinear time history analyses were conducted under two excitation scenarios: (i) horizontal components only, and (ii) combined horizontal and vertical components. The seismic response was assessed with particular focus on isolator performance, specifically evaluating both horizontal and vertical displacement demands of the isolation units. The findings indicate that the inclusion of the vertical ground motion component increased vertical displacement demands under compressive effects in all isolators of the three-story building, while in the six-story building, it slightly reduced the displacement demands in isolators subjected to tensile effects and slightly increased those in isolators under compressive effects.

Keywords: Seismically isolated building; Vertical components of earthquakes; Horizontal-vertical coupling effects

1. Introduction

Seismic base isolation primarily aims to decouple the superstructure from the foundation, thereby increasing the natural period of the structure and reducing the seismic demands transmitted to it. By extending the period, isolation systems shift the structure's response to a region of the response spectrum associated with lower accelerations. In addition, the supplemental damping provided by the isolators effectively dissipates seismic energy, which leads to a significant reduction in both inter-story drifts and floor accelerations. As a result, seismic isolation minimizes the lateral forces transmitted to the superstructure, contributing to the preservation of both structural integrity and the safety of non-structural components (Naeim & Kelly, 1999).

However, the performance of base isolation systems may be challenged under seismic scenarios dominated by near-fault effects. In this context, two major challenges are commonly identified. The first is the occurrence of long-period, high-amplitude velocity pulses, which are frequently observed in near-fault ground motions. The second involves the vertical ground motion component, which can exceed conventional levels in such events (Bray & Marek, 2004). When the period of the velocity pulse is close to the natural period of the isolation system, a resonance-like interaction may develop, leading to significant increases in isolator displacement demands (Hall, 1998; Alhan & Öncü-Davas, 2016). If these dynamic effects are not adequately addressed during the design process, isolators may exceed their capacity, resulting in potential structural failures such as tearing or buckling.

Although the vertical component of ground motion is typically lower in amplitude than the horizontal component and gravitational acceleration, studies have shown that in near-fault regions it can reach unusually high

golden light publishing

levels and have significant influence on structural response (Bozorgnia & Campbell, 2004). While it is widely accepted that horizontal ground motions generally exhibit higher amplitudes and that vertical components attenuate more rapidly in the far field (Campbell, 1997), recent research demonstrates that vertical ground motions may also play a critical role in the dynamic performance of structures located near active faults (Bozorgnia and Campbell, 2004). Observations from the 2023 Kahramanmaraş earthquakes are consistent with these findings, with peak ground velocity values in the vertical direction reaching up to 100 cm/s at certain stations (Ertuncay & Costa, 2025).

TBEC-2018 does not provide comprehensive provisions regarding the effects of vertical ground motion or the increased seismic demands that may arise under near-fault conditions in the design of base-isolated systems. However, such ground motions often lead to elevated vertical-to-horizontal peak acceleration ratios, which in turn generate significant dynamic demands on structural elements. Base isolation components such as high-damping lead-rubber bearings and frictional bearings may be subjected to substantial tensile forces and uplift effects under these conditions (Kasalanati & Constantinou, 2005). In this context, experimental studies conducted by Kumar et al. (2015) at the University at Buffalo investigated the tensile behavior of rubber isolators and identified cavitation as a potential failure mechanism that may occur under large tensile demands during major seismic events.

To investigate the effect of vertical ground motion on base-isolated structures, three-story and six-story reinforced concrete moment-resisting frame buildings equipped with Lead Rubber Bearings (LRBs) were modeled using SAP2000 (CSI, 2023). The isolation systems were designed for Soil Class ZD in accordance with the DD-1 seismic hazard level, which corresponds to a 2% probability of exceedance in 50 years. Ground motion records containing horizontal and vertical components were selected and scaled in accordance with TBEC-2018 to match the design spectra for each soil classification. Nonlinear time history analyses were carried out considering both horizontal-only excitations and combined horizontal–vertical excitations. The structural response was evaluated based on peak base displacements and vertical displacements in the isolators.

2. Methodology

2.1.Benchmark building model

For comparative analysis, two three-dimensional reinforced concrete moment-resisting frame building models were developed: a three-story and a six-story building. Both models were equipped with lead rubber bearing (LRB) systems designed in accordance with the DD-1 seismic hazard level, which corresponds to a 2% probability of exceedance in 50 years, for Soil Class ZD. As illustrated in the 3D and plan views in Fig. 1, the buildings have a regular plan layout consisting of five bays in the X-direction and three bays in the Y-direction. Each story has a uniform height of 3.5 meters. All columns were designed with cross-sectional dimensions of 50×50 cm, while the beams have cross sections of 30×60 cm. At each floor level, dead and live loads of 2000 N/m² are uniformly assigned to the 20 cm thick slabs.

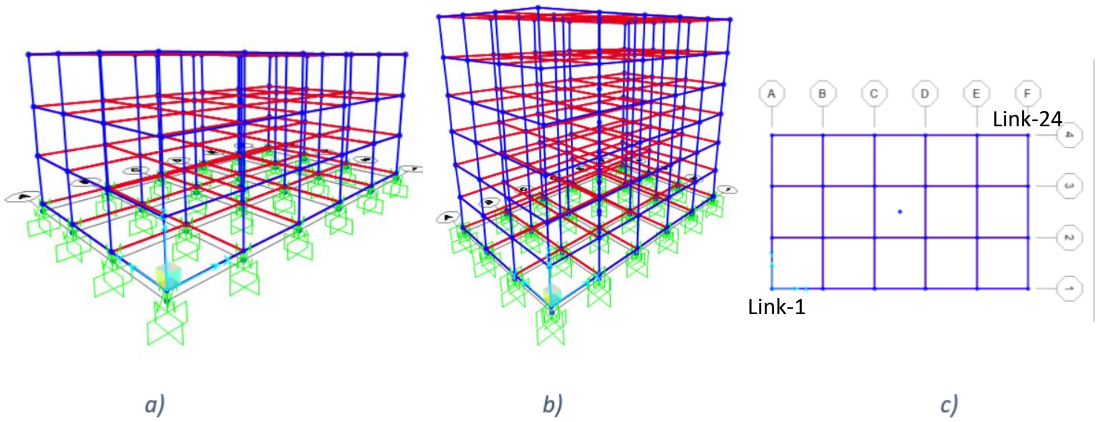

Fig. 1. 3D views of the seismically isolated buildings: (a) three-story model, (b) six-story model, and (c) plan view.

The LRB devices exhibit highly nonlinear hysteretic behavior, which can be effectively modeled using a bilinear force–deformation relationship. The cyclic response of these isolators is represented using the Bouc–Wen model formulation (Bouc, 1967; Wen, 1976), which captures both the pre-yield stiffness and post-yield energy dissipation. The fundamental mechanical parameters that govern the behavior of the Lead Rubber Bearing (LRB) system are derived based on a bilinear idealization of its force–displacement response. These parameters are calculated using a series of interrelated expressions as follows:

Post-yield stiffness (k_2) is determined using the following dynamic relation involving the total weight (W) of the structure and the characteristic period (T_0) of the isolation system:

$$k_2 = 4\pi^2(\frac{W}{g})/\,T_0{}^2 \tag{1}$$

Characteristic strength (F_Q), representing the force at the transition point between pre- and post-yield behavior, is calculated as:

$$F_Q = (k_1 - k_2)D_y \tag{2}$$

Pre-yield stiffness (k_1) is expressed in terms of post-yield stiffness and characteristic strength as:

$$k_1 = k_2 + F_Q/D_y \tag{3}$$

The ratio of post-yield to initial stiffness (α), is given by:

$$\alpha = k_2/k_1 \tag{4}$$

Finally, the yield force (F_y), which represents the onset of nonlinear behavior, is expressed as a function of pre-yield stiffness and yield displacement:

$$F_y = k_1 D_y \tag{5}$$

These equations are consistent with those proposed in the literature (e.g., Naeim & Kelly, 1999; Matsagar & Jangid, 2004), and they form the basis for characterizing the equivalent bilinear representation of LRB isolators in structural analysis.

In this study, the mechanical parameters defining the seismic isolation system were determined through an iterative procedure based on the methodology proposed by Constantinou et al. (2007), in compliance with the requirements of the Turkish Building Earthquake Code (TBEC-2018). In this context, a representative site located at coordinates (41.005427°, 28.940647°) was considered, assuming a ZD soil classification. The design spectral acceleration coefficients corresponding to the DD-1 earthquake level were taken as S_{DS} = 1.757 and S_{D1} = 0.891 for ZD soil. These coefficients were used to construct the design acceleration spectrum and to derive the spectral acceleration values (S_{ae}) required for the dynamic evaluation of the isolation system.

In this study, the mechanical characterization of the lead-rubber bearing (LRB) isolators was carried out through an iterative design process. The initial assumptions included a post-yield to pre-yield stiffness ratio (a) and a characteristic strength ratio (F_Q/W), both taken as 0.1. The shear yield stress of the lead core was assumed as τ_{yp} = 10 MPa, which plays a critical role in defining the isolator's hysteretic energy dissipation capacity. The elastomeric portion of the isolator consists of multiple bonded layers. Each individual layer has a thickness of t = 9 mm, resulting in a total elastomer thickness of T_t = 380 mm. The rubber material properties, specifically the shear modulus (G_v = 0.4 MPa) and the bulk modulus (K = 2000 MPa), were also taken into account, as they significantly influence the horizontal stiffness and volumetric deformation response of the isolator. According to TBEC-2018, when the hardness of the rubber material is assumed to be 60, the empirical constant k is taken as 0.6. For the three-story building model, all isolators are identical, with an elastomer diameter of 500 mm and a lead core diameter of 100 mm. For the six-story building, these dimensions are increased to 600 mm and 120 mm, respectively. Utilizing the aforementioned key parameters, the fundamental properties of the isolation system, including the effective stiffness (K_{eff}), effective period (T_{eff}), effective damping ratio (β_{eff}), and maximum base displacement (D), were calculated in accordance with the formulations provided in Equations 6 to 10.

$$K_{eff} = k_2 + F_Q/D_y \tag{6}$$

$$T_{eff} = 2\pi\sqrt{M/K_{eff}} \tag{7}$$

$$\beta_{eff} = 4Q(D - D_y)/(2\pi K_{eff} D^2) \tag{8}$$

$$\eta = \sqrt{10/(5 + \beta_{eff})} \tag{9}$$

$$D = 1.3T_{eff}^2\eta S_{ae}(T_{eff})g/(4\pi^2\,) \tag{10}$$

In this context, D_y denotes the yield displacement of the isolation bearings. To estimate the maximum displacement at the isolation level (D), it is essential to determine the spectral acceleration (S_{ae}) and the corresponding damping modification factor (η), which is derived based on the effective damping ratio (β_{eff}) of the isolation system. Assuming linear elastic behavior, the spectral acceleration corresponding to the effective period (T_{eff}) is obtained from the design response spectrum. The iterative process terminates once convergence is achieved, specifically when the difference between successive values of D becomes negligible. After the overall dynamic properties of the isolation system are determined using Equations (1)–(10), the mechanical parameters for each isolator are calculated by dividing the total system values by the number of isolation units implemented in the model. These parameters are presented in Table 1.

Table 1. Mechanical LRB parameters of two structures for earthquake level DD-1

In this study, the nonlinear behavior of Lead Rubber Bearings (LRBs) was modeled using multilinear plastic link elements to accurately represent their complex force–displacement relationships in both the vertical and horizontal directions under dynamic loading conditions. The fundamental periods of the structure in the horizontal and vertical directions were determined based on the mode shapes that achieve 95% mass participation, as specified in TBEC-2018, and are presented in Table 2. The load combinations to be considered in evaluating the forces acting on the elements located beneath and at the isolation interface are defined in Section 14 of TBEC-2018.

2.2. Near-fault earthquakes and basic scaling

Near-fault ground motions, defined as strong ground motions recorded within approximately 15 km of the fault rupture, are characterized by high-amplitude, long-period velocity pulses, which distinguish them significantly from far-field ground motions. In addition to their well-known horizontal effects, recent studies have shown that the vertical component of near-fault ground motions can also attain unusually high amplitudes, particularly in proximity to the fault rupture. This phenomenon has been observed in several destructive earthquakes and is of particular concern for base-isolated structures, where vertical excitation may induce additional demands on isolation systems.

In this study, the influence of vertical ground motion components on the seismic response of base-isolated buildings employing lead-rubber bearings (LRBs) is investigated. To this end, two representative near-fault ground motion records were selected from the PEER Ground Motion Database (2025). The selection and scaling procedures were carried out in accordance with the design response spectrum corresponding to the DD-1 seismic hazard level, which represents a 2% probability of exceedance in 50 years. In addition to matching the target spectrum, several key ground motion parameters were considered during the selection process, including fault rupture distance, moment magnitude (M_w), average shear-wave velocity (V_{s30}), and faulting mechanism.

Following the selection of ground motion records, amplitude scaling was conducted to ensure that the average response spectrum within the period range of $0.5T_{eff}$ to $1.25T_{eff}$ did not fall below 30% of the corresponding design spectrum over the same interval. To account for the influence of near-fault ground motions, the design spectrum was modified in accordance with the methodology proposed by Caltrans (2019) (Eq. 11). The coefficients employed in this spectral adjustment were defined by Equations 12 and 13. The scaling procedure was implemented based on the DD-1 seismic hazard level and site conditions corresponding to Soil Class ZD. Table 3 summarizes the principal parameters of the selected near-fault ground motions, including moment magnitudes (M_w), Joyner–Boore distances (R_{jb}), pulse periods (T_p), and applied scaling factors. Consistent with the definition of Soil Class ZD, the shear wave velocity in the upper 30 meters (V_{s30}) was assumed to be within the range of 180–360 m/s. In order to more accurately represent the seismic behavior of structures located in proximity to active faults, ground motion records classified as pulse-like in the literature and exhibiting pronounced directivity effects were specifically selected. These records were prioritized due to their significant impact on structural response, particularly in scenarios where near-fault effects are predominant. Figure 2 presents the acceleration response spectra of the scaled near-fault ground motion records, considering the horizontal and vertical elastic design spectra defined for the DD-1 earthquake level.

$$S_{a,modified}(T) = S_a(T)N_f \tag{11}$$

$$N_f = 1.2 \quad L_f(km) \le 15km \tag{12}$$

$$N_f = 1.2 - 0.02(L_f - 15) \quad 15km \le L_f(km) \le 25km \tag{13}$$

Table 3. The historical pulse-like earthquake records and their details

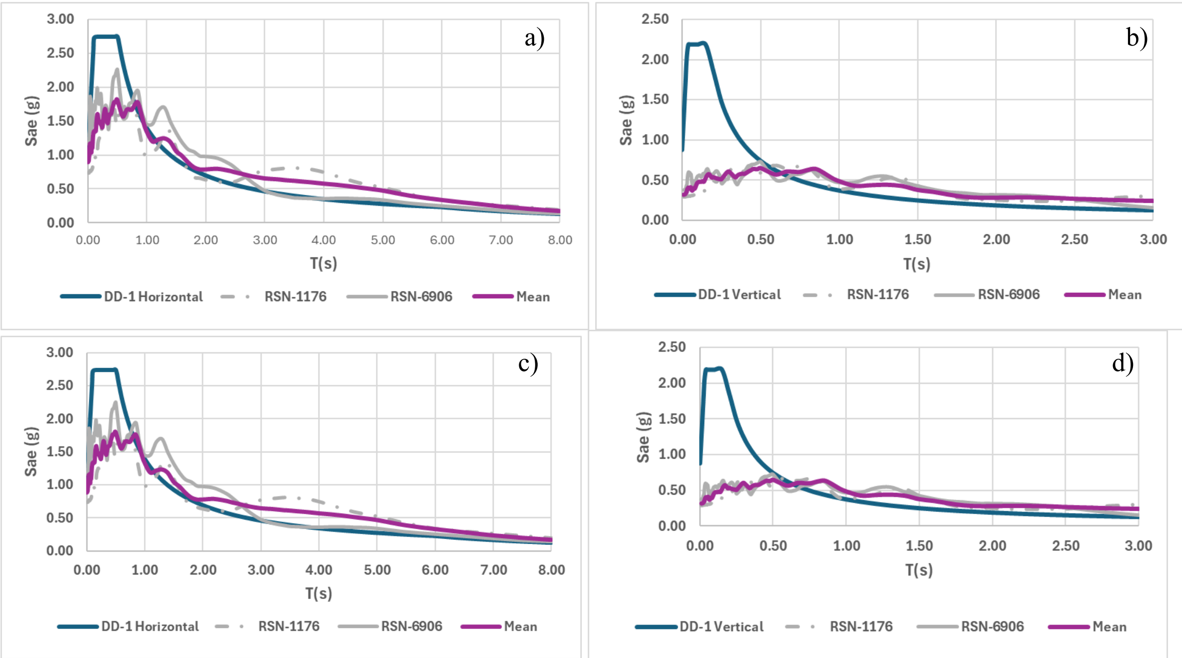

Fig. 2. Spectral acceleration responses of the scaled ground motions for each building model: (a) horizontal and (b) vertical components for the three-story building; (c) horizontal and (d) vertical components for the six-story building.

Based on the effective damping ratio of 19% and the effective isolation period of 3.4 s for the six-story base-isolated building, as provided in Table 2, the spectral displacement values for the x- and y-components of the RSN1776 ground motion were obtained as approximately 101 cm and 93 cm, respectively (see Fig. 3a and 3b). Similarly, for the RSN6906 ground motion, the spectral displacement values were approximately 55 cm and 71 cm for the x- and y-components, respectively (see Fig. 3c and 3d).

3. Results and discussion

For the three-story and six-story base-isolated buildings, scaled near-fault ground motion records were configured into four distinct combinations by rotating the horizontal components by 90 degrees and by including or excluding the vertical ground motion component. Fast nonlinear time history analyses were conducted using these combinations. The results were examined in terms of the horizontal and vertical displacement demands of the isolators for two cases: (i) application of horizontal components only, and (ii) combined application of horizontal and vertical components.

Figure 4 (a) and (b) present the maximum vertical displacement demands of all isolators in the three-story building under the RSN1776 near-fault ground motion record, corresponding to the cases with combined horizontal and vertical components and horizontal components only, respectively. Similarly, Figure 4 (c) and (d) illustrate the results obtained for the RSN9606 near-fault earthquake record. In a comparable manner, Figure 5 presents the results obtained for the six-story building under the same ground motion scenarios, in order to observe the effect of increased number of stories on the vertical displacement response.

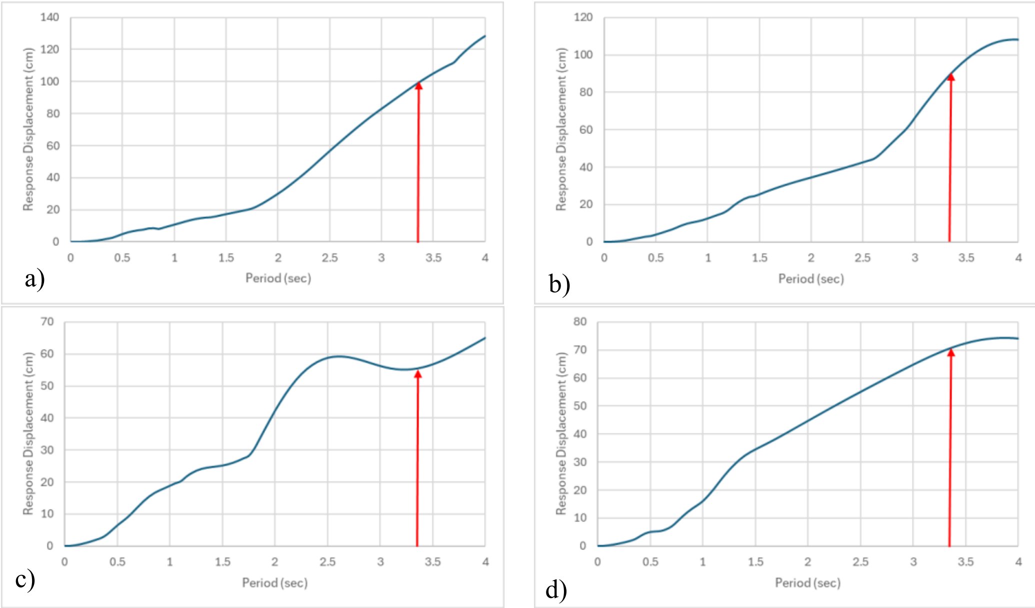

Fig. 3. Isolator damping ratio (19%) displacement spectrum in horizontal x (a) and y (b) directions of RSN 1776 earthquake, horizontal x (c) and y (d) directions of RSN 6906 earthquake at 6-story building

In these graphs, the orange-colored markers represent vertical displacement demands under compressive effects, while the green ones indicate displacements under tensile effects. As observed in Fig. 4, only compressive vertical displacements occurred in the three-story base-isolated building. Moreover, the inclusion of the vertical component (a and c) resulted in slight increases in compressive displacements for some isolators, while causing reductions in others, when compared to the cases with horizontal components only (b and d). Nevertheless, no tensile (uplift) response was observed in any scenario, indicating that the vertical dynamic demands on the isolators remained entirely within the compressive response range throughout the analyses.

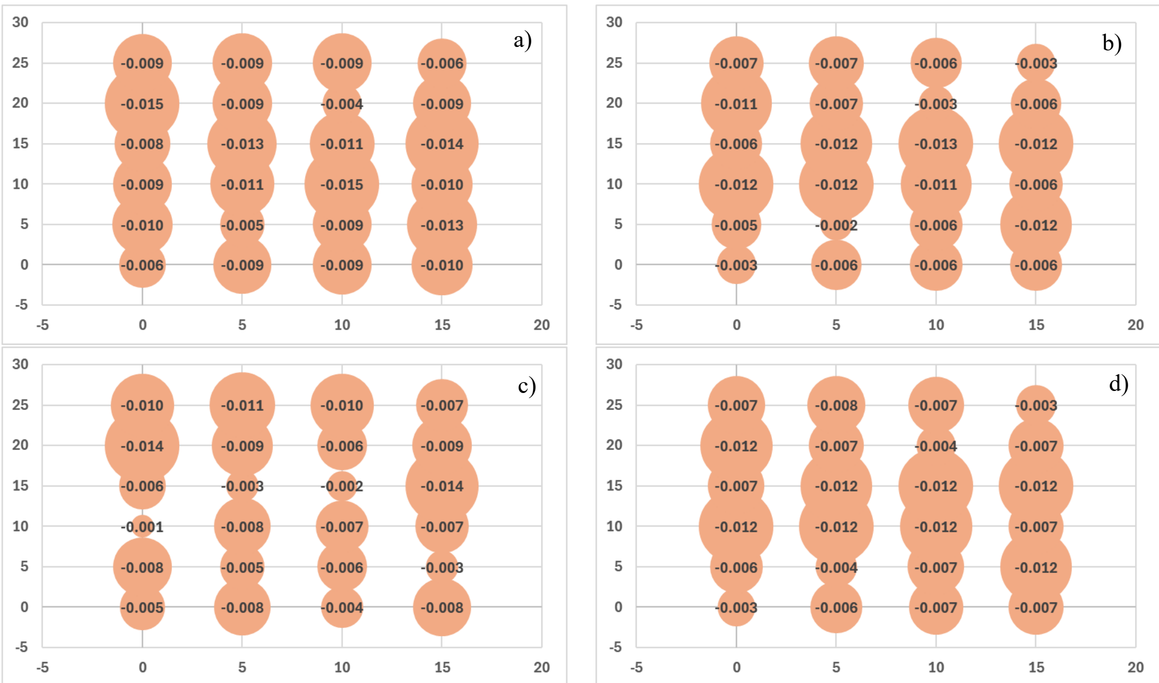

Fig. 4. Maximum vertical displacements (mm) of isolators in three-story base-isolated structure under RSN1176 (a, b) and RSN6906 (c, d) near-fault ground motions: (a, c) with vertical ground motion component, (b, d) without vertical component.

In contrast to the three-story structure, the six-story base-isolated building exhibited both compressive and tensile vertical displacement demands in the isolators, as shown in Fig. 5. The presence of green-colored markers in all four subfigures (a–d) clearly indicates the occurrence of uplift (tensile) responses, particularly in isolators located closer to the building edges. Moreover, the inclusion of the vertical ground motion component (Fig. 5a and 5c) appears to reduce the amplitude of tensile displacement demands in the isolators compared to the scenarios with horizontal components only (Fig. 5b and 5d).

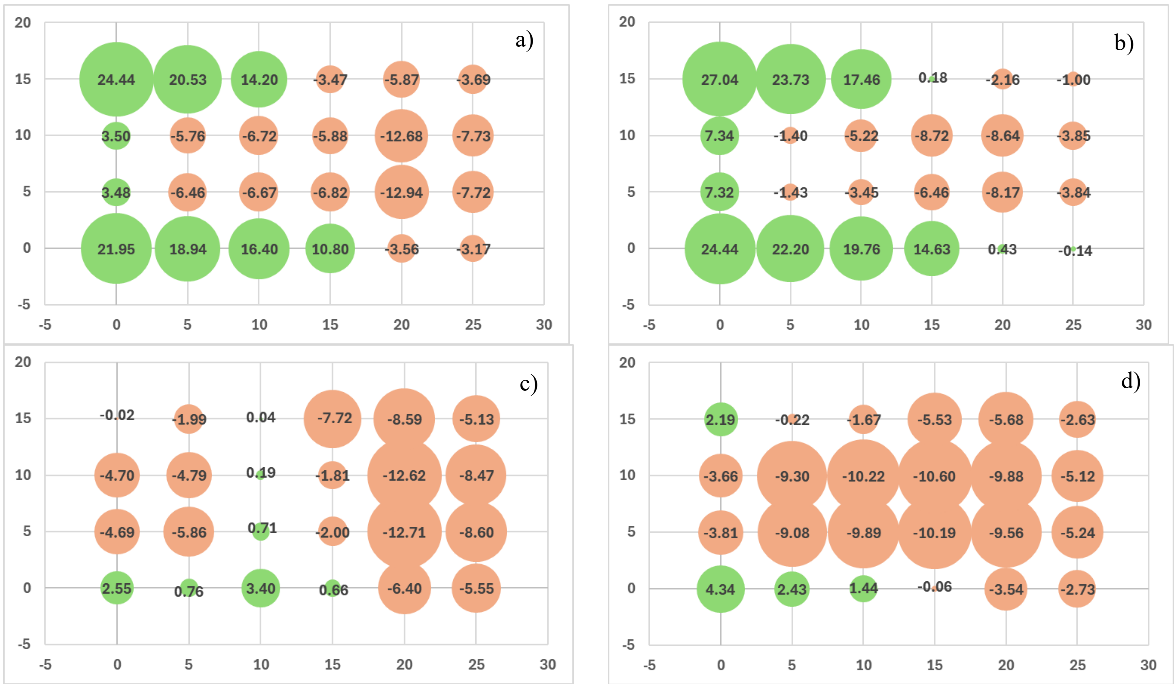

Fig. 5. Maximum vertical displacements (mm) of isolators in six-story base-isolated structure under RSN1176 (a, b) and RSN6906 (c, d) near-fault ground motions: (a, c) with vertical ground motion component, (b, d) without vertical component.

Figures 6 and 7 illustrate the vertical and horizontal displacement demands of the Link-1 and Link-24 isolators (identified in Fig. 1), located at diagonally opposite corners of the six-story base-isolated building, where the influence of vertical ground motion is most pronounced. Based on the combinations selected for maximum displacement demands, Figure 6 corresponds to the RSN1776 near-fault ground motion, while Figure 7 corresponds to the RSN9606 record. As observed in Figs. 6a–b and 7a–b, the Link-24 isolator exhibited its maximum vertical displacement under compressive action, whereas the Link-1 isolator reached its maximum vertical displacement demands under tensile effects. Notably, this tensile peak in Link-1 occurred during the RSN1776 excitation. Comparing the cases with and without vertical ground motion, it is evident that the tensile displacement in the case including vertical excitation (Fig. 6a) is slightly lower than that without vertical excitation (Fig. 6b). A similar trend is observed for the RSN9606 record, as shown in Figs. 7a–b. The peak horizontal base displacements presented in Figs. 6c–f for RSN1776 are consistent with the spectral displacement values in Figs. 3a–b, approximately 101 cm and 93 cm. Likewise, for the RSN9606 excitation, the peak horizontal displacements shown in Figs. 7c–f correspond well with the spectral displacements in Figs. 3c–d, approximately 55 cm and 71 cm. Furthermore, the tensile vertical displacements occurred simultaneously with the peak horizontal displacements for both ground motion records (Figs. 6c–f and 7c–f), indicating that the building model is susceptible to uplift effects under the given seismic excitations.

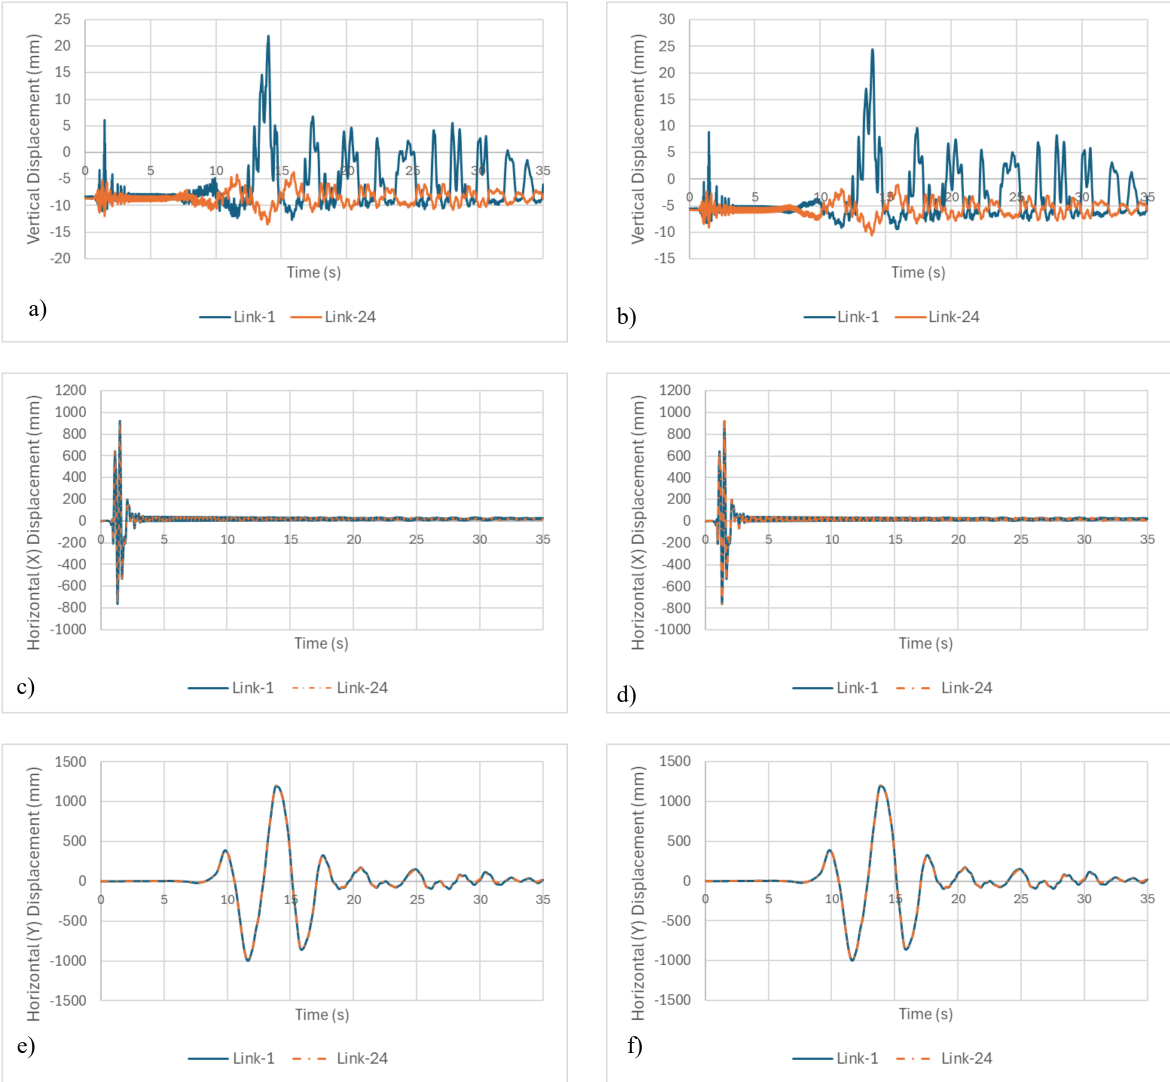

Fig. 6. Vertical (a–b), horizontal-x (c–d), and horizontal-y (e–f) displacement responses of isolators in the six-story building under the RSN1176 record, with (a,c,e) and without the vertical earthquake component (b,d,f).

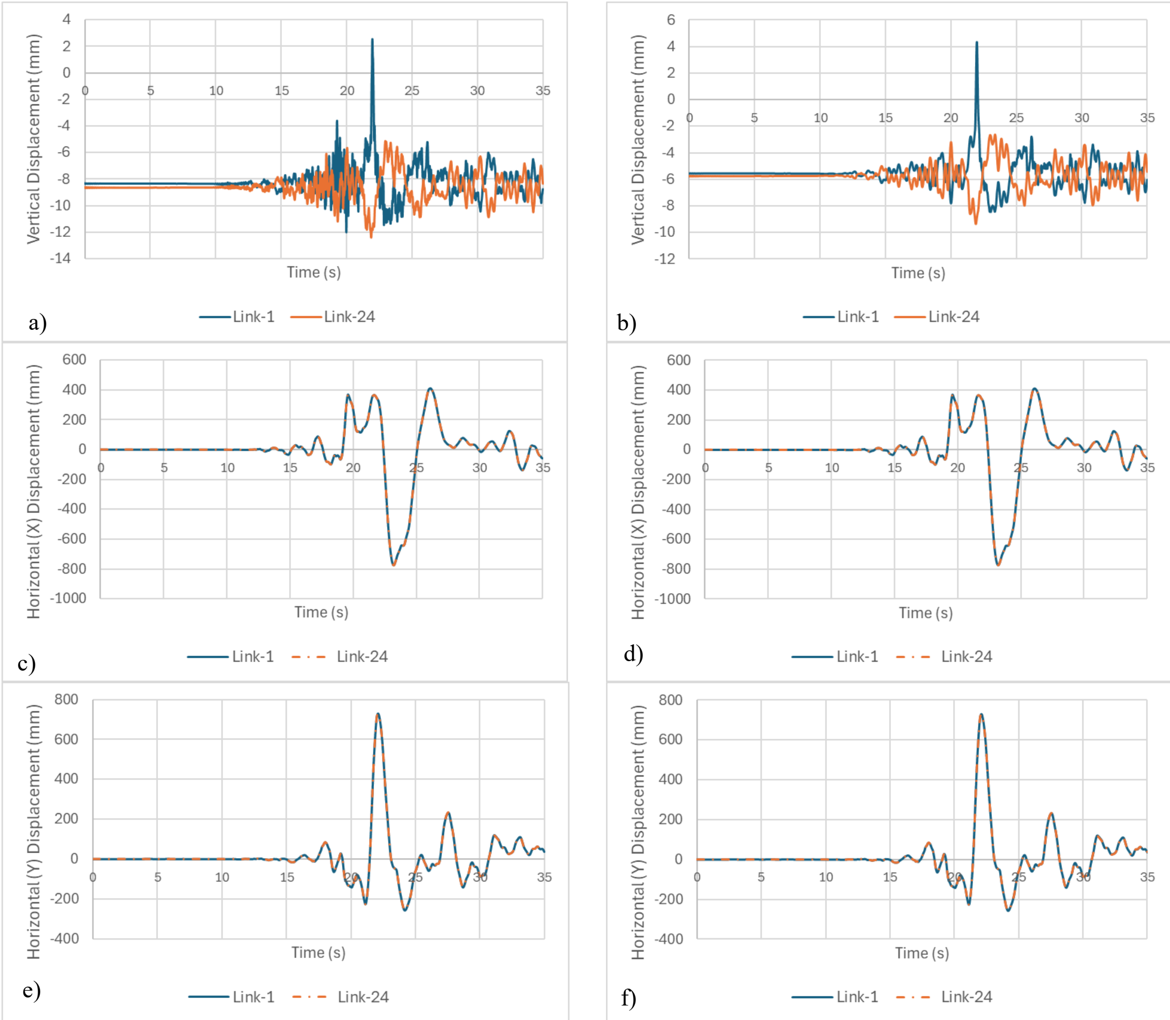

Fig. 7. Vertical (a–b), horizontal-x (c–d), and horizontal-y (e–f) displacement responses of isolators in the six-story building under the RSN9606 record, with (a,c,e) and without the vertical earthquake component (b,d,f).

4. Conclusions

This study examined the influence of near-fault ground motions, including the vertical component, on the seismic performance of three- and six-story base-isolated buildings. Nonlinear time history analyses were conducted using selected ground motion records (RSN1776 and RSN9606) under four different excitation scenarios, which involved rotating the horizontal components by 90° and either including or excluding the vertical component. The displacement responses of the isolators in both horizontal and vertical directions were evaluated, and the following conclusions were drawn:

- In the three-story base-isolated building, all isolators experienced only compressive vertical displacements, even when the vertical ground motion component was included. The inclusion of the vertical component resulted in a slight increase in compressive displacements in some isolators, indicating that the vertical seismic demand remained entirely within the compressive regime for this configuration.
- In contrast, the six-story building exhibited both compressive and tensile vertical displacements. Uplift effects were particularly pronounced in isolators located near the building corners.
- The maximum tensile vertical displacement observed in a corner isolator occurred simultaneously with the peak horizontal displacements. This simultaneity, observed under both RSN1776 and RSN9606 records, indicates a potential structural vulnerability to uplift. However, in certain cases, the inclusion of the vertical ground motion component slightly reduced the tensile response induced solely by horizontal excitation, suggesting that vertical excitation may partially mitigate uplift effects under specific dynamic conditions.

Abstract. As aftershocks are an inevitable phenomenon following a mainshock, their impact on the structural behavior of buildings is crucial. However, the consideration of aftershock effects is absent in current seismic design codes, leaving a critical gap in seismic performance evaluation. To address this issue, this study investigate the effect of mainshock-aftershock (MS-AS) sequences on steel moment resisting frames. In this context, 3-, 9- and 20-story steel moment-resisting frames, which were originally developed as part of the SAC steel project are utilized to evaluate their realistic seismic behavior under sequential earthquakes. The nonlinear time history analysis is performed using real sets of successive earthquakes. In analysis near-field and far-fault ground motions are included to provide comprehensive investigation of seismic demands of steel frames. Following the nonlinear analysis, several fundamental variables such as residual interstory drift, maximum displacement, and plastic hinge formation are evaluated to examine the cumulative damage caused by aftershocks. The findings of these analyses depicted the significant role of aftershocks in exacerbating of plastic deformations, distribution of damage, and overall structural strength of steel moment-resisting frames. Subsequently, to mitigate cumulative damage on steel frames, retrofitting strategies such as bracing systems are implemented on the structures. The results of improved systems were compared to the initial findings showed the improvement of seismic behavior of structures under mainshock-aftershock (MS-AS) events. This study highlights the inadequacy of assessment of the seismic performance of steel structures under a single earthquake as well as emphasizes the importance of consideration of multiple earthquake effects. Furthermore, it provides new insights into mitigating further damages by retrofitting existing structures under multiple earthquakes.

1. Introduction

Earthquakes are among the most destructive natural phenomena, which may cause major damage to structures and infrastructure, eventually leading to significant human casualties and economic loss. Even though, through the years, understanding the behavior of structures under earthquakes has advanced. There is a critical in assessing the real behavior of structures during earthquakes. Conventional seismic design analysis evaluates structures under a single earthquake; however, in real life buildings are subjected to a mainshock and one or more large aftershocks. The aftershocks impose cumulative damage on structures, especially for those that are already damaged from the mainshock, sometimes rendering the structures unrepairable or resulting in the collapse of them.

Fortunately, there are numerous studies that widely investigated the aftershock effects on the seismic behavior of steel structures. The preceding studies, such as Amadio et al. (2003) and Li and Ellingwood (2007), indicated that repeated aftershocks significantly increase structural damage by reducing the energy dissipation capacity and substantial residual drift compared to a single earthquake. Their findings constituted the foundation for understanding how aftershocks affect structural performance during an earthquake. Following studies expanded on this by evaluating various influencing parameters. Hatzigeorgiou (2010) and Hatzigeorgiou and Beskos (2009) investigated how ground motion characteristics, such as soil types and proximity to the fault, influence displacement and ductility demands. They concluded that sequential ground motions resulted in significantly higher deformation levels. Ruiz-García and Negrete-Manriquez (2011) depicted that near-fault aftershocks increase residual drift in steel moment-resisting frames compared to far-fault ground motions.

Further studies focused on more specific structural configurations. Parekar and Datta (2020) examined the stiffness irregularities and their effect on inter-story drift distribution. It is found that irregularities, especially in

* Corresponding author, E-mail: ozakgulk@itu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_278

lower stories, escalate damage under repeated earthquakes. Torfehnejad and Sensoy (2023) introduced the different collapse behavior in low- to mid-rise and high-rise special moment frames under recorded sequential seismic events. With regard to retrofitted or specialized systems, Mohsenian et al. (2021) evaluated the seismic stability of the eccentrically braced steel frames with vertical energy-dissipating links under mainshock-aftershock(MS-AS) sequences. They concluded that while vertical energy-dissipating links absorb the seismic energy, it helps other structural elements remain elastic. It is also found that EBFs have stronger performance and reliability under design-level earthquakes. Even though there are many studies that have already evaluated the seismic performance of steel structures under single-event and mainshock-aftershock sequences, there are limited investigations that compare the behavior of steel moment-resisting frames with their retrofitted counterparts. Also, it is necessary to evaluate cumulative damage in terms of residual inter-story drift, maximum displacement, and plastic hinge distribution for representative SAC buildings prior to and following retrofitting.

This study bridges the gap by examining and comparing the seismic behavior of steel moment-resisting frames without and with bracing systems. Through nonlinear time-history analysis under successive earthquakes, this research seeks to provide insightful information on how braces improve seismic performance, especially in terms of residual drift, maximum displacement, and plastic hinge distribution.

2. Structural models and seismic inputs

2.1. Structural models

Three standard 3-, 9-, and 20-story steel moment-resisting frames are selected as studied structures for this study. These structures originally developed as part of the SAC joint venture project. This project is designed to represent typical commercial office buildings in accordance with pre-Northridge seismic standards in Los Angeles, California (Gupta & Krawinkler, 1999). These buildings are used as standard models to evaluate the seismic behavior of structures with varying height and layout. Fig. 1 displays the three-dimensional (3D) finite element (FE) models of SAC buildings considered.

Each building has a regular, symmetric floor plan with exterior steel moment-resisting and interior gravity frames. While perimeter moment-resisting frames function as the primary lateral force-resisting frames, interior gravity frames resist vertical loads. The columns of the 3-story structure are modeled as fixed at the base. On the contrary, 9-story and 20-story buildings have pinned supports as well as one and two basement levels, respectively. The applied loads, including gravity, wind, and seismic loading of the steel frames, are consistent with the original SAC report (Gupta & Krawinkler, 1999). The utilized material for modeling beams is A36, and for columns it is A50 steel. In the original SAC Joint Venture study, all the necessary information about the structural members cross-section, the plans, and the loading are given in detail.

Fig. 2 shows the floor plans of steel moment-resisting frames. All three buildings are symmetric in plan, and the moment-resisting frames are shown in bold color. In Fig. 3 the elevation of frames is illustrated. The structures have uniform bay spacing and story height: 9- and 20-story structures incorporating basement levels.

The fundamental period and mass participation factor for the first three modes are compared for the steel frames.

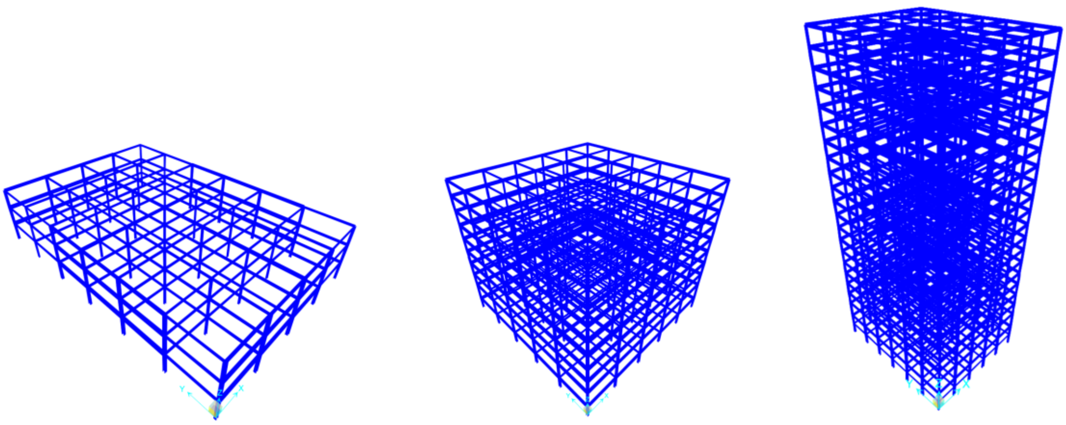

Fig. 1. 3D FE model views of 3, 9 and 20-story SAC buildings

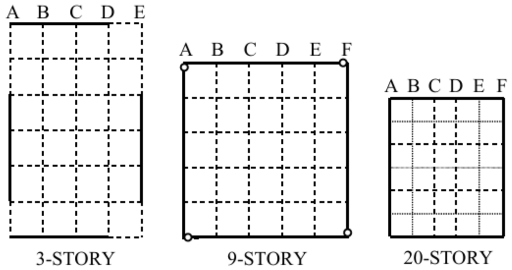

Fig. 2. Floor plans of 3, 9 and 20-story buildings (Gupta and Krawinkler, 1999)

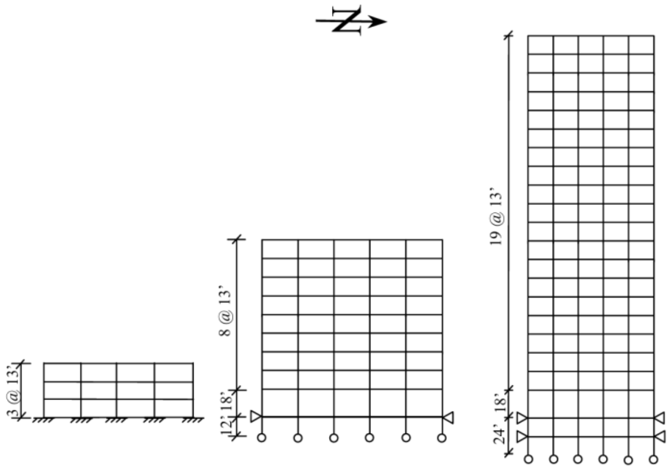

Fig. 3. Elevation for 3-, 9- and 20-story buildings (Gupta and Krawinkler, 1999)

Table. 1. Comparison of FE analysis results with those reported by Gupta and Krawinkler (1999)

No of story	Fundamental Periods (sec)					
	T1 obtained by FE analysis	T1 from the report	T2 obtained by FE analysis	T2 from the report	T3 obtained by FE analysis	T3 from the report
3	1.025	1.03	0.339	0.33	0.185	0.17
9	2.46	2.34	0.929	0.88	0.548	0.50
20	4.15	3.98	1.47	1.36	0.869	0.79

To ensure the accuracy of the developed models, the fundamental periods of the 3-, 9-, and 20-story buildings are compared with those reported in the SAC Joint Venture Project (FEMA 355C, 2000). Table 1 shows the comparison of the fundamental periods of structures. The periods obtained from modal analysis confirm the validation of the analyzed models with the reference structures.

2.2. Description of ground motion

In this study, a set of real mainshock-aftershock (MS-AS) ground motion sequences was considered to assess the seismic behavior of steel moment frame structures under multiple earthquakes. Mainshock-aftershock sequences can be constructed either artificial, repeated or as recorded real ground motions. However, Zhang et al. (2017) outlined that artificial sequences often result in scenario-specific seismic responses due to their inaccurate frequency characteristics. Furthermore, as repeated ground motion approaches assume the identical spectral content for mainshock and aftershock, they oversimplify the actual structural behavior. Therefore, to avoid these limitations as well as obtain realistic dynamic interaction, real recorded earthquakes were used in this study, following Basim et al. (2022), Mohsenian et al. (2021), and Hatzigeorgiou and Beskos (2009).

The selected ground motions include the Chi-Chi (Taiwan), Coalinga, Imperial Valley, Mammoth Lakes, Northridge, and Friuli earthquakes. The selection of these earthquakes was based on criteria such as large magnitudes ($M > 6.0$ for mainshock and $M > 5.0$ for aftershocks) and also the availability of free-field stations to avoid soil-structure interaction effects. Although each earthquake record consists of three components (two horizontal and one vertical), only horizontal components were included in nonlinear time history analysis to focus on the in-plane lateral response of the structures. In mainshock-aftershock sequences, a time gap of 10 seconds was inserted between the mainshock and aftershock to bring the structure to rest and ensure the decay of dynamic response from the mainshock before applying the aftershock.

This study included both near-fault and far-field ground motions to reflect the variability of expected seismic demands. While near-fault earthuqakes occur within a general distance of perhaps 15 to 20 km from the fault rupture, far-fault motions originate from greater distances and typically lack distinct directivity effects (Yang et al., 2015; Alavi & Krawinkler, 2004). All selected seismic records are scaled in accordance with ASCE/SEI 41-13 (2014), which requires the 5% damping ratio for ground motions to ensure the matched or exceeded target spectrum over the defined period range. This defined period ranges typically between 0.2T to 1.5T, where T is the fundamental period of the structure. In this study, a uniform scale factor is applied for the entire acceleration record. The scaling process was performed with emphasis on the period range of the first two fundamental modes, as these two modes predominantly affect the structural response under seismic loading. Table 2 shows the properties of selected earthquakes. It can be seen that these records cover a range of different site classes. This variety allows us to evaluate the seismic behavior of structures under diverse ground conditions and provide a comprehensive understanding of structural performance.

Fig. 4 presents only one horizontal component of the unscaled acceleration time histories of selected MS-AS sequences to provide a clear visual comparison.

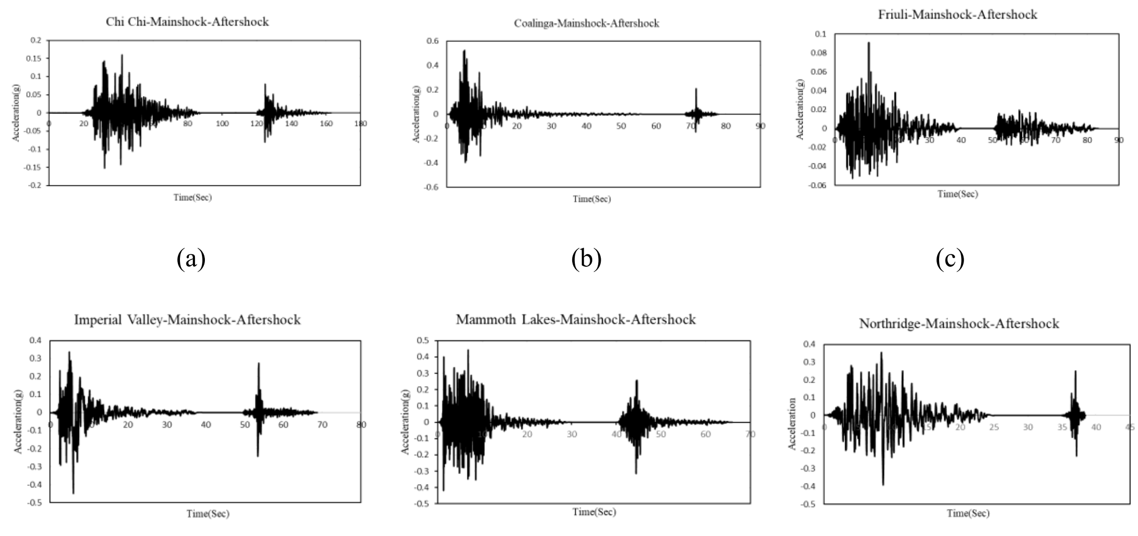
3. Analysis methodology

The nonlinear time-history analyses were performed to evaluate the seismic behavior of 3-, 9- and 20-story structures subjected to mainshock-aftershock(MS-AS) sequences. All buildings were modeled in SAP2000, and structural design were defined based on the SAC Joint Venture guidelines (FEMA355C, 2000). While the original models were generated with the as-designed conditions, the retrofitted (RT) structures were created using X-braces to improve lateral stiffness and energy dissipation. Fig. 5 shows the location of X braces for 3-, 9-, and 20-story steel frames.



(a) (b) (c)

(d) (e) (f)

Fig. 4. Acceleration time history for selected earthquakes

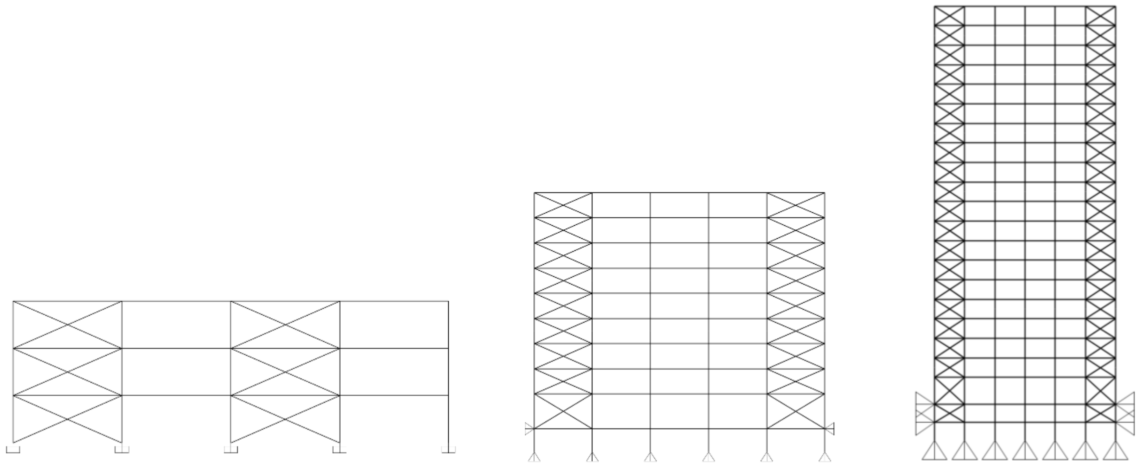


Fig. 5. Retrofitted SAC buildings

Nonlinear behavior of steel frames was simulated by assigning plastic hinges at both ends of the structural elements, beams and columns, where the inelastic deformations are expected to form during seismic events. For the columns and beams, plastic hinges were defined as P-M2-M3 interaction hinges, and M3 moment hinges according to ASCE/SEI 41-13 (2014), respectively.

4. Results and discussions

This section presents the results of nonlinear time history analysis performed on 3-, 9- and 20-story SAC steel moment-resisting structures under MS-AS sequences. Each building was evaluated in both original state and a retrofitted configuration with X-braces. To assess the aftershock effect and retrofitting effectiveness the seismic behavior of structures was determined in terms of inter-story drift ratio, maximum drift as well as plastic hinge formation.

Fig. 6 shows the inter-story drift ratio of evaluated structures under mainshock-only and mainshock-aftershock sequences. Results proved these structures under sequential earthquakes experience greater displacements. It was observed that as the height of the structure increased the inter-story drift decreased. This is due to the distribution of lateral deformation over more stories. Furthermore, since taller buildings has greater fundamental periods, therefore their spectral acceleration demands reduce.

As a representative example, Fig. 7 displays the plastic hinge formation for Chi-Chi earthquake, which has greater magnitude comparing to other selected earthquakes. Only one moment frame was selected for investigation in each structure. Green and red hinges exhibit the Immediate Occupancy(IO) and Collapse Prevention (CP) performance level, respectively. It is clear that the number of plastic hinges increased under sequential earthquakes which means the structures experienced more plastic deformations under multiple earthquakes. Furthermore, the concentration of plastic deformations are significant in lower floors of higher structures.

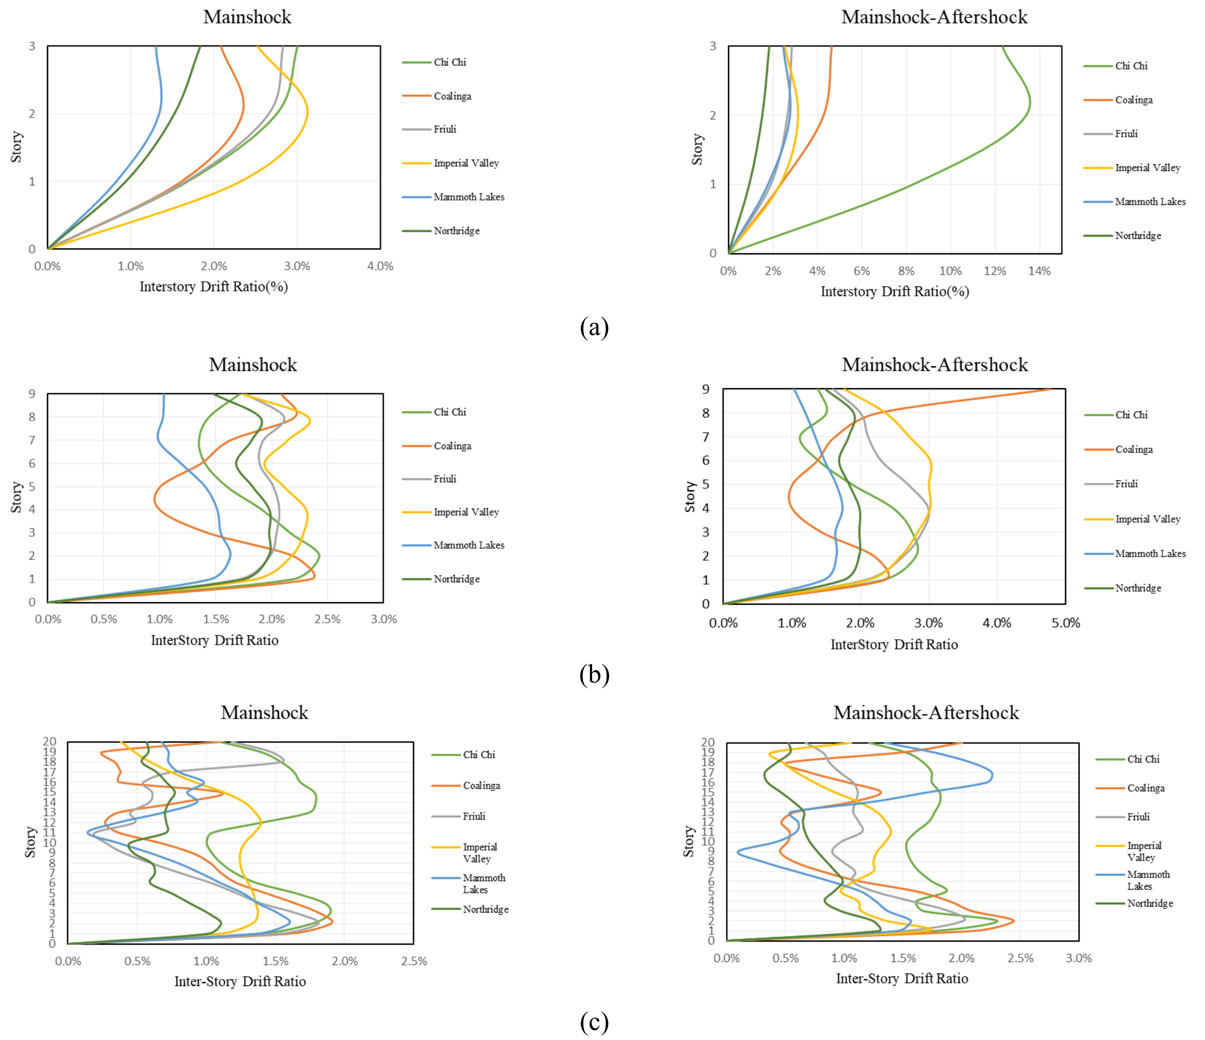

Fig. 6. Comparison of inter-story drift ratio for mainshock (MS)-only and mainshock-aftershock(MS-AS). (a) 3-story building, (b) 9-story building, (c) 20-story building

Fig. 8 displays the result of comparative analysis of the original and retrofitted (RT) structures under MS-AS events. The findings highlight the significant reduction of the residual displacement after retrofitting the steel frames. This reduction emphasizes X braces enhance seismic performance of structures by limiting the deformation and mitigating the cumulative damage under possible seismic sequences. The results also show the importance of the retrofitting after mainshock for damaged structures.

Fig. 9 displays the maximum inter-story drift ratio for all buildings considered. The bar chart shows how drastically the plastic displacement of the frames decreased after retrofitting which proves the importance of X-braces in the resilience of the structure. Moreover, in some earthquakes, such as Friuli, Imperial Valley, and Northridge, drift values were relatively small. This is due to the frequency content of the aftershock as well as the structures' capacity to dissipate seismic energy during the aftershock.

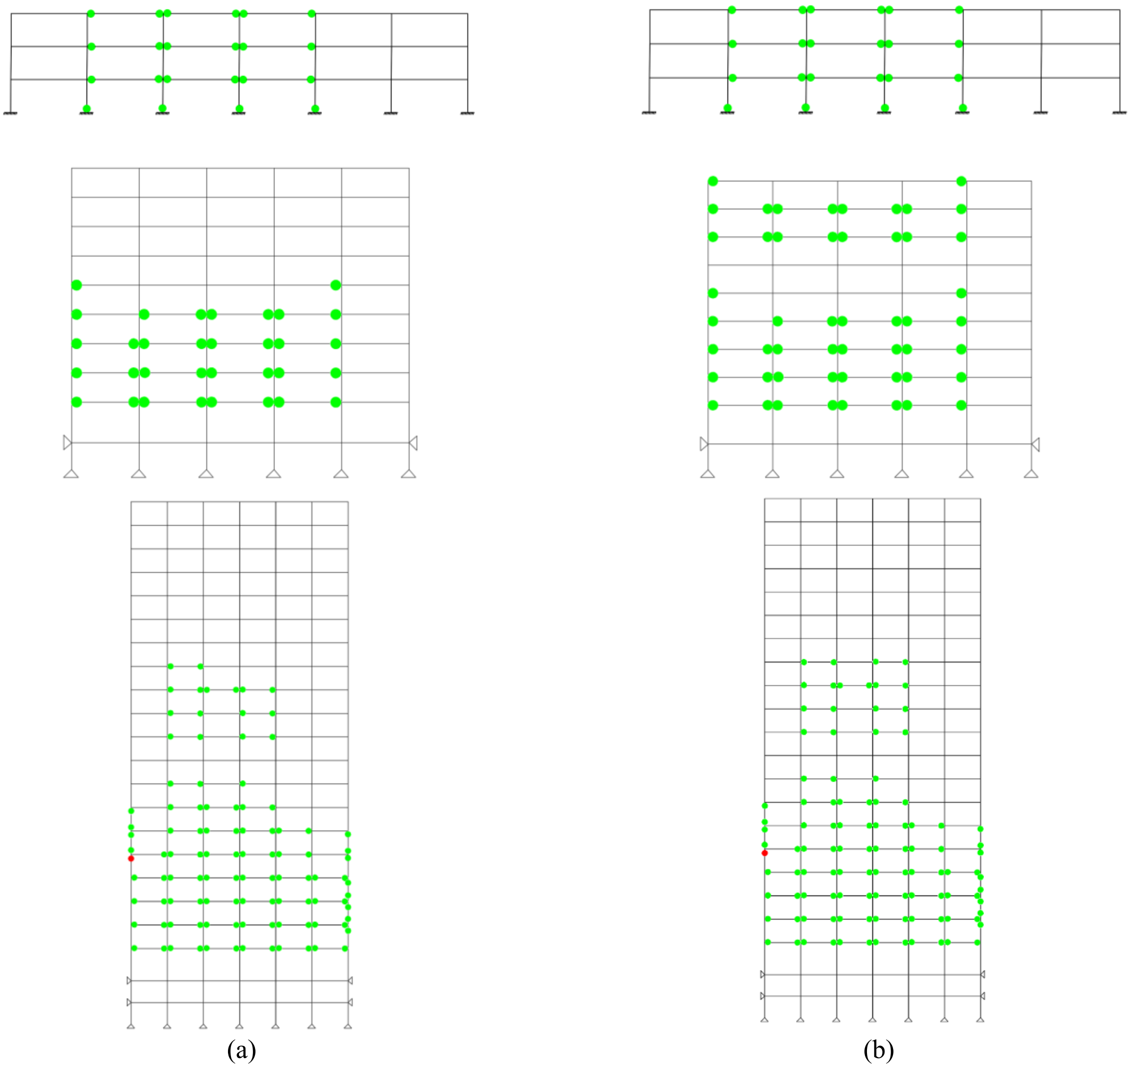

Fig. 7. Plastic hinge formation for 3-, 9-, and 20-story SAC buildings. (a) mainshock-only, (b) MS-AS sequences

4. Conclusions

This study presented the seismic behavior of low-, mid-, and high-rise moment resisting steel structures under successive earthquakes and compared to mainshock-only ground motions. The impact of the X braces in reducing maximum inter-story drift ratios and plastic hinge formation was investigated. The findings exhibited aftershocks significantly increased deformation demands, while retrofitting improved the structural seismic behavior under mainshock-aftershock sequences. The main results are:

- The maximum inter-story drift increased during mainshock-aftershock events compared to mainshock ground motion, which highlighted the cumulative damage effects associated with multiple earthquakes.
- The inclusion of aftershock effect in seismic performance displayed that drift demands decreased with increasing the height of the structure. The 3-story building showed the highest drift ratio among all frames.
- Plastic hinge formations illustrated that considering aftershocks in estimating the cumulative damage was critical. The increased number of plastic hinges proved the importance of the seismic sequence effect on the structures.
- The X-bracing system drastically decreased the inter-story drift ratio, resulting in enhanced seismic performance against mainshock-aftershock sequences.
- In some certain earthquakes, the, the maximum inter-story drift ratio for the mainshock and mainshock-aftershock were relatively close, which is attributed to the characteristics of the aftershock and the energy dissipation of the structures.
- Overall, this study emphasized the importance of considering aftershock effects in seismic design codes and provisions in order to obtain realistic structural behavior and prevent probable cumulative damage.

[1] *Yildiz Technical University, Department of Civil Engineering, 34000 İstanbul, Türkiye*

Abstract. Soft storey action is a common type of vertical stiffness irregularity encountered in earthquake sites. There are different code-defined approaches in terms of determining the presence of soft storey irregularity. Türkiye Building Earthquake regulation (TBDY-2018) requires the stiffness irregularity coefficient determined by the ratio of adjacent storey drift ratios to be greater than 2 to validate this irregularity. As for the American Society of Civil Engineers regulation (ASCE/SEI-7-10), the extreme soft storey is valid if lateral storey stiffness is smaller than 60% of the neighbourhood storey or 70% of the average of the 3 above storeys. As for Japanese regulation, the ratio of the inverse of the drift ratio to the average of the inverse of the drift ratios along all storeys is lower than 0.6. In this work, these stiffness irregularity parameters are calculated and compared with their limit value, both elastic and inelastic behavior of a 3D reinforced concrete frame system with ground storey height greater than other storeys. The variation of the effect of stiffness irregularity while continuing inelastic behavior is investigated by gradually increasing top displacement. The storey drifts, drift ratios, storey shear and stiffness irregularity factors of TBDY-2018, ASCE and Japanese regulations are calculated for all nonlinear pushover steps. The pushover curve and the values of stiffness irregularity factors in terms of top displacement are plotted. As a result of 2% top drift ratio, values of factors of inelastic analysis are obtained as 4-5 times of elastic analysis result.

Keywords: Soft storey; Stiffness irregularity factor; Pushover analysis; Reinforced concrete; Nonlinear modeling

1. Introduction

Soft storey action or interstorey stiffness irregularity is one of the most frequently encountered irregularity problem in earthquake sites, which may result in the collapse of buildings. "*Many failures and collapses can be attributed to the increased deformation demands caused by soft stories*" (Bruneau, 2002). The problem of structural collapse due to soft story irregularity is a phenomenon that can be observed not only in Türkiye. "*Similar damage patterns as a result of soft storey were found in earthquakes in other areas of the world*" (Sharma et al, 2016). As declared in Zhao et al, 2009; "*the data collected in the field shows that most of the reinforced concrete building frames did not perform as intended by the current Chinese code: most failures developed at the columns, either through shear failure or through excessive deformation demands at the ground floor columns in the presence of soft-storey mechanisms, leading to the partial of full collapse of the building structures*" (Zhao et al, 2009). As is known, soft storey action occurs due to interstorey stiffness difference caused by abrupt difference between storey height or unequal degradation of infill walls. That is why this irregularity is frequently encountered in mixed buildings, while the ground floor is used for commercial purposes, the other storeys are used for residential purposes. Another instance that meets this definition from Arlekar et al (1997) is "*Open first storey is a typical feature in the modern multistorey constructions in urban India*". Another example can be given as; "*Soft first storey is a typical feature in the RC buildings in Kathmandu Valley because the first stories of the building have been often used as commercial areas, shops, or car parking*" (Sharma et al, 2016).

As for Türkiye, the field investigations of past earthquakes showed that there is numerous instances of soft storey action. For example, a field investigation study done by Aydıner et al (2023) after recent major Kahramanmaraş earthquakes. In the study, the observed soft storey buildings compared with pre-earthquake state of themselves and the disastrous effect of this irregularity can be seen. The damages caused by earthquake resulted in inelastic behavior of structures. That is why, investigation of soft storey irregularity not only for elastic but also for inelastic behavior of building has own importance.

In the literature, there are studies that examined the impact of soft storey irregularity on the structural behavior of buildings, in reference to code criteria. Yousef et al. (2010) performed nonlinear time history analyses on high

https://doi.org/10.31462/icearc2025_ce_eqe_285

rise ductile buildings composed of both normal and high strength concrete, and compared the results with those from the ELF method. The applicability of the ELF method to buildings with vertical irregularities (in terms of mass, setback, and soft storey) was evaluated. The reliability of soft storey criteria in different seismic codes was assessed. The codes included UBC-97 (IBC-2000), Eurocode 8 (EC-8), Egyptian Codes for Loads (ECL-08), and ESEE-88. It was found that UBC-97 was not suitable for structures with mass or setback irregularities but was sufficiently conservative for soft storey irregularities. ESEE-88 was observed to be generally less conservative than ECL-08. The results indicated that the limit values in UBC-97 and ECL-08 criteria were satisfactory and could be extended by approximately 10%.

Döndüren and Nakipoğlu (2018) interpreted the soft storey criteria and corresponding limit values from DBYBHY-2007 (Türkiye), IS 1893-1-2002 (India), ASCE-7-2002 (USA), and the Japanese seismic design codes based on dynamic analyses conducted in SAP2000. 11 amount of models with varying ground floor heights were analysed. Factors such as the stiffness irregularity coefficient η_{ki}, storey stiffness ratio (k_1/k_2), and R_s values are calculated and compared with the respective limit values in the codes. The results revealed the onset of soft storey behavior and highlighted that the Japanese seismic code provided more reliable and conservative assessments.

Khanal et al. (2019) investigated the effects of varying ground floor heights on 5 amounts of 3D, 5 storey frame models using both linear static and nonlinear time history analyses. The presence of a soft storey was evaluated based on Japanese, Türkiye, and IS seismic codes. It is noted that while the Japanese and Türkiye code evaluations varied with the analysis method, the IS code provided consistent assessments regardless of the method. The Japanese code was found to be more conservative. Moreover, the study emphasised that story drift alone should not be the sole criterion for evaluating structural safety, as many models satisfied the drift requirement despite the presence of soft storey irregularity.

Zavala et al. (2022) explored the effects of stiffness irregularity and P-Δ effects on building response using 9 models of a 20 storey structure: 4 with both geometric nonlinearity and stiffness irregularity, 4 with only stiffness irregularity, and one reference model. Stiffness irregularity was evaluated on each storey according to ASCE-41-13 and nonlinear static pushover analyses were conducted. Results indicated that P-Δ effects became more critical in the presence of storey stiffness irregularity at lower storeys, with reductions in structural stiffness up to 56.3%. Literature studies on buildings with soft storey irregularity predominantly focus on relative displacements, natural periods, member damages, code based irregularity checks, and the quantification of irregularity degrees.

In this study, the code-defined soft storey evaluation methods are examined for both linear and nonlinear case. The code-defined stiffness irregularity factors calculated for each pushover step and compared with each other along with the pushover curve. The magnification effect of nonlinear behavior on soft storey action in a negative way is made visible by drawing graphs. Finally, the graphs drawn were interpreted.

2. Methodology

The examined building is 4 storey 2 bay reinforced concrete frame system with slabs (Fig. 2a, b). While the first storey height is 4.5 m, the others are 2.6 m, and the bay spacing is 3 m. In most cases, this case corresponds architecturally mixed purpose building, while the ground storey is used for commercial purposes, the other storeys are used as residential. Column sizes are determined as 30x25, and beam sizes are 30x40. The columns are placed so that the structure is weaker in the direction of loading (i.e. x axis). There is no infill and shear wall in the structural system. The source of soft storey action stems from the abrupt difference in column length at ground and one upper storey. All structural modeling done in SAP2000 structural analysis software (SAP2000, 2021). The view of structural system and ELF (equivalent lateral force) method loadings are given in Fig. 1a, b and d.

According to Article 28 of the Planned Areas Zoning Regulation of Türkiye, maximum ground floor height is 4.5 m if there is no mezzanine and the ground floor is used for commercial purposes (PAİY, 2017). Also, the minimum internal height of the floor should be higher than 2.6 m (PAİY, 2017). The structural design parameters are given in Table 1.

Table 1. Structural properties of the investigated building

Column section (cm)	30x25	Ground storey height (m)	4.5	Confinement diameters (mm)	12d
Beam section (cm)	30x40	Residential storey heights (m)	2.6	Confinement spacings (cm)	10
Bay width (m)	3	Concrete type	C30	Stiffness modifier of beam	35%
Support Type	Fixed	Reinforcement type	S420	Stiffness modifier of column	70%
Amount of storey	4	Slab type	Shell Thin	Stiffness modifier of slab (bending and membrane)	25%
Amount of bay	2	Column longitudinal rebar diameter (mm)	14d	Beam longitudinal rebar diameter (mm)	12d

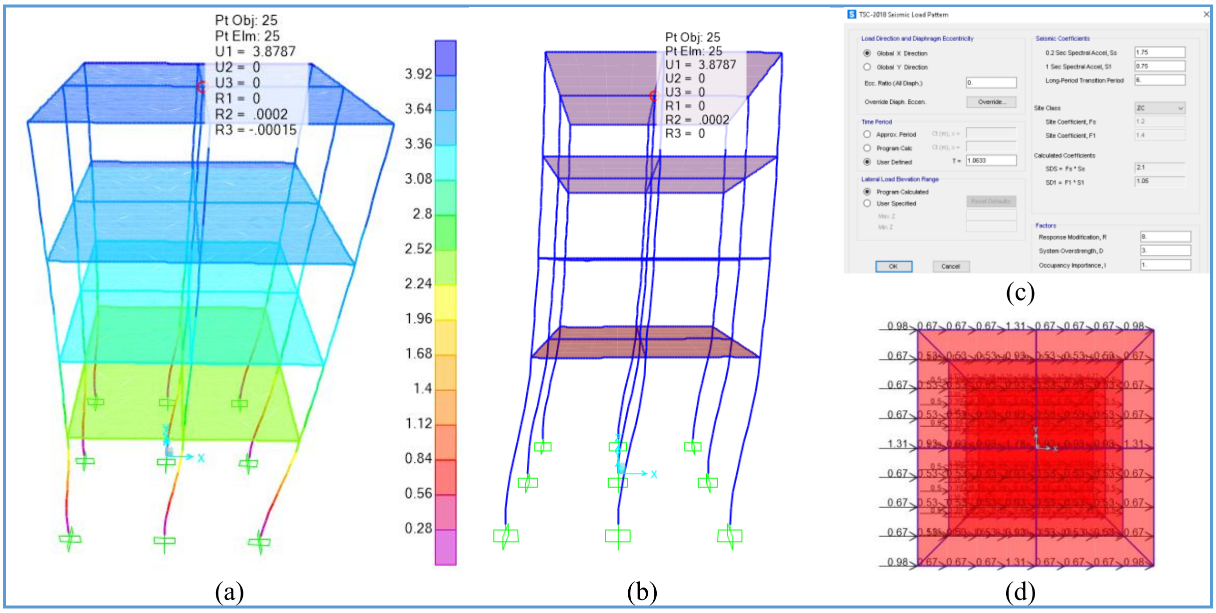

Fig. 1. SAP2000 Model of investigated structure of ELF method (a) displacement contour diagram of +5% eccentricity (b) displacement of zero eccentricity (c) Automatic TBDY-2018 quake loading (d) lateral loads distributed along floors

As indicated at the introduction, there are so many old building having soft ground storey in earthquake sites. As for old regulations like Specification for Structures to be Built in Disaster Areas 1997, size of 25x30 rectangular columns were permitted (ABYYHY, 1997). That was the minimum condition of column section sizes. In this study, the column size was selected in this opinion. For simplicity, all columns are placed at the same direction as the moment of inertia about y axis is weaker. The static loadings for both ELF and pushover acted on the weak direction of the structure, i.e. x direction at Fig. 1. The dead load is taken as $g = 1.5\ kN/m$, and so the live load $q = 2\ \ kN/m$. The mass source of the system is defined by $g + 0.3q$. The load bearing system is moment bearing reinforced concrete frame system which having high structural ductility. The system is assumed to satisfy the capacity and ductile design conditions. The slab thickness is taken as 12 cm and rigid diaphragm definition done at each storey level.

2.1. Soft storey irregularity criteria according to the different codes

In this paper, the soft storey action (i.e. interstorey stiffness irregularity) evaluated based on TBDY-2018 code, ASCE/SEI-7-10 code and BSL code. These codes defines a criterion and a limit value for checking whether the irregularity is valid or not. For Türkiye Building Earthquake Code (TBDY-2018), the criterion is based on whether the division of drift ratios of adjacent storeys is greater than 2. Thus, a stiffness irregularity factor is defined as (1).

$$\eta_{ki} = \frac{\frac{\varDelta_i}{h_i}}{\frac{\varDelta_{i+1}}{h_{i+1}}} > 2 \qquad (1)$$

Here $\varDelta$ denotes storey drift, h denotes storey height, the subindex i denotes related storey number, the ratio of $\varDelta_i/\ h_i$ denotes drift ratio of related storey, and η_{ki} denotes stiffness irregularity factor of related storey. If the inequality given in (1) is satisfied, that means the i th. storey is soft storey. As one can guess, if the ratio of drift ratios at (1) has been taken as upper storey divided by lower, then the inequality would change direction and the limit value would become 0.5.

The American Society of Civil Engineers ASCE/SEI-7-10 code criteria denotes the definition of a soft storey whose stiffness is less than 70% of the upper storey or 80% of the arithmetic mean of the three upper storeys. This criterion is the same one as UBC code. There is also definition of an extreme soft storey, which will be taken into account for this paper since the investigated structure already provides the extreme soft storey condition. The extreme soft storey condition clarified in the code given "*where there is a story in which the lateral stiffness is less than 60% of that in the story above or less than 70% of the average stiffness of the three stories above*" (ASCE/SEI-7, 2010). The condition defined in the text can be defined in an inequality form as $k_i < 0{,}6k_{i+1}$ and $k_i < 0{,}8k_m$, where k_i corresponds to the related storey stiffness, k_{i+1} corresponds to one upper storey stiffness and k_m corresponds mean storey stiffness of three upper storey and defined at (4). As one can guess, if the lateral stiffness of lower storey divided by upper adjacent storey or the mean lateral stiffness of three upper storey divided by the lateral stiffness of related storey, the limit value would became as the inequality given at (2) and (3).

$$\frac{k_{i\pm1}}{k_i} > 1{,}67 \tag{2}$$

$$\frac{k_m}{k_i} > 1{,}25 \tag{3}$$

$$k_m = \frac{k_{i+1} + k_{i+2} + k_{i+3}}{3} \tag{4}$$

As for Building Standard Law of Japan (BSL), the irregularity is investigated by whether the ratio of reciprocal of drift ratio to average reciprocal of drift ratios of all storeys is less than 0.6. In that regard, a factor symbolized as R_s and defined in (5) is calculated.

$$R_{si} = \frac{r_{si}}{\overline{r_s}} < 0{,}6 \tag{5}$$

$$\overline{r_s} = \frac{\sum_{j=1}^{n} r_{sj}}{n} \tag{6}$$

Here while r_{si} is reciprocal of the drift ratio and calculated as h_i/Δ_i, $\overline{r_s}$ is average reciprocal of the drift ratio along all storeys (Aoyama, 1981). In (6), the amount of storey of building symbolized as n.

To sum up, the soft storey action is valif if the value of stiffness irregularity parameters or factors defined in the codes satisfies the corresponding criteria. The criteria defines limit values of those factors. The irregularity is valid if the irregularity factor η_{ki} to be greater than 2 as for TBDY-2018, or if the k_{i+1}/k_i is greater than 1.67 and k_m/k_i is greater than 1.25, or if the factor R_{si} is less than 0.6 limit value. Here one can see that while the inequality direction of TBDY-2018 criteria and ASCE/SEI-7-10 criteria is same, it is inverse for BSL code. In order for them to be compared meaningfully, the inequality direction of (5) changed by taking inverse of the multiplication of each part of the inequality. Thus, the limit value became 1 per 0.6.

$$R_{si}^{-1} = \frac{\overline{r_s}}{r_{si}} > \frac{1}{0.6} = 1.67 \tag{7}$$

As can be understood from the inequality (7), there is soft storey irregularity if R_{si}^{-1} term is greater than 1.67, and that also means R_{si} term to be lower than 0.6. As for calculations, the inequality of (7) will be taken into account. The summary of code-defined stiffness irregularity factor terms and their criteria with limit values that taken into account for this paper given in the Table 2.

Table 2. The conditions of existence of soft storey irregularity of a storey according to investigated codes

The related code	Factor	Definition	Criteria	Limit Value
TBDY-2018[*1]	η_{ki}	$\dfrac{\frac{\Delta_i}{h_i}}{\frac{\Delta_{i+1}}{h_{i+1}}}$	To Be Greater Than	2
ASCE-7-10[*2]	$\dfrac{k_{i+1}}{k_i}$	-	To Be Greater Than	1.67
	$\dfrac{k_m}{k_i}$	$\dfrac{k_{i+1} + k_{i+2} + k_{i+3}}{3k_i}$	To Be Greater Than	1.25
BSL[*3]	R_{si}^{-1}	$\dfrac{\overline{r_s}}{r_{si}}$	To Be Greater Than	1.67

2.2. ELF analysis procedure

The linear elastic equilavent lateral force analysis done in order to determine the presence of soft storey irregularity. It is shown that the given structural design has soft story irregularity at the ground storey for all code criteria. The determination whether the irregularity is valid is done using TBDY-2018, ASCE/SEI-7-10 and BSL code criteria defined in (1), (2) and (3), (5) and (7) respectively. ELF procedure has been applied according to TBDY-2018 code. The load bearing system behavior factor is taken as $R = 8$. Site soil condition is taken as ZC. The soil magnification factors corresponding the ZC soil site condition is 1.2 for short period, and 1.4 for 1 second period. In terms of probabilistic seismic hazard assessment, the earthquake hazard level is taken as the earthquake having 2475 year recurrence period defined by TBDY-2018. While spectral acceleration for short period is taken $S_{ds} = 1.75\ g$, it is taken $S_{d1} = 0.75\ g$ as for 1 second period as can be seen from Fig. 1c. The deflected shape of structural system and top displacement can be seen from Fig. 1a, b. Lateral loading direction is taken as x axis and the distributed lateral loads along storey slabs can be seen from Fig. 1d. As can be seen from Fig. 1c, TBDY-2018 load pattern option at SAP2000 used for loading pattern. For both ELF and pushover method, the initial stiffness has been defined from $g + 0.3q$ loading. The calculated values of code-defined factors of ground storey according to linear elastic static analysis results given in the Table 3.

Table 3. The code-defined irregularity factors calculated from the ELF analysis results

$\Delta_1\ (mm)$	$\Delta_2\ (mm)$	$\Delta_3\ (mm)$	$\Delta_4\ (mm)$	$V_t\ (kN)$	$\Delta_1\ (kN)$
24.41	6.85	4.77	2.75	161.53	145.31
$V_3\ (kN)$	$V_4\ (kN)$	η_{k1}	k_2/k_1	k_m/k_1	R_{s1}^{-1}
115.04	72.30	2.059	3.206	3.607	2.786

Here in the Table 3; Δ_i corresponds relative storey drift, Δ_i corresponds storey shear, η_{k1} corresponds TBDY-2018 defined irregularity factor for ground storey, k_2/k_1. k_m/k_1 corresponds ASCE/SEI-7-10 defined criteria parameters for irregularity of ground storey and, R_{s1} is BSL defined factor calculated for ground storey. As for η_{k1}, the criterion is defined as (1), as for k_2/k_1 and k_m/k_1, the criterion is given at (2) and (3) respectively, and for R_{s1}^{-1}, the corresponding criterion is given in the inequality (7). These criteria are summarized at Table 2. One can see that the ground storey has stiffness irregularity for these three codes after comparing the irregularity factor results (Table 3), with their code-defined limit values (Table 2). Note that the storey shear of ground storey, V_1 corresponds to the base shear value.

2.3. Nonlinear static analysis procedure

As a nonlinear static analysis, displacement controlled nonlinear pushover analysis done up to the monitored top displacement of 24.6 cm, which corresponds to the 2% top drift ratio. The pushover load pattern is taken as the same one with equivalent lateral load pattern (Fig. 1.c) with zero eccentricity. The PΔ effects and large displacement taken into consideration, and the nonlinear static analysis began from the end of $g + 0.3q$ loading. The pushover curve is given in Fig. 2a.

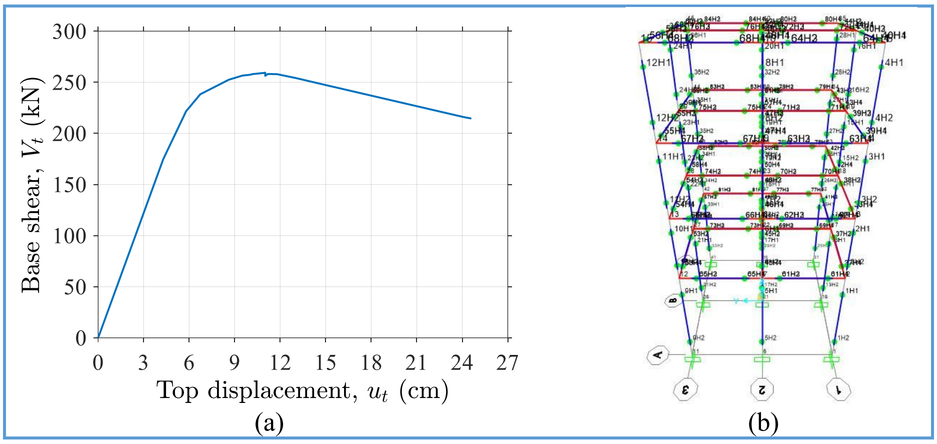

Fig. 2. Nonlinear static analysis case (a) Pushover curve of structure (b) assigned plastic auto hinges

The lumped plastic PMM hinges are defined using the idealised flexural hinge of the auto-hinge option of SAP2000. The assigned plastic hinges can be seen from Fig. 2b. The Plastic hinge length of the column has been calculated as half of the section width and assigned at the middle of the plastic hinge length. In that regard, while the plastic hinge length of columns is 15 cm, it is 20 cm for beams. Plastic hinge absolute distances are defined as 20 cm for columns and 25 cm for beams in x direction and 22.5 cm for beams in y direction, starting from the intersection point of the column and beam member axes.

3. Analysis results

In this paper, the values of code-defined stiffness irregularity factors through inelastic behavior of a reinforced soft storey structure are investigated and graphed along with incrementing top displacement. As can be understood from Table 2, relative storey drift values and storey stiffness values are needed to compute code-defined factors. The storey shear and drift values for all pushover steps are obtained from the SAP2000 analysis. The lateral storey stiffness, k_i calculated by dividing the storey shear, V_i into the relative storey drift, Δ_i. From the obtained results, values of code-defined factors are calculated for each pushover step. Nonlinear pushover analysis and irregularity factor results with the pushover step number given in the Table 4.

In Table 4, the values of irregularity factors are computed. They calculated using corresponding storey drifts and storey stiffnesses calculated from storey shear and storey drifts. The given analysis results are calculated only for the soft ground storey. In Table 4, step number corresponds the pushover step, u_{top} corresponds lateral top displacement for given pushover step, Δ_1, V_1 and Δ_2, V_1 corresponds storey drift and shear of ground and one above storeys and η_{k1}, k_2/k_1, k_m/k_1, R_{s1} are code-defined factors calculated for ground storey corresponding to given top displacement.

Table 4. The nonlinear pushover analysis results

Step No	u_{top} (cm)	Δ_1 (cm)	Δ_2 (cm)	V_1 (kN)	V_2 (kN)	η_{k1}	k_2/k_1	k_m/k_1	R_{s1}	R_{s1}^{-1}

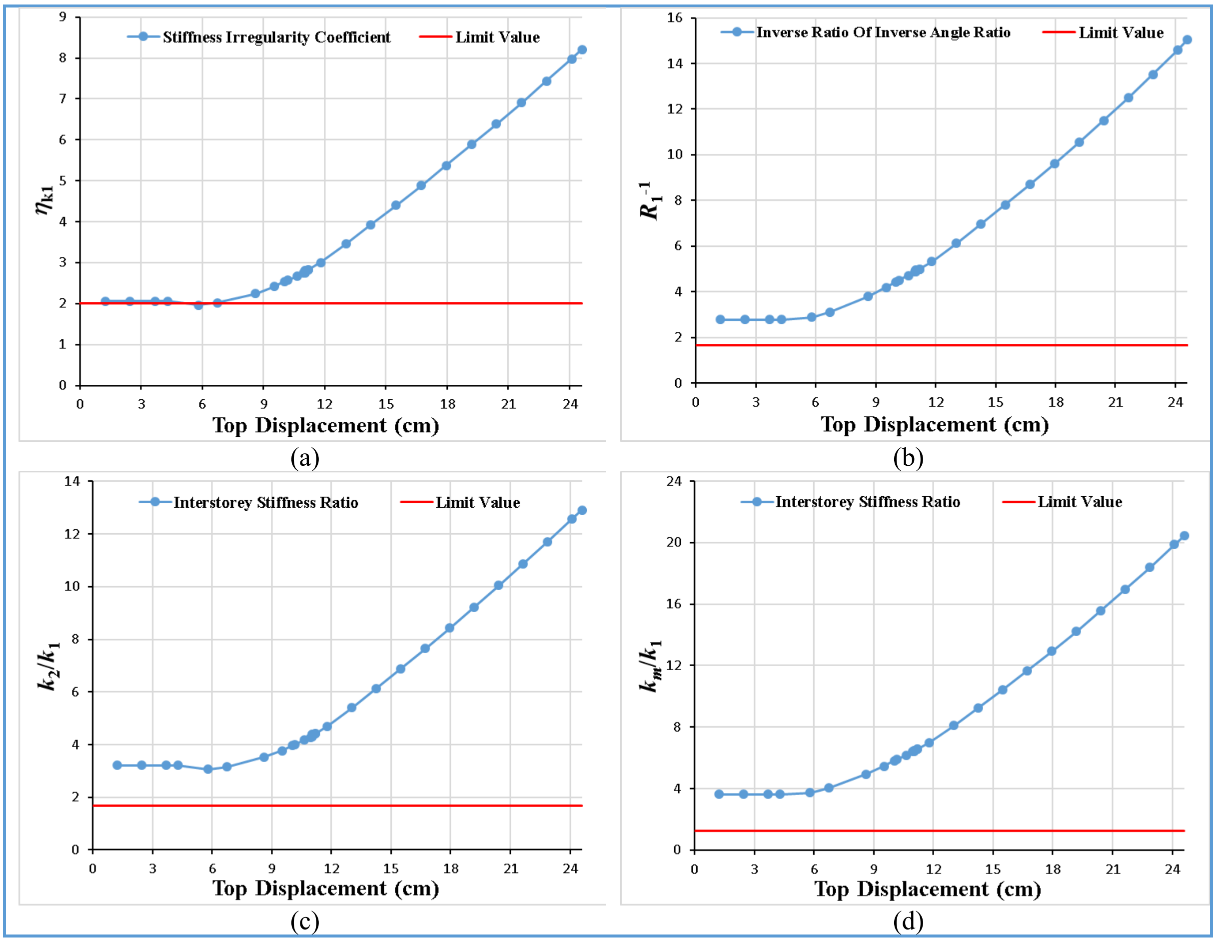

Fig. 3. Code-defined irregularity factor plots (a) TBDY-2018 (b) BSL (c) and (d) ASCE/SEI-7-10 codes

The pushover steps number 15 and 16 are repeated steps. That is why they were erased from Table 4. Storey shear is the sum of the shear force of the bottom section of columns at a storey, and the sum of the bottom section shear force of the ground storey corresponds to the base shear force. Storey stiffness, k_i obtained by the ratio of V_i to Δ_i. In order to observe the changing pattern of the factors of η_{k1}, k_2/k_1, k_m/k_1, R_{s1}^{-1} along with the inelastic behavior of the structure (Fig. 2a), the calculated values of factors are plotted according to the corresponding top displacement values obtained from SAP2000 and given in the Table 4. The plotted graphs are given in Fig. 3a, b, c and d.

In Fig. 3a, b, c and d, the red constant lines define corresponding code-defined limit values of criteria (1), (7), (2) and (3), respectively. The limit values for those inequality criteria are equal to 2 for Fig. 3a, 1.67 for Fig. 3b and Fig. 3c, and 1.25 for Fig. 3d. One can see that all irregularity factors tend to increase in the same manner, except slight decrease at 6 cm top displacement for Fig. 3a and Fig. 3c.

If one looks at all four graphs, one listed under the other, it can be understood that their patterns look identical. They become strictly increasing at the same top displacement, which is approximately 6 cm and corresponds to the governing of plastic hinges at columns. The structural stiffness is changing at the top displacement value approximately 6 cm and 11 cm drastically, as it can be seen from the pushover curve in Fig. 2. Both the slope of the elastic region and the post-strength slope is constant. In Fig. 3a, b, c and d, the corresponding slopes are nearly constant as well. While the increasing inelastic behavior of the structure, the irregularity factors also increased; on the other hand, if the structure remains elastic region, the irregularity factors remain unchanged. Also, it is seen that the pushover analysis results obtained when the frame behaves linearly elastic (the first four rows of Table 4), and the Table 3 results of irregularity factors obtained with the ELF method overlap with each other. This is valid until pushover step 5. This is not unpredictable since the pushover load pattern is taken as the same pattern defined at the ELF method and same stiffness modifiers are used. The first four pushover steps correspond to linear elastic analysis (until 4.3 cm top displacement) where no plastic hinge occurs. This can be seen from the pushover curve Fig. 2a as well.

Due to soft storey action, plastic hinges tend to occur at soft storey column ends before all beam end sections reach plastic moment capacity, resulting in less ductile behavior. But before reaching the ground storey mechanism, the governing of plastic hinges at ground storey beams could be the reason for the slight decrease in η_{k1} and k_2/k_1. The same slight decrease is not seen in Fig. 3b and d. Further investigation is needed to determine the exact reason.

The values of irregularity factors depend on the top displacement value for the inelastic region, and constant for elastic region of the building. That is why, instead of using the linear elastic ELF method to calculate irregularity factors and determine the presence of soft storey irregularity, the determination of soft storey can be evaluated for the top displacement of the inelastic displacement demand of the design earthquake as well.

4. Conclusions

Along with the nonlinear pushover analysis case, the inelastic behavior of the structure accounted for the calculation of each stiffness irregularity factor. Thus, the negative increase in soft story behavior is investigated for each code-defined criterion considered. From the analysis results and obtained graphs, the following can be said.

- The values of irregularity factors are constant for the elastic behavior of the structure. But if the structure crosses post-elastic region, the value of the irregularity factors increases with increasing top displacement for soft storey building. The considered codes have made a similar assessment in terms of the negative aggravation of the soft storey behavior throughout the inelastic behavior of the structure.
- The inequality direction of R_{s1} defined in the BSL code has been made the same inequality direction as TBDY-2018 and ASCE/SEI-7-10 criteria by taking into account of R_{s1}^{-1} using inequality (7) to be able to compare the code criteria in the same way. Thus, both elastic and inelastic behavior patterns of all four irregularity factors due to incrementing top displacement become similar.
- At 2% top drift ratio, the values of irregularity factors η_{k1}, k_2/k_1, k_m/k_1, R_{s1}^{-1} rose by 4, 4, 5.7 and 5.4 times respectively. The significant increase in code-defined stiffness irregularity factors begin by 6 cm top displacement where plastic hinges at ground storey columns occur and the factors increases up to 24.6 cm top displacement, which corresponds to 2% top drift ratio.
- The conservability of codes can be seen from how the elastic analysis results are far from the code-defined limit value. The ASCE/SEI-7-10 is the most conservative code, followed by the BSL code. As for investigated codes, the less conservative one is TBDY-2018. This result is consistent with literatüre review. Khanal et al (2019) was described Japanese code as more conservative than Türkiye code. Also Yousef et al (2020) denoted that UBC code is sufficiently conservative. This result is also consistent with the analysis done in this study since the ASCE and UBC criteria are same.

Abstract. Cross-Laminated Timber (CLT) shear walls and timber braced frames have emerged as efficient and sustainable systems for seismic areas, offering an alternative to traditional concrete core walls and steel braced frames. Resilient Slip Friction Joints (RSFJ) commercialized by Tectonus, enable low-damage structural performance through energy dissipation and self-centering behavior. These joints have been successfully implemented in projects across Canada and New Zealand, gaining regulatory approval for seismic applications in both countries. This paper explores the applicability of RSFJ connections in European seismic zones, focusing on compliance with Eurocode 8 requirements. A case study was conducted on a 10-story mass timber building, made of CLT shear walls, timber braces, and RSFJ joints. Seismic design analyses, including lateral force analysis, pushover, and nonlinear time history analysis, were performed assuming the building's location in Ljubljana, Slovenia. The results confirm the feasibility of using RSFJ connections in European multi-story timber structures and provide a design methodology for integrating these devices into low-damage construction aligned with Eurocode 8 standards.

Keywords: CLT; RSFJ; Earthquake; Eudocode 8; Resilient; Low damage

1. Introduction

Current environmental concerns are leading to new construction methods, new materials and a different approach to project design. In this context, timber is integrated more and more in the field of construction, even in high seismic areas (Shen et al., 2023). New designed buildings for seismic zones are often hybrid structures that implement timber as part of the overall structural system. In such structures, timber is combined with other materials such as steel or concrete to comply with seismic requirements. Indeed, wood, although having many advantages, such as its easy installation, its low weight, its high strength, its low environmental impact, has a low ductility, which does not allow a correct design in earthquake areas. Therefore, in newly designed hybrid structures, timber is used to support gravity loads, whereas steel or concrete are used to support lateral loads (earthquake, wind). To have structures that are fully made of timber, there is a need to find new ways that enable resisting to earthquakes without relying on steel or concrete structural components. To achieve that, it is for instance possible to use Resilient Slip Friction Joints (RSFJ) as the ones developed by the Tectonus company (Tectonus, 2022). Using such devices, it is possible to come up with assemblies having a high capacity to dissipate seismic energy and to resist several cycles of seismic loading. In addition, these systems are self-centring, which allows the structure to return to its original position after an earthquake without any residual damage. Such property allows extending the life of the structure without a necessity for intervention or maintenance, making the structure more resilient. The Keith Drive building is a 10 storey building under construction in Canada made of CLT shear walls and timber braced frames (Dickof et al., 2023). It was designed in a way to dissipate seismic energy through the use of resilient dissipative RSFJ joints based on the Canadian builing codes. This same building is considered in the present paper (in terms of geometry, *etc*). For the case study, it is supposed to be localized in Ljubliana in Slovania, which is a highly seismic European area. The characteristics of this area are considered (climatic loadings, pic ground acceleration, *etc*) and the building is designed to comply with Eurocode requirements. This article provides the methodology that could be used by practitioners in order to design a resilient fully timber building using RSFJ joints based on current Eurocode requirements (Standard B., 2005). It aims to show the efficiency of the RSFJ joints resilient technology in a European context.

golden light publishing

This article will be composed of 4 sections: in a first section, the lateral force method is applied to the structure in order to design the RSFJ joints. Then, a non-linear pushover analysis is performed on the structure in a second section. The third section presents results obtained when performing a non linear analysis on the office building under study. Last, a conclusion recalls the main findings of the article.

2. Lateral force analysis and design of the RSFJ joints

2.1. Geometry, materials and static design

The building under study is a 10 storey office timber building. It has a total height of 40 meters. Its plan view is shown in Fig. 1. The first 9 storeys have a similar layout wheas the last one is smaller as shown in Fig. 2 (ETAB model of the building). The building is made of CLT floors supported by steel beams. The structure is mainly made of timber seismic resisting systems: timber braces (as shown in blue in Fig. 2) and CLT shear walls (in red in Fig. 2). The thickeness of the shearwalls being equal to 320 mm. In addition, connections are made of resilient slip friction joints (RSFJ). The different structural elements of the builing were designed to comply with Eurocodes requirements: Eurocode 3 for steel (Standard B., 1993) and Eurocode 5 (Porteous & Kermani, 2008) for timber based on loadings presented in Table 1 (taken from Eurocode 1 based on the grographical location of the building).

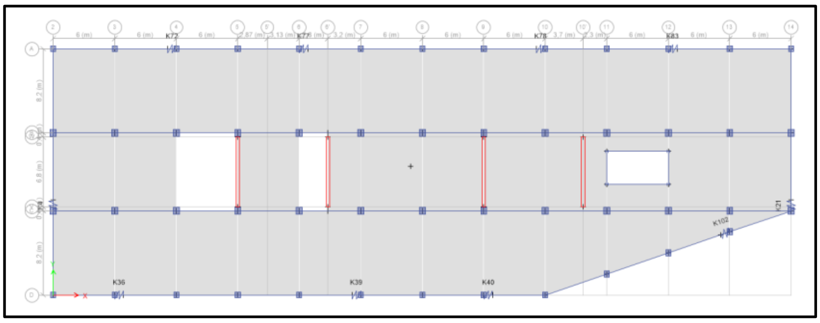

Fig. 1. Plan view of the structure

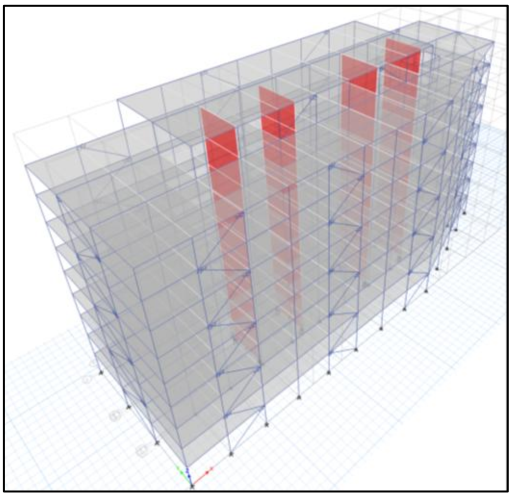

Fig. 2. 3D view of the structure

Table 1. Loads considered in the project

Floor	Areas	DL (kN/m^2)	SDL (kN/m^2)	LL (kN/m^2)	SL (kN/m^2)	WL
1st	All	1.3	1.40	4.80	-	-
2nd to 9th	Office area	1.3	2.50	2.50	-	-
	Exit corridors	1.3	2.50	4.00	-	-
10th	Pink area	1.3	4.90	2.40	-	-
	Blue area	1.3	4.00	4.80	1.51	-
	Snow accumulation	-	-	-	5.60	-
Roof	All	1.3	2.60	1.50	1.51	-

Glulam components are of grade GL28h whereas CLT members have a grade of C24.

Tables 2 and 3 summarize the types of verifications performed for the different timber and steel components. They also show sections chosen for the Etabs model.

Table 2. Verifications according to Eurocode 5 of Wood Sections

Name	Glulam Section GL28h	Verifications Eurocode 5

SC3	HEA 100	Axial compression and buckling

CLT members were designed using the "European Technical Assessment CLT" (European Technical Assessment – CLT, 2023) and the Swedish CLT Handbook (The CLT Handbook, 2025). 320 mm thick CLT floors were chosen for all the storeys and a 260 mm thick CLT was chosen for the roof. For the CLT shearwalls, a thickness of CLT equal to 320 mm was chosen.

2.2. Lateral force method (Eurocode 8)

For this case study, the regularity in plan is not met, because of the slenderness of the building (λ=5>4) but the regularity in elevation is met, the structural elements are continuous from the bottom to the top and there are no significant setbacks. A linear-elastic analysis using the lateral force method could be used for the study. To apply the lateral force method, it is necessary to make many seismic assumptions based on the localisation of the structure (Ljubjana in this case). Table 4 summarizes such properties. Since the structure under study is an office building, it has an importance factor of III. A coefficient q equal to 3 is used which is the value defined for timber for this kind of structure. An assumption of a soil type A (Table 5) was taken into account for the analysis of the structure. Referring to Table 5 in Eurocode 8, a soil type A corresponds to a Rock or other rock-like geological formation, including at most 5 m of weaker material at the surface.

Table 4. Seismic properties of Ljubljana

City	Ljubjana	
$a_{gR}\ (\frac{m}{s^2})$	2.698	T_{NCR} = 475 years

Coefficient q	Hollow square tube 254x254x16	*Table 8.1
Importance factor γ_l	HEA 240	*Table 4.3
Peak ground acceleration	HEA 100	T_{NCR} = 475 years
a_g calculation	0.330 g	

Table 5. Calculation values for LFM, ULS

Parameters	Value
Soil Type	A
S	1.0
T_B	0.15
T_C	0.40
T_D	2.0
Time Period (s)	0.795
Seismic weight (kN)	110200
Horizontal Design Spectrum $S_d(T)$	0.138
Base Shear (kN)	12910
Damping correction factor η	1.0

Using the properties described previously, it is possible to get the lateral force on each storey as shown in Table 6. These values enable getting the lateral force required for the ultimate limit state (ULS) as summarized in Table 6.

Table 6. ULS Values using the Lateral Force Method

	Mass (kN)	Height (m)	z_i(m)	F_i(kN)
Story 10	5000	4	40	1090
Story 9	16400	4	36	3210

Total	110200	40		

In reality, thanks to the use of the RSFJs, the damping of the structure is higher than 5% and therefore the damping correction factor should be lower than 1. This allows the reduction of the base shear of the structure and to save cost and materials for the construction. In the following subsection, the determination of the RSFJ will enable the determination of the correct damping factor of the structure.

2.3 Design of the RSFJ

The behaviour of RSFJ is defined by the curve shown in Fig. 3. The parameters depend on the design and the composition of the RSFJ such as the number of bolts, the precompression needed or the number of discs.

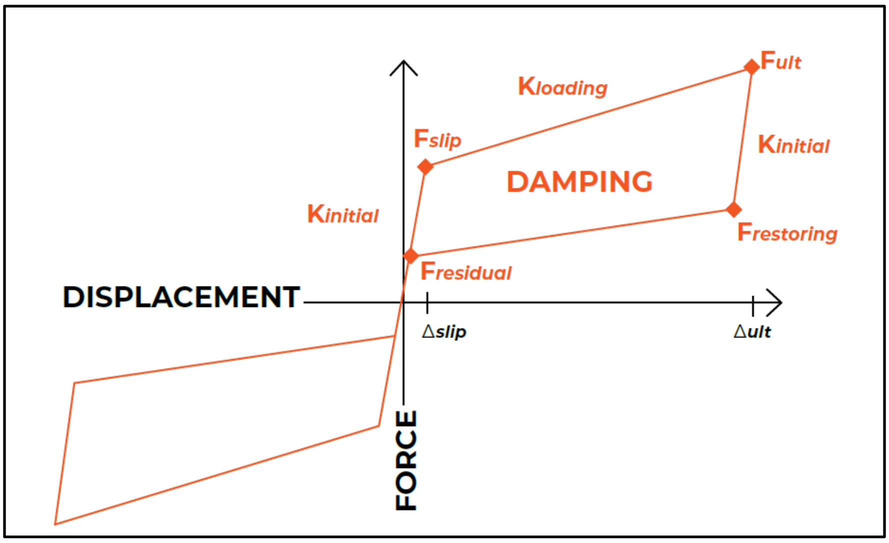

Fig. 3. Shape behaviour of RSFJ (Tectonus, 2022)

As shown in Fig. 3, the RSFJ is defined by 6 parameters: Fult, Fslip, Frestoring, Fresidual, Δslip, Δult. To make the analysis, it is necessary to define these parameters in order to model links in Etabs using appropriate values. Fult: Proceed of the lateral force method with ULS values. It means a no-collapse state for the building. It is determined by the maximum forces in the braces and in the base of the shearwalls. Fslip: Damage limit state. Δult: Defined by the geometry of the bracing and shearwall using the target displacement of the building demand. For this case study, the target displacement was taken equal to 1.5%. Δslip: This parameter is set equal to 2mm. This value is obtained from research and test on RSFJs. Frestoring: Approximatively equal to 30% of the Fult which is an approximation determined from testing of the RSFJs. Fresidual: Taken as 15% of the Fult value which is also an approximation determined from testing of the RSFJs. To define the RSFJ, it is necessary to know the force in the braces and the shearwalls in order to define the Fult of the device. These forces are obtained from the structural model analysis using the lateral force method described in part 2.2. of Eurocode 8. A linear analysis is first carried out to determine the Fult. In order to define correctly the RSFJ with the right damping ratio, it is necessary to make few iterations with the lateral force method, modifying the coefficient η at every iteration. The coefficient η enables one to take into account the damping of the building. Usually estimated to be equal to 5%, it will be greater than this value as a result of using dampers in the structure. The coefficient η is defined by the following formula (1):

$$\eta = \sqrt{\frac{10}{(5+\zeta)}} \geq 0.55 \quad (1)$$

The coefficient ζ corresponds to the damping of the structure and the damping of the RSFJ. The damping of the structure is usually between 2 and 3. 2.5 was the value fixed for the case study.

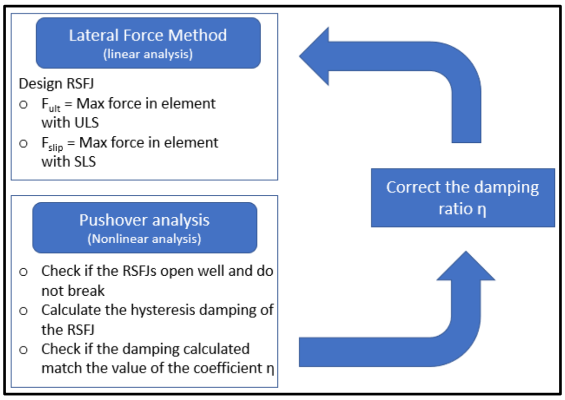

Fig. 4. Method to define RSFJ

The damping ratio is determined using the resulting pushover curve shown in Fig. 5. The “push” and “pull” curve is needed in order to determine the damping hysteresis of the RSFJ. The damping is calculated with the following formula (2):

$$\xi_{hyst} = \frac{2 * A_1}{\pi * A_2} \tag{2}$$

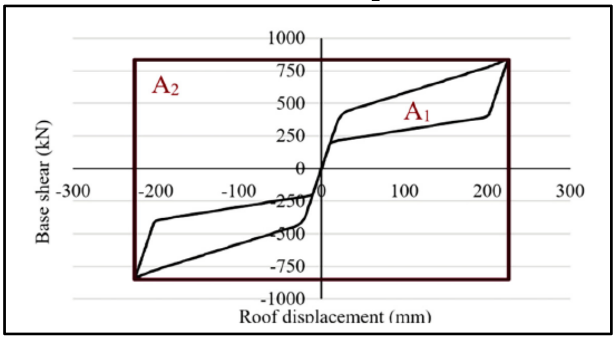

Fig. 5. Flah shape of the hysteresis of the RSFJ (Tectonus, 2022)

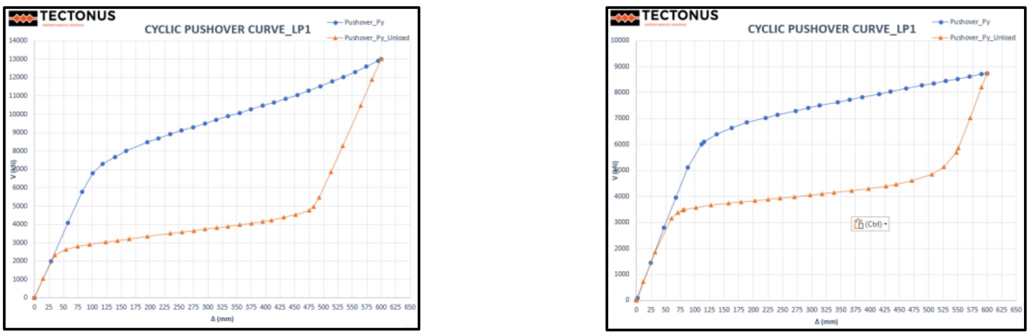
For the study, after 2 iterations, the damping of RSFJ was determined as equal to 10% in the y direction and as equal to 11.5% in x the direction and the graph obtained is shown in Fig. 6. X direction being the direction where there are only timber braces to withstand the lateral force and the Y direction is the one with shearwall and bracing system.



(a) (b)

Fig. 6. Hysteresis damping for (a) x and (b) y directions

Finally the value of the coefficient η is summarize in Table 9. Table 10 shows the different properties of the RSFJ designed to comply with self centering and ductility in the case study.

Table 9. Values for the damping correction factor

Direction	ζelastic	ζhysteresis	coefficient η
X	2.5	11.5	0.73
Y	2.5	10	0.76

Table 10. Properties of the different RSFJs of the structure under study

	Shearwall	A (grey)	B (Green)	C (Orange)	D (Blue)	E (Brown)	F (Red)	G (Purple)
Fult (kN)	3200	1800	1550	1150	1250	700	1400	300
Fslip (kN)	2240	1260	930	690	875	420	980	180

Delta slip (mm)	2	2	2	2	2	2	2	2
Delta ult (mm)	105	50	50	50	50	50	50	50

3. Pushover Analysis of the structure

After defining correctly the RSFJs of the building, a pushover analysis was performed to determine the non linear behavior of the structure (mainly bilenear thanks to the use of the RSFJs) as illustrated in Fig. 7. The acceleration displacement response spectrum (ADRS) curves for both x and y directions are shown in Fig. 7. The bilinear behaviour of the structure was obtained thanks to the RSFJ devices. The first part of the curves corresponds to the case when the force in the braces is still below the value of Fslip. The second part shows the damping of the structure possible thanks to the RSFJs. The graph presented in Fig. 7 shows also the ULS and SLS spectrums.

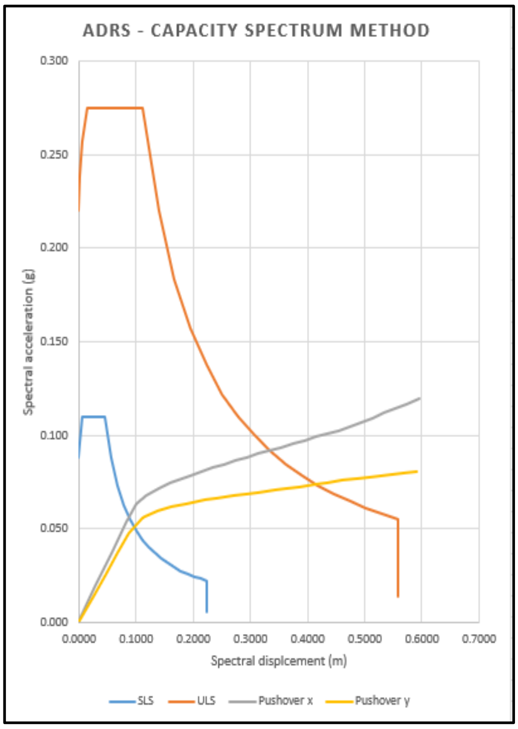

Fig. 7. ADRS Capacity Spectrum Method

Fig. 7 shows that the pushover curve starts its bilinear behaviour just after the blue curve, which is the SLS spectrum. It means that the RSFJs start to open after the SLS, which is the requirement for this kind of devices. In addition, with a graphical method, the intersection point between the pushover curve and the ULS spectrum gives the “performance point”. This point gives an idea about the value of the base shear of the structure. This value should be close to the value found with the lateral force method. For this study, the performance point in the x direction was 10 082kN and in the y direction it was 8 040kN. These values give an idea about the value of the base shear that should be obtained using a nonlinear time history analysis (NLTHA).

4. Nonlinear time history analysis

4.1. Seismic records

The purpose of this analysis is to show the behaviour of the RSFJs and the structure using records of real earthquakes. It allows to verify the design of the RSFJs for the ultimate level state and the Most Considered Earthquake (MCE) level. Even though the Eurocodes do not clearly specify the MCE case to consider, it's important to verify the structure for this case (in addition to the ultimate limite state). The MCE case used is the one given by the ASCE recommandations. Under the different loading scenarios (Ultimate limite state and MCE), the objective is to make sure that the RSFJs stay undamaged . The analysis was proceeded using 9 ground motion records as shown in Table 11. The Eurocodes recommend the use of at least seven records, but nine records were used to get significant results. Each ground motion is composed of two horizontal acceleration records. Each record was scaled. The base shear obtained was compared to the initial base shear found using the lateral method. Moreover, the story drift, the maximum displacement, the residual drift and the behaviour of the RSFJ (displacement and forces) were also analysed and verified. After that, a second series of Non linear analysis were performed using the records scaled to 150% of the design earthquakes (MCE load case).

Table 11.Records information used for the nonlinear time history analysis

RSN	**Name**	**Fault type**	**Region**	**Magnitude**
125	Friuli Italy-01	Reverse	Italy	6.5
169	Imperial Valley-06	Strike Slip	California	6.5
721	Superstition Hills	Strike Slip	California	6.5
828	Cape Mendocino	Reverse	Nothern California	7.0
953	Beverly hills, Mulhol	Reverse	Southern California	6.7
960	Northridge- 01	Reverse	Southern California	6.7
1116	Kobe, Japan	Strike Slip	Japan	6.9
1485	ChiChi, Taiwan	Reverse oblique	Taiwan	7.6
1602	Duwce, Turkey	Strike Slip	Turkey	7.1

In Etabs, the records are imported thanks to the time history function. The shape of the records is presented in Fig. 8.

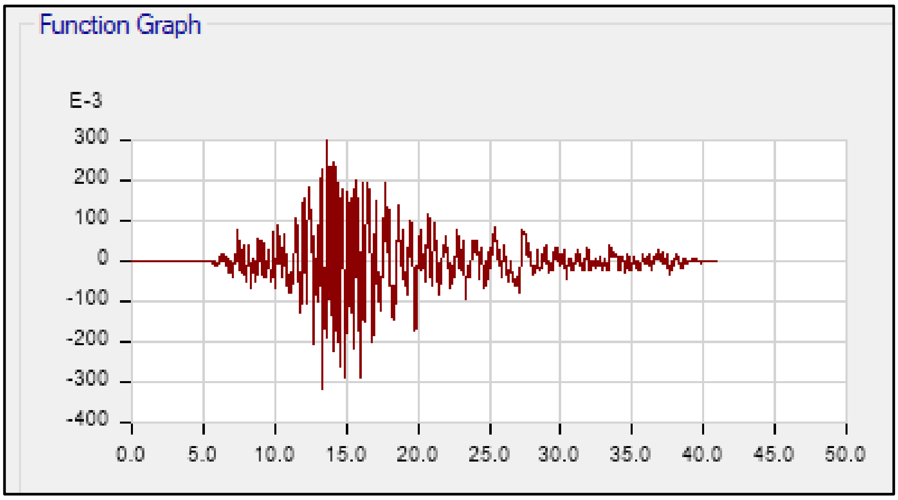

Fig. 8. Shape of the records for NLTHA in Etabs

4.2. Analysis and discussions

First things to compare are the base values of the base shears of the structure. To do that, the NLTHA with the ULS and the MCE were proceeded on the model. The base shear should be close to the base shear obtained with the lateral force method in section 2, which is 9,370kN for x direction and 9,700kN for y direction.

The average base shear showed in Fig. 9 for the x direction is 8,540kN which is below the value of 9,370kN. A similar observation can be done when considering the y direction. These values make sense and confirm that the model is correct. The same procedure was followed with the most considered earthquake (MCE).

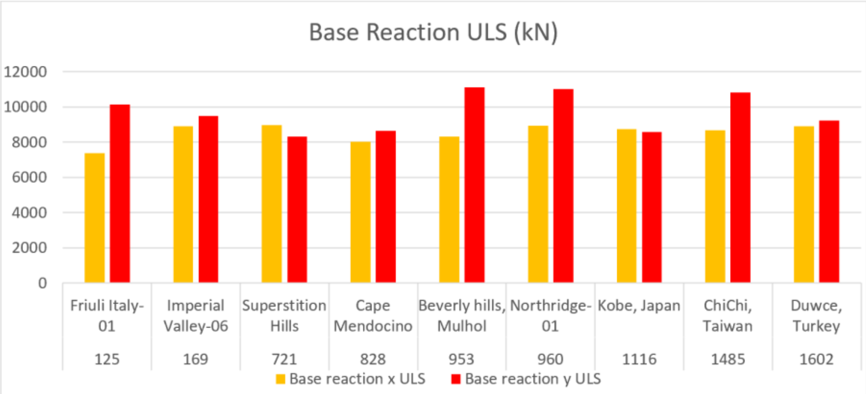

Fig. 9. ULS Base shear

The average value for the x direction is 11,220kN and for the y direction is 13,500kN. These two values are close to the design values, which is desired and correct. Indeed these values are approximately greater than 40% which is acceptable as long as it is not greater than 1.5 of the design value. Second, the displacement of the structure is controlled and verified. Both ULS and MCE cases are presented in Fig. 10.

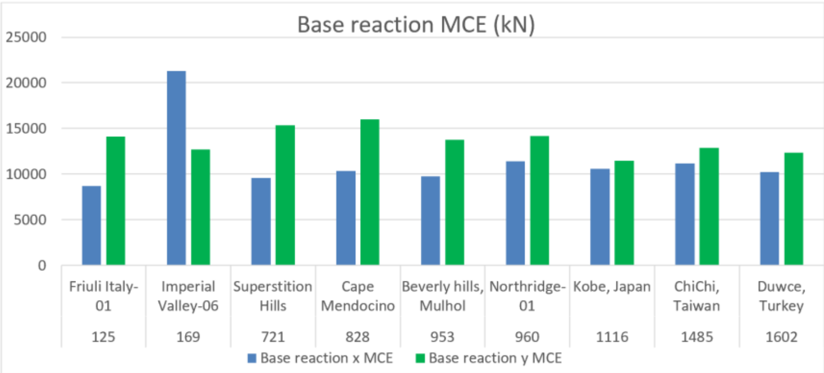

Fig. 10. MCE Base shear

The maximum displacement is 2.50% under the MCE case and there are only 3 values greater than 2.0%. These are really good results and the efficiency of the timber structure in this situation is confirmed. In addition, the average maximum displacement for ULS in x direction is 0.70% and in y direction is 0.75%. This is really close and really good for such a structure. For the MCE, an average of 1.05% and 1.20% were obtained for respectively the x and y directions.

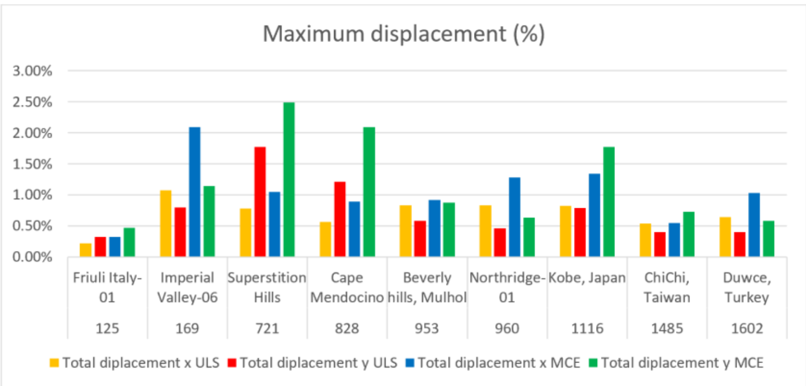

Fig. 11. MCE and ULS maximum displacement

The RSFJs were then checked to see if they don't break and how efficient they are. The properties of the designed RSFJs given in Tables 12 and 13, show that the maximum allowable displacement for the RSFJs in the braces is 50mm and for the shearwalls it is 105mm.

Table 12. RSFJ displacement under ULS

Ultimate Limit State	Max displacement (mm)	Δult (mm)
Brace	41	50
Shearwall	81	105

Table 13. RSFJ displacement under MCE

Most Considered Earthquake	Max displacement (mm)	Δult (mm)
Brace	54	50
Shearwall	109	105

The NLTHA show that the maximum displacement of the RSFJs is a little bit greater than the delta ult under the MCE load case. The delta ult of the RSFJs should be increased in order not to break and to guarantee the security of the building. At the stage of this study, obtained displacement values are considered acceptable. It is interesting to show the other main characteristic of the RSFJ: the self-centring behaviour. Fig. 12 shows the behaviour of one RSFJ (found in the braces) obtained thanks to the NLTHA.

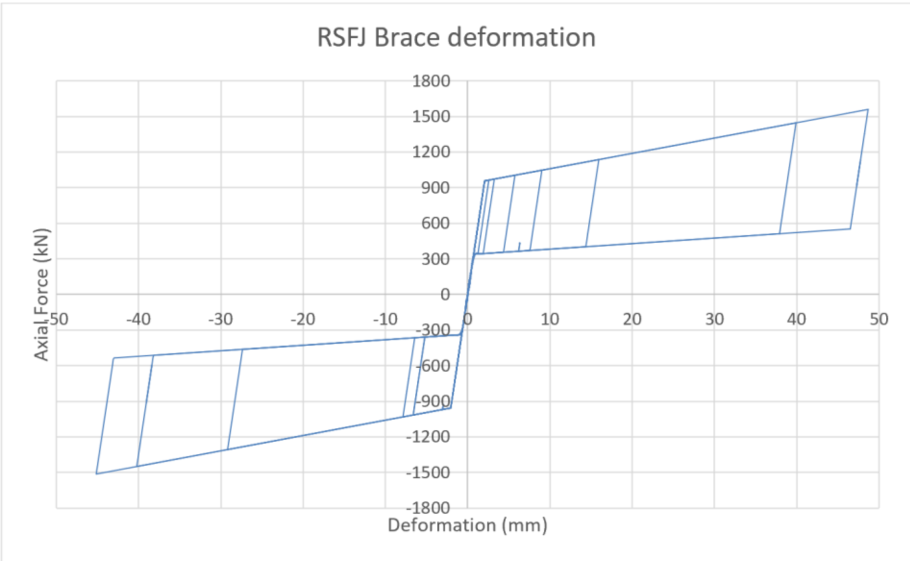

Fig. 12 - Flag shape behaviour of the RSFJ

Fig. 12 shows that the constitutive law of the RSFJ is an hysteresis curve. This corresponds to the flag shape previously described. Indeed, the RSFJ open well when the value of Fslip is reached, then damps to reach the Fult. When the force in the RSFJ decreases, the RSFJ comes back to its initial position. Even after many cycles, the RSFJ is still self-centring and does not show any sign of rupture. Now, that the self-centring behavior of the RSFJ was described, it's important to check the impact of these properties on the structure, especially the residual drift, which should be close to 0% with the RSFJ properties. Results are presented in Fig.s 13 and 14.

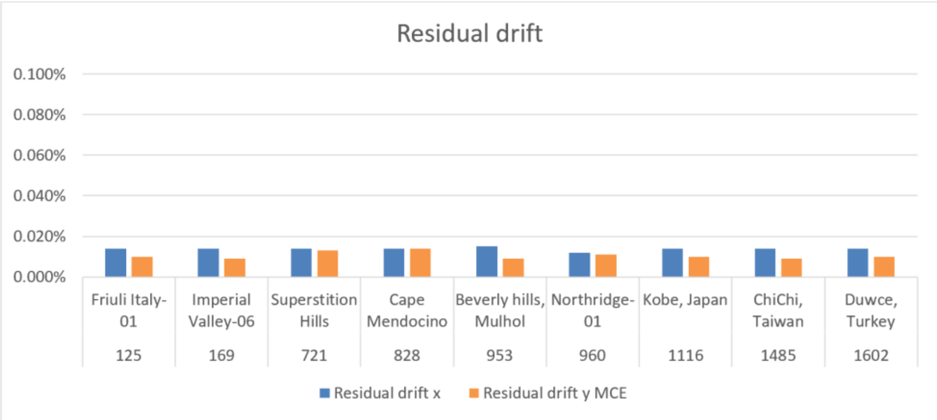

Fig. 13. Residual drift results under MCE records

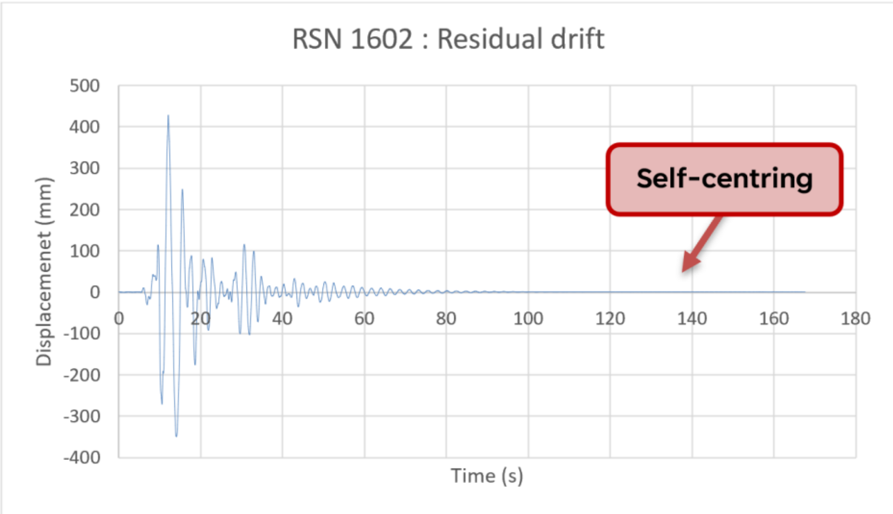

Fig. 14. Displacement of the structure vs time (example record 1602)

As expected, the residual drift of the structure is approximatively equal to 0%. Indeed, the maximum values obtained from the NLTHA are less than 0.020% with MCE configuration which is a really good result. In addition Fig. 43 shows clearly the self-centring properties of the structure obtained using the RSFJs, since after the earthquake event, the building comes back to its initial position on its own.

Another series of NLTHA were run on the same structure without considering any RSFJs or resilient devices. The objective is to show the benefits of the use of such devices in the reduction of the cross sections of the different elements of the structure (Table 14).

Table 14. Brace section comparison

	With RSFJ		Without RSFJ	
	Force demand (kN)	Section (mm^2)	Force demand (kN)	Section (mm^2)
Brace1	2250	450x450	8200	950x950
Brace2	1400	350x350	5500	760x760
Brace3	800	300x300	3000	550x550

Thus, thanks to the RSFJs, the size of the required sections is almost divided by 2, which is huge. The weight of the structure is also significantly reduced thanks to such devices which enables to save of a lot of money. In addition, making connections using RSFJs is less complicated and requires less materials than conventional ones.

Moreover, the force present in the braces is divided by up to 4 times thanks to the RSFJs, which also influences the total base shear of the structure. Therefore, the cost of foundation will decrease significantly with the use of the RSFJs (smaller foundation required necessitating less construction time).

Table 15. Determination of the behaviour factor q

	Base Shear ULS	Behaviour factor q
Both directions	38900	1
x-direction with RSFJ	8540	4.55
y-direction with RSFJ	9370	4.15

Table 15 shows the calculated behaviour factor q of the structure thanks to the use of the RSFJs. Its value is more important than the value 3 typically used for timber structures.

5. Conclusion

To conclude, this research article has explored the potential of integrating a sustainable and resilient technology in timber structures in Europe: The Resilient Slip Friction Joint (RSFJ), which is a New Zealand product.

The findings of this article show that the RSFJs, can be implemented in European timber projects. The various analysis proceeded: the lateral force method (LFM), a pushover analysis and the NLTHA show the very positive impact of such devices on timber structures. Thanks to the RSFJs properties such as their self-centring behaviour, their zero post event damage, the model achieves a high level of performance and an important and efficient energy dissipation. The use of RSFJs also implies on site to have to deal with less complicated connections and allows major savings (smaller cross sections needed, lighter structures). All in all, this article clearly gives the methodology that should be used by practitioners in order to design resilient timber structures using the Eurocodes thanks to the RSFJs.

Assessment of sequential earthquake response of the historic Karahan Mosque minaret

Adem Doğangün*[1], Muneeb Jadallah[1]

[1] *Bursa Uludağ University, Faculty of Engineering, Department of Civil Engineering, Turkey*

Abstract. On February 6, 2023, a devastating series of earthquakes struck Turkey, severely affecting historical structures, including the Karahan Mosque minaret in Malatya. This minaret, characterized by its stone base and masonry brick upper sections, exhibited extensive cracking, highlighting critical concerns about its structural integrity and preservation. This study investigates the seismic performance of the minaret under sequential earthquake loading, emphasizing its behavior during repeated seismic events. Nonlinear dynamic analyses, specifically time history simulations, were conducted using the Applied Element Method (AEM) in ELS software to model the structural response of the minaret under sequential seismic forces. Findings reveal that while the minaret exhibited resilience during a single earthquake, it suffered complete structural collapse when subjected to a series of identical seismic events. Key results demonstrated a notable reduction in the minaret's seismic capacity during sequential loading. The lateral displacement at the top of the minaret, measured at 167.8 mm after a single earthquake, increased significantly under sequential events, leading to instability. Furthermore, the maximum principal stress reached 10 MPa, surpassing the material's acceptable limits. After two identical earthquakes, the minaret failed to maintain structural stability and experienced total collapse. These results underscore the vulnerability of historical masonry structures to sequential earthquakes, emphasizing the need for enhanced retrofitting strategies. The study contributes valuable insights into the behavior of heritage structures under repeated seismic loading, guiding preservation efforts and structural reinforcement techniques for similar at-risk buildings.

Keywords: Sequential earthquakes; Karahan Mosque minaret; Nonlinear dynamic analysis; Applied Element Method (AEM); Structural collapse

1. Introduction

The February 6, 2023, Kahramanmaraş earthquakes (Mw 7.7 and Mw 7.6) caused catastrophic damage across southern Turkey, particularly affecting historical masonry structures, including mosques and minarets (Atmaca et al., 2024; Kocaman et al., 2024). These events underscored the vulnerability of heritage buildings to sequential seismic loading, raising critical concerns about their structural resilience and preservation. Previous studies have extensively examined the seismic behavior of historical minarets, revealing their susceptibility to dynamic forces due to their slender geometry and material degradation (Türkeli et al., 2015; Aymelek et al., 2023). However, the impact of repeated earthquakes on such structures remains insufficiently explored, despite evidence that sequential ground motions can exacerbate damage and lead to progressive collapse (Jadallah et al., 2025; Erkek & Yetkin, 2025). Recent research has focused on both the assessment and retrofitting of historical masonry minarets. Studies such as those by Kocaman & Gürbüz (2023) and Gürbüz & Kocaman (2024), and Jadallah et al. (2025) have analyzed collapse mechanisms and proposed reinforcement techniques, including Fiber Reinforced Cementitious Matrix (FRCM) and Fiber Reinforced Polymer (FRP) composites. Similarly, Cosgun et al. (2023) and Şentürk et al. (2022) have investigated post-restoration seismic performance and strengthening methods for historical mosques, emphasizing the need for advanced numerical modeling approaches. The Applied Element Method (AEM) has emerged as a reliable tool for simulating nonlinear dynamic behavior, as demonstrated by Trešnjo et al. (2023) and Onat et al. (2023), offering insights into structural responses under seismic excitation.

This study examines the seismic performance of the Karahan Mosque minaret in Malatya, which suffered extensive cracking during the 2023 earthquakes. Unlike previous research focusing on single-event analyses, this work investigates the minaret's behavior under sequential earthquake loading, addressing a critical gap in the literature. Using AEM -based nonlinear time-history analysis, the study evaluates displacement patterns, stress distribution, and collapse mechanisms under repeated seismic events. The findings contribute to a deeper understanding of cumulative damage effects in historical masonry.

By integrating field observations with advanced numerical simulations, this research provides valuable insights into the progressive failure of heritage minarets under sequential earthquakes. The results emphasize the necessity of improved reinforcement techniques to mitigate seismic risks, supporting ongoing preservation efforts for vulnerable historical structures in seismically active regions.

2. Description of minaret architectural and material properties

The Karahan Mosque minaret in Malatya, shown in Fig. 1, is a representative example of traditional Ottoman-era masonry architecture, characterized by its slender cylindrical form and distinctive structural elements. The naming of the structural parts of a typical historical masonry minaret is shown in Fig. 2.

Fig. 1. The Minaret of The Karhan Mosque (RESTAŞ, 2024)

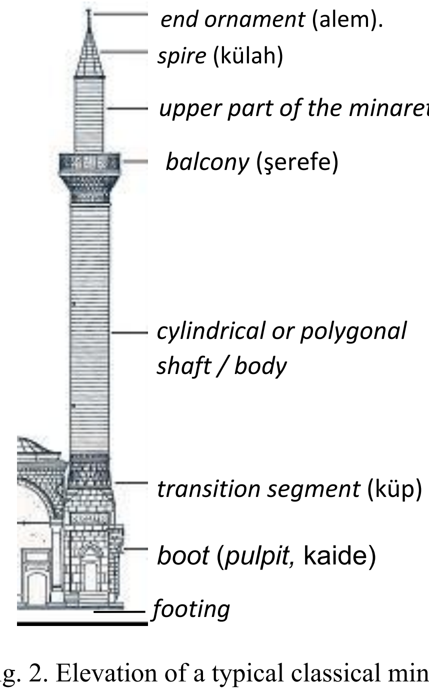

Fig. 2. Elevation of a typical classical minaret (Tuncer, 1996)

The minaret rises from a square stone base and transitions into a circular brick shaft, which terminates in a conical balcony and a pointed spire (külah) at the top. Standing at 19.25 meters in height, the structure was constructed using locally sourced stone for the base and masonry materials for the upper sections, following traditional building techniques. An internal spiral staircase extends up to the balcony level. On February 6, 2023, the mosque was severely affected by a major earthquake, with the minaret sustaining significant damage, including the formation of multiple visible cracks (Fig. 3).

Fig. 3. Horizontal cracks in the minaret

Architectural features:

- Base Section: Constructed from locally sourced cut stone, the height of the base is 3.2m
- Shaft: The main body consists of brick masonry laid in lime mortar, the shaft/body with a height of 7m and the upper shaft with a height of 2.8m.
- Balcony (*Şerefe*): A projecting balcony supported by decorative corbelling marks the transition to the upper section.
- Spire (*Külah*): The pinnacle is built with lightweight timber framing, often clad in lead for weather protection.

Material properties:

- Stone Base: Composed of andesite, exhibiting high compressive strength but limited tensile capacity.
- Brick Masonry: Clay bricks with varying dimensions, bonded with low-strength lime mortar, resulting in anisotropic behavior under seismic loads.
- Mortar: Traditional lime-based mortar, prone to degradation over time, reducing cohesion between bricks.

Material testing and historical records indicate average compressive strengths of 7 MPa for brick masonry and 15 MPa for stone, with negligible flexural resistance. The mortar's weak adhesion exacerbates vulnerability to shear and tensile stresses during earthquakes.

3. Modeling of buildings

This study employs the Applied Element Method (AEM) ASI (2004), a nonlinear analysis technique used to evaluate the seismic behavior of the minaret. AEM is particularly well-suited for analyzing historical masonry structures, as it enables the simulation of structural response from the onset of loading through to complete failure. The method effectively bridges the capabilities of both the Finite Element Method (FEM) and the Discrete Element Method (DEM). While FEM is commonly used to simulate structural behavior up to the point of element separation, DEM is applied to model post-separation behavior. AEM integrates both approaches by representing structural components as an assembly of small discrete elements interconnected by a series of normal and shear springs, as illustrated in Fig. 4. These springs simulate the transfer of stresses and strains across element interfaces. Under extreme loading conditions, these springs may fail, allowing the elements to separate and thus capturing progressive collapse mechanisms. Each element possesses six degrees of freedom—three translational and three rotational—which enables detailed modeling of structural motion, as shown in Fig. 5.

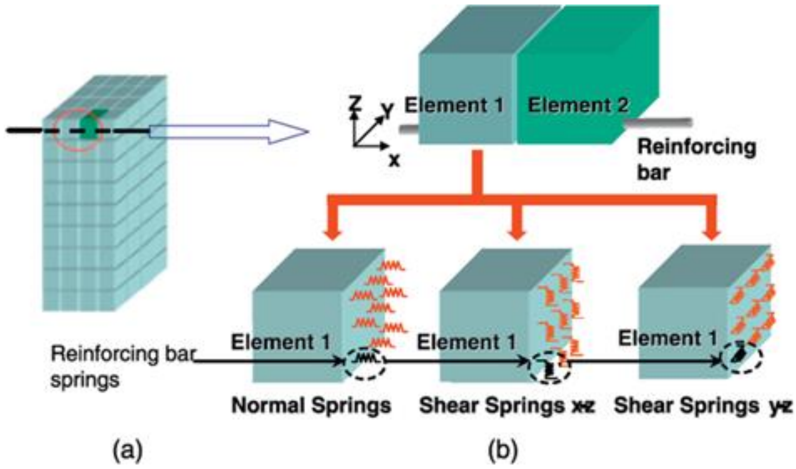

Fig.4. Element of a structure modeled by AEM (ELS website) ASI (2004)

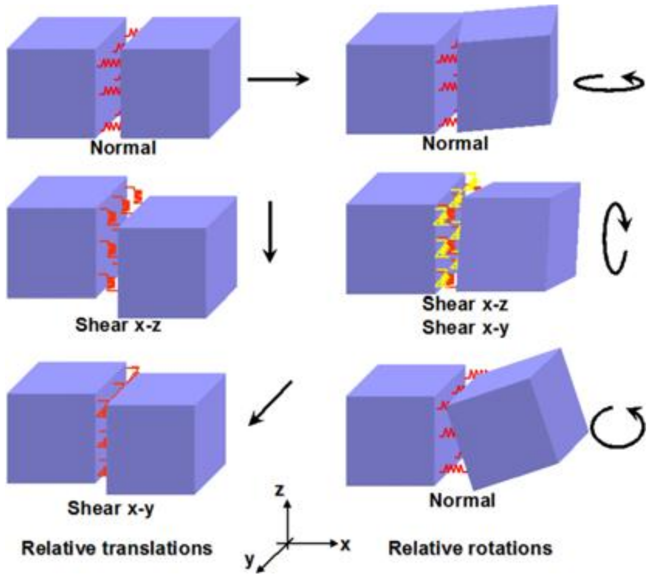

Fig. 5. Element degrees of freedom (ASI website) ASI (2004)

4. Description of the minaret model

The three-dimensional model of the Karahan Mosque's minaret was developed using ELS software Version 10, as illustrated in Fig. 6. The internal spiral stone staircase was also included in the model, extending from the base of the minaret up to the upper balcony.

5. Non-linear time history analysis

A nonlinear analysis was conducted using the earthquake records from the seismic event that occurred on February 6, 2023. The peak ground acceleration (PGA) in Gaziantep, where the Karahan Mosque is located, was recorded at 0.35g, as shown in Fig. 7.

Non-linear time history analysis is a critical method for assessing the seismic performance of structures, particularly historical masonry buildings like the Karahan Mosque minaret. This technique applies a series of ground motion records to a detailed structural model, simulating actual earthquake events to evaluate the structure's behavior under dynamic, non-linear conditions.

Two nonlinear dynamic analyses were performed on the Karahan Mosque minaret using earthquake records to assess its seismic performance. The first scenario, illustrated in Fig. 8, simulates the minaret's response to a single earthquake event. The second scenario, shown in Fig. 9, involves two identical successive earthquakes: the minaret is first subjected to an initial seismic event, and then (without repairing the damage) it experiences a second identical earthquake. This approach allows for evaluating the cumulative damage and the structure's residual capacity under sequential loading. The two considered scenarios are (1) a single-earthquake event using the record in Fig. 8 and (2) a twin-earthquake event using the record in Fig. 9. These analyses aim to examine the minaret's resilience under repeated high-intensity seismic events, which is especially relevant in regions prone to aftershocks.

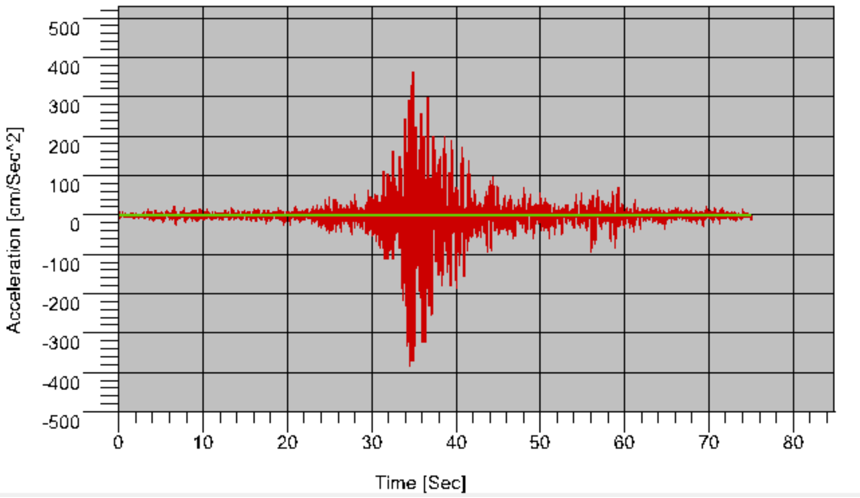

Fig.7. Accelerogram in the X direction.

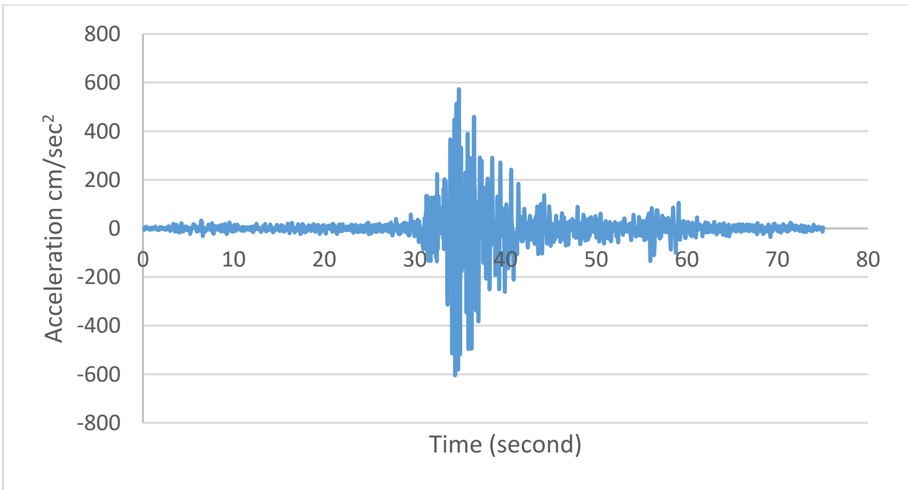

Fig. 8. Accelerogram in the X direction. (AFAD record 2023).

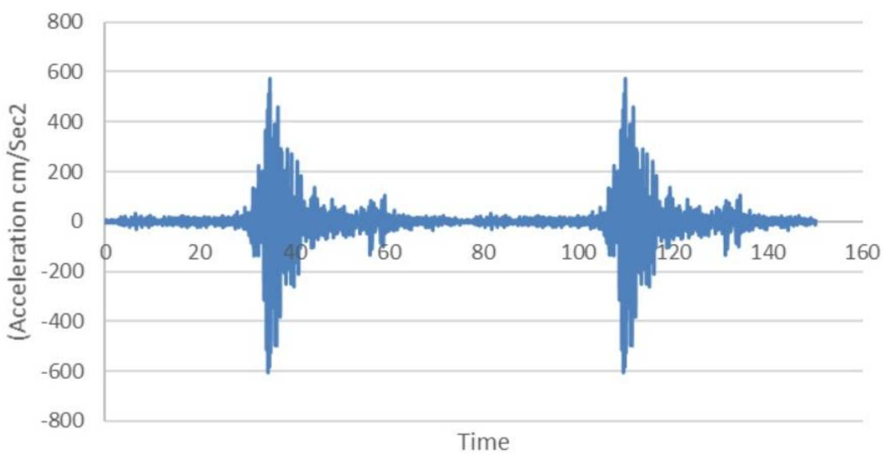

Fig. 9. Twin accelerograms in the X direction. (AFAD record 2023).

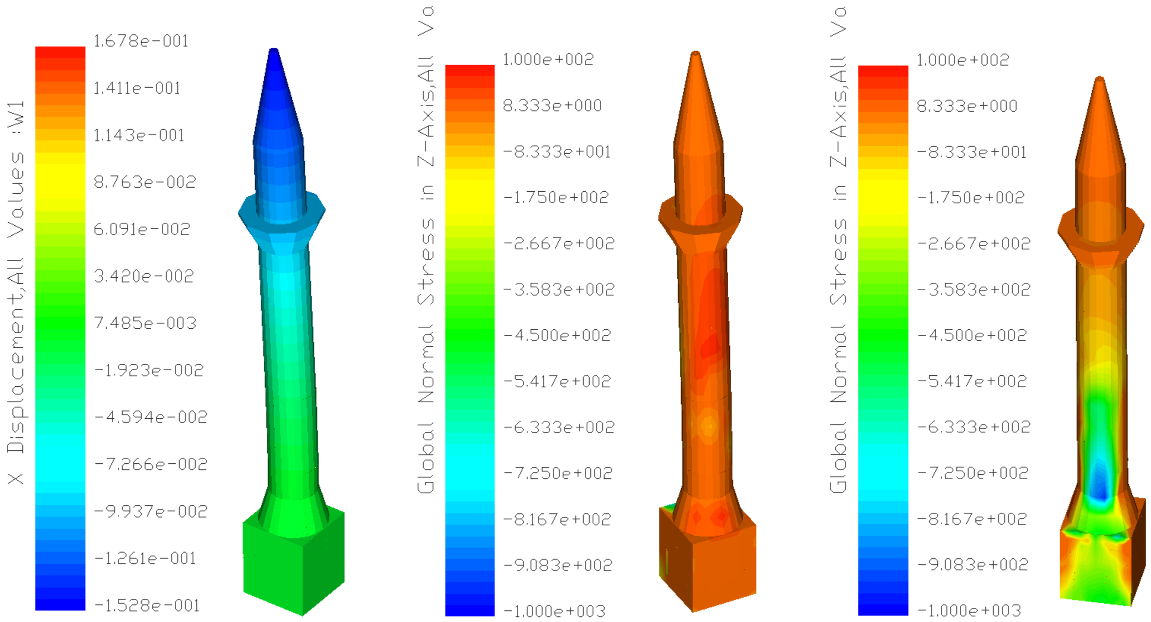
6. Results and discussion

6.1. Single seismic event

Under the single earthquake scenario, the analysis revealed that the minaret remained standing without collapsing. However, the structure exhibited a maximum lateral displacement of 167.8 mm, indicating a high susceptibility to seismic forces and a considerable risk of structural damage, as shown in Fig. 10 (a). Significant cracking developed along the shaft due to excessive lateral drift during the seismic event. The maximum compressive stress in the minaret was recorded at 10 MPa, Fig. 10 (b, c), exceeding the compressive strength of the brick masonry, which was limited to 7.0 MPa. This overstressing contributed to the formation of cracks, particularly in the shaft region, as illustrated in Fig. 11. Although the analysis identified localized element separations and masonry crushing under lateral loading, these damages were not extensive enough to compromise the overall structural stability of the minaret.



a) Displacement(m) b) Normal stresses (t/m^2) c) Normal stresses (t/m^2)

Fig. 10. a) Maximum displacement in the X direction (m). b) Maximum Normal stresses (tonf/m^2).

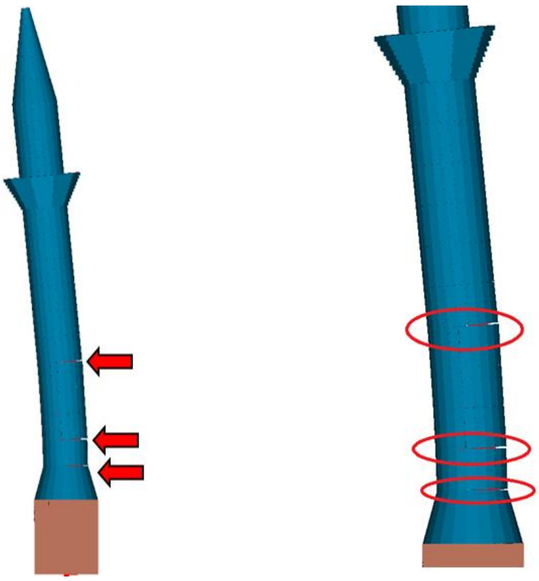


Fig.11. Cracks in the minaret obtained from the single seismic analysis of the minaret (ELS)

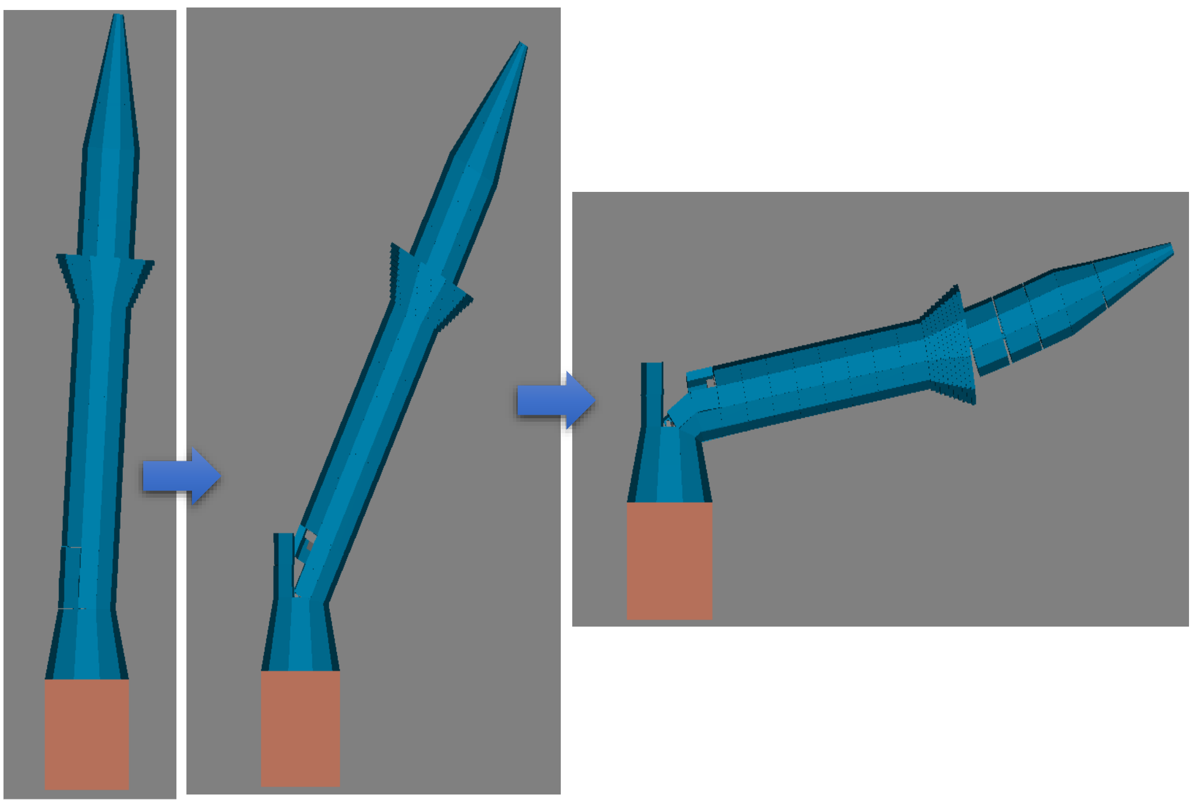
6.2. Repeated seismic event

As previously noted, the analysis incorporates the acceleration records shown in Fig. 9, which represent a scenario where the Karahan Mosque minaret is subjected to two identical consecutive earthquakes regardless of whether the structure sustained damage during the first event. The nonlinear analysis results indicate that, in its existing unreinforced condition, the minaret collapsed during the second seismic event. This outcome, illustrated in Fig. 12, highlights the structure's inability to endure repeated seismic loading and underscores its vulnerability to sequential earthquake scenarios.



@t= 117s @t= 120s @t= 121.4

Fig.12. Collapse steps of minaret during the second earthquake

7. Conclusion

The devastating earthquake that struck Turkey on February 6, 2023, had a significant impact on the province of Gaziantep. Among the historical structures affected, the Karahan Mosque's minaret experienced noticeable damage. Although the main mosque remained standing and the minaret did not collapse during the initial seismic event, visible cracks developed in the minaret's shaft. However, nonlinear analysis shows that if the same earthquake were to strike twice in succession, mimicking a sequence of strong mainshock-aftershock events, the minaret would not be able to withstand the cumulative damage and would collapse. This highlights the urgent need for structural assessment and retrofitting of such historical structures.

- Under the effect of a single earthquake record, the minaret remained standing, but significant cracks formed in the shaft due to excessive lateral drifts of 167.8mm. The analysis showed that the compressive stresses in some areas exceeded the capacity of the brick masonry, indicating high vulnerability to seismic loading.
- When subjected to two identical consecutive earthquakes representing a more realistic seismic sequence scenario, the minaret collapsed during the second event. This was primarily due to the residual damage from the first shock, which weakened the structure and reduced its capacity to withstand further loading.
- To preserve the historical and architectural integrity of the minaret while enhancing its structural resilience, suitable retrofitting measures are needed. Strengthening solutions should increase both the shear and bending capacity, ideally using minimally invasive methods.

Acknowledgments

We gratefully acknowledge the support provided by the Bursa Uludağ University's BAP project number FDK-2025-2169 in the preparation of this article. In the preparation of this article, RESTAŞ information and files for the project were used. Autoencoder based damage detection in masonry structures

Tunahan Aslan[1], Kemal Hacıefendioğlu [*1], Ayşecan Bostan[1], Cemile Duman[2]

[1] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye
[2] Gazi University, Department of Civil Engineering, 06570 Ankara, Türkiye

Abstract. This study aims to detect and evaluate damage in masonry structures using a contactless structural health monitoring method integrated with an Autoencoder deep learning model. Video recordings of a scaled minaret model constructed in a laboratory environment were taken at specific intervals using an industrial camera-based monitoring system. Subsequently, controlled damage was incrementally applied to the minaret model, and new video recordings were captured. Time-dependent displacement data from four different elevations of the scaled minaret model were extracted using a custom Python® script. A separate code based on an Autoencoder deep learning model was employed to calculate the damage index of the minaret model using the displacement data. Analyses conducted in the undamaged state revealed a stable damage index below 5%. However, analyses performed after the controlled damage steps showed that the damage index exceeded 5%. This study introduces a practical and rapid method for damage detection in masonry and similar engineering structures, facilitating faster diagnostic and decision-making processes in the field of structural health monitoring.

Keywords: Damage detection; Structural health monitoring; Masonry structures; Deep learning; Autoencoder

1. Introduction

Masonry structures represent a significant portion of the world's architectural heritage and are commonly found in both historical and modern constructions due to their durability, low cost, and ease of use. Despite these advantages, masonry buildings are highly vulnerable to various forms of damage, particularly under dynamic loads such as earthquakes. Given their widespread use and cultural importance, ensuring the structural integrity of masonry structures through effective damage detection and monitoring techniques is of utmost importance.

Structural health monitoring (SHM) is critical for ensuring the safety and longevity of civil infrastructure (Anjum et al., 2024; Avci et al., 2022). Machine learning (ML) techniques have emerged as powerful tools for detecting structural damage, with autoencoder-based methods gaining prominence due to their ability to handle unsupervised learning and dimensionality reduction. This response compares autoencoder-based methods with other ML techniques, highlighting their strengths, weaknesses, and applications in civil engineering (Gil Bravo et al., 2024; Mghazli et al., 2024).

Autoencoders, particularly variational autoencoders (VAEs), have shown promise in SHM by learning latent representations of structural data. These models are effective in unsupervised anomaly detection, requiring only normal (undamaged) data for training. For instance, VAEs combined with Hotelling's T2 statistical tool have demonstrated superior performance in identifying and quantifying structural changes in civil structures (Spínola Neto et al., 2024). Similarly, convolutional autoencoders have been successfully applied to detect damage locations in mechanical systems by analyzing changes in stiffness (Bono et al., 2023).

The integration of autoencoders with other techniques, such as mechanics-informed models, has further enhanced their capabilities. For example, a mechanics-informed autoencoder can detect and localize unforeseen damage with minimal training data, achieving up to 35% better performance than standard autoencoders (Li et al., 2024). Additionally, multi-objective VAEs have been used to fuse multi-sensor data for damage detection and localization, outperforming state-of-the-art methods (Anaissi et al., 2023).

Traditional ML techniques, such as K-nearest neighbors (KNN), Gaussian mixture models (GMMs), and one-class support vector machines (OCSVMs), have been widely used for structural damage detection. These methods rely on feature engineering and supervised or semi-supervised learning paradigms. While they are effective in specific scenarios, they often struggle with high-dimensional data and require labeled datasets, which can be challenging to obtain in real-world applications (Che & Tian, 2024; Wang & Cha, 2025).
In contrast, autoencoder-based methods excel in unsupervised settings and can automatically learn features from raw data, reducing the need for manual feature engineering. For example, a comparative study on a laboratory-

[*] Corresponding author, E-mail: kemalhaciefendioglu@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_315

scale steel bridge demonstrated that autoencoders outperformed KNN and GMMs in detecting loosened bolts, highlighting their robustness in unsupervised damage detection (Wang & Cha, 2025).

Deep learning techniques, such as convolutional neural networks (CNNs) and recurrent neural networks (RNNs), have also been applied to SHM. These methods are particularly effective in processing time-series data and capturing temporal patterns. For instance, a deep residual network (DRN) optimized with Bayesian methods has shown superior performance in detecting, localizing, and quantifying structural damage compared to traditional ML methods (Alazzawi & Wang, 2022; Atia et al., 2024; Fernandez-Navamuel et al., 2024).

Moreover, hybrid models combining autoencoders with other deep learning architectures, such as long short-term memory (LSTM) networks, have been developed to enhance damage diagnosis. A multi-head self-attention LSTM autoencoder has demonstrated superior performance in detecting minor damage and localizing multiple damage locations on a full-scale bridge (Ghazimoghadam & Hosseinzadeh, 2024).

component of ML-based damage detection. Traditional methods often rely on handcrafted features, such as modal parameters and frequency-domain metrics, which can be time-consuming and require domain expertise. Autoencoders, on the other hand, can automatically learn damage-sensitive features from raw data, such as acceleration responses and vibration signals (Bono et al., 2023; Spínola Neto et al., 2024).

The effectiveness of autoencoders in feature extraction is further enhanced by their ability to handle multi-sensor data. For example, a multi-objective VAE has been used to fuse data from multiple sensors, capturing correlations and improving damage detection accuracy (Anaissi et al., 2023). Similarly, a deep convolutional variational autoencoder (DCVAE) has been shown to effectively extract features from multisensor data, outperforming traditional methods like principal component analysis (PCA) (Wan et al., 2025).

Autoencoder-based methods are computationally efficient and can be deployed in real-time SHM systems. For instance, a mechanics-informed autoencoder can learn from just 3 hours of data and autonomously detect and localize damage, reducing the need for human intervention (Li et al., 2024). Additionally, autoencoders can be trained on non-standardized time-series data, making them suitable for unsupervised damage localization without requiring extensive preprocessing (Römgens et al., 2023, 2024).

However, the performance of autoencoders can be influenced by the quality and quantity of training data. While they excel in unsupervised settings, their accuracy may degrade in the presence of noisy or incomplete data. Addressing these challenges requires careful data preprocessing and the integration of domain knowledge into the model architecture (Li et al., 2024; Wan et al., 2025).

This study presents a novel application of an Autoencoder-based deep learning approach integrated with a non-contact monitoring system to detect and evaluate damage in masonry structures. A scaled minaret model was constructed and subjected to a series of controlled damage scenarios in a laboratory setting. Displacement data were extracted from video recordings using a custom Python® script, and the damage index was calculated based on the Autoencoder's performance. The findings demonstrate that the proposed method can effectively distinguish between undamaged and damaged states, offering a practical and efficient alternative for structural diagnostics in masonry and similar engineering structures. Autoencoder-based methods have emerged as powerful tools in structural damage detection due to their advantages in unsupervised learning, automatic feature extraction, and ability to handle high-dimensional, multi-sensor data. Building upon these strengths, this study contributes to the advancement of SHM technologies by demonstrating a robust, data-driven approach that can be applied in real-world scenarios, while also highlighting the potential of hybrid models and domain-informed architectures for future research.

2. Materials and methods

Within the scope of this study, a scaled model of a historical masonry minaret was constructed at the Structural Health Monitoring Laboratory of Karadeniz Technical University. This model consists of four main sections: the podium, transition zone, body, and upper body, all designed to align with the architectural elements of minarets. These structural sections were meticulously designed to analyze the real behavior of the minaret through the scaled model. The model, with a total height of 3.85 meters, is supported from the inside by wooden staircase steps. Fig. 1 shows images of the miniature minaret model. After the completion of the model, a curing period of one month was expected. During this period, measurements were taken at regular intervals to observe the behavior of the structure. The aim is to obtain the horizontal and vertical displacements of the structure without subjecting it to any dynamic load through the measurements taken. Using these displacement values, damage detection can be performed through an Autoencoder-based method.

Fig. 1. Construction phase of the miniature minaret model

These measurements were carried out using a system built with high-speed industrial cameras. The most critical aspect of the video camera-based monitoring system is the hardware system created to record video footage. With this system, video recordings can be taken both in the laboratory environment and outdoors. The system consists of four industrial cameras, a camera lens for each of these cameras, a recording device to capture the images, a computer for connecting the CoaExpress recording device and CoreView software, and cables. The technical specifications of each component of the hardware system are provided in Table 1.

The Victorem™ CoaXPress series is a wide range of compact industrial video cameras featuring high-performance Sony CMOS image sensors and high-bandwidth CoaXPress video output. There are various models with different sensors available, allowing the selection of the appropriate Victorem camera for each application. These powerful cameras, with resolutions ranging from 0.4 MP to 26.2 MP and frame rates up to several hundred frames per second, are ideal for performance-oriented applications such as volumetric video capture, machine vision, and automatic optical inspection. When sensors generate hundreds or even thousands of megabytes of video data per second, systems using Victorem™ CoaXPress cameras need ways to access this data stream. The CoaXPress video interface is a perfect match for the bandwidth of these sensors and can support the full resolution and bit depth rate of each sensor without limitations. Other interfaces, such as GigE Vision or USB3 Vision, offer lower bandwidth than CoaXPress, requiring either fewer frames per second or lower bit depth. The CoaXPress protocol is standardized and widely adopted, allowing the use of low-cost, flexible coaxial cables over long distances of more than 100 meters. The CMOS sensors used in Victorem™ CoaXPress cameras offer state-of-the-art features, such as high resolution, low noise, excellent dynamic range, and color accuracy (URL-1, 2024). The cameras are equipped with adjustable exposure settings and image correction tables for gamma or contrast enhancement. They can be used either manually or automatically. Some lenses feature an in-camera correction algorithm to correct for vignetting effects and can be adjusted for flat-field homogeneity. For fast-moving objects, adjustable window settings allow the sensor's smaller areas to output at higher frame rates. The schematic of the created hardware system is provided in Fig. 2.

Table 1. Hardware components technical specifications

Components	Model	Technical Specifications
Video Camera-1	IO Industries CoaxPress VICTOREM 16B276MCX	Maximum Resolution: 1456×1088 Number of Frames: 276 FPS Pixel size: 3,45×3,45 µm²
Video Camera-2	IO Industries CoaxPress VICTOREM 32B216MCX	Maximum Resolution: 2064 x 1544 Number of Frames: 216 FPS Pixel size: 3,45×3,45 µm²
Video Recorder	IO Industries DVR Express Core 2 CoaXPress	Video Format: 8/10/12/14/16-bit Monochrome 24-bit RGB

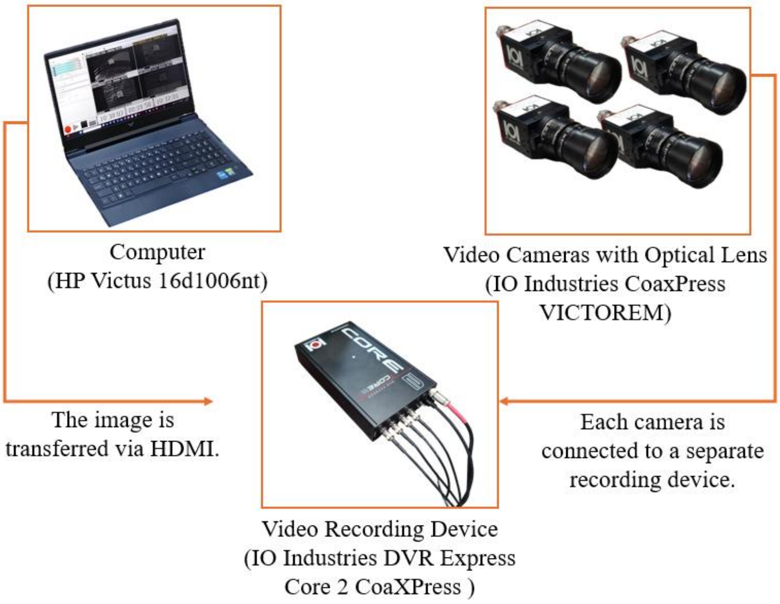

Fig. 2. Monitoring System Hardware Schematic

2.1. Obtaining displacements

A system utilizing template-matching-based displacement sensors has been developed for video camera-based monitoring of objects. Tested on a miniature minaret model in the laboratory environment using templates such as QR codes, the system operates on selected regions of interest (ROIs) on the minaret surface during field measurements. By determining the positions in the initial and final frames, object tracking is performed, and with the use of high-speed industrial cameras, better results are aimed to be achieved compared to conventional methods. The main objective of the study is to evaluate the performance of this system in capturing structural vibrations. Displacement values were obtained from pixel coordinates by applying a scaling factor (Hacıefendioğlu et al., 2024).

The optical flow method differentiates itself from other techniques in computer vision by focusing on object motion tracking. This method is more effective than traditional methods for detecting displacements in video images, as it tracks object movements through image sequences and calculates displacements. Although various methods have been developed to calculate optical flow, the Lucas-Kanade method, which is important for structural health monitoring in this study, has been employed (Lucas & Kanade, 1981). Developed by Bruce D. Lucas and Takeo Kanade, this method assumes that pixel intensity does not change significantly between consecutive frames and predicts pixel displacements by solving a linear system of equations for each point.

The Lucas-Kanade optical flow algorithm may exhibit performance degradation in the presence of large displacements and varying brightness conditions. To overcome these limitations, the Pyramidal Lucas-Kanade Optical Flow technique has been developed.

The Lucas-Kanade method calculates velocity by using the spatial and temporal derivatives of image intensity, and this process is expressed by Equation (1):

$$I(x,t) = I(x+\delta x, t+\delta t) \quad (1)$$

This equation explains the basic assumption of the optical flow method, known as the brightness conservation principle. The intensity of a pixel at position x and time t remains constant after a small time interval δt and a small displacement δx .

This assumption can be expressed in Equation (2) as follows:

$$\nabla I_t(x,t)u + I_t(x,t) = 0 \quad (2)$$

Here, $\nabla I(x,t)$ represents the spatial derivatives across the image, and $I_t(x,t)$ represents the temporal derivatives. u denotes the two-dimensional optical flow vector.

To determine the displacement vector, the least squares approach is applied, and this approach is expressed in Equation (3):

$$E(u) = \sum \left[\nabla I(x,t)u + I_t(x,t) \right]^2 \quad (3)$$

The minaret model has been placed on the shaking table and fixed to the table using anchors. Subsequently, the monitoring system has been positioned perpendicular to the templates. Fig. 3 shows the positioning of the minaret on the shaking table and the monitoring system.

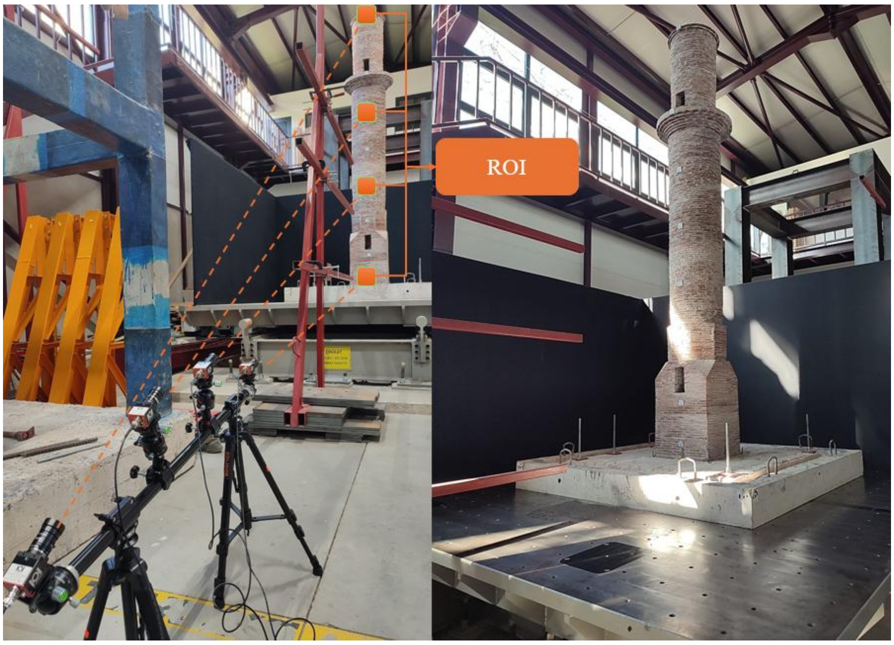

Fig. 3. Monitoring system positioning and shaking table

The miniature minaret model, along with the reinforced concrete block on which it was built, has been fixed to the shaking table with a total of six 50 cm long anchors. As shown in Fig. 3, the front camera is focused on the template located at the bottom of the minaret model, while the rear camera is focused on the template at the top. Four cameras have been mounted on a steel pipe with a 30 cm interval, and the system has been completed with two tripods. This arrangement has completely restricted the movement of the cameras, preventing deviations in the results. A three-stage test was performed on the unidirectional shaking table. The dynamic load was gradually increased, applying a sinusoidal wave to the minaret with the following parameters: 1 Hz frequency, 10 mm amplitude, and 5 cycles; 1 Hz frequency, 20 mm amplitude, and 5 cycles; and 1 Hz frequency, 30 mm amplitude, and 5 cycles. During the final loading, a fracture was observed on the body 30 cm above the transition zone, which was recorded via video. After the tests, an inspection revealed a crack in this region.
The horizontal displacement graphs obtained are shown in Fig. 4. Each graph represents the displacements at the level of the templates tracked by the cameras. These displacements, which are too small to be visible to the naked eye, show a decrease in values when moving from the top to the bottom. These graphs were obtained as a result of analyses performed before and after the shaking table tests. In this way, the data can be compared in the autoencoder-based damage detection system to determine the percentage of damage.

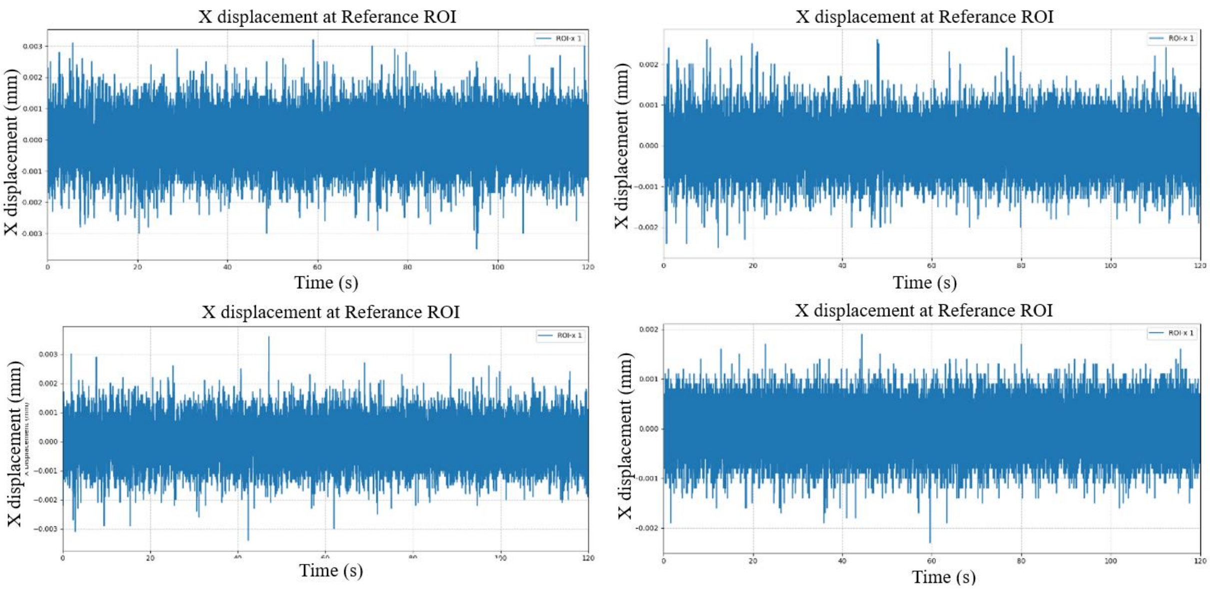

Fig. 4. Horizontal displacements of the miniature minaret model

This study presents a machine learning-based analysis method for structural damage detection using sensor data. The process of separately processing and comparing healthy and damaged data for each sensor enabled the determination of the damage percentage for each sensor. The model predicts reconstructions of the healthy and damaged data, and the reconstruction errors are calculated. The damage percentage is then determined by comparing the errors of the damaged data with a threshold derived from the healthy data. The results are visualized using bar charts, where the sensors with a damage percentage exceeding the threshold are marked. This approach allows for an effective detection of damaged sensors, and the average damage percentage across all sensors is calculated, providing an overall assessment of the structural health. The graphs presented in Fig. 5 were calculated separately for the 30 healthy days. Measurements taken during healthy days revealed that the damage index remained below 5%. After the damage was introduced, the same analyses were performed, and it was observed that the damage percentage exceeded 5%. The damage index graph obtained for both healthy and damaged states is shown in Fig. 6.

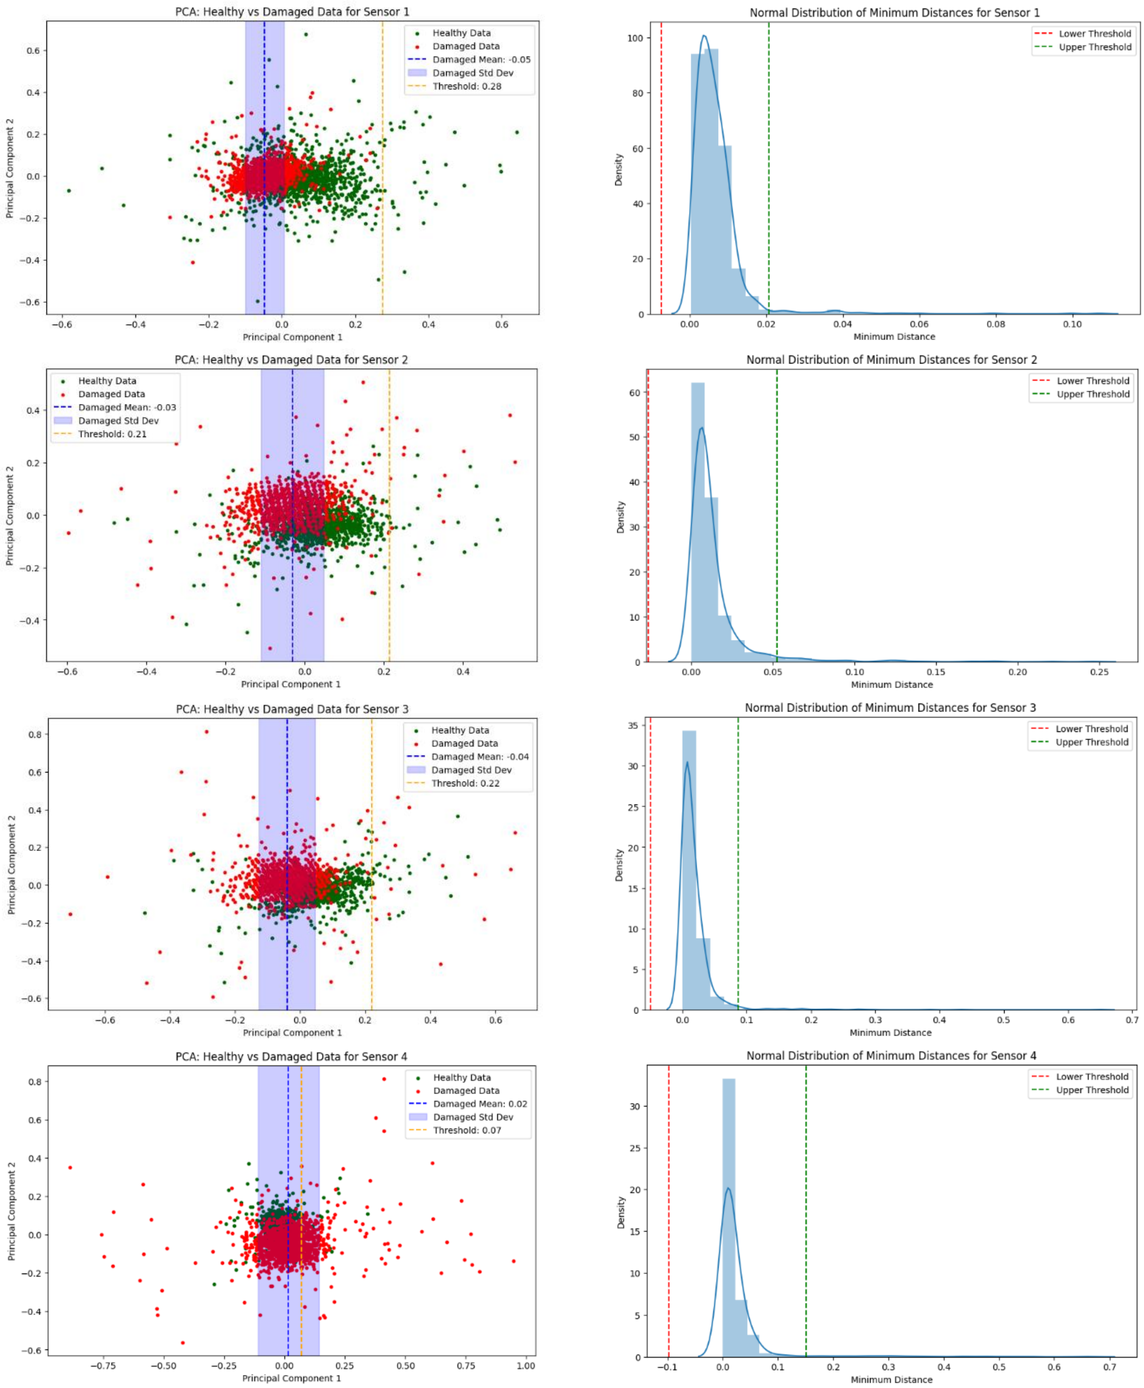

Fig. 5. Calculation of damage index values using the autoencoder model

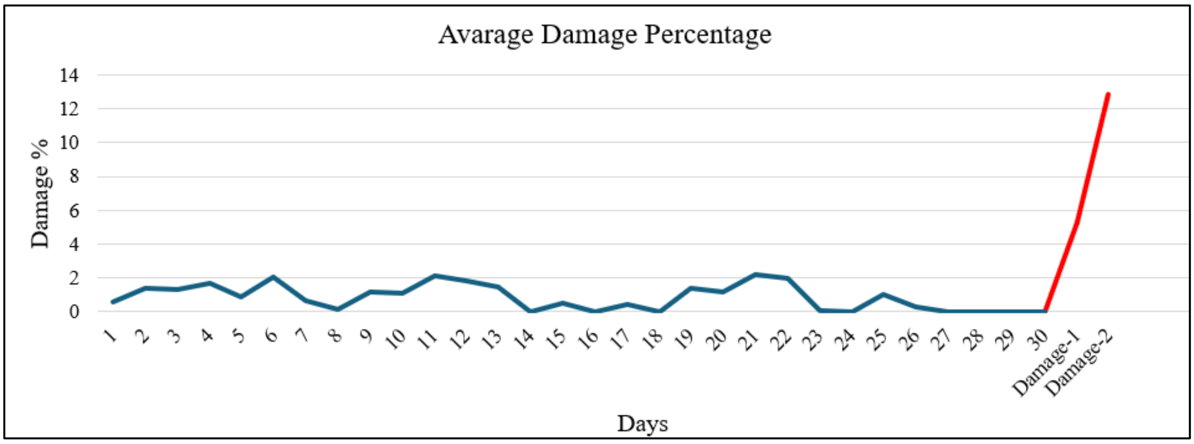

Fig. 6. Average damage percantage

The methodology includes the calculation of reconstruction errors for each sensor and the use of a Z-score-based adaptive threshold for damage detection. This innovative approach enhances the sensitivity of the damage detection process by employing statistical measures to account for variability in the reconstruction errors. A threshold is set based on the standard deviation of healthy reconstruction errors, and the damage percentage is computed by evaluating the reconstructed data of the damaged set against this threshold. The results are presented visually using aesthetically enhanced bar graphs, which also highlight the sensors likely to be damaged. This method, with its detailed and robust analysis, offers a reliable approach for assessing structural health using sensor data and machine learning techniques.

3. Conclusions

This study presents a novel and effective approach to structural health monitoring (SHM) for masonry structures using a non-contact method integrated with an Autoencoder-based deep learning model. The proposed methodology, applied to a scaled minaret model in a controlled laboratory setting, demonstrates the potential of combining advanced machine learning techniques with optical flow-based displacement measurement for the detection and evaluation of damage in masonry structures.

- The results highlight that the Autoencoder-based approach can successfully differentiate between undamaged and damaged states of the structure by calculating a damage index derived from displacement data. The key advantage of this approach lies in its ability to work in an unsupervised manner, relying solely on healthy state data for training, thus eliminating the need for labeled data. This is particularly significant as it reduces the complexity and time-consuming nature of traditional damage detection methods, which often require extensive data labeling and feature engineering
- The laboratory-scale experiments, which involved incremental damage applied to the minaret model, provide compelling evidence that the proposed method can detect even subtle damage changes. In the healthy state, the damage index remained below 5%, but after controlled damage was introduced, the index consistently exceeded 5%, clearly indicating the presence of structural degradation. This threshold-based detection method, enhanced with Z-score adaptive thresholds, allows for a more sensitive and precise assessment of the structural condition, making it a reliable tool for real-time SHM applications.
- One of the critical aspects of this study is the integration of video camera-based monitoring systems and optical flow methods to obtain precise displacement data, which is crucial for accurate damage assessment. The use of industrial-grade cameras and advanced image processing algorithms ensures that the displacement measurements are both accurate and reliable, even under dynamic loading conditions. Moreover, the ability to track displacements at multiple elevations and across different sections of the minaret model further strengthens the robustness of the proposed methodology.
- The application of Autoencoder models, particularly in damage detection tasks, provides several benefits over traditional machine learning methods. By automatically extracting features from raw data and reducing the dimensionality of the input data, Autoencoders are able to identify patterns and anomalies that might not be apparent using conventional methods. Additionally, the ability of these models to handle multi-sensor data and high-dimensional inputs allows for comprehensive damage detection across large-scale structures, such as full-sized masonry buildings or bridges.
- While the current study focused on a scaled model of a masonry minaret, the methodology is highly transferable to other masonry or similar engineering structures, such as historic buildings and infrastructure. The ability to monitor these structures with minimal human intervention, using automated damage detection systems, offers significant advantages in terms of efficiency and cost-effectiveness. Furthermore, this study

contributes to the broader field of SHM by demonstrating how machine learning techniques, particularly Autoencoders, can be seamlessly integrated with modern sensor systems for real-time structural diagnostics.

- Looking forward, future research can explore the enhancement of the current model by incorporating hybrid techniques, such as the combination of Autoencoders with other deep learning architectures, like convolutional neural networks (CNNs) or recurrent neural networks (RNNs). Additionally, expanding the dataset to include a wider variety of damage scenarios, as well as implementing the method on full-scale structures, could further validate and refine the model's performance in real-world applications.

In conclusion, this study not only presents a robust and efficient method for damage detection in masonry structures but also sets the stage for further advancements in SHM through the integration of machine learning techniques. The promising results of this approach suggest that Autoencoder-based models can play a crucial role in the future of structural health monitoring, enabling faster, more accurate, and less resource-intensive damage detection in civil engineering applications.

Prediction of newmark displacement via gene expression programming

Arman Atasoy*[1], Adil Yiğit[1], Fatih Çıbuk[1], İbrahim Yüksel[1]

[1] Istanbul Rumeli University, Department of Civil Engineering, Istanbul, Türkiye

Abstract. One of the most important effects of an earthquake is the permanent ground deformation (PGD) that it can cause in the ground, especially on slopes. Estimation of permanent ground displacements is important for both superstructures and infrastructures, and various methods have been developed to calculate this amount of ground movement. Newmark Sliding Block Model is one of these methods. There are many regression equations derived based on this method in the literature. Within the scope of this study, a new equation has been produced by processing strong ground motion records of 28 earthquakes of world-wide importance. The correlation generation process has been carried out with the Gene Expression Programming (GEP), one of the machine learning algorithms that has been widely used in recent years. Newmark Ground Displacement (δ) has been obtained by using the input parameters Arias Intensity (Ia), maximum acceleration (amax) and critical acceleration (a_c) in deriving the equation. The obtained equation results have been compared statistically with the results of the equations suggested by different researchers in the literature. As a result of the evaluation, it has been determined that the correlation obtained using GEP in this study gave the most appropriate output.

Keywords: Newmark sliding block model; Gene expression programming; Ground displacement; Arias intensity; Earthquake

1. Introduction

Newmark (1965) has been devoloped a unique method to predict of any slope during an earthquake. Depending on Newmark suggestion, earthquake induced movement of any slope can be calculated from this record of the earthquake and critical acceleration of the slope. In that approximation, ground is accepted as a sliding block that moves due to the earthquake acceleration values above the critical acceleration value of the slope (Fig.1).

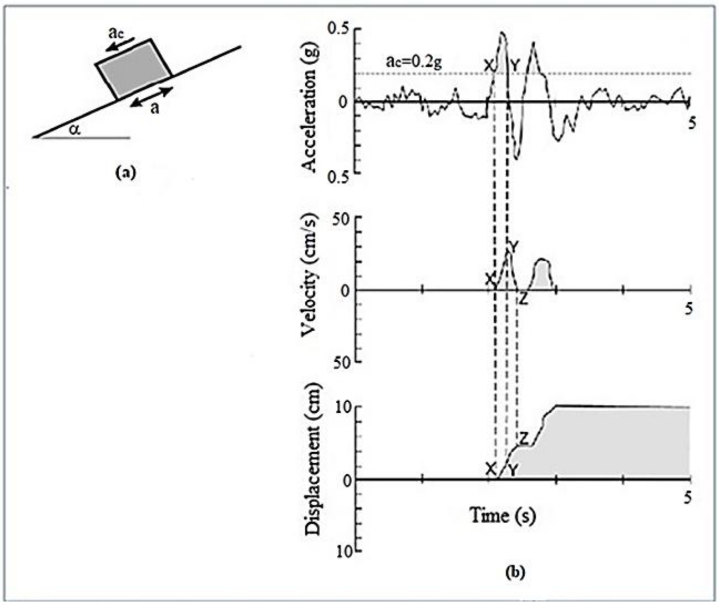

Fig. 1. Newmark approximation (Yigit, 2021)

With the developing technology, machine learning programs come to the fore in deriving correlations. Today, algorithms such as Artificial Neural Networks (ANN), Backpropagation Neural Network (BPNN), Genetic Algorithm (GA), Gradient Boosting Trees (GTB), Random Forests (RF), Support Vector Machines (SVM), Decision Trees (DT), Radial Basis Function Neural Networks (RBFNN), Gaussian Process Regression (GPR) and Multiple Linear Regression (MLR) are among the promising methods in artificial intelligence-based analysis. The main purpose of these algorithms is to learn the relationships between the input and output parameters in the data set and to model these relationships. The mentioned methods learn by analyzing the patterns in the data set; then, using these learned patterns, they predict the outputs corresponding to new data. Basically, a machine learning algorithm tries to predict the correct output or response to a new observation with the information it obtains from past data which are obtained by Hou, C., & Zhou, X. G. (2022). In this study, a new relationship was derived using the Gene Expression Programming (GEP) technique and compared with the existing relationships in the literature with the help of statistical parameters.

2. Summary of experimental data

In this study, a new equation was produced by processing the strong ground motion records of 28 earthquakes of worldwide importance.

3. Review of existing formulations for newmark method

According to time-acceleration record (Fig. 1), values of acceleration before X point are less than the sample value of critical acceleration of the slpoe (a_c=0.2g). Therefore, any ground movement doesn't occur. Between X and Y points, acceleration data are above the ciritical acceleration value and integrating this part of the acceleartion-time diagram, velocity-time graph can be obtained as a rising curve. Due to the inertia of the block, movement goes on to Z point. Reverse displacement and friction force cause to stop of the block at this point. Total displacement of the block can be calculated by integrating the velocity-time diagram when the same process continuous at the points that the acceleration values exceed the critical acceleration.

Siyahi et al. (2003) has suggested below equation to calculate the critical acceleration for any slope,

$$a_c = g\left[\frac{c}{\gamma h} + \cos\alpha\tan\phi - \sin\alpha\right] \tag{1}$$

Where, g is the gravitational acceleration, α is the angle of the plane of sliding block with horizontal, Ø is the friction angle of soil, c is the soil cohesion, γ is the unit weight of soil and h is the slope thickness.

Depending on this approximation Ambraseys and Menu (1988), Jibson et al. (1998), Jibson (2007), Hsieh and Chyi-Tyi (2011) and Yigit (2020) have devoleped equations 2-5 respectiveley.

$$\log\delta = 0.90 + \log\left[\left(1-\frac{a_c}{a_{max}}\right)^{2.53}\left(\frac{a_c}{a_{max}}\right)^{-1.09}\right] \tag{2}$$

$$\log\delta = 1.521\log I_a - 1.993\log a_c - 1.546 \tag{3}$$

$$\log\delta = 0.847\log I_a - 10.62a_c + 6.587a_c\log I_a + 1.84 \tag{4}$$

$$\log\delta = 1.2185\log I_a - 1.3669\log a_c + 1.5811\log\left(1-\frac{a_c}{a_{max}}\right) - 0.5532 \tag{5}$$

In these equations, ac is the critical acceleration in g and amax is the maximum acceleration in g, δ is displacement in cm, Ia (m/s) is Arias intensity described as follows by Arias (1970):

$$I_a = \frac{\pi}{2g}\int_0^{T_d}[a(t)]^2 dt \tag{6}$$

Depending on moment magnitude (M) and the earthquake source distance (R, km) Wilson and Keefer (1983) have suggested the Eq.7 to calculate Arias Intensity.

$$\log I_a = M - 2\log R - 4.1 \tag{7}$$

3.1. Gene Expression Programming (GEP)

Machine learning (ML) is one of the promising artificial methods increasingly used in engineering applications because it enables the extraction of meaningful information from large datasets and the optimization of processes. Gene expression programming (GEP) is a machine learning algorithm that learns the relationships between variables within datasets and creates models that explain these relationships. The model creation process with gene expression programming (GEP) begins with the random generation of chromosomes from the population within the defined dataset. These random chromosomes are evaluated for fitness and modified to create generations that acquire new characteristics. The chromosomes in these new generations undergo a similar development process, and this process is repeated until a suitable solution is reached. Thanks to the multiplication of chromosomes, genes are transferred to the next generation, and diversity is fostered through genetic operators. In deriving relationships with GEP, overly narrowing the application range of genetic operators can hinder the achievement of the correct solution by slowing the evolution rate of the population. Conversely, Ferreira, C. (2001 & 2002) showed that excessive expansion of the application range results in the emergence of numerous solutions that are far from optimal. In this study, model estimation was conducted using the GeneXproTools 5.0 program (GeneXproTools, 2023).

$$N_{GEP} = N_1 + N_2 + N_3 + N_4 + N_5 + N_6 \tag{8}$$

$$N_1 = \frac{\sin(-6{,}57766 * d_3) * (d_2 + \frac{d_0}{-6{,}57766})}{-(d_1 + 2{,}3284)} \tag{8a}$$

$$N_2 = \frac{d_3 * d_0}{\frac{d_0}{d_2} + (12{,}10504 - d_0)} \tag{8b}$$

$$N_3 = \frac{\sin(1{,}22610 * d_0) - d_3}{1 - \frac{6{,}12414}{d_1}} + d_0 \tag{8c}$$

$$N_4 = -\frac{d_3 - d_0 + \frac{1}{d_3}}{134{,}49739 * d_1} \tag{8d}$$

$$N_5 = \sin(\sin(d_3)) * (\sin(2d_1 - d_0 - d_2))^2 \tag{8e}$$

$$N_6 = e^{(\sin(d_0 * d_2) + d_1)} * (-1{,}20253 - d_3) \tag{8f}$$

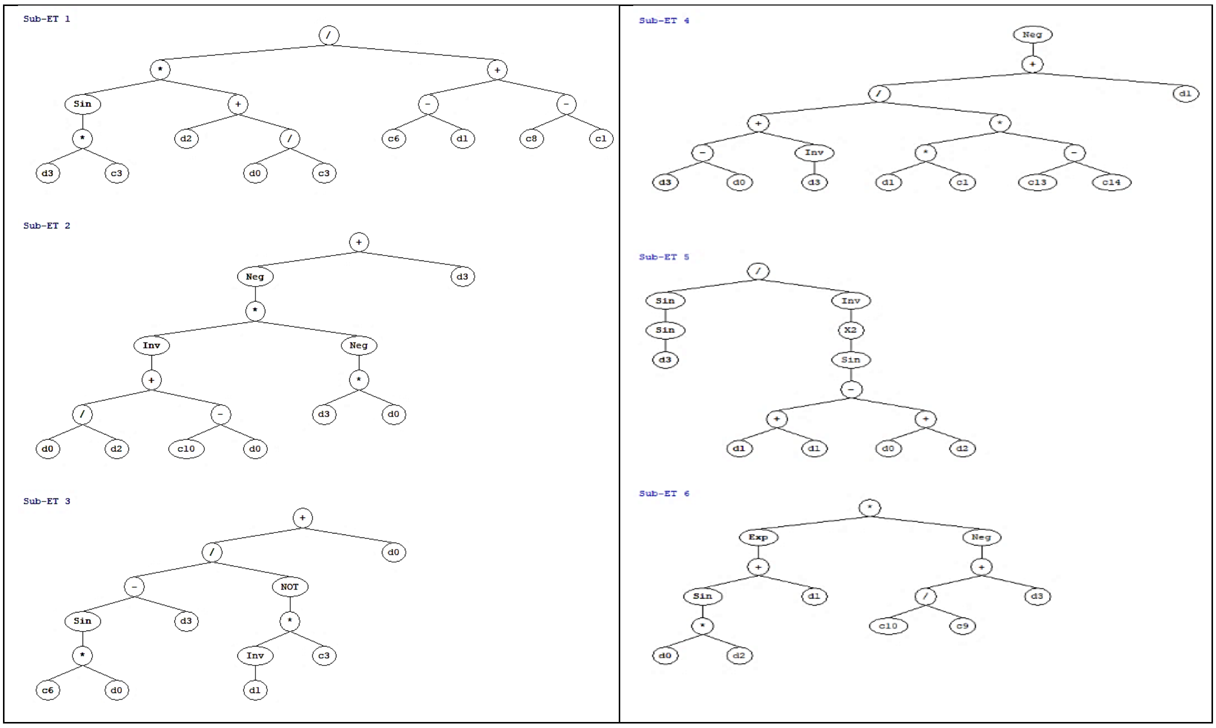

Fig. 2. GENE expression flowchart

To obtain the best fit result, the effects of linkage type, chromosome number, head and gene numbers, and selected mathematical functions on the relationship were explored through trial and error. The gene correlation equations that yielded the best fit results are presented below and displayed in the expression flowchart in Fig. 2.

Table 2. Optimal hyperparameters for ML models

Model	Details of Hyperparameters	
GEP	Input parameters	$\log I_A$, $\log A_C$, $\log(A_C/A_{max})$, $\log(1-A_C/A_{max})$
	Output parameter	$\log d$
	Training records (%75)	3790

4. Rerults and discussion

4.1. Model performance evaluation

In this study, the existing relations and the estimation results of the GEP Model were made based on statistical measures such as coefficient of determination (R^2), mean value (M), coefficient of variation (Cov), standard deviation (SD), mean absolute percentage error ($MAPE$) and root mean square error ($RMSE$).

Table 3.Statistical criteria

Statistical criteria	Formulation
Mean absolute percentage error	$MAPE = \frac{100}{n}\sum_{i=1}^{n}\left\lvert\frac{exp - model}{exp}\right\rvert$
Root mean square error	$RMSE = \sqrt{\frac{\sum_{i=1}^{n}(exp - model)^2}{n}}$
Coefficient of determination	$R^2 = \sqrt{\frac{\left[\sum_{i=1}^{n}(exp - \overline{exp})(model - \overline{model})\right]}{\sum_{i=1}^{n}(exp - \overline{exp})\sum_{i=1}^{n}(model - \overline{model})}}$
Coefficient of variation	$Cov = \frac{SD}{M} = \frac{\sqrt{\frac{\sum_{i=1}^{n}(\frac{exp}{model} - M)^2}{n-1}}}{\frac{\sum_{i=1}^{n}\frac{exp}{model}}{n}}$

4.2. Model comparison

The results of statistical comparisons using 3790 training and 1263 testing experiment data collected from the literature are compared in Table 4 for detailed analysis and visually in Fig. 3.

As a result of the comparisons, it was seen that the most reliable estimation result was obtained from the GEP Model. In the comparisons made with the help of statistical parameters, the GEP Model gave the closest results to the real results with the values of R^2=0.860, M=0.906 and RMSE=0.375.

Table 4. Comparisons of different statistical researchers' models

Researcher	$\boldsymbol{R^2}$	$\boldsymbol{COV}$	$\boldsymbol{M}$	$\boldsymbol{SD}$	$\boldsymbol{MAPE}$	$\boldsymbol{RMSE}$
GEP Model	0.860	1.502	0.906	1.361	63.328	0.375
Yiğit (2020)	0.842	1.494	0.826	1.233	61.598	0.401
Hasieh and Chyi-Tyi (2011)	0.691	3.430	0.678	2.325	117.021	0.653
Jibson98 (1998)	0.773	1.798	0.727	1.306	67.857	0.496
Anbraseys ve Menu (1988)	0.687	4.361	0.756	3.297	157.933	0.737

Fig. 3 shows the comparison of the researcher's relations with the measurement results. There is a line with a slope of y=x in the graph. If the experimental and relation results are equal, the points are on the line. If there is a separation in the experimental and relation results, the points move away from the line.

When Table 4 and Fig. 3 are examined, they show a comparison of models from different researchers based on statistical performance criteria. Overall, the GEP Model delivers the best results when all metrics are considered. With an R^2 value of 0.860, it stands out as the model with the highest explanatory power, while the lowest RMSE and MAPE values indicate that this model has very low error rates. This also shows that GEP best captures the relationships among the data and has the least deviation in its predictions.

When looking at the Yiğit (2020) model, the R^2 value is quite high at 0.842 and shows a success that is quite close to the GEP model. When looking at the MAPE value, the Yiğit model offers the lowest percentage error and leaves GEP behind in this metric. This indicates how successful the model is in making predictions, especially proportionally. However, since it makes slightly more errors than the GEP model in the RMSE value, it ranks second in overall accuracy.

One of the older models, Jibson (1993), shows a moderate success in terms of R^2 value, while both MAPE and RMSE values are higher than the GEP and Yiğit models. This shows that although the model provides acceptable accuracy, it falls short of newer methods.

The Hasieh and Chyi-Tyi (2011) model has a very high error rate and a low R^2 value. The model has limited explanatory power for the data and its estimation errors are significantly high. Similarly, the Ambraseys and Menu (1988) model also has low performance. This model is at the bottom of the list with both the lowest R^2 value and the highest MAPE and RMSE values, and is inadequate to meet today's modeling needs.

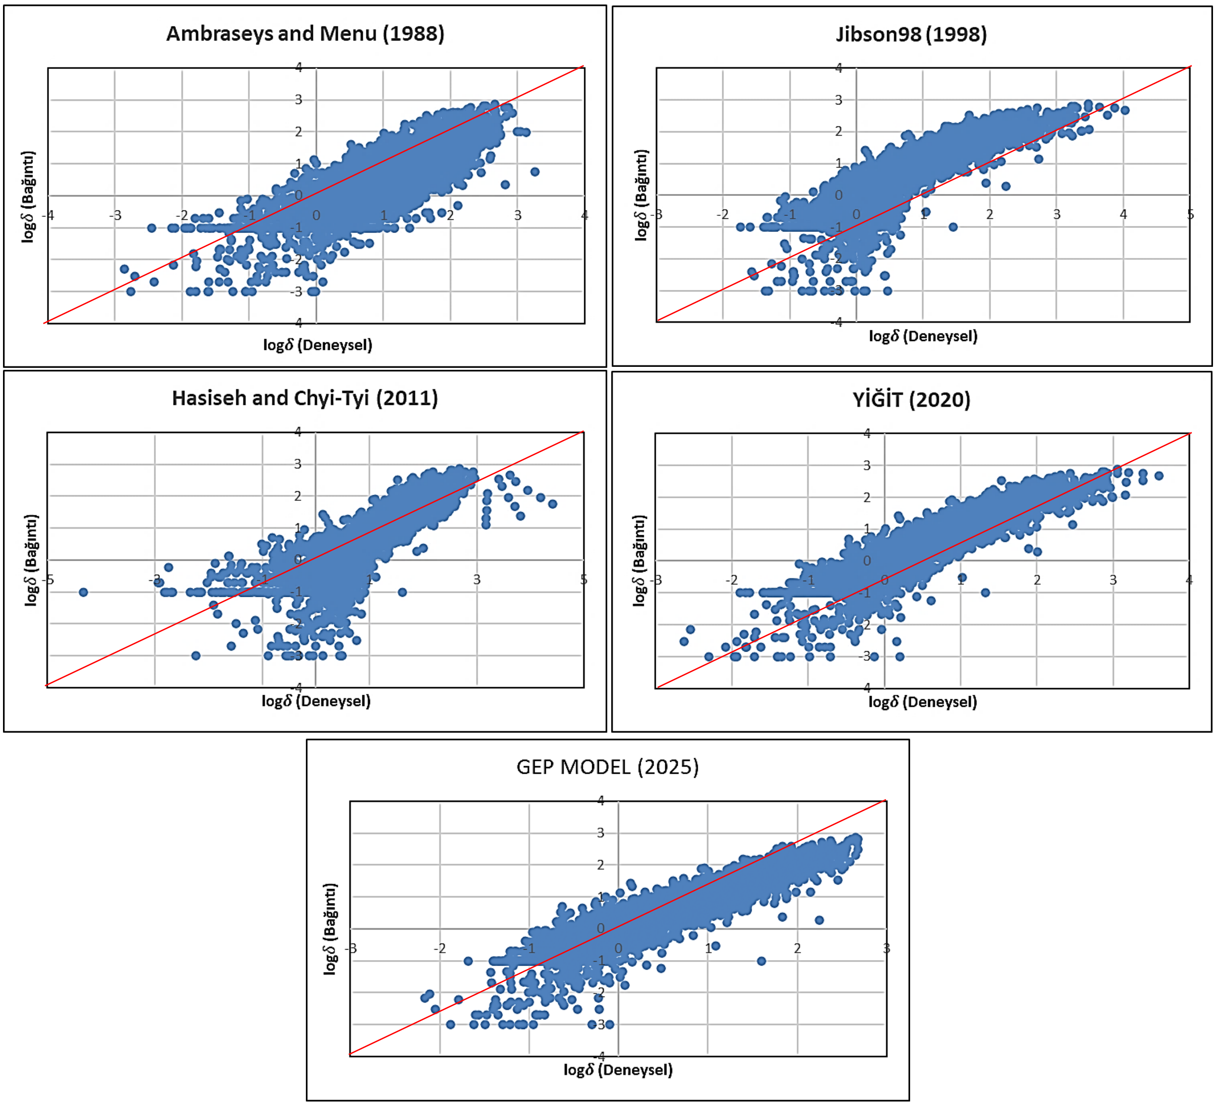

Fig. 3. A comparison of statistical models created by different researchers

5. Conclusions

In this study, Gene Expression Programming (GEP) was used to estimate the ground displacement according to the Newmark Method. These predictions were made using 28 earthquake acceleration records collected from the literature. The prediction results of the GEP Model were compared statistically with the prediction results of the existing correlations obtained from the earthquake acceleration records. The results obtained within the scope of this study are summarized below.

- As a result, when we evaluate the table in general, it shows that the GEP and Yiğit models fit the data better and provide more reliable results. In particular, the GEP Model stands out as the most successful model by exhibiting a balanced and superior performance in all metrics. It is clearly seen that the old models cannot reach the high accuracy and low error levels obtained with current methods.

[1] *Atatürk University, Department of Civil Engineering, 25240 Erzurum, Türkiye*

Abstract. Cement used in concrete production contributes to environmental problems and global warming due to high energy consumption, carbon footprint, and excessive use of natural resources. In this direction, research into sustainable binders is increasing. Geopolymer concrete, which has superior mechanical and durability properties, stands out as an environmentally friendly alternative due to its potential to use industrial waste as a raw material. In this study, the effect of 15% substitution of ground blast furnace slag (GBFS) with natural zeolite (NZ) and 0.3% and 0.6% by volume of glass fiber (GF) on the physical and mechanical properties of concrete in geopolymer composite based on GBFS, an industrial by-product, was investigated. The conclusion display that adding GF and NZ reduces the geopolymer composite's porosity and water absorption percentage. As a result of the reduction in porosity, an increase in flexural and compressive strength was noted in the specimens containing GF and NZ. When compressive strength and mass loss were evaluated by exposing the samples to temperatures of 200°C, 400°C and 600°C, the strength increased with increasing gel formation at 200°C. In comparison, a decrease was observed at 400°C and 600°C. However, increasing fiber content and zeolite addition positively affected high-temperature strength. It was also found that adding NZ and GF reduced the loss of compressive strength in specimens subjected to 18 freeze-thaw cycles. In general, 15% zeolite substitution and 0.3-0.6% GF were found to improve the performance of geopolymer composite.

Keywords: Geopolymer; Zeolite; GBFS; Glass fiber; Durability

1. Introduction

Cement production, the raw material for concrete, the most widely used building material in the construction industry, involves much energy consumption and CO2 gas emissions (rashadll et al., 2016; Rashad et al., 2023). At the same time, the need for natural raw materials in cement production leads to the over-exploitation of natural resource reserves, which causes serious environmental problems in the concrete industry (Summerbell et al., 2016). There has been a search for sustainable materials with low energy consumption and carbon footprint to address these issues. Geopolymer, developed as an alternative to cement and first introduced by J. Davidovits in the 1970s, is a result of this search. Geopolymer is an inorganic polymeric building material formed by the reaction of alumina and silicate-rich materials such as metakaolin, GBFS with strong alkalis such as Na2SiO3, KOH under appropriate curing conditions (Davidovits, 1999). Geopolymers have properties such as high early strength, good thermal resistance, fire resistance, high resistance to sulphate and acid attack, low shrinkage, and disposal of industrial wastes such as blast-furnace slag (BFS) and fly ash (Das & Rout, 2021).

Precursor materials, the raw materials used in geopolymer production, can be natural materials such as zeolite, kaolin and fly ash, or industrial wastes such as metakaolin, BFS and fly ash, which are commonly used in geopolymer production (Nikolov et al., 2017). Among these materials, GBFS, which has pozzolanic and cementitious properties, is an industrial by-product of steel production (Feng et al., 2024). The main product formed by the reaction between high calcium slag and alkaline activator is aluminium (Al) and calcium silicate hydrate with a structure known as C-A-S-H (Das & Rout, 2021). The main problem with GBFS-based geopolymers is their poor workability and rapid setting (Das & Rout, 2021). Each of these precursors has some limitations and good properties. For this reason, many studies aim to obtain geopolymer concrete with better properties by combining different precursor materials. Apart from these, natural pozzolans are also used as geopolymer precursors. For example, the inexpensive and widely available zeolite is a microporous volcanic mineral composed of hydrated aluminosilicate minerals. Due to its microporosity, it reduces workability and increases water requirements. Still, its fine particles can help fill microvoids in the concrete matrix, increasing strength and reducing permeability (Shoaei et al., 2024). However, in some studies where cement and zeolite were used

* Corresponding author, E-mail: gamzeucdemir@atauni.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_337

together, a decrease in strength was observed due to increased zeolite (Milović et al., 2022; Karakurt & Topçu, 2011).

Huseien et al. (2018) researched the properties of geopolymer mortars obtained using metakaolin instead of 0-15% GBFS. The mechanical properties of geopolymer mortars were also compared with those of mortars made with Portland cement. According to the results obtained, it was observed that as the metakaolin ratio increased, the setting time increased and the workability of the mortar decreased. In addition, it was found that the flexural and tensile strength of geopolymer mortars reached higher values compared to Portland cement mortars. In another study, the effect of zeolites on geopolymers was studied. It was found that the properties of the hybrid materials formed this way are superior to the raw materials that create them. While the hybrid material formed in this study has high strength due to the geopolymer, the zeolite gives the hybrid material a high surface area and adsorption capacity (Rożek et al., 2019). In the study conducted by Wongsa et al. (2020), the fire behaviour of geopolymer mortar obtained by replacing high calcium fly ash with zeolite and mullite at 10%, 20% and 30% by weight was investigated. According to the results, the fire resistance of the geopolymer mortar obtained using zeolite and mullite alone and together increased. Das and Rout (2021) investigated the properties of fly ash and GBFS based geopolymer materials. As a result of the study, it was found that the strength of fly ash based geopolymer increased due to the formation of N-A-S-H and C-A-S-H gel with the addition of GBFS. Zhang et al. (2023) investigated the effect of silica fume on the drying shrinkage behaviour of FA and GBFS based geopolymer pastes. It was observed that adding silica fume delayed the hydration of calcium silica in the geopolymer and reduced the early strength of the geopolymer. In addition, an improvement in the 28-day compressive strength and a decrease in the drying shrinkage stress were observed due to the reduction of pores in the geopolymer when the silica fume content reached 20%. Amari et al. (2024) studied the properties of zeolite-based geopolymer materials containing different amounts of blast-furnace slag. The study found that geopolymer concrete significantly reduced CO2 emissions compared to conventional cement concrete and showed that the compressive strength did not always increase in direct proportion to the amount of slag, but increased the rate of initial setting. It was also found that the geopolymers produced were resistant to temperatures of up to 800°C.

Chemical fibers such as carbon, steel, and glass fibers are widely used in composites to improve mechanical properties such as flexural strength and control micro-cracks in the material. In addition, depending on the type of fiber, it can be used for various purposes such as increasing electrical conductivity and fire resistance. Although artificial fibers are not sustainable, they are generally more reproducible than natural fibers due to their higher strength (Růžek et al., 2023). Noushini et al. (2018) investigated the effect of different sizes of polypropylene and polyolefin synthetic fibers on the mechanical performance of fly ash-based geopolymer concrete. Due to the low strength of the fibers reinforced in the geopolymer concrete, a decrease in compressive strength was observed compared to concrete without fiber addition. However, an increase in flexural toughness and fracture energy was observed. Alves et al. (2021) examined the effect of adding glass fibers at different ratios to a geopolymer whose precursor is blast-furnace slag on the geopolymer. According to the study results, while the composite's machinability decreases with increasing fiber content, shrinkage cracks are under control thanks to the fibers. The mechanical properties of the geopolymer increase in direct proportion with increasing fiber content up to 0.75% fiber content. On the other hand, the mechanical properties and durability of the geopolymer were negatively affected as the composite obtained by adding 1% fibers was not homogeneous. The study by Hussain et al. (2024) investigated the changes in the mechanical properties of concrete by adding different proportions of steel and polyvinyl alcohol fibers to geopolymer concrete prepared using fly ash, silica fume and slag precursors. The study reported that the fibers limited the shrinkage due to rapid gelation in slag concrete. In addition, the strength of the geopolymer with steel fibers increased more than that of the concrete with polyvinyl alcohol fibers. Still, after exposing the concrete specimens to acid attack, it was observed that the strength of these concretes decreased less than that of those with steel fibers due to the corrosion resistance of the polyvinyl alcohol fibers. Hamdi and Farhan (2025) investigated the effect of glass fibers and ground glass fibers, a by-product of glass fibers, on slag based geopolymer concrete. The workability of the mixes changed depending on the fiber content and length. While the workability decreased with the use of glass fibers and increased fiber length, it was observed that the workability increased with the use of ground glass fibers by up to 10%. Similarly, increased compressive strength was observed with ground glass fiber up to 10%, while increased fiber content decreased strength. An increase in compressive strength was observed with the use of 5% and 10% ground fibers at 150 and 300˚C compared to concrete without fibers, but at 600 and 800˚C concrete specimens with fibers exhibited lower compressive strength than those without fibers.

Many studies in the literature determine the mechanical and durability properties of geopolymer mortars produced using artificial or natural precursors. This study investigated the effect of substituting 15% of GBFS with zeolite and adding glass fiber in different proportions on the properties of concrete in GBFS-based geopolymer concrete mixes. The mechanical properties of the prepared geopolymer specimens were determined, and their resistance performances, such as those of fire and chemical attacks, were evaluated. The effects of zeolite and glass fiber admixtures on GBFS-based geopolymer concrete were comprehensively investigated.

2. Materials and methods

2.1. Raw materials

This study used GBFS and natural zeolite (NZ) as binder materials to produce geopolymer blends. GBFS's specific gravity is 2.84, and its surface area (Blaine method) is 5200 cm2/g. NZ's specific gravity is 2.34, and its surface area is 3200 cm2/g. Table 1 presents the chemical characterisation of GBFS and NZ.

Pumice aggregate with a specific gravity of 1.82 and a water absorption rate of 10.3% was used to prepare geopolymer mixtures. The particle distribution of pumice aggregate with 0-4 mm sieve opening according to ASTM C33 standard is given in Fig. 1. The technical properties of the 12 mm long glass fibre (GF) used in the production of the blends are shown in Table 2.

In this study, sodium hydroxide (NaOH, 12M) and sodium silicate (Na_2SiO_3, liquid) were used as alkali activators in the production of geopolymer mix. Each of these materials plays a critical role in the alkali activation process and ensures the formation of the geopolymer matrix. Sodium hydroxide is a potent alkaline compound that provides a highly alkaline environment. This solution's concentration determines NaOH's effectiveness in initiating solubility and alkali activation reactions. This study used a 12 molar (12M) sodium hydroxide solution. Sodium hydroxide dissolves silicate-based materials (e.g. GBFS, fly ash) in an alkaline environment, breaking the bonds between silica and alumina and promoting the initiation of the geopolymerisation reaction. The NaOH solution was prepared 24 hours before casting. Sodium silicate (Na_2SiO_3) is an alkali metal compound with a silicate structure and is used as an essential activator, especially in alkali activation systems such as geopolymers. The specific gravity of Na_2SiO_3 solution is 1.42 and the silica modulus is 2 (Na_2O=:15.9%, SiO_2: 31.4%).

Table 1. Chemical characterisation of GBFS and NZ

	CaO	SiO_2	Al_2O_3	Fe_2O_3	MgO	Na_2O	K_2O	SO_3	LOI*
GBFS	41.1	33.1	9.8	1.3	13.4	0.3	0.5	0.1	0.3
NZ	1.8	67.7	8.9	1.8	0.2	0.8	1.9	0.1	16.7

Table 2. Technical specifications of the GF

Length (mm)	Diameter (μm)	Tensile strength (MPa)	Modulus of Elasticity (GPa)	Elongation (%)	Density	Color
12	19	1700	72	3.8	2.60	White

2.2. Mix design

GBFS and NZ were used as the main binder in preparing geopolymer mixtures at a 750 kg/m3 dosage. NZ has been replaced by GBFS by 15 per cent by weight. GF added to the mixtures were 0.3% and 0.6% by volume. Alkaline solution consisting of NaOH and Na_2SiO_3 was used at 98% of the binder amount. Due to the high water absorption rate of pumice aggregate and the use of fibre in the mixtures, the amount of alkaline solution was selected high. This way was chosen to reduce the workability losses caused by these two components. The ratio of Na_2SiO_3 and NaOH is 2.5 in all mixtures. Material quantities and mixing ratios of geopolymer blends are given in Table 3.

Table 3. Material quantities and mixing ratios of geopolymer blends

kg/m^3	0GFZ0	3GFZ0	6GFZ0	0GFZ15	3GFZ15	6GFZ15
GBFS	750	750	750	637,5	637,5	637,5
NZ	0	0	0	112,5	112,5	112,5
NaOH	210	210	210	210	210	210
Na_2SiO_3	525	525	525	525	525	525
GF	0	8	16	0	8	16
Pumice aggregate	393	387	380	371	364	358

2.3. Mixing, casting and curing

Mixing was started by mixing GBFS and NZ at low speed for 1 minute. Afterwards, the alkali Solutions were added to the dry mixture and the wet mixture (paste) was obtained by mixing at low speed for 1 minute and at high speed for 2 minutes. In the third step, pumice aggregate was added to the mixture and the mortar mixture was obtained by mixing at low speed for 1 minute and high speed for 2 minutes. In the last step, GF was added to the mortar mixture and mixed at low speed for 1 minute and at high speed for 3 minutes (until homogeneity was obtained). The fiber reinforced geopolymer mixture was then placed in the moulds, covered with cling film and immediately placed in the oven. In the oven with a heating rate of 5 ºC/min, all samples were cured at 70 ºC for 16 hours. The specimens were cooled in the oven at the end of thermal curing. After approximately 1 day (including cooling in the oven), the specimens were removed from the moulds and immediately subjected to physical, mechanical and durability tests.

2.4. Experimental setup

Physical properties of the samples such as water absorption, apparent porosity and dry density were measured. Water absorption and apparent porosity tests were started 24 hours after casting. For this aim, 50x50x50 mm cube specimens were produced following ASTM C642 standard. TS EN 1015-18 standard was used for capillary water absorption test. In this context, 24 50x50x50 mm cube specimens were produced and the amount of water absorbed by capillary at the end of 24 hours was measured. The compressive strength of the specimens was determined approximately 1 day after casting. For this purpose, flexural strength (three-point) was determined by ASTM C348 standard. For flexural strength, 40x40x160 mm specimens were produced. Compressive strength was measured per ASTM C349 standard for specimens broken in half in the flexural test. A muffle furnace was used to determine the high temperature resistance of the samples at 200, 400, and 600 oC. The heating rate of the muffle furnace is 10 ºC/min. The samples were kept for 2 hours after reaching the target temperature and then cooled under laboratory conditions (removed from the muffle furnace). After obtaining constant weight values, weight losses of the samples were determined and compressive strengths were measured. In addition, 20 freeze-thaw cycles (F-T) were applied to the samples to assess the freeze-thaw durability. F-T resistance was performed according to ASTM C666 standard. The samples were kept at -20 ºC for 7 hours and at +4 ºC for 5 hours, and 2 cycles per day were completed. As a result of the cycles, the specimens' weight loss and compressive strength were determined. 50x50x50 mm cube specimens were used to determine the high temperature and freeze-thaw resistance.

3. Results and discussion

This research focused on determining the effect of 15% NZ substitution and different amounts of GF on the physical and mechanical properties of GBFS-based geopolymer blend. The results of the experiments are presented in detail in the following sections.

3.1. Physical properties

The apparent porosity and oven dry density values of the geopolymer blends are shown in Fig. 2. As shown in Fig. 2, the apparent porosity decreases from 2.6 to 8% as the GF content increases. Similarly, the oven dry density increases from 1.6 to 4.2% as the GF content increases. It can be concluded that the GF used in the mixes acted as a micro-aggregate and thus the apparent voids were relatively reduced. In the study by Öz et al. (2023), it was shown that in hot cured GBFS-metakaolin based geopolymer blends, as the amount of polyvinyl alcohol fibers increased, the apparent porosity decreased as a result of the fibers exhibiting microaggregate properties. In addition, Xie et al. (2022) found that using fibers reduced porosity and water absorption because fibers break the connection between pores in the matrix and fill some pores.

A decrease in the apparent porosity value was generally observed by adding NZ. This may be due to the zeolite acting as a micro-filler in the matrix and reducing the porosity of the mortar (Wang et al., 2024). In the mixes where NZ was used, there was a 4.7% decrease in the apparent porosity value of the no GF mix, a 1.6% decrease in the 0.6% vol. GF mix and a 1% increase in the 0.3% vol. GF mix. Thus, the NZ contributed more to the reduction in apparent porosity in the no GF mix. In contrast to porosity, oven dry weight decreased by 4.2 to 4.7% using NZ. The lower specific gravity of zeolite can explain this compared to GBFS (Efe et al., 2024).

Fig. 3 shows geopolymer blends' percentage of submerged and capillary water absorption. The graph shows that increasing GF content decreases the submerged and capillary water absorption rate. This is due to the hydrophilic properties of the GF, which creates a tight adhesion between the matrix and the GF, reducing the porosity and decreasing the sample's water absorption (Mohseni et al., 2016; Yuan & Jia, 2021). With the use of NZ, the percentage of submerged water absorption was obtained in parallel with the porosity, as expected, and there was a decrease ranging from 1.9 to 6.6% among the blends. Hosseinzadehfard and Mobaraki (2024) focused on determining the impact of microsilica and natural pozzolan on the strength and durability of concrete. Similar results were obtained in the study by Sharbaf et al. (2022). However, using NZ increased the capillary water absorption of the mixes by between 5.7 and 24.5%. Similarly, in the study by Sharbaf et al. (2022), there was a decrease in the percentage of water absorption as the amount of pozzolan increased, while the rate of capillary water absorption increased. This shows that despite reducing the amount of voids, the interconnection between the voids increases.

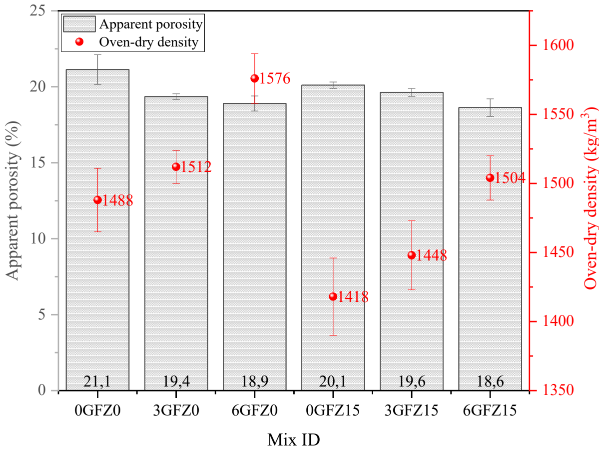

Fig. 2. Apparent porosity and oven-dry density of geopolymer mixes

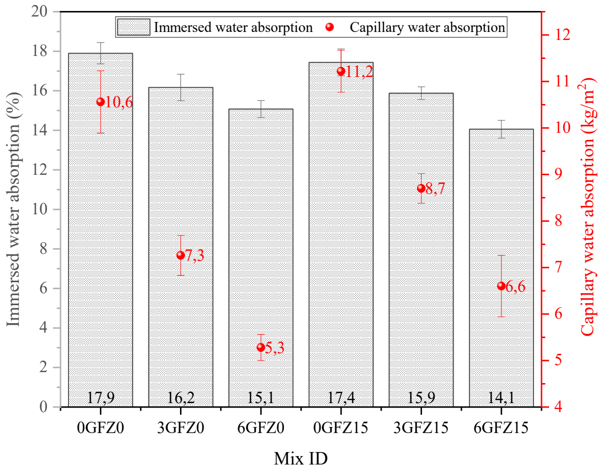

Fig. 3. Immersed water absorption and capillary water absorption of geopolymer mixes

3.2. Mechanical properties

In this part of the work, the impact of NZ and GF on the mechanical properties of GBFS based geopolymer blend was investigated. Fig. 4 shows the test results for flexural and compressive strength of the geopolymer mixes. Fig. 4 shows an increase in compressive strength ranging from 7.4 to 19% depending on the rise in GF ratio. Moreover, a higher GF ratio led to a rise in flexural strength ranging from 22 to 30%. In the previous section, the porosity of concrete is reduced due to the GF used in the mixes acting as a micro-aggregate. The results obtained here support the increase in compressive strength. As mentioned earlier, using fiber has resulted in a more compact concrete by exhibiting micro-aggregate properties. Therefore, the compressive strength of concrete with fewer voids is also higher (Ganesh & Muthukannan, 2021; Yuan & Jia, 2021; Akarken & Cengiz, 2023; Çelik & Özkiliç, 2024). The flexural strength of concrete was increased because the GF used limited cracking (Alves et al., 2021; Akarken & Cengiz, 2023; Çelik & Özkiliç, 2024). In addition, the flexural and compressive strength increased due to the increased amount of zeolite, as zeolite acts as a microfiller and reduces the amount of voids (Andrejkovičová et al., 2016).

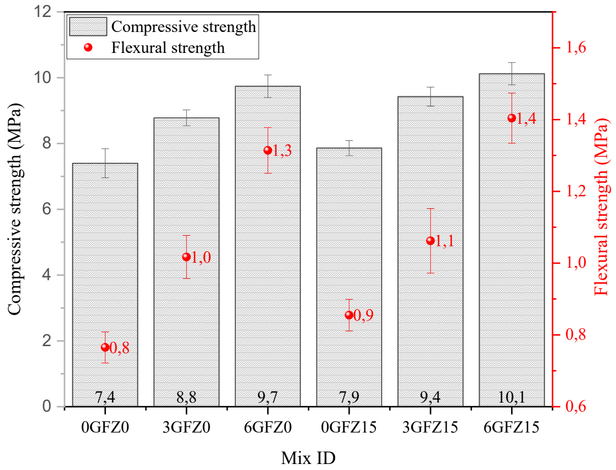

Fig. 4. Compressive strength and flexural strength of geopolymer mixes

3.3. High-temperature resistance

The prepared geopolymer mixes were exposed to 200, 400 and 600˚C for 2 hours to test their high-temperature resistance. Fig. 5 shows the compressive strength of the specimens exposed to high temperature. With the use of GF, the compressive strength of the specimens exposed to 200˚C increased from 33.8% to 57.4%, while 400 and 600˚C temperatures were detrimental to the internal structure of the specimens and reduced the strength. The decrease in compressive strength of concrete specimens exposed to 400˚C temperature varies between 1.3-16%, while the decline at 600˚C temperature varies between 13-23%. As the temperature increases, the gel structure in the matrix degrades more, accelerating the increase in strength loss. In addition, Fig. 5 shows an increase in strength with the rise in GF content between the mixtures with and without NZ. In general, the rise in compressive strength of the samples without NZ at 200˚C is 41.4% on average, whereas the rate of rise in the samples with NZ is 52.4%. As can be seen, the rise in compressive strength is higher for the specimens with NZ. At a temperature of 400˚C, the loss rate of compressive strength in specimens without NZ is 9.2% on average, while this rate is 7.5% in specimens with NZ. A similar situation was observed for specimens exposed to 600˚C. At 600˚C, the average rate of strength loss in the mixtures without NZ is 19.4%, while this rate is 14% in the mixtures with NZ. As seen from this, the loss of compressive strength is reduced using NZ in specimens exposed to high temperatures. In addition, there is an rise in strength with increasing GF content between the mixes with and without NZ. It should also be noted that the most significant decrease in strength at both 400 and 600˚C occurred in the specimen without NZ and with 0.3% GF by volume. Furthermore, as mentioned in section 3.3, increasing the amount of NZ and GF positively affected the strength. Degirmenci (2018) investigated the freeze-thaw and high temperature resistance of pozzolan-based geopolymeric mortars. The strength and mass loss results of GBFS and GBFS+zeolite-based geopolymer mortars exposed to temperatures 300, 600 and 900˚C were evaluated. The results show that using NZ increases the compressive strength of the mortar after high temperature and reduces the mass loss.

The mass loss values of the samples exposed to high temperature are shown in Fig. 6. As can be seen from the figure, the mass loss increases as expected with increasing temperature. The main reason for this is the evaporation of the water contained in the alkaline activators from the matrix in the geopolymer samples exposed to high temperature and the consequent dehydration of the mortar sample. In addition, capillary and microcracks formed in the samples under the influence of high temperature expand over time and turn into macrocracks. This process results in the development of voids in the microstructure of the samples (Guler & Akbulut, 2022). In addition, the mass loss decreases with increasing GF content. In addition, while the mass loss rate of the samples without NZ at 200˚C is 6.3% on average, this rate is 5.8% for the samples with NZ. At 400 and 600˚C the mass loss rate of the samples without NZ is 15.4% and 17.6% respectively, while the mass loss rate of the samples with NZ is 13.9% and 16.7% respectively. It is evident that the mass loss decreases with the addition of NZ in concrete specimens exposed to high temperatures.

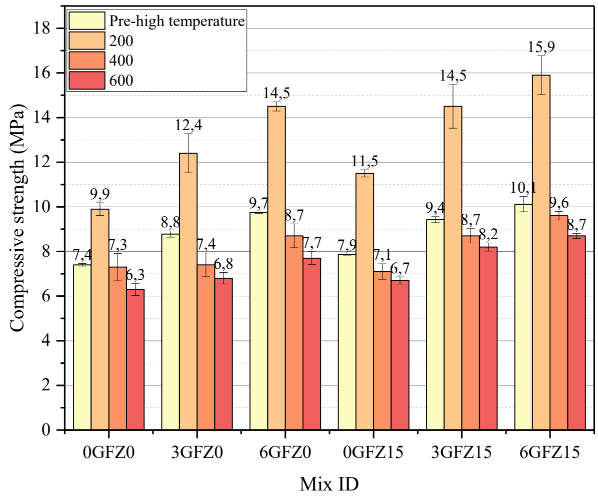

Fig. 5. Compressive strength of geopolymer mixtures exposed to high temperature

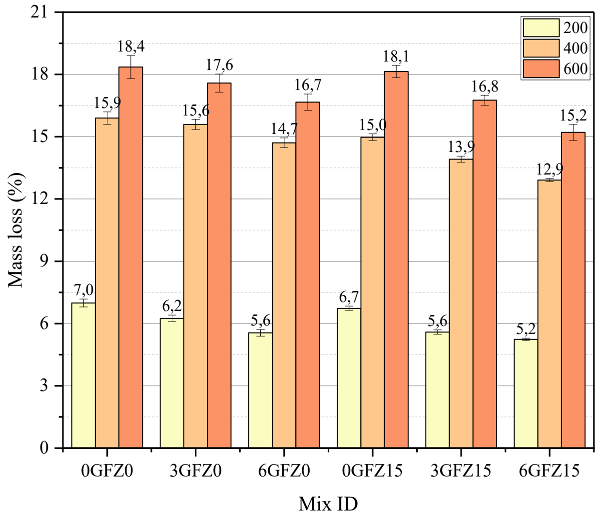

Fig. 6. Loss of mass in geopolymeric mortar samples exposed to high temperatures

3.4. Freeze and thaw resistance

A total of 20 cycles of freeze-thaw testing were performed (Fig. 7). The compressive strength and mass loss values obtained as a result of the test are shown in Fig. 8. While the average loss in compressive strength was 17.4% for the samples without NZ, this was reduced to 10.2% for the mixtures containing NZ. When the glass fibre contribution was examined, the loss in strength was found to be 9.95% in the samples containing 0.3% glass fibre and 5% in the samples containing 0.6% glass fibre. The results show that the strength loss decreases as the fibre content increases.

When evaluated in terms of mass loss, the highest loss was observed in the mixtures without NZ and fibre (Fig. 8). While the average mass loss in the NZ-free samples was 7.9%, this was reduced to 5.5% in the NZ-added samples. When the effect of glass fibre was examined, the average mass loss was 6.1% in samples containing 0.3% glass fibre and 3.7% in samples containing 0.6% glass fibre. The results show that the mass loss decreases with increasing glass fibre content. The results show that using glass fibre and NZ significantly reduces freeze-thaw damage in geopolymer samples.

Fig. 7. Appearance of geopolymer mortar specimens subjected to freeze-thaw cycles

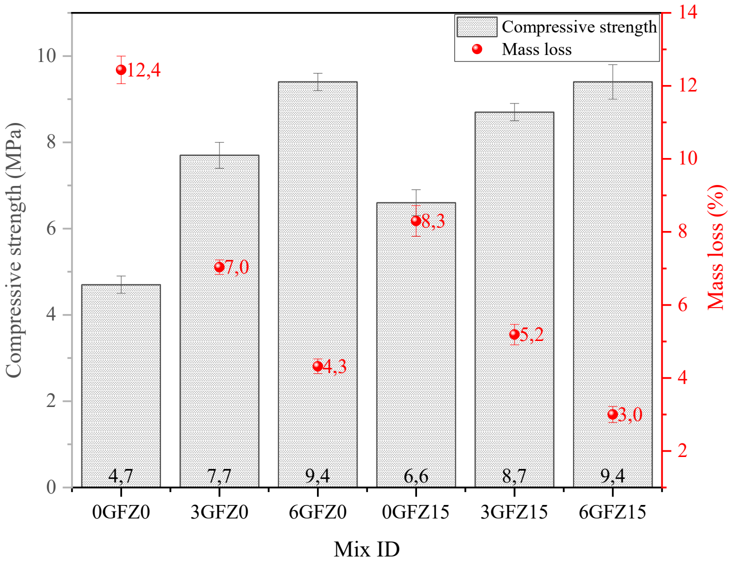

Fig. 8. Compressive strength and mass loss values of geopolymer mortar specimens subjected to freeze-thaw cycles

No study in the literature examines the F-T resistance of NZ-containing geopolymers in detail. The freeze-thaw resistance of NZ is mainly investigated in cement-based composites. The freeze-thaw resistance of the zeolite-based geopolymer mortars is lower than that of those based on fly ash and GBFS, with the residual compressive strength after 25 freeze-thaw cycles dropping to around 74%, indicating a reduction in durability (Degirmenci, 2018). The freeze-thaw resistance of zeolite-containing geopolymers is enhanced by the moist environment during curing, which promotes continuous slag activation and strength development, resulting in improved freeze-thaw durability, particularly in low cycle applications (Aygörmez, 2021). The freeze-thaw resistance of geopolymer-zeolite cementitious composites (GZCC) is poor. All samples fractured after 2 to 20 cycles due to increased open porosity caused by zeolitic crystal formation, allowing easy water ingress during freeze-thaw exposure (Khalid, 2023).

4. Conclusions

Many studies are currently being conducted to develop alternative binders to cement, the main concrete component widely used in buildings due to the high CO_2 emissions and energy consumption required in production. Recently, geopolymer blends obtained by alkaline activation of alumino-silicate compounds have been investigated intensively because they are more environmentally friendly and offer higher strength and durability than cement-based concretes. The present study, the effect of partial replacement of GBFS with zeolite at a rate of 15% and the use of GF at rates of 0.3% and 0.6% on the physical and mechanical properties of GBFS-based geopolymeric mortars was investigated and the results are presented below.

- The GF used in the mixes acts as a micro-aggregate and reduces the apparent porosity of the matrix. As the void content of the blends obtained decreases, the oven dry density rises as the GF content increases. As a result of the zeolite acting as a micro-filler in the matrix, the apparent porosity value generally decreased. However, the specific gravity decreased when zeolite, which has a lower specific gravity than GBFS, was used in the mortar.
- As the porosity decreased with the use of GF, the mortar's water absorption and capillary water absorption percentages decreased. However, when zeolite was added to the mixture, the water absorption percentage decreased as the number of voids decreased. In contrast, the capillary water absorption percentage increased as the connection between voids increased.
- When the mechanical properties of geopolymer mortars were investigated, it was found that GF and NZ made a positive contribution. The mortars' compressive and flexural strength increased with GF and NZ.
- When the resistance of the mortars to 200, 400, and 600˚C temperatures is examined, there is an increase in strength and a decrease in mass loss due to the rise in NZ and GF. Here, as gel formation increased in the matrix structure of the mixes exposed to 200˚C temperature, the strength showed an increase relative to the control mix. However, at 400 and 600˚C the gel structures in the matrix deteriorated and therefore the strength decreased.
- Similar results were observed in mortars subjected to 20 cycles of freeze-thaw. Increasing the amount of zeolite and glass fibre increased the compressive strength and reduced the mass loss. Accordingly, substituting GBFS with 15% NZ and using 0.3% and 0.6% GF improved the mechanical properties of the mortars and had no adverse effect after high temperature and freeze-thaw damage.

Abstract. The aim of this study is to evaluate the seismic performance and risk estimation of 100 m³ capacity elevated water tanks commonly constructed in Turkey. Although elevated water tanks were widely used in the past, their use has significantly decreased with the technological progress. However, elevated water tanks that are partially operational or idle, especially in agricultural and industrial facilities, may pose significant risks during potential earthquakes due to factors such as material strength degradation over time and lack of maintenance. These structures pose risks that could threaten human life and economic activities in both residential and industrial areas. Considering the low concrete strength and inadequate confinement effects observed in the current stock of elevated water tanks, it is essential to conduct a detailed evaluation of their structural condition and potential seismic performance. In this study, an elevated water tank with low concrete strength (C10), no confinement effect, and S220 reinforcing steel was analyzed. The tank levels (empty, half-full, and full) were considered as parameters. A total of 150 earthquake records, scaled according to $S_a(g)(T=1s)$, were generated: 15 records within the 0.1g–0.4g range and 15 within the 0.5g–1g range for both directions. Time-history analyses were performed, and the effects of tank filling on the fragility of elevated water tanks were investigated based on the results. The findings indicate that under poor material quality and unfavorable conditions, changes in water levels have no significant mitigating effect on structural response.

Keywords: Elevated tanks; Fragility curves;Performance evaluation

1. Introduction

Water is one of the fundamental resources for life, and its procurement and storage have a history as old as humanity itself. In the early periods, settlements were established around water sources, initiating a process that evolved over time with the development of various applications for water transportation and storage. Different designs have been created for water storage, among which elevated water tanks gained widespread use in the 19th century. Following the May 1960 Chile earthquake, investigations into damaged elevated water tanks revealed the necessity of considering the movement of water relative to the tank. In this context, Housner (1963) developed a mass-spring model by identifying that, in the presence of a free water surface, the system comprises two distinct masses. After this study, the use of elevated water tanks became more prevalent, leading to various research efforts focused on their design. Notable studies include those by Veletsos (1974), Dieterman (1988), Dutta et al. (2000), and Livaoğlu (2005).

In recent years, advancements in technology and improvements in the quality of construction materials have led to significant changes in water supply methods. Today, pressurizing and transmitting water directly from the main source using specialized equipment has become a common practice, enabling instant access to water. The widespread adoption of this new system has resulted in a noticeable decline in the number of elevated water tanks, which were frequently used in the past. However, elevated water tanks are still utilized in areas where continuous access to water is of critical importance, such as industrial facilities and regions with intensive agricultural activities. Historically, these structures were constructed in compliance with both national and international standards for water storage. However, over time, environmental factors have led to their deterioration, significantly compromising their structural integrity. Today, these aging elevated water tanks pose serious risks, particularly in the event of natural disasters such as earthquakes. Therefore, considering the existing structural degradation, a comprehensive assessment is essential, taking into account regional seismic hazard levels and the dynamic characteristics of these structures (Livaoğlu & Doğangün, 2003).

Fragility curves are fundamental analytical tools widely used to assess the seismic performance of various structural types and components. These curves enable the determination of structural fragility levels by accounting for uncertainty factors such as seismic hazard estimation, structural characteristics, soil-structure interaction, and site conditions. The development of fragility curves can be based on experimental, observational, expert judgment-based, and analytical methods. However, due to data limitations, experimental and expert judgment-based approaches may not always be feasible. Therefore, analytical methods provide a significant alternative for deriving fragility curves (Shinozuka et al., 2000).

The creation of fragility curves using analytical methods involves various numerical techniques, such as static pushover analysis, nonlinear time-history analysis, and incremental dynamic analysis. Particularly with advancements in technology and the increased computational capacity of computers, the use of nonlinear time-history analyses has become more widespread, leading to more accurate results. The obtained results are processed using appropriate fragility functions, providing an effective method for predicting the behavior of structures under potential earthquake scenarios. This process offers a crucial tool for evaluating the seismic performance of structures and determining possible damage levels.

For this study, the nonlinear dynamic analysis method in the time domain was chosen as the structural analysis technique. Selecting the necessary earthquake records plays a significant role in conducting these analyses. To ensure that scaling factors do not reach exaggerated values and deviate from accuracy, 15 different earthquake records scaled between 0.1g and 0.4g, and 15 different earthquake records scaled between 0.5g and 1g were selected, resulting in a total of 30 earthquake records. To obtain fragility curves for elevated water tanks, 150 dynamic analyses were performed for each of the three models with weak resistance (C10), representing fully filled, partially filled, and empty states. Fragility curves were derived based on the damage limit for the load-bearing elements, such as columns, using the concrete and reinforcement unit displacement limits.

2. Materials and methods

The creation of fragility curves to determine the seismic performance of structures is a critical area of research in earthquake engineering. However, limitations in obtaining experimental data and the subjective nature of expert judgment-based approaches make it necessary to develop these curves using analytical methods.

The role of analytical methods in the development of fragility curves is becoming increasingly important. To produce reliable results, it is essential to create a finite element model that accurately represents the physical and mechanical properties of the structural system. This model must reflect the geometry, material properties, and boundary conditions of the structure as closely as possible and should be capable of accurately predicting its behavior under seismic effects.

The accuracy of the finite element model directly impacts the reliability of the fragility curves. Therefore, analytical approaches should be applied meticulously during the calibration process of the fragility curves, and high precision must be maintained in the modeling procedures. In this study, a fiber model, which considers distributed plastic behavior, has been chosen to accurately represent the mechanical behavior of the load-bearing elements. Material assumptions were made considering the absence of confinement effects on the load-bearing elements. The damage limits were formulated based on the unit elongation and shortening of the concrete and reinforcement materials.

To evaluate the structural performance under seismic events, the aim is to generate fragility curves using the widely used Multiple Stripe Analysis (MSA) technique in earthquake engineering. This method includes structural analyses conducted at different intensity measure (IM) levels, with different ground motion records being used for each IM level. IM is a measure that expresses the intensity of ground shaking through spectral acceleration (Sa), peak ground acceleration (PGA), or other parameters.

One of the key reasons for selecting Multiple Stripe Analysis (MSA) over other methods (e.g., IDA, TIDA) is that it involves using independent ground motion records for each IM level, rather than scaling a single ground motion record to various intensity levels. This approach allows for a more realistic evaluation of structural behavior at different seismic intensity levels. Moreover, the accuracy and reliability of the method are enhanced through the use of conditional spectra or other advanced techniques when selecting appropriate ground motions for a specific region and IM level.

The purpose of Multiple Stripe Analysis is to comprehensively understand the performance of structures at different seismic levels. By analyzing how the structure responds to multiple ground motion records at various intensity levels, engineers can assess the performance of the structures, identify potential weak points, and determine areas that require design improvements. The analysis results provide critical data, such as fragility curves and capacity-demand diagrams, offering essential information for earthquake risk assessment and seismic structural design (Jack Baker, 2015).

A lognormal cumulative distribution function is often used to define a fragility function:

$$P(C|IM = x) = \Phi\left(\frac{\ln(x/\theta)}{\beta}\right) \tag{1}$$

P(C|IM = x) represents the probability of a ground motion with IM = x causing the collapse of the structure. Φ() stands for the standard normal cumulative distribution function. θ is the median of the fragility function (the IM level with a 50% collapse probability), and β is the standard deviation of ln IM (sometimes referred to as IM dispersion). Equation 1 implies that the IM values of ground motions causing the collapse of a specific structure follow a log-normal distribution; this is a widely accepted assumption in many cases Ibarra and Krawinkler (2005).

Structural analyses, for each intensity measure level IM = xj, generate a certain number of collapses from the total count of ground motions. Assuming that the observation of either collapse or non-collapse for each ground motion is independent of observations for other ground motions, the probability of observing zj collapses out of nj ground motions with IM = xj is given by the binomial distribution.

P(z_j collapses in n_j ground motions) :

$$\binom{n_j}{z_j} p_j^{zj}\left(1-p_j\right)^{nj-zj} \tag{2}$$

Here, pj represents the probability of a ground motion with IM = xj causing the collapse of the structure. Our objective is to determine the fragility function that predicts pj and the maximum likelihood approach identifies the fragility function that maximizes the probability of observing the collapse data obtained from structural analysis. When analysis data is obtained at multiple IM levels, the likelihood for the entire dataset is obtained by multiplying the binomial probabilities at each IM level (from Equation 2). Likelihood can be obtained as below.

$$\prod_{j=1}^{m}\binom{n_j}{z_j} p_j^{z_j}\left(1-p_j\right)^{n_j-z_j} \tag{3}$$

Here, m represents the number of IM levels, and Π is a product that goes over all levels. Subsequently, we substitute Equation 1 for pj, allowing the fragility parameters to be explicitly present in the likelihood function.

$$Likelihood=\prod_{j=1}^{m}\binom{n_j}{z_j}\Phi\left(\frac{\ln\left(x_j/\theta\right)}{\beta}\right)^{z_j}\left[1-\Phi\left(\frac{\ln\left(x_j/\theta\right)}{\beta}\right)\right]^{n_j-z_j} \tag{4}$$

The estimates of fragility function parameters are obtained by maximizing this likelihood function. To achieve the same outcome and facilitate numerical calculations, it is equivalent to maximizing the logarithm of the likelihood function. Therefore, it can perform this transformation as below:

$$\{\theta,\beta\}=\operatorname{argmax}\sum_{j=1}^{m}\left\{\ln\left(\binom{n_j}{z_j}+z_j ln\Phi\left(\frac{\ln\left(\frac{x_j}{\theta}\right)}{\beta}\right)+\left(n_j-z_j\right)ln\left(1-\Phi\left(\frac{\ln\left(\frac{x_j}{\theta}\right)}{\beta}\right)\right)\right\} \tag{5}$$

3. Modeling and analysis

Given that elevated water tanks in older building stock are known to be vulnerable to seismic effects due to low concrete strength and inadequate reinforcement arrangements, a typical elevated water tank with a 100 m³ storage capacity, designed by the General Directorate of Highways, Water, and Electricity (YSE) of the Republic of Turkey, was selected for this study. Considering the observed low concrete strength and reinforcement characteristics in these tanks, a seismic fragility analysis of this type of building stock has been conducted.

3.1. Selection and scaling of earthquakes

In order to perform seismic fragility analyses reliably, it is necessary to select and scale appropriate earthquake records. In this context, 30 earthquakes were selected, including 15 earthquakes scaled between 0.1g-0.4g and 15 earthquakes scaled between 0.5g-1g, taking into account factors such as site conditions, distance to the fault, and scaling coefficients. The station information, earthquake magnitudes, distance to the fault, and fault mechanisms for the selected earthquakes are presented in Table 1.

During the scaling process, the commonly accepted maximum scaling factor of 4 and minimum factor of 0.25, as found in the literature, were used to determine the earthquake scaling coefficients. These limits were applied to ensure that the changes in the frequency content of the earthquake records remained within acceptable levels and to guarantee the realistic scaling of the selected data set. In this study, analyses were performed using both the east-west and north-south components of each earthquake record. This approach aims to better reflect the multi-directional response of the structure to seismic effects.

During the earthquake data scaling process, the geometric average of the acceleration values corresponding to a 1-second period in both directions was calculated. Using these averages, a weighted acceleration value was determined. This method aims to represent the effects of earthquake records in different directions in a balanced manner. Table 2 presents the acceleration spectral values for the east-west and north-south directions of the selected 30 earthquakes, along with their geometric averages. After determining the spectral acceleration (Sa, g) values corresponding to the geometric averages, the earthquake records were either reduced or amplified using the necessary scaling coefficients. This process ensured that the intensity measure (IM) used in the analyses was obtained at the desired level.

Table 1. Selected earthquake records

RSN	Earthquake Name	Year	Station Name	Magnitude	Mechanism	Rrup (km)	Vs30 (m/sec)

The spectra obtained for both components of the selected 30 earthquakes were calculated, and then the scaled earthquake spectra based on the selected earthquake spectra and IM (intensity measure) values were presented. The scaled spectra for the 0.1g-0.4g range are shown in Fig. 1, and the scaled spectra for the 0.5g-1g range are shown in Fig. 2.

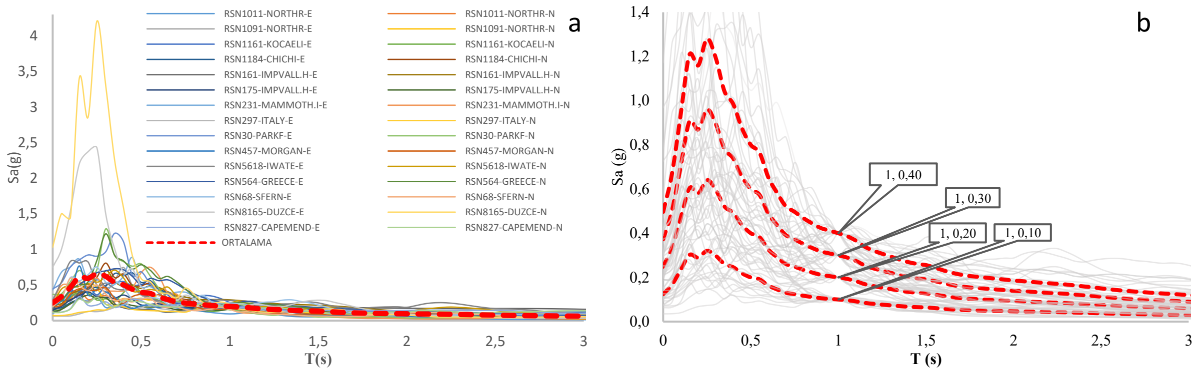

Fig. 1. Selected Spectra for 0.1g-0.4g IM Level (a), Scaled Spectra for 0.1g-0.4g IM Level (b)

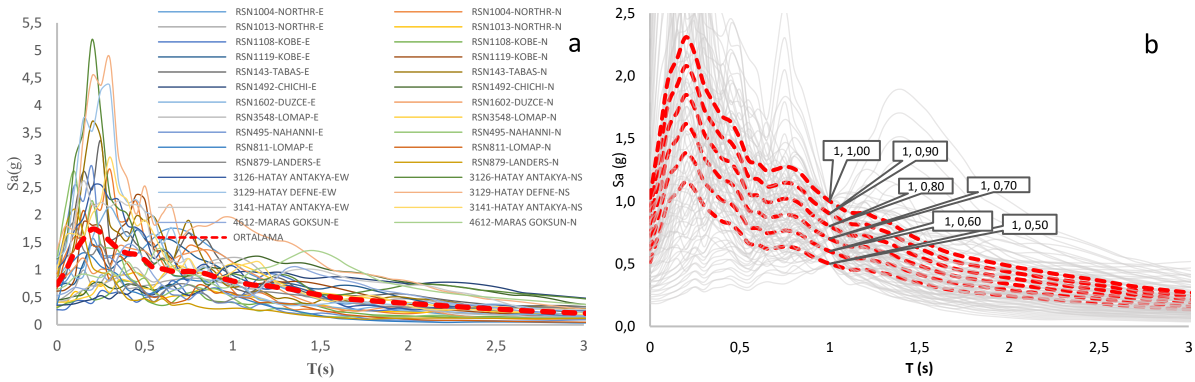

Fig. 2. Spectra selected for 0.5g-1g IM level (a), Scaled spectra for 0.5g-1g IM level (b)

3.2. Modeling of structural elements

As previously mentioned, the elevated water tank was modeled based on the 100 m³ capacity elevated water tank projects prepared by the General Directorate of Roads, Water, and Electricity (YSE) of the Ministry of Rural Affairs of the Republic of Turkey in 1976. The structure consists of a total of 6 floors, with a height of 5 meters per floor, making the total building height approximately 36 meters, including the tank length. Fig. 3 shows the schematic and ETABS model representation of the 100 m³ elevated water tank with a frame system.

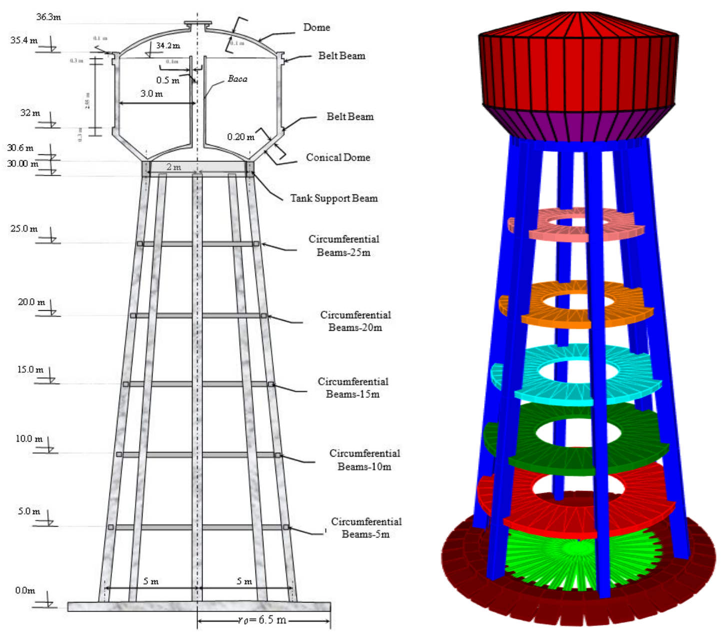

Fig. 3. The 100m³ elevated water tank with a frame system used in the study

The column cross-section between the 0-5 m levels of the elevated water tank is shown in Fig. 4(a), the column cross-section between the 5-30 m levels is shown in Fig. 4(b), and the beam-slab cross-sections from the 5 m level to the 30 m level are shown in Fig. 4(c). The foundation cross-section is presented in Fig. 4(d). Additionally, the floor plan of the elevated water tank is provided in Fig. 4(e).

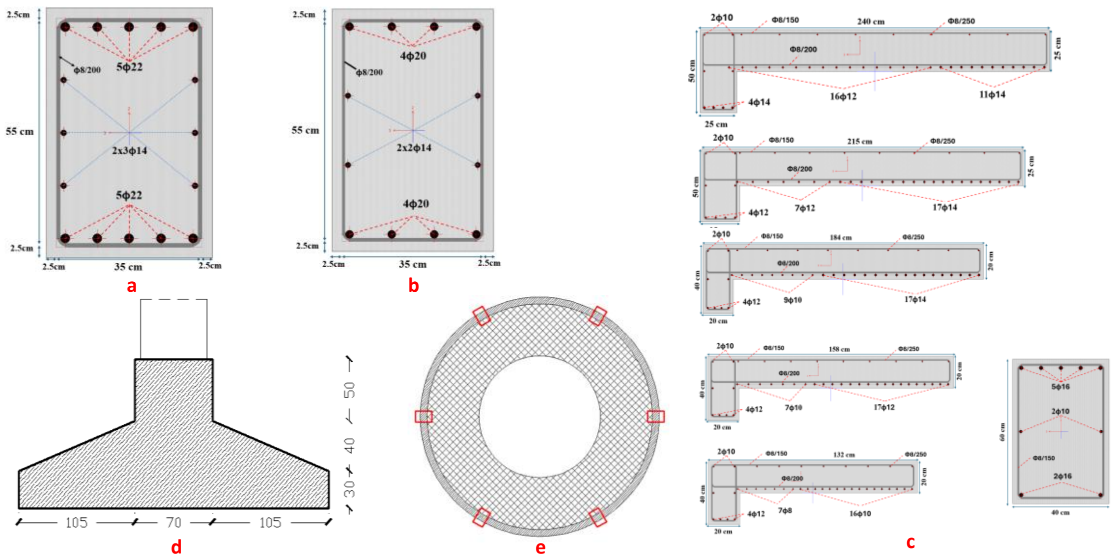

Fig. 4. Load-bearing elements of the 100m³ elevated water tank

3.2.1 Modeling of columns and beams

Although there are different approaches to deformation-based structural modeling in the literature, the modeling of inelastic elements is generally examined under three main categories. These categories are classified based on how the post-elastic behavior is modeled:

1- Concentrate Plastic Model (Macro Model): It is assumed that the post-elastic behavior will accumulate at specific points.

2-Fiber Model (Meso Model): It is assumed that plastic deformation will spread over a certain region.

3-Finite Element Model (Micro Model): It is assumed that plastic behavior will spread throughout the entire section.

Additionally, within the scope of the piled plastic behavior model specified in Article 5.3.1 of TBDY2018, auto M3 plastic hinges are defined in the ETABS software for the body beam elements in accordance with ASCE 41-13. The schematic representation of the piled plastic behavior model is shown in Fig. 5(a), while the plastic hinges defined for the beams in the structure are shown in Fig. 5(b). For the sections where the plastic hinge is not defined, the effective section stiffness factors (0.35) of reinforced concrete structural elements specified in Table 4.2 of the Turkish Building Earthquake Code 2018 (TBDY2018) were used.

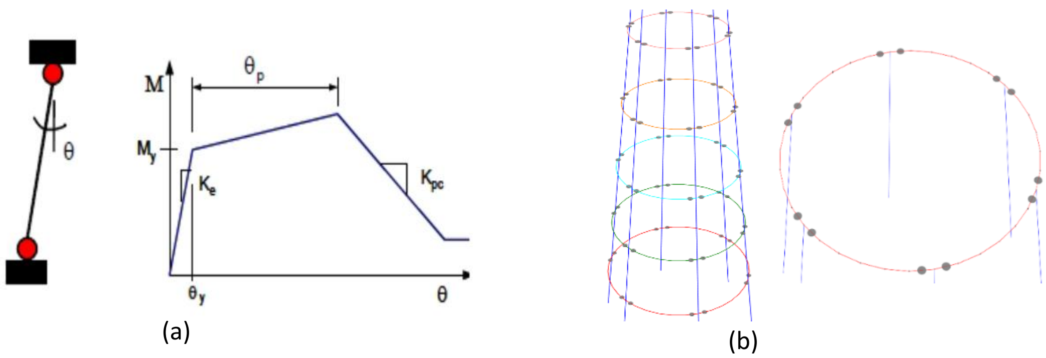

Fig. 5. Beam plastic hinge model and plastic hinge regions

For the columns, the distributed plastic behavior model specified in Article 5.3.2 of TBDY 2018 was used to model the column cross-sections. In Fig. 6(a), the column element cross-sections between the 0-5 m and 5-30 m levels are shown in their divided fiber form, with each red dot indicating the position of a fiber.

It is assumed that there is no confinement effect in the column elements, and the analyses were carried out based on this assumption. In Fig. 6(b), the schematic representation of how the column elements were modeled in the Perform3D program is provided. Here, the stiffness of the column-beam joint regions is defined using the "End Zone" concept, while the stiffness reduction factors specified in the code are applied for the elastic regions. To model the inelastic behavior, fiber cross-sections were defined, adopting a more realistic approach to the analysis.

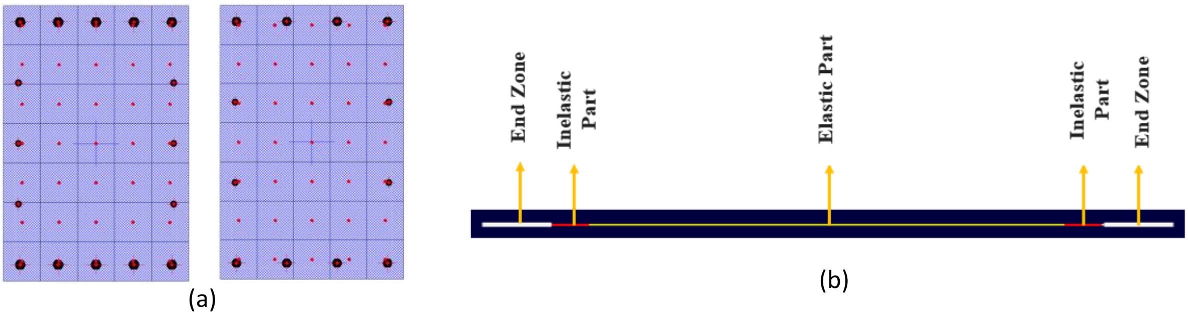

Fig. 6. Column distributed fiber model

3.3. Material and damage limits

In this study, it was assumed that the existing building stock is aged and has weak material properties, and material selections were made accordingly. In this context, the concrete class was determined as C10, and the reinforcement material used was ribbed S220 steel. This selection, which represents the low concrete strength and inadequate reinforcement properties commonly encountered in the older building stock, aims to model the behavior of structures under seismic effects more realistically.

3.3.1. Reinforcement steel

In this study, nonlinear time-history analyses based on displacement were performed. For the analyses, S220 reinforcement steel was used in accordance with TBDY2018 (Article 5A.2). The modulus of elasticity of the reinforcement steel was taken as $E_s = 2\times10^5$ MPa, nd the necessary general information about the steel material used is provided in Table 3.

Table 3. Information on Reinforcement Steel

Quality	f_{sy}*(Mpa)*	ε_{sy}	ε_{sh}	ε_{su}	f_{su}/f_{sy}
S220	220	0.0011	0.011	0.12	1.2

In Article 5.8.1.1 (b) of TBDY2018, the limit for the failure prevention performance level of reinforcement steel is defined in terms of unit strain ε_{su} (unit elongation corresponding to tensile strength) by Equation 6. Using this equation, the failure damage limit value for the reinforcement is determined as ($\varepsilon_s^{(CP)}$) 0.048.

$$\varepsilon_s^{(CP)} = 0.4\,\varepsilon_{su} \tag{6}$$

It is assumed that the reinforcement steel exhibits ideal elastic-perfectly plastic (EPP) behavior, and it has been idealized accordingly, as shown in Fig. 7.

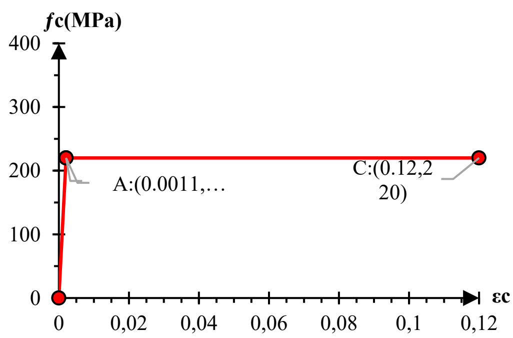

Fig. 7. Idealized reinforcement material model

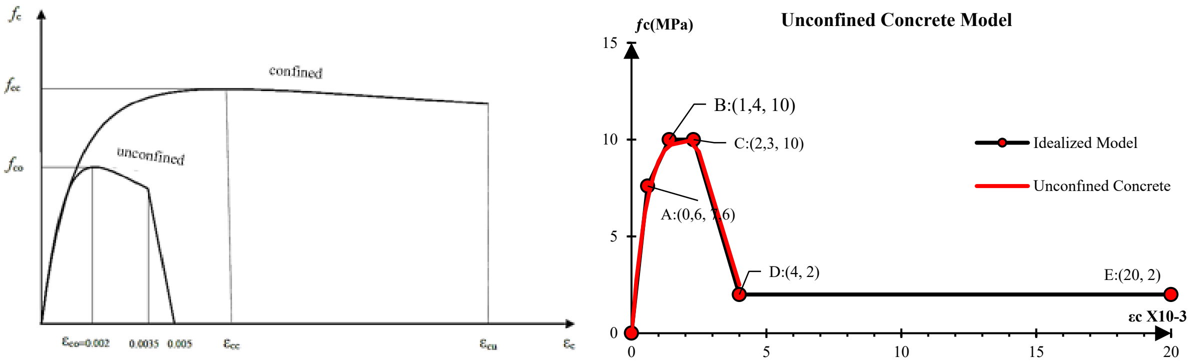
3.3.2. Unconfined concrete material

In this study, a model without confining reinforcement has been chosen to represent the case where the concrete does not exhibit the effects of confinement due to the absence of confining reinforcement or significant corrosion in the confining reinforcement caused by environmental factors.

$$E_c \cong 5000\sqrt{f_{co}} \quad (MPa) \tag{7}$$

In this study, concrete grade C10 (fc = 10 MPa) has been assumed, and the elasticity modulus of concrete has been calculated as 15,811 MPa using Equation 7 provided in Annex 5A.1 of TBDY 2018. The mechanical properties of concrete play a crucial role in determining the material's load-bearing capacity and deformation behavior. In this context, the behavior of unconfined concrete has been evaluated based on the model defined in the relevant regulation (see Fig. 8a). Additionally, the damage limit for unconfined concrete, corresponding to a strain of 0.0035, along with its idealized form, is presented in Fig. 8.



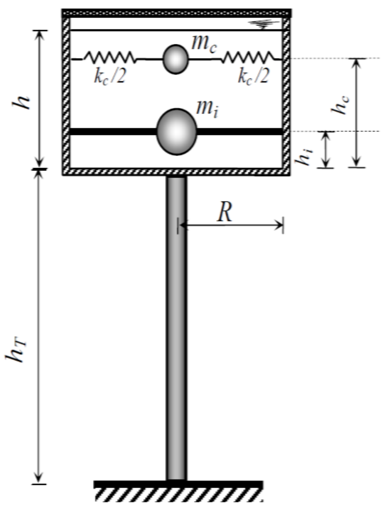
(a) (b)

Fig. 8. TBDY2018 unconfined concrete model and idealized concrete model

3.4. The Modeling of Fluid-Structure Interaction

Various methods have been developed to model the dynamic behavior of the fluid in elevated water tanks. These methods are primarily classified into single-mass and multi-mass systems. Under dynamic loads, tank-fluid systems exhibit two main types of motion. The first is the impulsive mass, where the fluid moves together with the tank. The second is the oscillatory mass, where the fluid oscillates independently of the tank with a certain period (Livaoğlu, 2005).

The mechanical model developed by Housner, which treats the fluid in the tank as two separate masses, is also used as the foundation for this study. This model is shown in Fig. 9 (Housner, 1963). Later, Epstein reformulated the equations of Housner's two-mass model to provide an alternative mathematical formulation (Epstein, 1976).



$$\omega^2 = \frac{g}{R} 1.84 \tanh\left(1.84\ \frac{h}{R}\right)$$

$$k_c = m_c \frac{g}{R} 1.84 \tanh\left(1.84\ \frac{h}{R}\right)$$

$$m_c = m_w 0.318 \frac{R}{h} \tanh\left(1.84\ \frac{h}{R}\right)$$

$$m_i = m_w \frac{tanh\left(1.74\frac{R}{h}\right)}{\left(1.74\frac{R}{h}\right)}$$

$$h_c = \left[1 - \frac{cosh(1.84^{h}/_{R})-1}{1.84\frac{h}{R}\, sinh(1.84^{h}/_{R})}\right] h$$

$$h_i = \frac{3}{8} h$$

Fig. 9. Mechanical model of elevated tank-liquid system (Livaoğlu,2005)

In the given equations, k_c denotes the rigidity of the oscillating mass, m_c is the oscillating mass, m_i is the impulse mass, h_c describes the height of the oscillating mass, and h_i describes the height of the impulse mass.

Table 4. Two-mass system approach data

	Liquid Mass (m_w) (kg)	Oscillating Mass (m_c) (kg)	Impulse Mass (m_i) (kg)	Oscillating Mass Stiffness (k_c) (N/m)	Oscillating Mass Height (h_c) (m)	Impulse Mass Height (h_i) (m)
FULL	102403	24065	67720	142703	2.63	1.5
HALF	50644	19754	20093	102126	1.2	0.8

In this study, the gap-hook model was used for modeling the water in the Perform3D program. Models were created based on the mathematical formulations provided above and the data given in Table 4. Fig. 10 shows the model images of the elevated water tanks with the water in the tank section in the following conditions: full (10a), half-full (10b), and empty (10c).

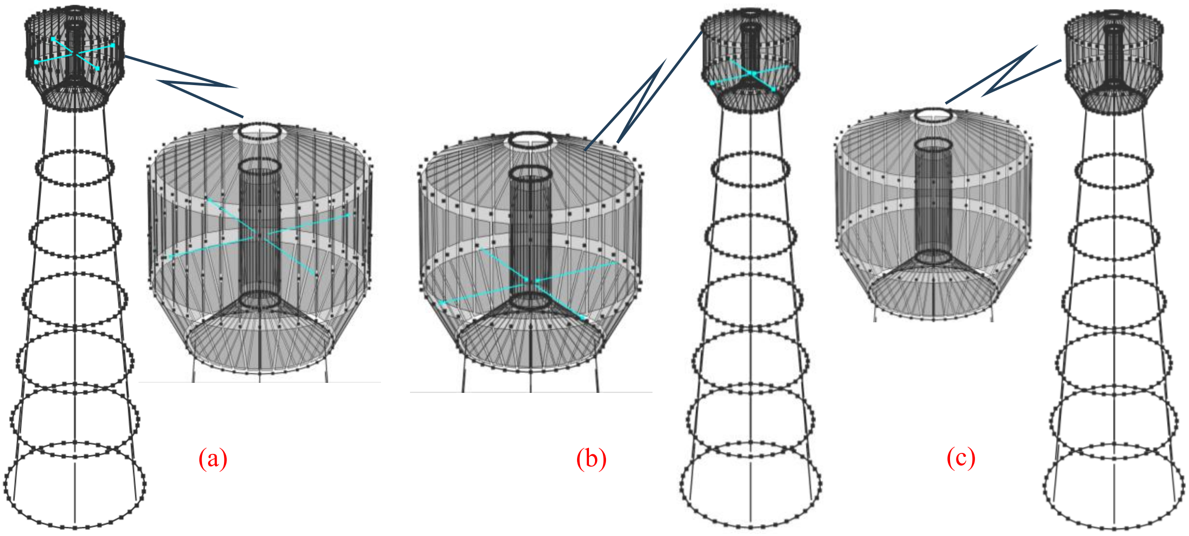


Fig. 10. Perform3D Tank Capacity Fully Filled (a), Half Filled (b), Empty (c) Models

The oscillation periods of the water calculated using the two-mass model proposed by Housner (1963) were compared with the oscillation periods obtained in the Perform3D software. As a result of the analyses, the difference between the two methods was determined to be 2.86% when the tank was completely full, and 1.91% when the tank was half-full. The obtained period values and differences are presented in Table 5.

Table 5. Fluid-structure interaction

Model Feature	Perform 3D Oscillation Period T(s)	Housner Model Oscillation Period T(s)	(%)
C10-S220-FULL	2.65	2.58	2.86
C10-S220-HALF	2.82	2.76	1.91

3.5. Modal information

The elevated water tank, being an axis-symmetric structure, exhibits equal modes in the x and y directions. For the three different models, structural modes other than the water oscillation mode were examined, and the dominant x-y modes resulting from axis-symmetry are presented in three modes (1), (2), and (3) along with their mass participation in Table 6.

Table 6. Structural Modes

Model Description	(1) x-y T(s)	z T(s)	(2) x-y T(s)	z T(s)	(3) x-y T(s)	Mass Participation Ratio (1)	Mass Participation Ratio (2)	Mass Participation Ratio (3)
C10-S220-FULL	1.542	1.319	0.682	0.557	0.347	0.683	0.090	0.046
C10-S220-HALF	1.396	1.024	0.644	0.492	0.337	0.728	0.089	0.056
C10-S220-EMPTY	1.346	1.021	0.620	0.491	0.329	0.805	0.090	0.057

The mode shapes corresponding to the five different mode values presented in Table 6 were examined to better understand the structural behavior. In this regard, as an example, the dynamic behavior of the elevated water tank when the tank is fully filled was analyzed, and the effects of the mode shapes on the general vibration characteristics of the structure were visualized and presented in detail in Fig. 11.

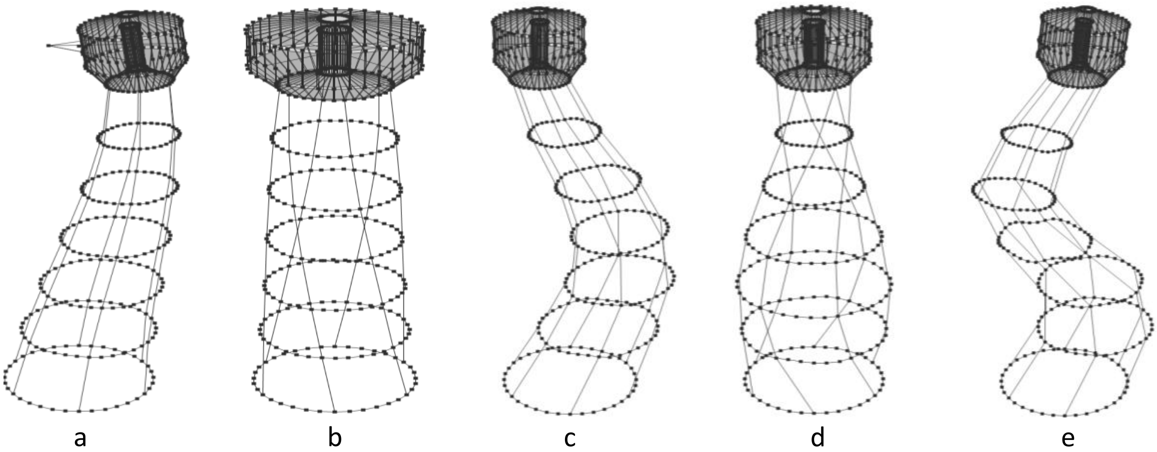

Fig. 11. The mode shapes corresponding to the modes given in Table 6 are presented in the x-y direction (a-c-e) and the z direction (b-d).

3.6. Fragility curves

In this study, fragility curves for the elevated water tank with a frame system were obtained using Multi-Stripe Analysis for three different tank filling levels. In the creation of the fragility curves, the Collapse Prevention (CP) limit states for both the concrete and reinforcement materials were determined for damage definition, and fragility curves were derived based on these values. Since an element-based evaluation was conducted, the fragility curves were created based on the condition where the six column elements on each floor simultaneously exceed their respective limit states.

Initially, the six elements on the first floor were examined, and if all elements exceeded their material damage limits for a specific earthquake, it was assumed that the elevated water tank had reached the Collapse Prevention (CP) state. If not all elements on the first floor were damaged, the elements on the upper floors were examined, and this process continued until the top floor. These values were then solved to generate the fragility curves. Fig. 12 presents the fragility curves of the elevated water tank for three different filling levels, based on both the Collapse Prevention (CP) and Life Safety (LS) limit states..

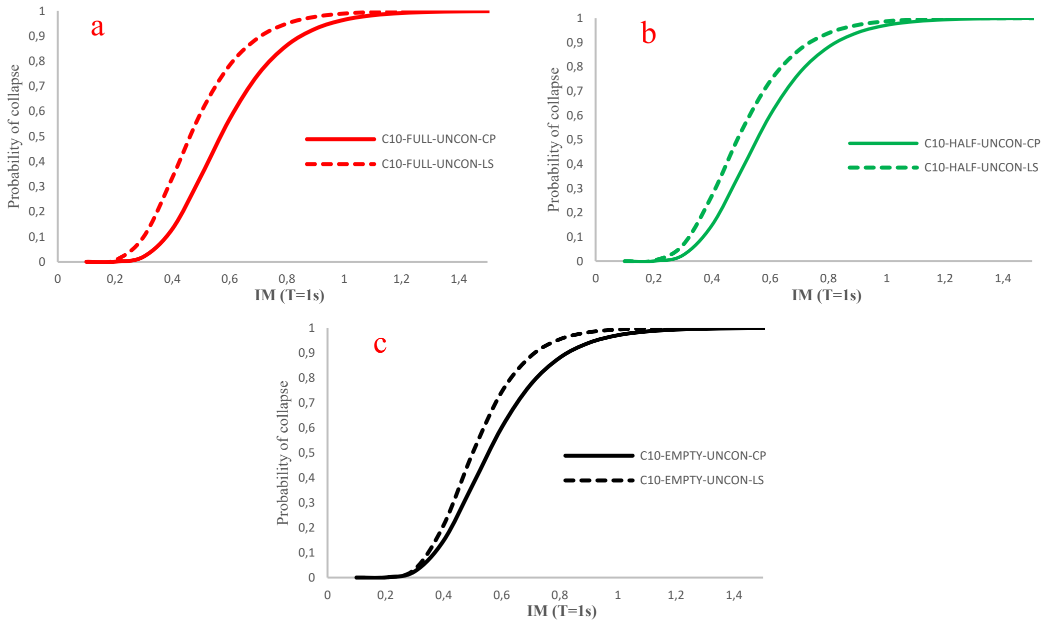

Fig. 12. Fragility curves for three different conditions (full-half-empty) according to CP and LS limit states.

In the case where the tank capacity is full, based on the Collapse Prevention (CP) limit state, the fragility curve representing the scenario where all elements on each floor reach the collapse state (C10-FULL-UNCON-CP) results in an acceleration value of 0.570g for a 50% exceedance probability at T=1s. For the Life Safety (LS) state in the full condition, the corresponding acceleration value for this exceedance probability is determined to be 0.463g, as shown in Fig. 12(a). The fragility curves for the Half and Empty tank capacity conditions are shown in Fig. 12(b) and Fig. 12(c), respectively. The acceleration values corresponding to a 50% exceedance probability at T=1s for all conditions are provided in Table 7.

Table 7. Acceleration values corresponding to a 50% exceedance probability in the elevated water tank.

	CP	LS
C10-FULL-UNCON	0.570	0.463
C10-HALF-UNCON	0.556	0.488
C10-EMPTY-UNCON	0.556	0.500

In the case where the material quality is low and there is no confinement effect in the structural elements, it is observed that for the Collapse Prevention (CP) limit state, the full tank capacity condition is safer compared to the other conditions, while for the Life Safety (LS) limit state, the fragility results indicate a more critical situation. For the Collapse Prevention limit state, the fragilities obtained for the half-full and empty tank conditions are found to have the same values corresponding to the 50% exceedance probability. Furthermore, as shown in Table 7, the acceleration value corresponding to the 50% exceedance probability for the LS condition is determined to be 0.5g for empty tank , while this value decreases to 0.463g for the full tank condition. This indicates that the critical situation in the elevated water tank increases as the tank transitions from empty to full.

When investigating the reason for this situation, it is found that in high-intensity earthquakes, almost all floors suffer damage, while in low-intensity earthquakes, the damage tends to be concentrated on the upper floors. This is due to the additional liquid mass in the tank, which causes more damage to the columns of the top floor supporting the tank. When evaluated from the CP limit state, fragility arises due to damage in the lower floors, as not all elements on the top floor are damaged. However, when considering the LS limit state, it becomes clear that the top floor plays a more critical role in determining the boundary scenario.

As mentioned in Section 3.1, the selected earthquakes were scaled based on acceleration values corresponding to the geometric average for T = 1s. This scaling method provides a rapid fragility assessment using the design spectral acceleration coefficient for a 1.0-second period, as specified in TBDY2018 for SD1. Fig. 13 presents the fragility curves for three different tank capacities, evaluated according to two distinct damage limit states.

The vertical lines in this graph indicate the expected earthquake levels for the design and maximum considered earthquakes for ZC and ZD soil classes, with a point of an example location in the Antakya district of Hatay province. These lines represent the spectral ordinate for T = 1s, obtained from AFAD, corresponding to the city center location's design earthquake (DD2: 10% exceedance probability, 50-year return period, 475-year return period) and maximum considered earthquake (DD1: 2% exceedance probability, 50-year return period, 2475-year return period).

Importantly, these fragility curves show that under such poor initial tank conditions, the structural response becomes highly critical. The predicted acceleration values serve as a strong indicator of the potential risk. Considering the observed accelerations during the Maraş earthquakes and the typical soil characteristics of agricultural areas where these tanks are often constructed, the actual acceleration response is easiliy estimated that it was even higher. In addition, the soils in these areas tend to be softer than the class C soils defined in TBDY2018, exacerbating the vulnerability of the structures.

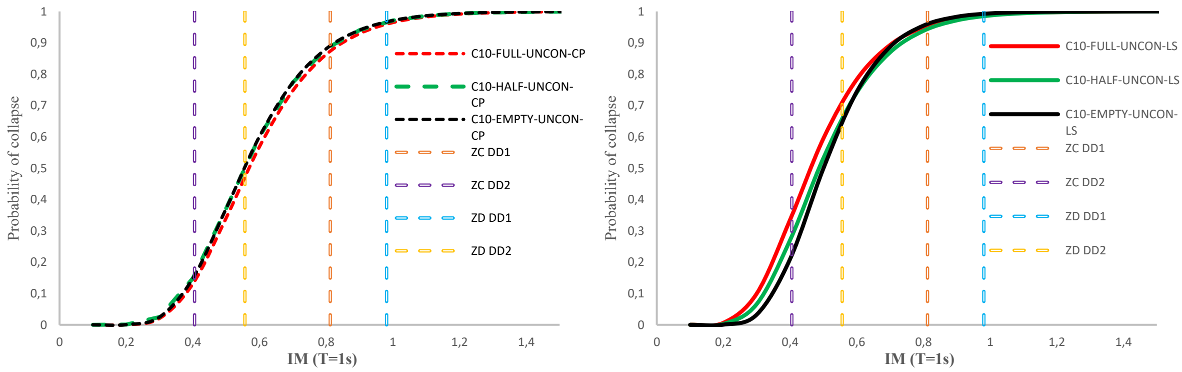

Fig. 13. Fragility curves according to CP and LS damage limits.

Table 8. Acceleration values of earthquake ground motion levels based on local soil classes.

ZC DD2 (g)	ZD DD2 (g)	ZC DD1 (g)	ZD DD1 (g)
0.405	0.556	0.812	0.981

For the examined elevated water tank located in the selected region, in the scenario where the soil class is ZC, and an earthquake with a 2475-year return period occurs, the material grade used in the study is found to be inadequate, and the confinement effect can be neglected. In this case, the exceedance probabilities for the tank being FULL, HALF and EMPTY are observed to be as high as 87.1% and 88.8%, respectively. This situation results in much higher levels for the Life Safety (LS) damage limit state, and these results are presented in Table 9. For the DD2 earthquake, expected to occur with a 475-year return period, in a scenario where the soil class is worse, the values corresponding to the LS damage limit are determined to be 48.1% for the full tank condition, 41.7% for the half-full condition, and 37.2% for the empty tank condition.

Table 9. Exceedance probabilities corresponding to SD1 values in elevated water tanks

	FULL		HALF		EMPTY	
	CP	LS	CP	LS	CP	LS
ZC DD1	87.1%	95.3%	88.8%	94.2%	88.8%	95.8%
ZC DD2	14.1%	34.9%	16.0%	28.4%	16.0%	22.5%
ZD DD1	95.8%	98.7%	96.5%	98.4%	96.5%	99.2%
ZD DD2	24.9%	48.1%	27.3%	41.7%	27.3%	37.2%

4. Conclusions

This study aims to develop fragility curves to assess the seismic vulnerability of a six-story elevated water tank with a capacity of 100 m^3. In this context, different filling ratios have been analyzed under scenarios where there is no confinement effect and material strength is low.

The findings indicate that under severely deteriorated conditions, variations in the water level have no significant mitigating effect on the structural response. While the presence of water slightly reduces the likelihood of exceeding the Collapse Prevention (CP) limit, this effect is minimal and does not improve overall safety. In contrast, for the Life Safety (LS) limit, the additional effects of water significantly increase the exceedance probability, exacerbating the vulnerability of the structure.

Moreover, the fragility assessments emphasize that in regions with poor soil conditions—such as agricultural areas where these tanks are commonly built—the observed acceleration response can be significantly higher than anticipated. Lessons from recent earthquakes, including the Maraş earthquake, highlight that these structures face an even greater risk due to softer soil conditions than the C-class category defined in TBDY2018. The fragility curves, along with spectral acceleration predictions, provide an urgent warning of potential structural failure in such cases.

To ensure the safety of these structures and proactively mitigate risks, a robust evaluation and decision-making mechanism must be established based on the seismic hazard level of the region. A nationwide database should be developed to assess the current condition of these tanks, whether in use or idle, through systematic field studies. By identifying high-risk structures and implementing necessary reinforcements or replacements, earthquake-related hazards can be significantly reduced, contributing to overall structural resilience.

Abstract. Historical masonry buildings are essential components of cultural heritage, yet their structural vulnerability-particularly under seismic actions-necessitates comprehensive evaluation and strengthening strategies. This study presents a structural assessment and retrofitting design for a two-story masonry school building located in Tbilisi, Georgia. The building, characterized by load-bearing stone masonry walls and timber flooring systems, was evaluated to determine its structural performance under both vertical and seismic loading conditions. A detailed three-dimensional finite element model was developed using SAP2000, incorporating all architectural openings and material properties. Structural analyses were conducted separately for gravity loads and lateral earthquake effects in accordance with TS EN 1995-1-1 and the Turkish Building Earthquake Code (TBEC, 2018). Material parameters for masonry and timber elements were defined based on international standards and national guidelines for historical structures. Initial analyses revealed that the existing timber floor system exhibited inadequate shear and bending capacity, as well as excessive deflection under serviceability conditions. Additionally, the unreinforced masonry walls displayed critical tensile and compressive stress concentrations under seismic loading. In response, a strengthening solution was developed, consisting of new steel beams (HEA140 and UPN140) integrated into the floor structure and the application of 2 cm thick fiber-reinforced cement-based repair mortar on the interior surfaces of the masonry walls, combined with 100 kN/m geogrid mesh reinforcement. Post-strengthening analysis results demonstrated that the proposed interventions significantly improved the overall behavior of the structure, reducing stress concentrations and displacement demands to acceptable levels. The strengthened system meets the Life Safety performance level under the DD-3 seismic design scenario. The study underscores the importance of combining traditional conservation with modern engineering tools to ensure the structural integrity of historical buildings without compromising their heritage value..

Keywords: Cultural heritage; Finite element model; Life safety performance; Masonry building

1. Introduction

Masonry structures represent one of the oldest and most widespread forms of construction throughout history, particularly in educational, religious, and residential architecture. These buildings, often composed of natural stone or fired brick bonded with lime or cement mortar, are known for their durability, thermal comfort, and cultural significance. In many regions, such as the Caucasus and Anatolia, masonry buildings constitute a substantial portion of the architectural heritage and serve as living witnesses of local identity and historical continuity.

Despite their historical and architectural value, unreinforced masonry structures are particularly vulnerable to seismic loads due to their brittle behavior, lack of ductility, and limited tensile strength. Earthquakes in recent decades have repeatedly demonstrated the susceptibility of such structures to partial or total collapse, especially in the absence of horizontal diaphragm action and proper wall-to-wall and wall-to-roof connections (Tomazevic, 1999; Lourenço, 2002). The seismic fragility of these buildings poses not only a risk to public safety but also threatens the irreversible loss of cultural heritage.

In parallel with the growing awareness of the need for seismic safety, there has been an increasing focus on conservation-compatible strengthening strategies. Interventions in heritage buildings must balance structural requirements with architectural and historical integrity. The ICOMOS guidelines (ICOMOS, 2003) emphasize the use of minimal intervention, reversibility, and compatibility as core principles in structural retrofitting of historic buildings. Several studies have proposed retrofit techniques ranging from external steel bracing, grout injection, and reinforced shotcrete to more reversible and less invasive solutions such as fiber-reinforced composites or

golden light publishing

geogrid-reinforced mortars (Taghdi, 2000; Abrams & Lynch 2001; ElGawady et al. 2004; Corradi et al., 2008; Binda & Saisi, 2005). These methods are innovative methods that aim to improve performance without compromising originality, and are quite successful in increasing structural strength.

Although numerous experimental and numerical studies have addressed the mechanical characterization of masonry units and traditional mortars (Valluzzi et al., 2004; Lagomarsino & Cattari, 2015), there remains a gap in the literature regarding the performance verification of these materials when applied in real heritage structures using full-scale engineering simulations.

This study addresses this challenge through a case study involving a four-story historical masonry school building located in Tbilisi, Georgia. The building comprises load-bearing stone masonry walls and timber floor systems and has suffered from material deterioration and structural deficiencies. Using a performance-based engineering approach, the study presents the development of a three-dimensional finite element model, assesses the existing condition of the building, and proposes a strengthening solution that combines traditional materials with modern reinforcement techniques. The seismic behavior of the structure before and after retrofitting is evaluated in accordance with the Turkish Building Earthquake Code (TBEC, 2018), offering a quantitative assessment of the intervention's effectiveness and safety.

The findings contribute to the ongoing discourse on the preservation of heritage buildings, demonstrating how structural engineering tools can be harmonized with conservation ethics to ensure the long-term resilience and cultural continuity of historical masonry assets.

2. Architectural and structural characteristics of the building

The case study building is a four-story historical masonry school structure located in Tbilisi, Georgia. According to the architectural documentation and on-site inspections, the building was constructed using traditional stone masonry techniques and timber-based floor systems. The building has a rectangular plan geometry and is composed of thick load-bearing masonry walls constructed from irregular stone units bonded with lime-based mortar. The ground floor houses large corridor spaces and classroom areas, while the upper floor continues with similar functional zoning. The interior partitions are also masonry, contributing to the overall stiffness of the structure. Large openings for windows and doors are symmetrically arranged along the façades, which, while architecturally significant, result in stress concentrations in seismic conditions.

Floor systems consist of timber beams spaced approximately 50 to 60 cm apart, supporting wooden floorboards that span between masonry walls. The roof system is also timber-based, constructed with inclined rafters and covered with lightweight roofing material. However, structural inspections revealed that the timber components, particularly those supporting the floor, have experienced degradation and loss of stiffness over time.

The foundation system was originally constructed with stone footings, without continuous reinforced concrete beams. As a result, differential settlements and minor cracking were observed in several load-bearing walls, particularly near door and window openings.

The architectural configuration includes long corridor spans, which presented challenges in lateral load distribution due to the lack of diaphragm action. Furthermore, the floor-to-wall connections were found to be insufficient to transfer seismic forces effectively, necessitating the design of additional structural measures to ensure integrity and stability during earthquake events.

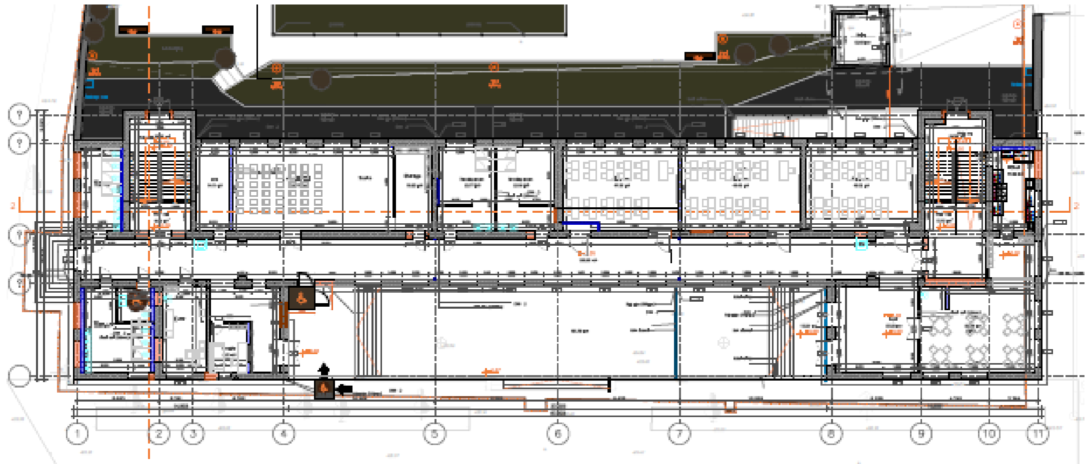
Figs. 1 and 2 present architectural drawings of the building and some images of the on-site inspection. The combination of thick masonry walls, aged timber elements, and discontinuous connections between horizontal and vertical systems illustrates the complex nature of seismic vulnerability in such heritage buildings. These characteristics were carefully incorporated into the finite element model to ensure realistic simulation of the building's behavior under various load cases.

3. Finite element modeling approach

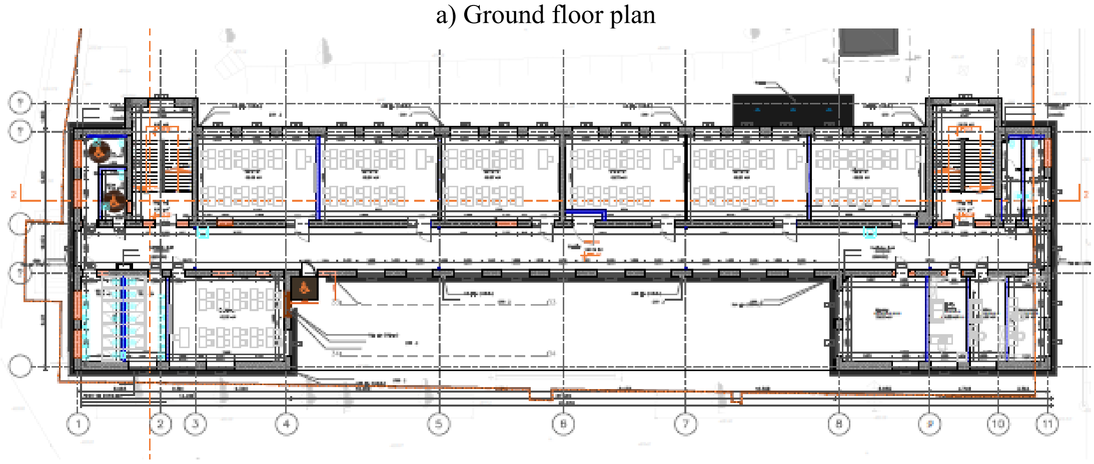
A three-dimensional finite element model of the historical masonry-timber school building was developed using SAP2000 software to simulate the structural behavior under gravity and seismic loading conditions. The modeling approach adhered to the guidelines outlined in TS EN 1996-1-1 for masonry structures and TBEC (2018) for seismic assessment of existing buildings.

3.1 Model geometry and element types

The building geometry was modeled based on architectural plans and verified with site inspection data. Load-bearing masonry walls were modeled using four-node shell (area) elements to accurately capture in-plane and out-of-plane behavior. Timber beams were modeled using frame (bar) elements with linear elastic properties. All architectural openings, including doors and windows, were explicitly defined in the model to reflect local stress concentrations. Images of the finite element model are given in Figure 3.



a) Ground floor plan



b) Plans for floors 1-3

Fig. 1. Architectural drawings of the building

Fig. 2. Some images of the on-site inspection of the building

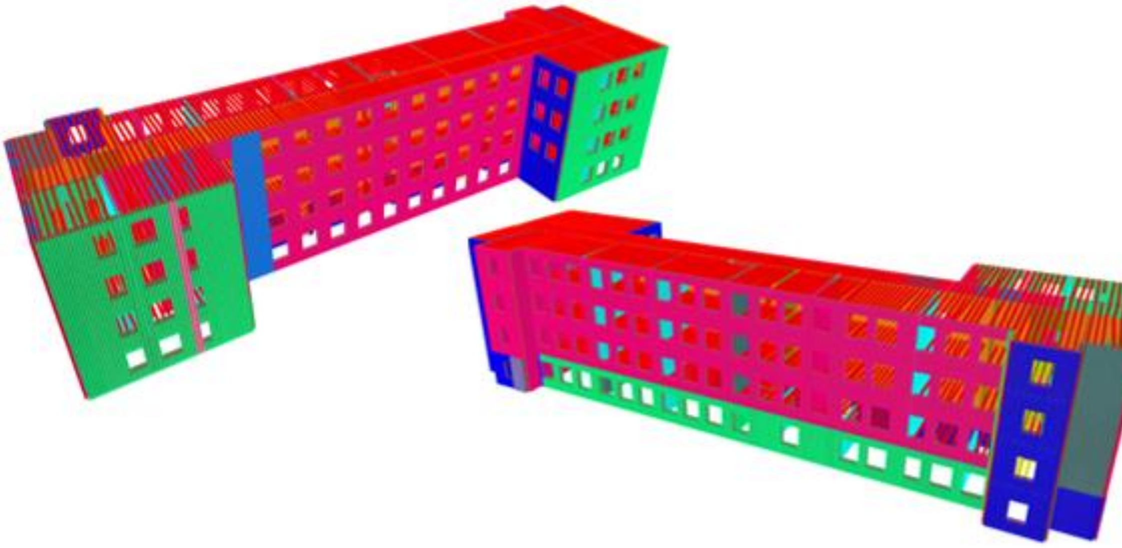


Fig. 3. Finite element model of the building

3.2. Metarial properties

Within the scope of the analysis, the strength classes and material properties of structural timber elements were determined in accordance with the specifications outlined in TS EN 1995-1-1 (Eurocode 5). This standard classifies structural timber into two main groups and twenty distinct strength classes based on their mechanical performance. The classification is derived from a series of mechanical criteria, including bending strength, tensile strength parallel and perpendicular to the grain, compressive strength parallel and perpendicular to the grain, shear strength, modulus of elasticity parallel and perpendicular to the grain, shear modulus, and density.

For the purposes of this study, timber elements were modeled using the mechanical properties corresponding to the C22 strength class. In SAP2000, these properties were assigned as an orthotropic material model to accurately simulate the anisotropic behavior of timber. All timber members in the finite element model were assigned this C22 orthotropic material definition. In accordance with TS EN 1995-1-1, two primary limit states were considered in the structural design and evaluation process:

- Ultimate Limit State (ULS): Ensuring structural safety against collapse under maximum design loads.
- Serviceability Limit State (SLS): Verifying usability and limiting deformations under normal service loads.

Material properties were calculated separately for both limit states, and finite element analyses were conducted accordingly. Table 1 summarizes the material parameters used in the model under ULS and SLS design conditions.

Table 1. The material parameters for the model under ULS and SLS design conditions

Limit State	Design Elasticity Modulus (kN/mm^2)		Design Shear Modulus
	$E_{d//}$ (Parallel)	$E_{d\perp}$ (Perpendicular)	(G_d)
Ultimate	7.69	0.25	0.48
Serviceability	3.33	0.11	0.21

In the determination of the mechanical properties of masonry stone elements, the "Earthquake Risk Management Guide for Historical Structures" published by the Turkish Directorate General of Foundations has been taken into account. This guideline provides appropriate approaches for assessing the material properties of registered historical buildings and aims to ensure realistic modeling of their structural behavior. The masonry stone material parameters used in the analyses within the scope of this study are presented in Fig. 4.

3.2. Determination of loads

The determination of structural loads was carried out in accordance with the load calculation provisions of TS EN 1995-1-1, which governs the design of timber structures, and the EN 1991 series, which addresses environmental actions. According to TS EN 1995-1-1, in order to carry out structural design and verification for timber structures, the loads must be determined in accordance with the following standards:

- TS498: Densities, self-weight, and imposed loads on structures
- •Seismic loads, on the other hand, were determined according to the national standard TBEC (2018).

Wall Type	Compressive Strength (f_m) (MPa)	Shear Strength (τ_0) (kPa)	Elastic Modulus (E) (MPa)	Shear Modulus (G) (MPa)	Unit Weight (w) (kN/m³)
Rubble stone masonry wall	0.6–0.90	20–32	690–1050	115–175	19
Rough stone masonry wall	1.1–1.6	35–51	1020–1440	170–240	20
Well-connected cut stone masonry wall	1.5–2.0	56–74	1500–1980	250–330	21
Soft stone (limestone, tuff) masonry wall	0.8–1.2	28–42	900–1260	150–210	16
Smooth cut stone, plastered masonry wall	1.8–2.8	78–98	2340–2820	390–470	22
Lime mortar brick masonry wall	1.8–2.8	60–92	1800–2400	300–400	18
Cement mortar perforated brick masonry wall	3.8–5.0	240–320	2800–3600	560–720	15
Brick masonry wall with <45% void ratio	4.6–6.0	300–400	3400–4400	680–880	12
Mortarless brick masonry wall with <45% void ratio and vertical joints	3.0–4.0	100–130	2580–3300	430–550	11
Concrete block masonry wall with 45–65% void ratio	1.5–2.0	95–125	2200–2800	440–560	12
Grouted concrete block masonry wall	3.0–4.4	180–240	2700–3500	540–700	14

Fig. 4. Material properties of masonry elements in FEM

The floor loads considered in the structural analysis were defined in accordance with the relevant usage areas within the school building. A uniform dead load of 50 kg/m² was applied to represent the weight of non-structural floor finishes and coverings. The self-weight of the structural system (including beams, slabs, and walls) was automatically calculated by the analysis software. Regarding live loads, 350 kg/m² was assigned to the classroom areas, and 500 kg/m² was applied to the school corridors, in line with typical usage requirements. The roof slab was considered inaccessible, and therefore no live load was applied to this area during the analysis. For the calculation of earthquake loads, the Turkish Building Earthquake Code 2018 (TBEC, 2018) was followed. In the corresponding design spectrum, the site was classified as soil type ZD, which represents medium dense to dense sand, gravel, or very stiff clay layers. The spectrum characteristic parameters for the building site were obtained via the Turkish Earthquake Hazard Maps Interactive Web Application. The values obtained for Erzincan Province which have similar seismic characteristics in Tbilisi, Central District are summarized in Fig. 5. The response spectrum generated based on the parameters obtained from Fig. 5 is presented in Fig. 6. In accordance with the Turkish Building Earthquake Code (TBEC, 2018), the structural classification parameters for the timber building were determined as follows: the Building Height Class (BYS) was selected as 8, the Building Occupancy Class (BKS) as 1, the Earthquake Design Class (DTS) as 2a, and the Importance Factor (I) as 1.5. Although the structural system of the building is not explicitly listed under the predefined categories in Table 4.1 of Article 4.3.2, appropriate seismic design parameters were selected based on the overall configuration and behavior of the load-bearing system. Accordingly, the Structural System Behavior Coefficient was taken as Rx = Ry = 3, and the Overstrength Factor was assumed as D = 1. The loads and load combinations considered in the structural analysis of the building were defined in accordance with relevant codes and implemented in the SAP2000 model.

Input / Output	Value
Seismic Design Level	DD-3 (50% probability of exceedance in 72 years)

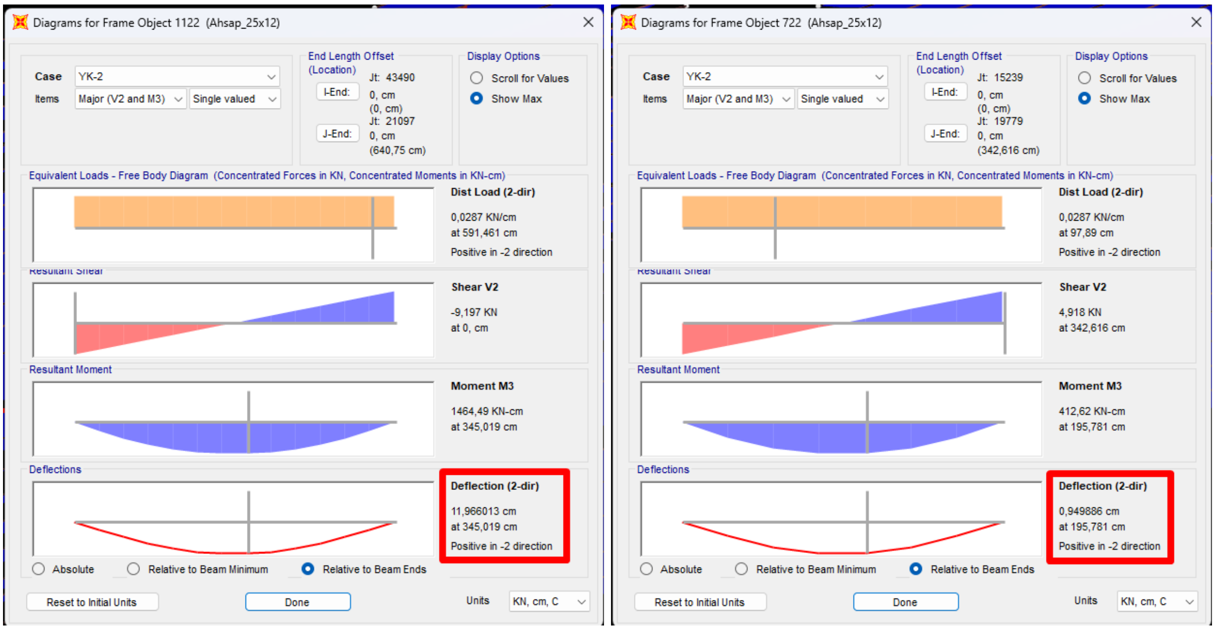
4. Finite element analysis

4.1. Evaluation of timber floor system
Within the scope of the study, the structural adequacy of the existing timber floor beams is evaluated through detailed calculations. The assessment included the verification of cross-sectional resistance, deformation under service loads, shear capacity, and compatibility with deflection and vibration criteria. The verification process is based on both ultimate limit state (ULS) and serviceability limit state (SLS) requirements.

According to the ULS analysis results, the stresses obtained from the moments and shear forces derived from the finite element model indicate that the bending performance of the timber beams remains within the acceptable limits. However, deficiencies were observed under the effect of shear forces, suggesting that the current configuration may not fully satisfy the shear capacity requirements in its existing state.

Upon examining the SLS analysis results, it is observed that the deflections of the flooring in the classrooms do not fall within permissible limits (Fig. 7). In structural elements with a timber beam load-bearing system, due to inadequacies in both shear verification and deflection, it has been decided to use a steel floor instead of a timber floor.



Classrooms: 11.96cm > 2.1 cm ❌ General Corridors: 0.94cm < 1.14 cm ✅

Fig. 7. SLS analysis results of timber floor system

To address these deficiencies, a revised structural analysis was carried out within the scope of this study using steel profile reinforcements as an strengthening method. Based on the results obtained from the finite element analysis:

- In classroom areas, where the design live load was defined as 350 kg/m², it was determined that HEA140 steel profiles provided sufficient flexural and shear resistance.
- In corridor areas, which were subject to a higher live load of 500 kg/m², UPN140 profiles were found to satisfy the structural requirements, particularly due to their adequate performance in shear.

For the roof floor, no significant live load is considered in the design due to its inaccessible nature. Therefore, only the self-weight of the slab was taken into account, and the structural analysis indicated that this dead load could be safely carried by the existing slab configuration without the need for additional strengthening. Strengthening proposal is given in Fig. 8.

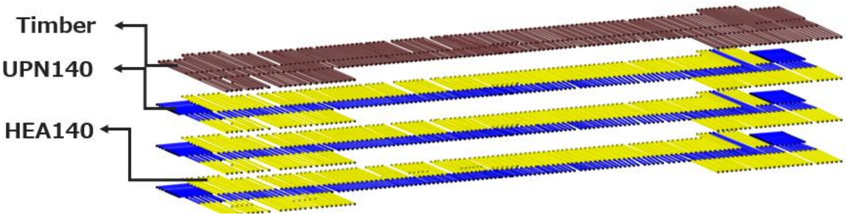


Fig. 8. Proposed alternative strengthening

In timber check results, according to the ULS and SLS analysis results, the stresses obtained from the moments and shear forces derived from the finite element model indicate that the bending effect, shear force and displacement ratio remains within the specified limits (Fig. 9).

4.1. Evaluation of masonry system

The DD-3 earthquake level, as defined in the Turkish Building Earthquake Code (TBEC,, 2018), corresponds to a seismic event with a 50% probability of exceedance in 50 years, which equates to a return period of approximately 72 years. This level of ground motion represents a design earthquake scenario used for evaluating the expected performance of existing structures under moderate seismic demand. Taking into account the nature of the structure and its occupancy classification, the performance assessment of the building was conducted based on the “Life Safety” (Fig. 10) performance level defined in TBEC (2018). This performance objective aims to ensure that the structure retains its overall stability and prevents partial or total collapse under the DD-3 level seismic event, thereby protecting life safety even in the event of moderate damage.

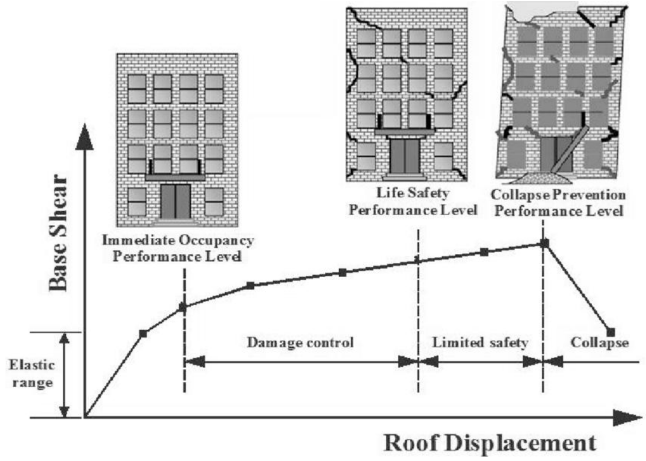

Fig. 10. Performance levels for structural assessment

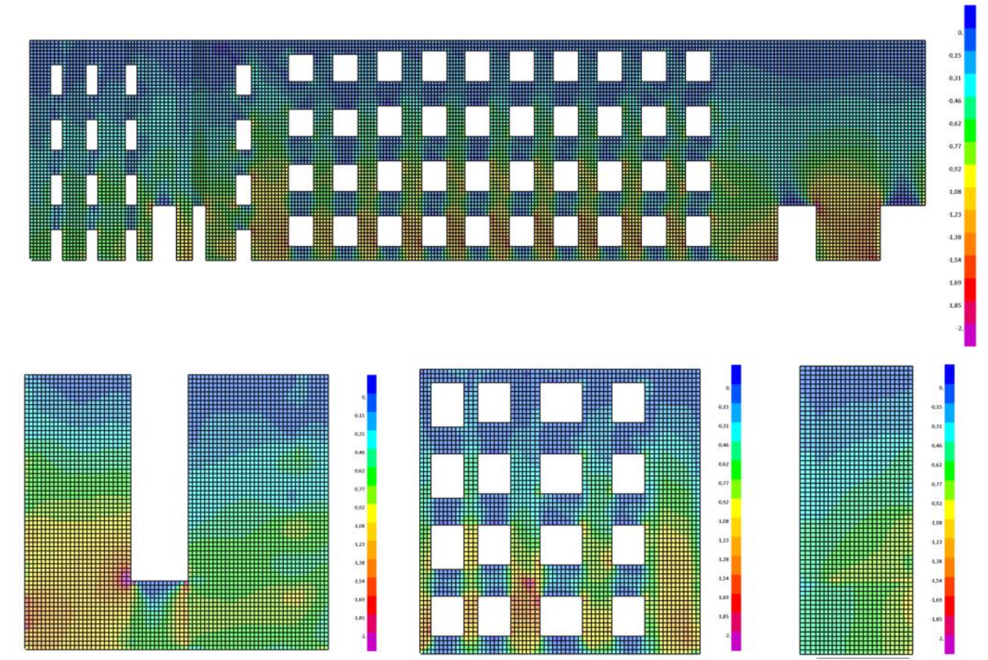
In line with the Life Safety Performance Objective defined in TBEC (2018), a detailed structural assessment of the building was carried out under the DD-3 level earthquake scenario using finite element analysis. The objective was to evaluate whether the structural system could maintain overall stability and protect human life during a moderate seismic event. The analysis results, including stress distributions, deformation diagrams, and critical regions of failure, are presented in Fig. 11.

When the analysis results were evaluated with respect to the material properties and permissible limits, it was observed that the compressive stresses exceeded the allowable values in several areas, particularly on the first and second floors. These findings indicate insufficient vertical load-carrying capacity in certain masonry wall sections.

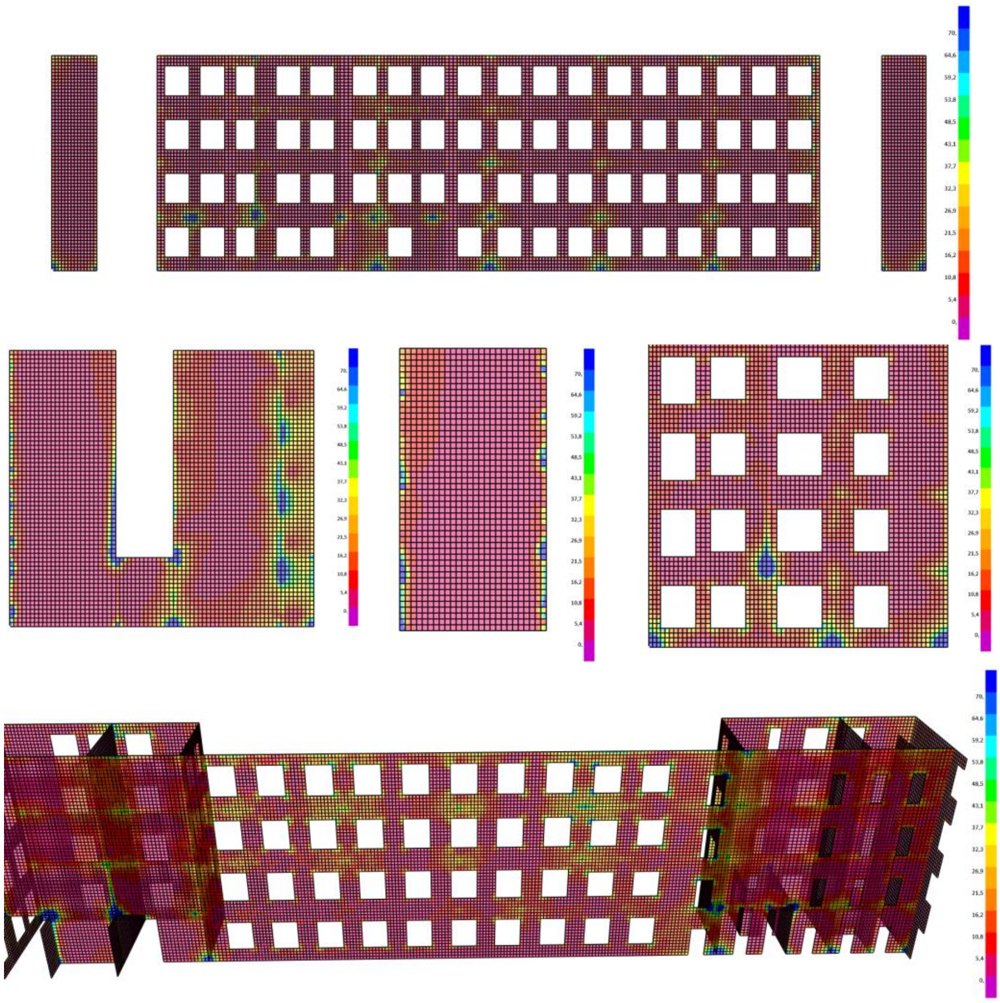
In addition, the shear stress distribution revealed more widespread deficiencies. Shear-related weaknesses were identified across all floors, especially concentrated around the wall-to-wall connections, wall-to-floor joints, and window openings. These regions exhibited localized overstressing, suggesting a lack of ductility and inadequate energy dissipation capacity in the existing structural configuration.

Some representative images from the analysis outputs have been provided to illustrate the most critical failure mechanisms and overstressed zones.

Based on these findings, it has been conclusively determined that the existing structural system does not meet the life safety requirements, and that the school building requires retrofitting to address the identified weaknesses. Strengthening interventions should particularly target shear-critical regions and compressive overstress areas to improve the building’s seismic resilience and ensure compliance with performance-based design objectives.



a) Distribution of Principal Compression Stress (G+Q+Ex+0.3Ey+0.3Ez , Units: MPa)



b) Distribution of Principal Principal Shear Stress (G+Q+Ex+0.3Ey+0.3Ez , Units: MPa)

Fig. 11. Some of figures for evaluation structural system results

In response to the widespread deficiencies observed in both compressive and shear stress capacities throughout the structural walls, a practical and structurally effective retrofitting strategy has been suggested. Instead of using shotcrete, the proposed method involves applying a cement-based thick repair mortar to all structural walls. This approach was selected not only for its mechanical effectiveness, but also for its ease of application, compatibility with existing masonry materials, and minimal intrusion on the building's original architectural features.

In the strengthened model, a 2 cm thick layer of cement-based repair mortar will be applied to both faces of each wall, thereby enhancing cross-sectional stiffness, ductility, and energy dissipation capacity under seismic loading. To further improve the tensile behavior and control potential cracking, fiber reinforcement will be incorporated within the repair mortar. The use of fiber-reinforced mortar eliminates the need for traditional rebar cages, reducing the complexity of construction while providing multidirectional stress distribution capacity.

For the exterior walls, the repair mortar will only be applied to the interior face in order to preserve the historical appearance of the facade. Additionally, reinforced bond beams are proposed around window and door openings, where stress concentrations were clearly identified in the analysis. These localized enhancements aim to improve continuity, reduce deformation, and prevent failure in regions susceptible to in-plane and out-of-plane forces.

Post-retrofit finite element analyses confirm that this strengthening configuration significantly reduces stress demands throughout the structure, allowing both compressive and shear stresses to remain within acceptable performance limits. As a result, the building is expected to meet the Life Safety Performance Level under the DD-3 earthquake scenario as defined in TBEC (2018).

The material properties of the cement-based repair mortar and fiber mesh reinforcement (KBT – Basalt Georid 100 kN 40x40mm) used in the strengthening analysis are presented in Figs. 12 and 13, including relevant mechanical parameters such as compressive strength, tensile strength, modulus of elasticity, and unit weight. These values were used in the finite element model to accurately simulate the contribution of the repair layer to the overall stiffness and strength of the structural system.

3. Conclusions

This study presented a performance-based structural evaluation and retrofitting proposal for a four-story historical masonry-timber school building located in Tbilisi, Georgia. The assessment process was carried out using a detailed finite element model developed in SAP2000, incorporating the architectural and structural features of the building, as well as material properties and loading conditions compliant with TS EN and TBEC (2018) standards.

The initial analyses revealed that the existing structural system was inadequate to meet safety and serviceability requirements under both gravity and seismic loads. In particular, the timber floor systems exhibited excessive deflection and insufficient diaphragm action, while the unreinforced masonry walls were prone to tensile cracking and shear failure under earthquake loading. To address these vulnerabilities, a dual-stage strengthening solution was proposed. This included the addition of HEA140 and UPN140 steel profiles combined with a reinforced concrete slab to improve the horizontal diaphragm, and the application of a geogrid-reinforced fiber mortar layer on masonry walls to enhance in-plane and out-of-plane performance. The retrofitted model demonstrated significant improvements in stiffness, stress distribution, and displacement control.

- Post-retrofit analyses confirmed that the building met the Life Safety (LS) performance objective under the DD-3 earthquake level, as defined for locally significant heritage buildings.
- The interventions successfully brought all critical stress zones within permissible limits and ensured sufficient seismic resilience.

Overall, this study underscores the value of combining modern structural engineering tools with conservation-sensitive retrofitting techniques. The adopted methodology provides a replicable framework for the assessment and strengthening of similar historical masonry buildings, ensuring both their structural safety and cultural continuity for future generations.

Ground motion parameters importance in machine learning-based damage prediction

Yasin Fahjan[1], Bilal Ein Larouzi*[1]

[1] Istanbul Technical University, Department of Civil Engineering, 33469 Istanbul, Türkiye

Abstract: Post-earthquake damage assessment is a crucial process for effective disaster management, requiring rapid and accurate evaluation to prioritize response efforts. This study proposes a machine learning-based approach to predict building damage levels by analyzing ground motion parameters and building footprint data. A case study was conducted in the Izmir region, which experienced a devastating earthquake in 2020. The dataset utilized combines real field-collected data with existing datasets containing building footprint geometry. A Random Forest algorithm was employed to develop a predictive model that classifies buildings into three damage levels. Key ground motion parameters—Peak Ground Acceleration (PGA), Peak Ground Velocity (PGV), and Intensity—were tested to determine their importance. Results indicate that PGA is the most critical parameter, achieving an accuracy of 84%, followed by PGV (80%) and Intensity (77%). However, combining all three ground motion parameters yielded the highest model performance, with an accuracy of 90% and an F1 score of 0.90. The study also highlights the importance of incorporating building footprint area as an additional feature for improved predictions. These findings demonstrate the potential of using machine learning models to enhance post-earthquake damage assessment by integrating multiple ground motion parameters and building characteristics. The proposed approach provides a scalable and efficient solution for rapid damage evaluation in seismic-prone regions, supporting effective disaster response strategies.

Keywords: Post-earthquake damage assessment; Machine learning; Ground motion parameters; Random Forest algorithm.

1. Intorduction:

Earthquakes are among the most significant natural disasters, impacting human lives and causing substantial economic losses. These impacts arise not only from the immense energy released due to ruptures in the Earth's crust but also from the inherent unpredictability of such events. Consequently, post-earthquake damage assessment and disaster management are critical areas of research that play a crucial role in mitigating loss of life and minimizing economic repercussions following seismic events. One of the traditional methods employed for earthquake risk assessment is the fragility curve. This probabilistic tool compares the seismic capacity of structures with seismic demand, thereby estimating the probability of exceeding predefined damage limit states. The seismic demand is typically represented by ground motion parameters such as Peak Ground Acceleration (PGA), Peak Ground Velocity (PGV), or intensity.

The selection of an appropriate ground motion parameter for describing seismic demand in fragility analyses has been a significant topic of research. Meral (2024) stated that parameters within the velocity and acceleration groups exhibit stronger correlations compared to those in the frequency and displacement groups. However, it should be noted that frequency- and displacement-related parameters tend to have lower correlation values. Acceleration-related parameters demonstrate superior correlation performance for short-period structures, such as four-story buildings, whereas velocity-related parameters are more effective for medium-period structures, including seven-story buildings. Pellissetti et al. (2023) suggested that uncertainties associated with structural capacity, when assessed solely in terms of PGA, can be reduced by developing a vector-valued fragility surface that incorporates both PGA and the PGA/PGV ratio. Furthermore, Massumi et al. (2016) observed that as a structure's natural period increases, the influence of acceleration-related parameters on damage assessment decreases, whereas velocity-related parameters become more significant.

Machine learning (ML), a subfield of artificial intelligence, has been increasingly utilized in generating models capable of classification and prediction based on historical data collected from real-world observations or

* Corresponding author, E-mail: Larouzi20@itu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_392

generated through simulations. In recent decades, ML has been effectively applied in post-earthquake damage assessment, demonstrating its predictive capabilities. For instance, Zhang et al. (2022) introduced a rapid damage assessment model for reinforced concrete frames using machine learning techniques. Similarly, Tang et al. (2021) developed a machine learning model for rapid seismic risk assessment, utilizing datasets generated for various regions in China and comparing the performance of different machine learning algorithms. Additionally, Cosgun (2023) presented a machine learning model for evaluating existing buildings in the Istanbul region of Türkiye. The study revealed that the model, employing the Random Forest algorithm, exhibited high accuracy when compared to simulated results, and it also highlighted the significant impact of building age on the assessment outcomes.

This study aims to conduct a comparative analysis to identify the most influential ground motion parameters used in post-earthquake damage assessment models based on machine learning algorithms.

2. Fragility curve:

Fragility curves are probabilistic tools that quantify the likelihood of a structure exceeding specified damage thresholds under varying seismic intensities. Formulated as cumulative distribution functions, these curves correlate ground motion parameters—such as peak ground acceleration (PGA), peak ground velocity (PGV), or spectral acceleration—with discrete damage states, serving as foundational instruments in performance-based earthquake engineering (PBEE) for evaluating potential structural and socioeconomic losses.

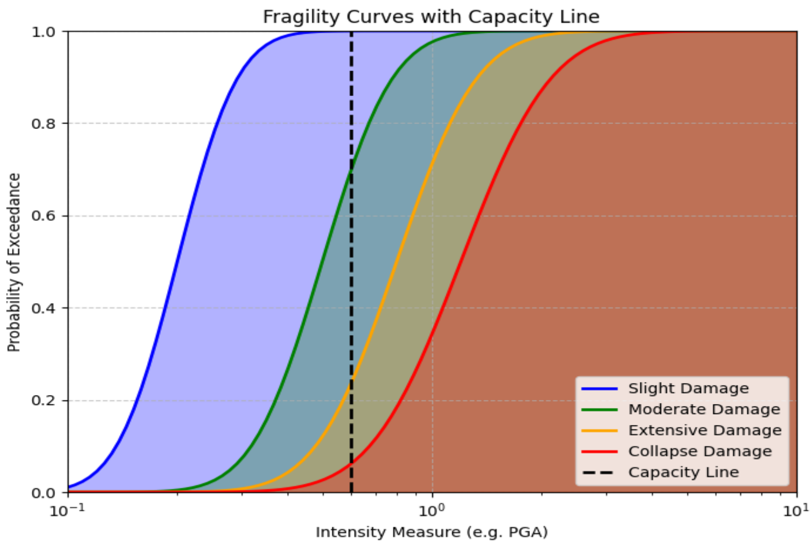

Fig. 1. Seismic fragility curve illustration for 4 damage limit state

3. Machine learning for estimating earthquake damage:

Over the past decade, numerous methodologies and models leveraging artificial intelligence (AI) and machine learning (ML) have been proposed for seismic damage estimation. Unlike fragility curves, which provide probabilistic assessments of damage exceedance, ML models inherently predict discrete damage states for structures subjected to earthquake excitation, offering deterministic outputs aligned with observed or simulated structural responses. The development of ML models for seismic damage estimation entails a systematic workflow:

1. Data collection:

Data collection poses significant challenges due to the difficulty of obtaining representative datasets that accurately reflect real-world conditions. Three primary approaches are employed:

- Structural Simulation: Models are often constructed using synthetic datasets generated from Finite Element Method (FEM)-based simulations of code-compliant structures. These simulations employ nonlinear static (pushover) or dynamic (time-history) analyses to evaluate structural responses under seismic loading. Input features typically include geometric properties (e.g., height, shear area), material characteristics (e.g., concrete strength, steel ductility), and mass distributions, with damage states classified using metrics such as the inner story drift ratio (IDR).
- Real-Building Simulation: Some studies utilize FEM models of existing structures, incorporating material properties derived from laboratory testing of samples extracted from actual buildings. These models undergo nonlinear static or dynamic analyses to estimate damage levels under seismic excitation.

- Field Data Collection: Empirical datasets are compiled from post-earthquake surveys and engineering assessments, correlating observed damage states with structural attributes and ground motion parameters. This approach captures real-world variability but relies on subjective engineer evaluations for damage classification.

2. Building the model:

After the data is collected, the next step is to create the ML model:

- Preparing the Data: Clean the data by fixing errors or removing incomplete information. Adjust the data so all values are on a similar scale, making it easier for the model to learn. Handle missing or noisy data to ensure accuracy.
- Choosing the Algorithm: Selecting an ML algorithm that fits the problem and dataset. Common choices include decision trees, support vector machines (SVMs), and random forests. Simpler problems use basic algorithms, while more complex ones need advanced methods.
- Training the Model: Training the model using the prepared data. During training, the model learns patterns to make accurate predictions.

3. Testing the Model:

Ensuring the model performs well using part of the training data. Metrics like accuracy are used to evaluate its performance. This step ensures the model can handle new data and isn't just memorizing the training examples. It also confirms the model's reliability in real-world scenarios.

4. Random forest:

Random Forest, an ensemble learning method, leverages the power of multiple decision trees to enhance predictive accuracy and robustness. The algorithm constructs a multitude of decision trees during the training phase, each trained on a bootstrapped sample of the original dataset and a random subset of features. This process, known as bagging, introduces diversity among the individual trees, mitigating the risk of overfitting and improving generalization performance.

For classification tasks, Random Forest employs a majority voting scheme, assigning the observation to the class with the most votes across all trees. In regression scenarios, the algorithm averages the predictions of the individual trees to produce a final estimate. Furthermore, Random Forest provides a measure of feature importance, offering insights into the relative contribution of each feature to the model's predictive power. Its ability to handle high-dimensional data, coupled with its inherent robustness and ease of implementation, has led to its widespread adoption.

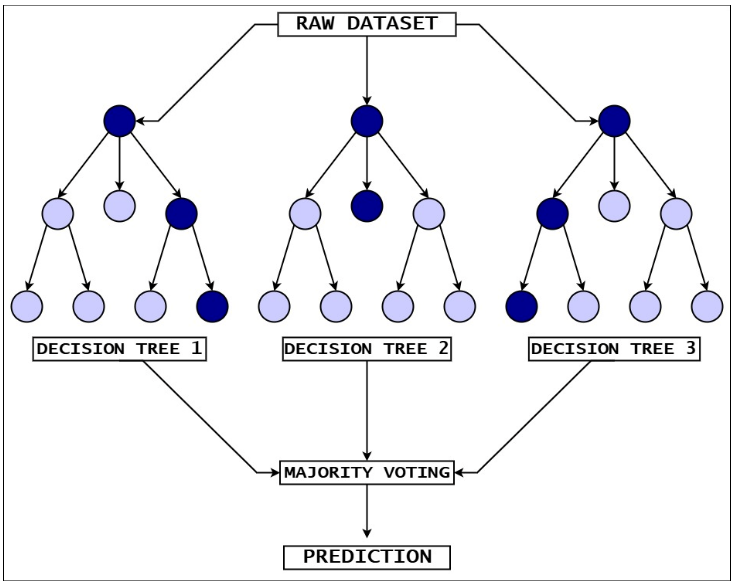

Fig. 2. Random Forest alogrithm

5. Study case:

This paper presents a study case for the data has been collected from field after earthquake stroke the Izmir region in western region of Turkiye in 2020. The dataset is consisting to nearly to 500 data points. The methodology and process of this study is consisting of main steps:

5.1. Data collection:

The data for this study case has been collected and generated from three main sources:

- Observation from field: The data has been collected from the field consisting of damage level and the location of the building after the seismic event.
- Generating ground motion parameters: Using these locations, the ground motion parameters is collected using REDAS software applying the scenario that simulated the seismic event.
- Footprint and elevation: Using the locations and OpenStreetMap the footprint of the region has been generated and using QGIS software the area for each building has been calculated. Using the location coordinate and Open Elevation API the elevation of each coordinate point has been collected.

5.2. Machine learning model creation:
The creation of machine learning model is created and consisted of main steps:
- Preparing Dataset: After collecting the data the dataset has been created by clearing the noises and damage data points, normalizing the features, grouping and classifying some features.
- Model creation and training: The Random Forest algorithm has been used aiming to use the features to predict the damage level. The dataset has been splinted by 80% and 20% as training and testing sets respectively.
- Model performance evaluation: In order to evaluate the model, the confusion matrices has been generated then the accuracy and F1 score have been calculated.

5.3. Damage classification:
The damage level has been classified into three categories based on the observation from field as following:
- Highly Damaged (HD): This class represents collapsed, need to be demolished, and severely damaged buildings
- Moderately Damaged (MD): This class contain the moderate damage and low damage building that need further investigation but that not dangerous for occupation.
- Non-Damaged (ND): This class represents the building that not get damaged in the seismic event.

5.4. The datasets:
As aiming to catch the most critical ground motion parameter seven datasets is prepared. For each dataset the ground motion parameter has been examined separately. Also, the area of the building has been examined to determine the importance of the building area features. The Dataset is shown below by case number:
- Case 1: The dataset is consisting of 7 features as following: The Age of the building, The Number of stories of the building, The elevation of the base of the building from the sea level, The Rupture distance (Rrup), The VS30, Peak Ground Acceleration (PGA) and the damage level.
- Case 2: Same of the case 1 but the ground motion parameter is represented by Peak Ground Velocity (PGV) instead of (PGA).
- Case 3: Same of the case 1 but the ground motion parameter is represented by intensity instead of (PGA).
- Case 4: Same as the case 1 and the footprint area of the building is taking into consideration.
- Case 5: Same as the case 2 and the footprint area of the building is taking into consideration.
- Case 6: Same as the case 3 and the footprint area of the building is taking into consideration.
- Case 7: In this case study the ground motion has been represented by PGA, PGV, and intensity together and the footprint area of the building took into consideration.

5.5 Results:
In order to be able to evaluate the results the confusion matrices, accuracy and F1 score has been calculated for each case.
- Case 1: The confusion matrix shows the model are able to predict the HD by 80% accuracy and there is no confusion between HD and ND classes. The ND class has high accuracy to be predicted correctly in this model as shown in Fig.4 (A).
- Case 2: The confusion matrix shows the model are able to predict the HD by 75% accuracy and there is some confusion to predict HD class as ND, The ND class still have high probability to be predicted correctly as shown in Fig.4 (B).
- Case 3: The confusion matrix shows the model are able to predict the HD by 65% accuracy and there is chance by 35% to predict HD class as MD or ND, The ND class still have high probability to be predicted correctly However, still lower than case1 and case2 as shown in Fig.5 (A).
- Case 4: The confusion matrix shows the model are able to predict the HD by 100% accuracy and there is no confusion between HD and other classes. However, the MD class has high confusion to be predicted as ND as shown in Fig.5 (B).

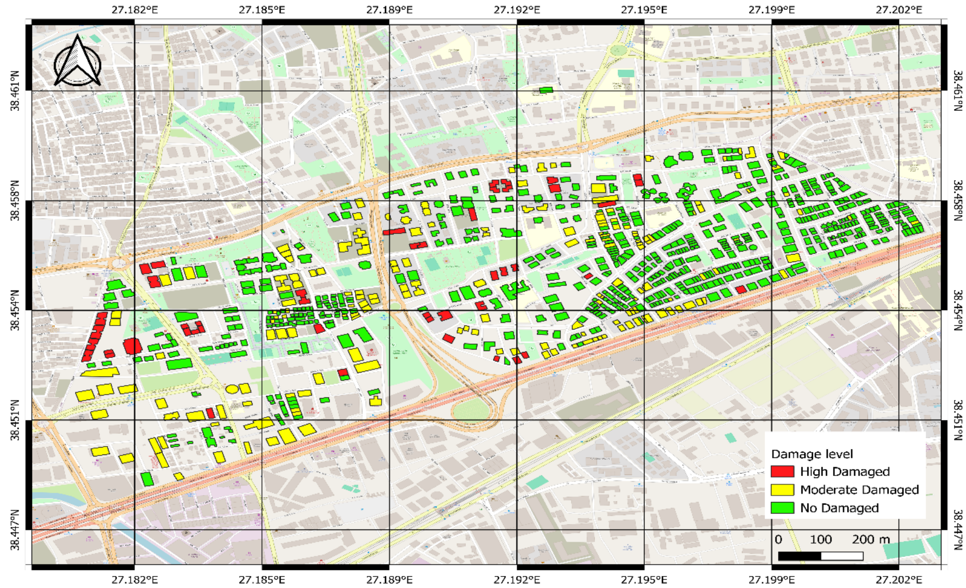

Fig. 3. Building footprint of the area of the studycase classified by damage class

- Case 5: The confusion matrix shows the model are able to predict the HD by 80% accuracy and there is a confusion between HD and MD class. However, the MD class has some confusion to be predicted as ND as shown in Fig.6 (A).
- Case 6: The confusion matrix shows the model are able to predict the HD by 75% accuracy and there is a confusion between HD to be predicted as MD or ND classes. However, the MD class has 35% probability to be predicted incorrectly as shown in Fig.6 (B).
- Case 7: The confusion matrix shows the model are able to predict the HD by 100% accuracy. The MD class has 27% probability to be predicted incorrectly as shown in Fig.7.
- Accuracies and F1-Scores: The accuracy and F1 score represent the performace of the model. The results show that the PGA is most accurate ground motion parameter with 82% accuracy when the area of the building not taken into consideration followed by PGV 78% then the Intensity 76%. However, the area of the building feature could improve the accuracy by 2% reaching 0.83 as F1-score for Case 4, 0.81 for case 5 and 0.77 for case 6. For case 7 the accuracy and F1 score reach 89.7% and 0.89 respectively shows that taking multi ground motion parameters may improve the accuracy of the prediction significantly as shown in Fig.8 and Fig.9 respecivly.

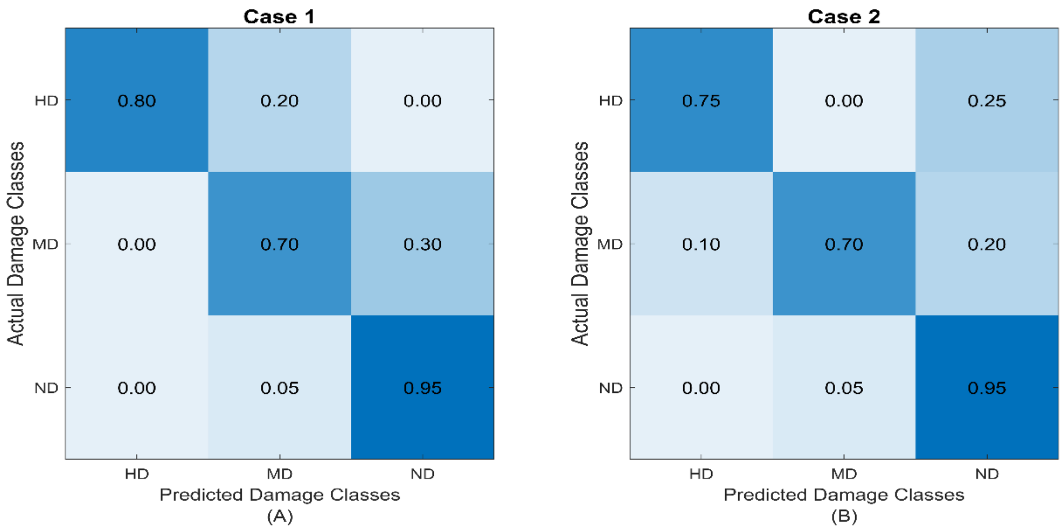

Fig. 4. Confusion matrices (A) Case 1 (B) Case 2

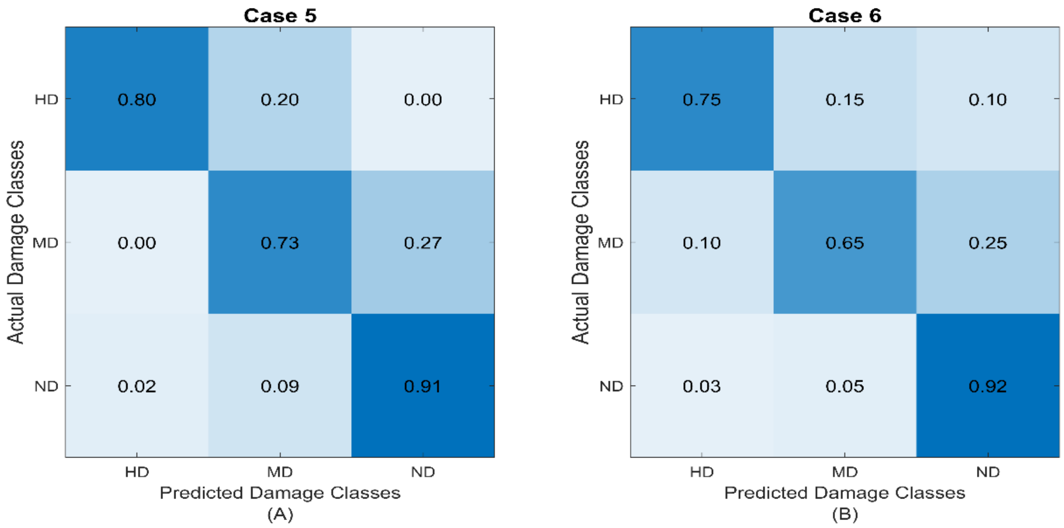

Fig. 6. Confusion matrices (A) Case 5 (B) Case 6

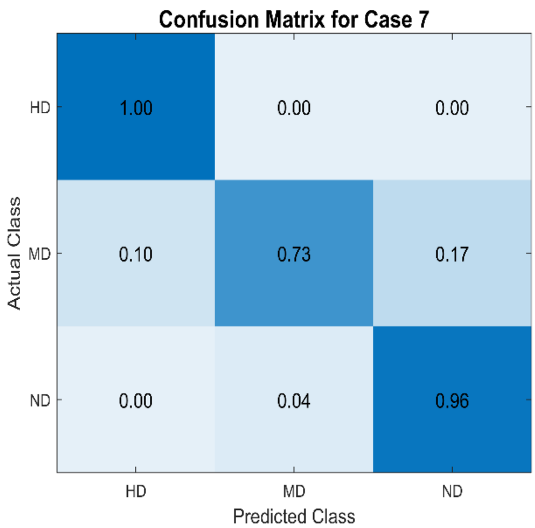

Fig. 7. Confusion matrix for Case 7

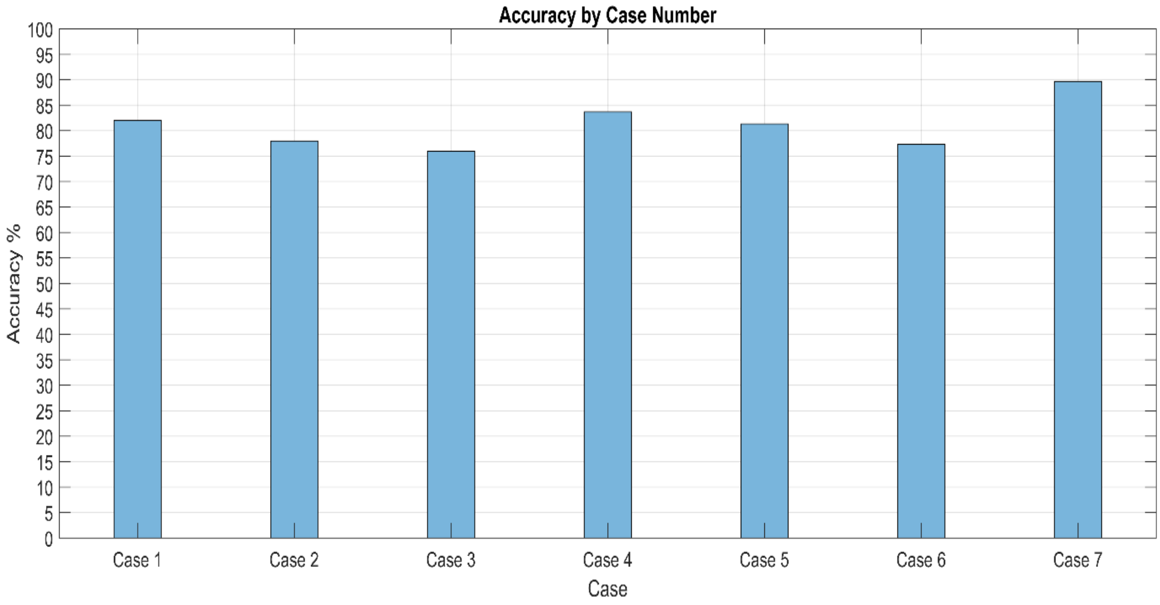

Fig. 8. Accuracy value by case number

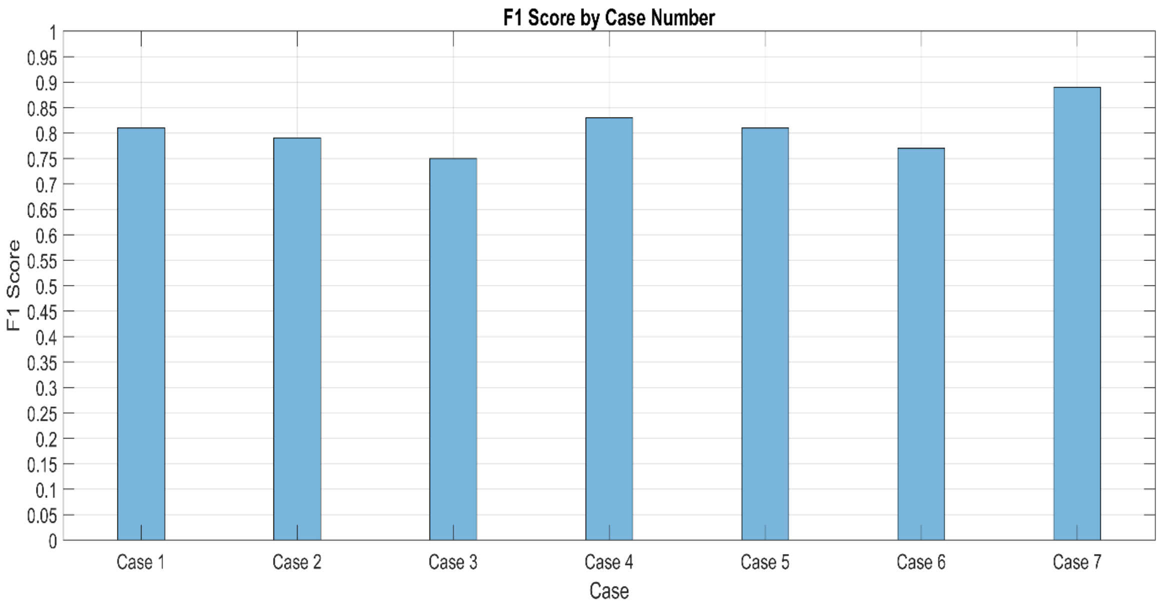

Fig. 9. F1-Score by case number

6. Conclusion:

In summary, this study provides compelling evidence of the efficacy of machine learning techniques—specifically the Random Forest algorithm—in conducting post-earthquake damage assessments. The analysis of various ground motion parameters indicates that Peak Ground Acceleration (PGA) is the most significant individual predictor of building damage, followed by Peak Ground Velocity (PGV) and Intensity. Moreover, the integration of building footprint area as an additional feature further refines the model's accuracy.

The optimal performance was attained by combining all three ground motion parameters with the building footprint area, yielding an accuracy of 90% and an F1 score of 0.90. These results underscore the potential of machine learning to facilitate rapid and precise damage assessments, which are vital for effective disaster response and management in seismically active regions. Overall, the proposed methodology presents a scalable and efficient framework for incorporating multiple ground motion parameters and building characteristics, thereby enhancing the reliability of damage predictions and supporting more informed decision-making in post-earthquake scenarios.

Abstract. Istanbul is confronted with a considerable seismic hazard, since analysts anticipate the likelihood of a substantial earthquake occurring within this century. The precise time of this event is indeterminate; however, its potential severity necessitates immediate preparedness to mitigate loss of life and infrastructural damage. This research examines the creation of an earthquake reaction robot, a notion currently implemented in nations such as Japan to improve rescue operations during seismic occurrences. The proposed robot is engineered to execute many essential tasks, such as locating survivors ensnared in debris and evaluating the structural stability of edifices. Furnished with sophisticated sensors, high-definition cameras, and autonomous navigation systems, it can traverse debris, identify humans requiring rescue, and assess the safety or peril of structures. This robot utilizes advanced technology to enhance the speed and effectiveness of emergency responses in disaster-affected regions, thereby saving lives and mitigating the effects of earthquakes. The robot's design integrates fundamental ideas of civil engineering and disaster management, enabling effective operation in hazardous and complex conditions. This paper presents a novel and pragmatic answer to the rising global incidence of earthquakes, with the capacity to revolutionize disaster response operations and improve public safety.

Keywords: Seismic hazard; Earthquake; Earthquake response robot; Emergency response

1. Integrated system architecture and communication framework

The earthquake response robot system is designed to integrate advanced mechatronic and civil engineering principles for use in high-risk disaster environments. It provides rapid autonomous inspection, real-time communication, and decision-making capabilities essential for search and rescue operations. This section outlines the system-level architecture, communication technologies, and integration strategies that enable the robot to function reliably in post-earthquake scenarios (Kottege et al., 2019).

Wireless communication enables seamless data exchange between the robot and external control systems, allowing for remote operation and continuous monitoring. Infrared (IR) is employed for short-range communication where line-of-sight conditions are available, though it can be affected by environmental factors such as sunlight (Li et al., 2018). Wi-Fi technology, based on IEEE 802.11 protocols, allows for fast data transmission but is generally limited in range and effectiveness in obstructed disaster zones (Li et al., 2018). Satellite communication, utilizing GPS signals, provides global connectivity and is crucial when traditional networks are compromised (Lin et al., 2021). Cellular networks enhance geographic coverage and facilitate communication across large disaster zones by connecting the robot to base stations (Li et al., 2018).

The robot's sensor integration plays a vital role in situational awareness. A fusion of RGB-D cameras, LiDAR, and inertial measurement units (IMUs) provides comprehensive perception capabilities. By merging sensor inputs, the robot enhances accuracy in obstacle avoidance, localization, and structural assessment (Wang et al., 2021). These data inputs are processed in real-time by onboard computing systems, enabling immediate autonomous responses and reducing reliance on remote operators.

Control system integration is also essential. The robot incorporates actuators and control algorithms that process sensory data to execute precise movements and manipulations. This integration ensures that environmental inputs are translated into responsive action during navigation and interaction with objects or survivors (Sahashi et al., 2013). Advanced machine learning algorithms, particularly convolutional neural networks, support crack detection, object recognition, and survivor identification using visual and thermal data (Kabilan et al., 2021).

https://doi.org/10.31462/icearc2025_ce_eqe_420

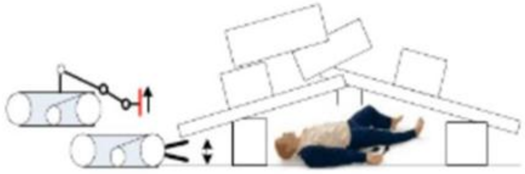

Fig. 1. Working scenario of Earthquakes robots

To facilitate human-robot interaction (HRI), multiple interface options are implemented. These include voice commands, touchscreen inputs, and wireless controls. HRI ensures that the robot can communicate feedback and receive high-level instructions from operators during collaborative missions (Bonarini, 2020; Pajaziti et al., 2021). Integration of user-friendly control devices such as joysticks and mobile platforms further enhances operational flexibility.

SOLIDWORKS is used to develop a detailed mechanical design of the robot, ensuring optimized placement and integration of sensors, actuators, and power modules. This modeling phase is crucial for testing mobility systems, simulating structural responses, and validating the feasibility of deployment in collapsed environments (Kottege et al., 2019).

Communication redundancy is another key feature. The robot is equipped with backup systems such as ad-hoc mesh networks and satellite links to ensure continued operation even if the primary network is disrupted (Lin et al., 2021). This layered communication strategy significantly improves operational resilience and ensures data availability in real time during rescue missions.

In summary, the integrated architecture of the earthquake response robot is designed to meet the demands of harsh disaster environments by combining robust hardware, intelligent software, and multi-layered communication systems. These features collectively enhance the robot's ability to assist human responders, assess structural damage, and save lives.

2. Subsystem: Structural analysis and civil engineering integration

2.1. Emergency communication and response integration system (ECRIS)

Earthquakes as natural hazards have caused substantial economic losses and significant human fatalities worldwide. This project introduces a novel integration system capable of conducting automated inspections and delivering emergency responses following seismic events. This system highlights the critical role of earthquake response robots in modern disaster management strategies (Kottege, Nannapaneni, & Peiris, 2019; Aracil et al., 2020).

The sub-team dedicated to this subsystem was tasked with developing capabilities for human and animal detection, fracture recognition, and prioritization of collected information for effective resource deployment. The integration of intelligent algorithms and advanced sensors enhances the robot's operational efficiency in post-earthquake scenarios

2.2. Requirements

The primary requirements for the subsystem include reliable communication, accurate detection capabilities, rapid response, terrain adaptability, integration with other systems, and robustness and scalability (Wang et al., 2021). Centralized emergency communication centers play a key role in facilitating coordination between human operators and deployed robots, utilizing satellite, wireless, mesh networks, and sensor-based systems to ensure data transmission under emergency conditions (Lin, Huang, & Putranto, 2021). The robot must possess mobility features that enable it to adapt to complex terrain, avoid obstacles, and remain operable remotely in earthquake-affected environments (Sahashi et al., 2013; Kabilan et al., 2021). For inspection tasks, it is equipped with LiDAR and ultrasonic sensors to autonomously assess environments and detect structural anomalies (Li et al., 2018; Lin et al., 2021). Structural assessment is performed using RGB-D cameras, microphones, and accelerometers, while collaborations with industry professionals enhance data precision and improve the training of artificial intelligence algorithms (Wang et al., 2021; Sahashi et al., 2013).

Localization and mapping are facilitated by onboard sensors that create accurate environmental maps, supporting navigation and obstacle avoidance. The robot’s autonomous navigation system uses these maps to safely traverse uneven terrain and access restricted areas (Aracil et al., 2020). Object detection and recognition algorithms continuously scan the environment to identify human and animal forms, aiding in victim search and classification. Once victims are located, the robot uses visual and video data to evaluate their condition and determine the most appropriate course of action. All collected information is transmitted to command centers in real time, while the robot simultaneously enables direct communication with victims when necessary. It also collaborates with human rescuers by guiding them to the exact location of trapped individuals and delivering logistical support throughout the mission.

The robot is capable of continuous operation and environmental monitoring to ensure uninterrupted area coverage, which increases the likelihood of successful rescues. Its multilingual communication system allows it to interact with survivors from diverse linguistic backgrounds, offering verbal guidance and support (Pajaziti et al., 2021; Pajaziti, Bajrami, & Pula, 2021). For emergency response assistance, the robot performs a wide range of functions including debris removal, delivery of supplies, communication relay, and hazard detection (Lin et al., 2021). It is also equipped to handle hazardous materials remotely using appropriate sensing and containment technologies. Human-machine interaction is made possible through intuitive interfaces that enable operators to issue commands and receive feedback in real time (Bonarini, 2020). The entire subsystem is designed for durability and reliability, ensuring it can withstand the harsh physical and environmental stress typical of post-earthquake settings. Finally, its power-efficient architecture ensures prolonged deployment capabilities without requiring frequent recharging, making it suitable for extended rescue operations in critical zones.

2.3. Technologies and methods

Historical cases highlight human-robot applications in disasters. Robots were used during Hurricane Wilma (2005), the Great Eastern Japan Earthquake (2011), and Italian earthquakes in 2012. Technologies such as Kinect-based 3D modeling and convolutional neural networks supported human motion analysis (Aracil et al., 2020) (Aracil et al., 2020).

Fall detection was studied using vision-based approaches involving silhouette extraction and motion analysis, achieving high accuracy compared to other sensing methods (Wang et al., 2021) (Wang et al., 2021).

2.4. Conceptualization

Three concepts were considered: (1) wheeled robot with LiDAR, (2) legged robot with RGB-D, and (3) wheeled robot with both RGB-D and LiDAR. The third concept offered the best balance of mobility, mapping, and localization capabilities.

Table 3. Conceptual design comparison

Component	Concept 1 (Wheeled Robot with Lidar)	Concept 2 (Legged Robot with RGB-D)	Concept 3 (Wheel Robot with RGB-D and Lidar)
Motor System	High-torque motor system	Specialized leg mechanisms	High-torque motor system
Image Processing	Powerful onboard computer	High-performance onboard Computer	High-performance onboard computer
Control Algorithm	SLAM techniques	Advanced computer vision techniques	Advanced computer vision techniques
Mobility	Good maneuverability on flat surfaces	Superior mobility over rough terrain	Good maneuverability on flat surfaces
Mapping Capabilities	Efficient mapping capabilities	Limited mapping capabilities compared to Lidar	Efficient mapping capabilities
Complexity	Moderate complexity	Higher complexity	Higher complexity
Cost	Moderate cost	Potentially higher cost	Highest cost

2.4.1. Physical architecture

The robot consists of a wheeled base, RGB-D cameras, microphones, LiDAR, a motor controller, and an onboard computing system. It integrates power management and communication interfaces.

2.4.2. Robot operation

Upon earthquake alerts, the robot initiates inspection using real-time imaging and autonomous navigation. Scenario-based simulations demonstrate its ability to assess injury levels, interact with victims, and direct rescuers.

In diverse building simulations, the robot differentiated between critical and non-critical cases and communicated multilingual guidance. It avoided high-risk zones when information was unclear, and prioritized high-value interventions based on available data.

2.5. Materialization

System materialization included selecting components aligned with functional needs and assembling them in a mechanical and electronic framework. Communication modules such as Wi-Fi, Bluetooth, and cellular were integrated with software protocols to ensure reliable data exchange. Workshops and iterative testing refined subsystem performance.

2.6. Evaluation

Evaluation included comparing conceptual solutions and validating the chosen system's ability to navigate debris, perform rescue tasks, and coordinate with human operators. The wheeled robot with RGB-D and LiDAR was found to be the most efficient in meeting operational goals under real-world constraints.

Rigorous testing confirmed the subsystem's reliability and relevance for disaster response, offering insights into system adaptability and future improvements.

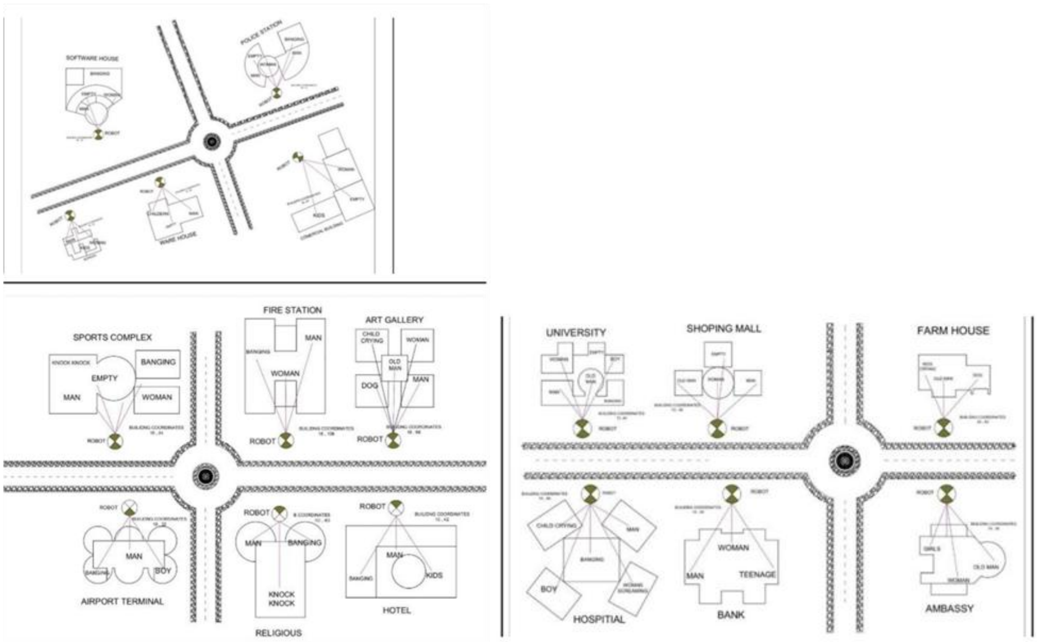

Fig. 5. Evaluation of robot performance across building case studies

3. Subsystem: Mechatronic control and sensory integration architecture

3.1. System overview and functional capabilities

This project is focused on the development of an earthquake response robot aimed at improving post-earthquake rescue operations. The robot's core functionalities include evaluating structural damage, navigating through hazardous environments, and transmitting real-time data to support rescue teams. It is specifically designed to assist in locating and rescuing individuals trapped under debris by providing essential supplies, such as water or blankets, especially in situations involving cold weather.

A key aspect of the robot's design is its ability to prioritize rescue efforts based on real-time assessments of building safety. This is achieved through an advanced voice recognition system that can distinguish between individuals' voices, such as children, the elderly, and animals, within each building. In addition, the robot employs machine learning techniques to assess building safety. The algorithm is trained using a large dataset of images showcasing both safe and damaged buildings, which enables the robot to identify and differentiate between structurally stable and unstable structures based on parameters such as cracks, deformations, and overall stability.

The robot's machine learning model allows for real-time decision-making, enabling it to evaluate the safety of buildings and determine which structures are suitable for entry. This prioritization ensures that rescue efforts are executed efficiently, reducing risk to both the rescuers and the individuals being rescued. The integration of advanced sensor technologies, machine learning, and autonomous decision-making represents a significant advancement in robotics for disaster response.

3.1. Communication and integration subsystem

The communication and integration subsystem is essential for the earthquake response robot, enabling seamless interaction between hardware and software components. It facilitates autonomous operation, real-time decision-making, and effective coordination with external systems. Key features include networking, remote control, fault detection, data logging, and sensor fusion, which enhance the robot's performance in complex disaster scenarios. Additionally, control system integration and human-robot interaction ensure efficient collaboration with human operators, improving the robot's adaptability and reliability during rescue operations.

This subsystem enables the robot to connect with external networks for remote control and monitoring. Key functions include fault detection, data logging, and telemetry. It also integrates multiple subsystems (locomotion, perception, manipulation) and incorporates sensor fusion from cameras, LiDAR, and IMUs. Human-robot interaction through voice, gestures, and wireless communication ensures collaboration with operators in high-risk environments.

3.1.1. Requirements for the earthquake response robot

The robot must fulfil critical performance requirements including survivability, mobility, accurate detection, and reliable communication. The design employs SOLIDWORKS and includes an experimental setup for real-world readiness. Ethical considerations emphasize transparency about the robot’s capabilities.

System integration requirements include real-time communication, sensor fusion, onboard data processing, integrated control systems, user interface support, and power efficiency. These ensure autonomous execution of search, rescue, reconnaissance, and sensing tasks.

3.1.2. Technologies and methods

The robot uses wireless communication, IR, Wi-Fi, satellite, and cellular networks to ensure flexibility and redundancy. Sensor fusion from cameras, LiDAR, and IMUs supports decision-making. SOLIDWORKS aids subsystem integration. Human-robot interaction includes voice and gesture recognition. Redundant systems like mesh networks ensure connectivity during failures.

3.1.3. Conceptualization of the earthquake response robot subsystem

The subsystem must enable seamless communication, coordination, and decision-making. This includes:

- *Integration and Communication:* Coordination between subsystems and external systems with real-time feedback.
- *System Architecture:* Managing data flow and subsystem interaction.
- *Communication Protocols:* Ensuring compatibility and reliability.
- *Redundancy:* Including backup communication mechanisms.
- *Localization:* Using GPS, inertial navigation, and synchronization.
- *Decision Support:* Fusing sensor data for informed action.
- Data acquisition involves high-resolution sensors with real-time processing. Error handling includes self-diagnostics, error-detection codes, and noise filtering.
- Future enhancements include hyperspectral imaging, advanced acoustic sensors, and 3D LiDAR. AI applications such as deep learning, NLP, and predictive analytics improve decision-making.

3.1.4. Physical architecture

The architecture supports autonomous or assisted operation, integrating sensors, actuators, and communication tools. It employs SLAM for navigation and deep learning for victim assessment. Sensors include depth cameras, LiDAR, and acoustic sensors. Actuators and embedded computing enable mobility and processing.

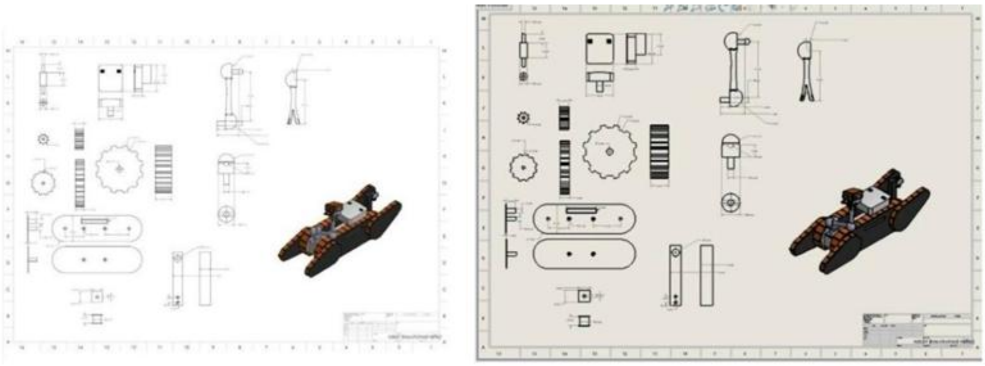

Fig. 6. Technical drawing sheets and 3D assembly view of the earthquake response robot developed using SOLIDWORKS, illustrating the mechanical components and structural integration

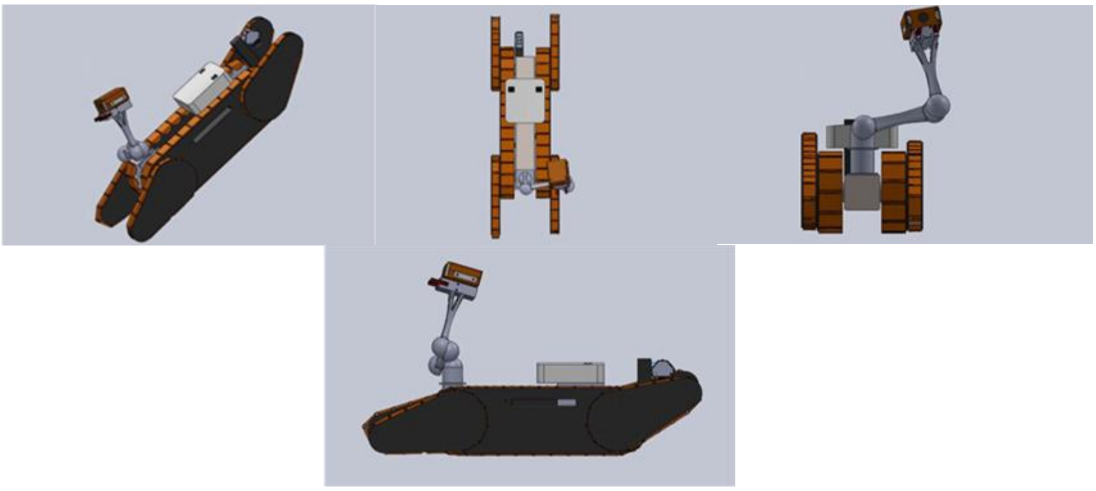

Fig. 7. Multiple perspective views of the earthquake response robot, including front, side, top, and isometric orientations, illustrating its mechanical structure and sensor-arm articulation

4. Conclusions

The earthquake response robot represents a significant advancement in the application of artificial intelligence and modern technologies to the field of disaster management. By integrating intelligent sensing systems, such as LiDAR and infrared imaging, with real-time data analysis and seismic monitoring, the robot enhances both the speed and effectiveness of post-earthquake operations. One of its primary functions is to improve safety in earthquake-prone regions through the early detection of seismic activity and the systematic exploration of affected areas. Furthermore, its ability to provide critical situational data to emergency response teams facilitates more informed and timely decision-making during rescue missions.

The development and deployment of this robotic system mark a transformative step in the management of natural disasters, particularly in high-risk regions like Turkey. Continued investment in such technologies is essential, as it not only improves immediate response capabilities but also contributes to long-term public safety, infrastructure resilience, and national disaster preparedness strategies:

- Effective structural damage assessment
- Survivor detection via sound and heat
- Autonomous navigation in complex terrain
- Real-time data transmission
- AI-powered prioritization of rescue areas
- Low-cost and scalable prototype
- Collaborative data training with real-world inputs
- Reliable power and processing architecture
- Durability and environmental resistance
- Multi-role capability

Acknowledgments

The authors would like to express their deepest gratitude to Prof. Gökhan Gelişen and Prof. Beste Bahçeci for their exceptional mentorship, continuous encouragement, and unwavering support throughout every phase of this project. Their expertise, constructive feedback, and dedication not only enriched our technical development but also inspired us to strive for excellence.

We would also like to sincerely thank our fellow teammates and colleagues for their hard work, collaboration, and perseverance during the development of this project. Their commitment and team spirit played a vital role in overcoming the many challenges we encountered.

A heartfelt thanks goes to our families and friends, whose endless support, understanding, and motivation gave us the strength to remain focused and determined. Their patience during long working hours, and their encouragement through stressful moments, were truly invaluable. This achievement would not have been possible without their love and belief in us.

Effect of concrete discharge on tensile strength and fibre distribution of UHPFRC

Marwa M. Ibrahim[1], Raafat El-Hacha[*1]

[1] University of Calgary, Department of Civil Engineering, 2500 University Drive NW, Calgary, Alberta, Canada

Abstract. Ultra High-Performance Fibre Reinforced Concrete (UHPFRC) is a next-generation material known for its exceptional mechanical strength and ductility. In addition to its well-documented compressive strength (>120 MPa), it exhibits a unique post-cracking tensile strength that is UHPFRC-exclusive. Accurately quantifying this tensile performance is critical to fully leverage the material's structural benefits. However, this tensile strength is influenced by fibre content and distribution within the matrix, which are significantly affected by the concrete discharge method during casting. Therefore, this study investigates the effect of the concrete discharge method on the tensile strength of a commercially available UHPFRC mix incorporating steel fibre and carbon nanofibres. Two discharge methods were examined: discharge from one stationary point: one end, and discharge from one stationary point: center. Dog-bone shaped specimens were cast in a single concrete layer and subjected to pure tensile loading. After testing, specimens were transversely cut near the failure location to analyze the fibre distribution within the cross-section. Results indicate that the one stationary point discharge method significantly enhances tensile strength compared to random discharge. Moreover, within the one stationary point category, the one-end location exhibited superior tensile properties over the center location. These findings underscore the critical role of discharge techniques in optimizing fibre distribution and tensile performance. Standardizing placement methods is essential to ensure consistent testing protocols and fair performance comparisons across different UHPFRC compositions. Future research should explore additional variables, like fibre geometry, to refine the application of UHPFRC in construction.

Keywords: Tensile strength; Fibre distribution; Concrete discharge; UHPFRC

1. Introduction

Concrete is the second most consumed material on Earth, after water. Its global usage reaches approximately 30 trillion tonnes per year. In contrast, wood consumption is around 1 trillion tonnes, and steel is about 1.6 trillion tonnes annually (Future Cleantech Architects, 2022). This widespread use is due to concrete's high versatility and energy efficiency. It outperforms many traditional construction materials in cost, durability, and availability. These advantages have driven research into advanced cement-based composites. In the 1980s, the introduction of superplasticizers and pozzolanic materials enabled the development of Ultra-High-Performance Concrete (UHPC), which greatly outperforms conventional concrete. UHPC showed excellent strength and durability, but also exhibited significant brittleness (ACI Committee 239, 2018). To overcome this, fibers were added to improve ductility and fracture resistance. This led to Ultra-High-Performance Fiber-Reinforced Concrete (UHPFRC). During development, some researchers questioned calling it "concrete". However, the term "concrete" was used instead of mortar to highlight the enhanced ductility of UHPC with fibres (Azmee and Shafiq, 2018). Similarly, the term ultra-high performance is selected rather than strength to highlight the wider characteristics of the material, including both mechanical strength and durability performance (Fehling et al., 2014). For context, UHPFRC's compressive strength is more than seven times that of conventional concrete, while its tensile cracking is three times greater (Graybeal, 2009). This combination, accompanied by excellent durability, makes it ideal for a plethora of construction applications, whether structurally demanding, environmentally demanding, or both.

The science behind UHPFRC is simple: removal of coarse aggregates, usage of a low water-to-cementitious materials ratio, utilization of pozzolans and superplasticizers, and optimization of the mix gradations. The preceding results in a 28th-day compressive strength of at least 120 MPa. On the other hand, the incorporation of fibres, mostly high-strength steel fibres at a volumetric ratio of 2%, gives the material an extraordinary post-cracking tensile strength that is steel-like (typically about 5 MPa (Ullah et al., 2022)). Reported UHPRC tensile strengths in the literature are as high as 14.2 MPa (Xu & Wille, 2015). As a result, UHPFRC contributes to the internal tensile load-resisting mechanism in flexural structures, unlike in conventional concretes where this tensile

[*] Corresponding author, E-mail: relhacha@ucalgary.ca

https://doi.org/10.31462/icearc2025_ce_eqe_425

strength is negligible. Recognizing this contribution can offer several advantages. One key benefit is the potential reduction in required longitudinal reinforcement. However, to fully utilise the tensile capacity of UHPFRC, it must be accurately characterised and quantified.

2. Problem definition

The tensile strength of UHPFRC represents a significant advancement in the evolution of concrete technology. This tensile strength must first be accurately quantified to fully exploit the material's attributes. Once established, appropriate subsequent modifications in the design process shall be made to account for this tensile strength and its implications on the member strength and ductility. However, the tensile performance of UHPFRC is influenced, in turn, by various factors, including fibre type and content, specimen or member dimensions, and concrete discharge during casting. This study specifically investigates the influence of the latter on tensile strength and fibre distribution.

3. Experimental testing program

3.1. Materials and mixing

The material utilized in this investigation is a proprietary UHPFRC mix enhanced with Carbon Nanofibres (CNF). Including nanomaterials improves the matrix by bridging nanoscale microcracks, while steel microfibres span larger cracks, enhancing the overall tensile strength. The material is supplied in separate components: bags of steel fibres, a CNF liquid pail, a superplasticizer, and a pre-blended mixture of cementitious and anhydrous materials. The mixing procedure largely mirrors conventional UHPFRC mixing, with an additional step to accommodate the CNF. The shipped CNF pail is first thoroughly mixed to ensure homogeneity before the required quantity is extracted. The CNF is then blended with superplasticizer and water, remixed, and subsequently incorporated into the dry pre-blend. Steel fibres are added gradually, and mixing continues for 10–15 minutes after water addition. Fibre contents are maintained at 2% by concrete volume for steel fibres and 0.75% by binder mass for CNF.

3.2. Companion compressive strength specimens

Three companion compressive cylinders (75 mm × 150 mm) were prepared to evaluate CNF-UHPFRC's compressive strength. Each cylinder was cast in a single layer to preserve the continuity of the fibre network formed during mixing and to avoid creating a potential weak plane at the interface of discrete layers. Following casting, each specimen was manually lightly vibrated to reduce internal voids. Then, the cylinders were immediately covered, demoulded after 24 hours, and then stored in a fog room under standard curing conditions (23 °C and 90% relative humidity) (ASTM, 2021). Prior to testing, the ends of all specimens were ground to ensure uniform axial load distribution. Compressive strength testing was conducted at the 28th-day of curing in accordance with ASTM C39 (ASTM, 2020) and ASTM C1856 (ASTM, 2017). The compressive strength recorded was 139.76, 136.07, and 134.72 MPa for cylinders 1, 2, and 3, respectively, with an average value of 136.86 MPa and a standard deviation of 1.56 MPa.

3.3. Tensile strength specimens

Six dog-bone specimens were fabricated following the guidelines outlined in the Swiss recommendations (Architects, 2016). To ensure continuity in the fibre network, fresh concrete was cast in a single layer, similar to the compressive strength cylinders. However, two distinct concrete discharge types were evaluated: discharge from a fixed point at the end of the mould (labelled "E"), and discharge from a fixed point at the centre (labelled "C"; see Fig. 1 (a)). Specimens were designated based on a two-part naming convention comprising the discharge type (E, C, or R) and a specimen identifier (SP1, SP2, or SP3). After casting, the specimens were also covered with a plastic sheet to prevent moisture loss, demoulded after 24 hours, and cured in a fog room under standard conditions (23 °C and 90% relative humidity).

3.4. Instrumentation and testing

The specimens were tested at the 28-th day of curing. The loading protocol consisted of two displacement-controlled phases: 0.2 mm/min during the elastic and post-cracking hardening stages, and 0.4 mm/min during the softening stage. Initially, a lower rate was used to accurately capture the response during the early loading phases. Due to the challenge of locating a testing machine capable of simultaneously applying axial and lateral hydraulic forces, a custom steel collar was designed and fabricated in-house to laterally restrain the specimen prior to axial loading. The collar enclosed the specimen and included welded transverse plates to prevent out-of-plane displacement, as well as separate aluminum wedges for confinement. Screws were used to engage the wedges and apply lateral pressure. Different wedge configurations—varying in length and angle—were examined in a preliminary phase to optimize the confinement system before initiating the tensile tests (Fig. 2 (a)). During testing, two Linear Variable Displacement Transducers (LVDTs) were mounted on each specimen to measure strain and crack openings. A custom-designed aluminum LVDT holder with a 200-mm gauge length was used to secure the sensors. Fig. 2 (b) illustrates the experimental setup immediately before the application of uniaxial tensile loading.

4. Results

4.1. Cracking behaviour

UHPFRC is well known for its multi-cracking behaviour under tensile loading (Fig. 3). As such, distributed cracking along the full length of the specimen is typically expected. Table 1 details the acceptance or rejection status of each specimen based on the failure location. Specimens were excluded from further analysis if the localized crack occurred outside the central 200-mm gauge length. Such cases were deemed invalid for the purposes of evaluating tensile behaviour and were accordingly rejected.

Table 1. Summary of the cracking response of the tested dog-bone shaped specimens

Specimen	Visible Cracks	Location of the localizing crack	Condition	Maximum Stress (MPa)
C-SP1	One	within the gage length	Accepted	7.80
C-SP2	One	within the gage length	Accepted	4.93
C-SP3	One	within the gage length	Accepted	6.80
E-SP1	One	Outside the gage length	Rejected	4.06*
E-SP2	Multi-cracking	Outside the gage length	Rejected	9.00
E-SP3	Multi-cracking	Two major cracks within the gage length	Accepted	9.59

*abrupt failure

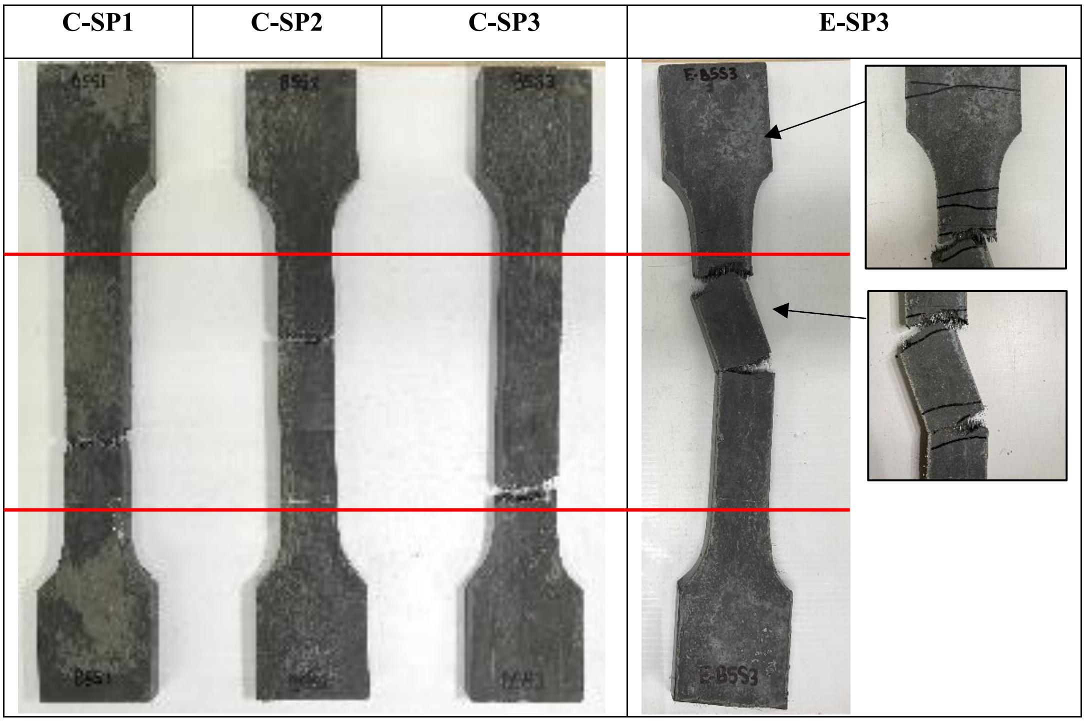

Fig. 3. Photos of accepted specimens: C-SP1, C-SP2, C-SP3, E-SP3 showing multi-cracking behaviour; red lines represent the borders of the instrumented gage length

4.2. Stress-strain response

Fig. 4 shows the full tensile stress-strain behaviour of UHPFRC, with two main cardinal points: cracking and localization. While the cracking onset is common for all concrete types, the post-cracking steel-like behaviour and the accompanying localization onset is UHPFRC inclusive. It is worth noting that the cracking characteristics are matrix-related, while the localization ones are steel fibre related. Therefore, the localization onset refers to the onset of fibre pullout where the fibres can no longer sustain the tensile load. Table 2 summarizes the stress and strain values of these cardinal points for each specimen. It is evident from Fig. 4 that the one end cast specimen showed superior post-cracking behaviour compared to all three centre-cast specimens. This is mainly attributed to the fibre distribution affected by the discharge location, as discussed below.

Table 2. Tabulated Stress-strain results of tested dog-bone shaped specimens under direct tensile load

Specimen	C-SP1	C-SP2	C-SP3	E-SP3
$f_{t,cr}$ *(MPa)*	5.55	4.21	4.22	5.55
$\varepsilon_{t,cr}$ (%)	0.010	0.012	0.017	0.016
$f_{t,loc}$ (MPa)	7.80	4.93	6.80	9.59
$\varepsilon_{t,loc}$ (%)	0.119	0.169	0.228	0.287

$f_{t,cr}$ is the cracking tensile strength; $\varepsilon_{t,cr}$ is the cracking tensile strain; $f_{t,loc}$ is the localization tensile strength; $\varepsilon_{t,loc}$ is the localization tensile strain

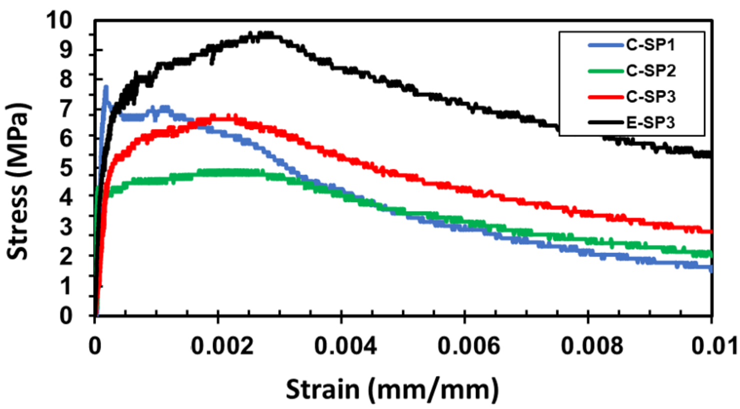

Fig. 4. Stress-strain response of CNF-UHPFRC dog-bone shaped specimens under direct tensile load

4.3. Effect of the discharge type on the tensile strength

While several factors—such as matrix strength, specimen size, and geometry—impact the post-cracking tensile behavior of UHPFRC, the type and volume of fibres at the cracking location are generally the most significant. These fibre-related parameters, however, are influenced by additional factors. The method of concrete discharge determines the fibre distribution along the specimen's length, while the fresh mix flowability governs the distribution of fibres within the cross-section, particularly in terms of potential fibre settlement. Fig. 4 illustrates that specimens cast from one end exhibited the highest tensile strength and strain capacity. Specimen E-SP3 developed multiple cracks, with two dominant ones contributing to enhanced strength and an extended multi-cracking phase. This discharge method preserves the fibre network developed during casting and promotes fibre alignment as fibres orient uniformly along the flow direction. The next observed behaviour corresponds to specimens cast from the centre, where the concrete flow splits into two opposing directions during placement (refer to

Fig. 5). Among these, specimen C-SP1 achieved the highest peak strength in its group but showed an abrupt post-peak strength drop. In contrast, specimens C-SP2 and C-SP3 exhibited more gradual post-peak softening, albeit with reduced peak strengths.

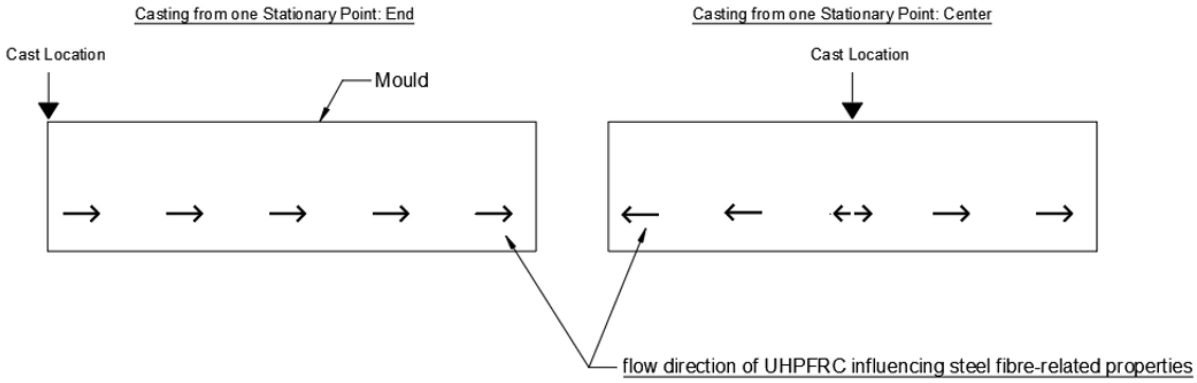

Fig. 5. Schematic demonstrating the influence of the cast direction on the flow properties and steel fibre-related properties of UHPFRC

The Swiss recommendations suggests grinding the surfaces of the hardened CNF-UHPFRC specimen prior to testing to ensure a uniform thickness. However, this practice is likely to introduce microcracks, creating localized weaknesses that can reduce the measured tensile strength and increase variability in test results. Given that the tensile strength of UHPFRC, although superior to that of conventional concrete, remains significantly lower than its compressive strength, such inconsistencies can substantially impact the reliability of test results. As an alternative, applying Tuck Tape to the interior surfaces if the wooden formwork (

Fig. 1 (a)) has proven effective. This, combined with the self-levelling properties of CNF-UHPFRC, yields smooth, uniform and crack-free CNF-UHPFRC surfaces from all sides. In addition, this is also advantageous from a practical point of view.

On the other hand, the application of Tuck Tape to the inner surfaces of the wooden formwork facilitated the visualization of the fibre orientation on the bottom surface of the hardened CNF-UHPFRC specimens. As depicted in

Fig. 6, fibres located near the stationary discharge points —either at the centre or end—exhibited random, non-aligned orientations. However, as the distance from the discharge location increased, fibres demonstrated a tendency to align with the direction of flow. This alignment was particularly evident in end-cast specimens at the critical section (middle cross-section), where fibres traversed a substantial, uninterrupted path, promoting better alignment.

In specimens cast from the centre, fibres are required to traverse distances comparable to those in end-cast specimens to reach the extremities. However, two primary factors often compromise alignment at these terminal regions. Firstly, widening of the cross-section at transition zones induces lateral dispersion of the mix, disrupting fibre orientation. Secondly, the proximity of formwork boundaries at the specimen ends imposes constraints on fibre movement, leading to circular alignment patterns as fibres navigate these spatial limitations (wall effects). This behaviour is consistently observed at end locations across both discharge types. These observations underscore the critical importance of controlled casting procedures to ensure consistent fibre alignment and reliable material behaviour.

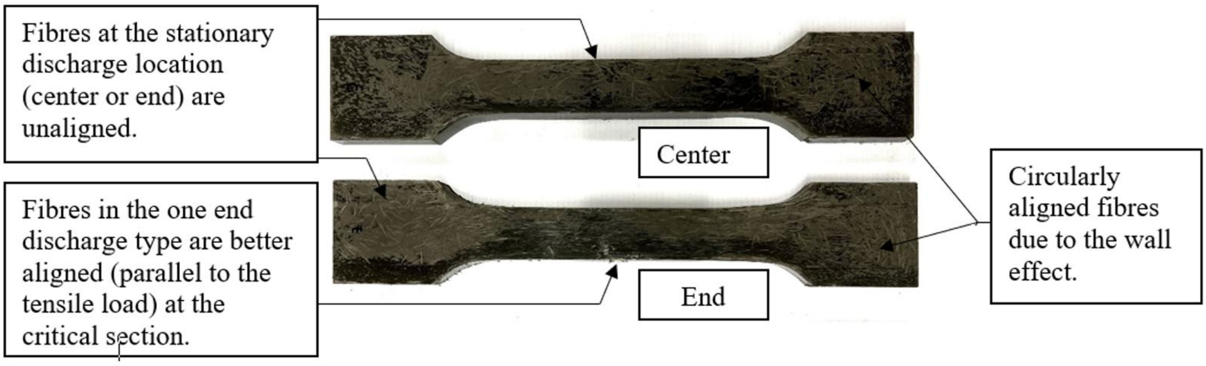

Fig. 6. Behaviour of fibres at the bottom side of the cast specimens

4.4. Effect of the discharge type on the fibre distribution and settlement

The tested dog-bone shaped specimens were transversely cut 10-mm away from the failure location using a wet saw to assess the fibre distribution within the cross-section (

Fig. 7). After conventional post-processing of the captured cross-sectional images, the contrast between the fibres and the surrounding matrix is increased to further differentiate specifically between the grains in the UHPFRC matrix and the fibres. Next, binary images are created, followed by fibre analysis.

Fig. 8 shows that fibres are denser close to the bottom casting side, attributed to potential fibre settlement due to the flowability being on the high end of the acceptable range. It is also evident that specimens cast from a stationary end location generally exhibited a higher fibre density across the cross-section. Conversely, specimens cast from a central stationary point displayed more linear fibre patterns with visible fibre lengths, indicative of less aligned fibres near the failure location. This central casting approach resulted in a lower overall fibre count across the cross-section, compromising the tensile performance of the material.

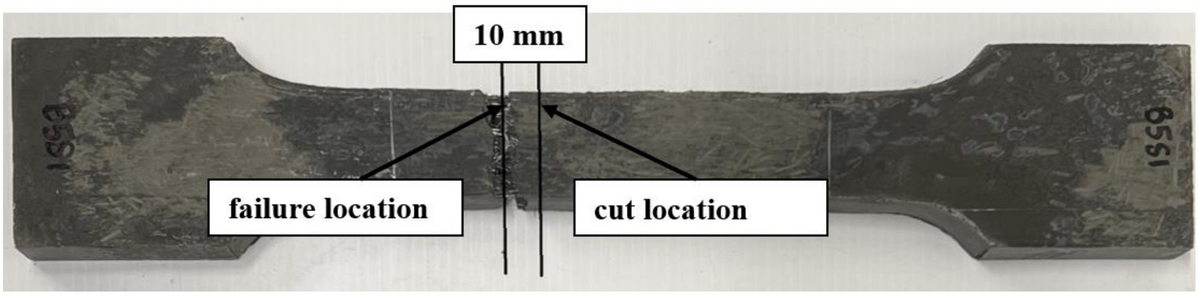

Fig. 7. Cut location of the tested specimen

Table 3 Summarizes the fibre analysis results, including fibre count and average fibre size. These findings align with previous observations: specimen E-SP3, cast from one end, exhibited the highest fibre count and an average fibre size closest to the manufacturer's specified diameter of 0.2 mm, leading to the observed superior tensile strength. The average fibre size within a cross-section serves as an indicator of fibre orientation. When the average fibre size closely matches the actual fibre diameter specified by the manufacturer, it suggests that fibres are predominantly aligned parallel to the applied tensile load and perpendicular to potential crack planes, thereby enhancing crack-bridging effectiveness and tensile resistance. Conversely, a larger average fibre size implies that fibres are oriented parallel to the crack plane, offering minimal resistance to crack propagation and reduced tensile strength. Table 3 also shows that the specimens cast from one stationary point at the centre location (C-SP1, C-SP2, and C-SP3) consistently showed larger average fibre sizes than the one end cast specimen, indicating less aligned fibres due to their proximity to the discharge location.

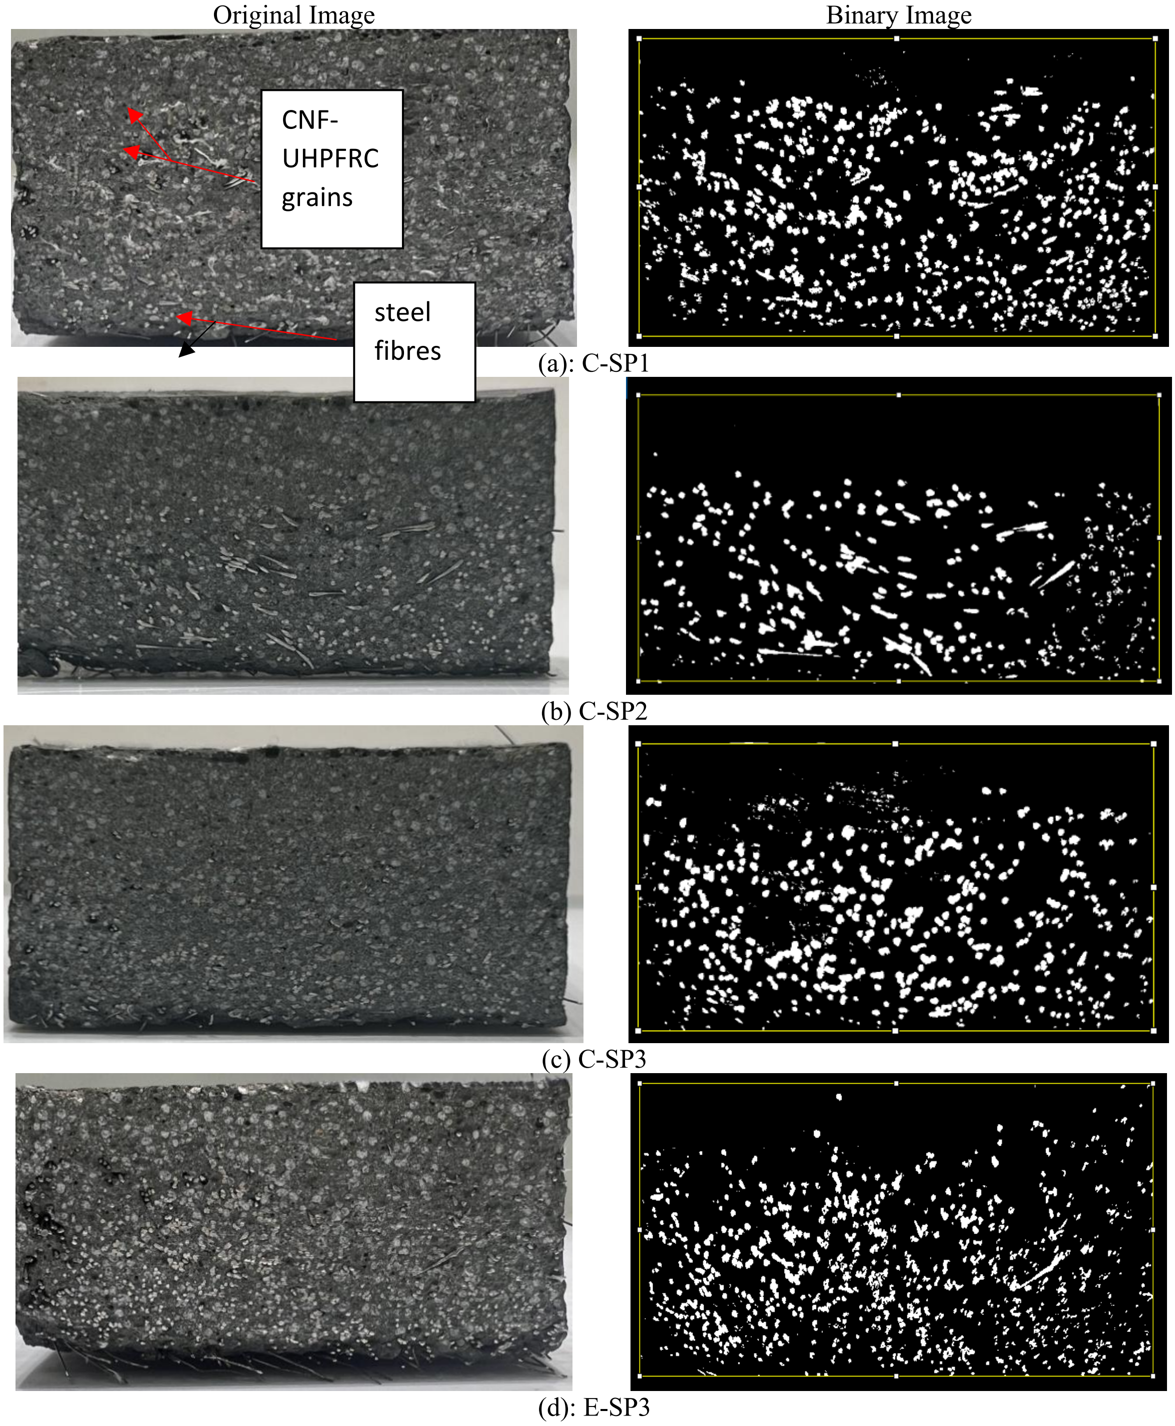

Fig. 8. Original and binary images showing the fibre distribution along the cross-sections of the tested specimens

Table 3. Results of fibre analysis showing the total number and average size of fibres

Specimen	Total number of fibres identified at the cut section	Average fibre size (mm)
C-SP1	505	0.36
C-SP2	300	0.30
C-SP3	410	0.40
E-SP3	555	0.23

The above fibre distribution and tensile strength observations align with the data presented in Fig. 9. Specifically, all centre-cast specimens exhibited a lower fibre count compared to that cast from the end. Notably, specimen C-SP1 had a 9% lower fibre than E-SP1; however, the average fibre size differed significantly (56.52% higher than E-SP1). This variation in fibre size contributed to the 22.94% higher tensile strength observed in E-SP1.

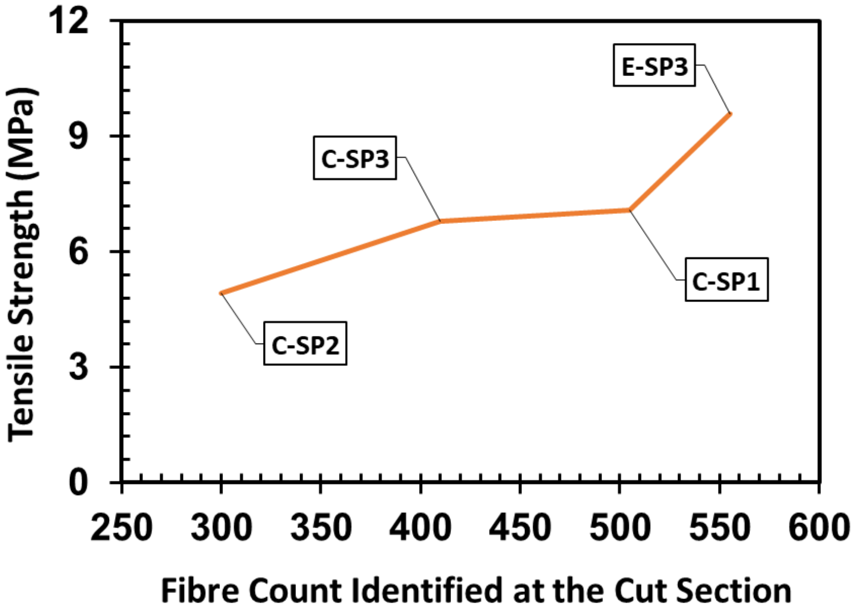

Fig. 9. Relationship between the fibre count identified at the cut section and the maximum tensile strength of each specimen

5. Discussion

The experimental results underscore the critical influence of casting methods on the tensile performance of UHPFRC. Specimens cast from a stationary end position exhibited superior tensile strength and strain capacity, attributed to enhanced fibre alignment along the flow direction, which facilitates effective crack-bridging mechanisms and delays crack propagation. Conversely, specimens cast from a central stationary point showed larger average fibre sizes, indicating less aligned fibres due to their proximity to the discharge location, leading to earlier crack initiation and reduced tensile strength.

These findings highlight two key considerations. First, the stationary discharge type from one end yields the most favourable tensile behaviour. Consequently, implementing this method is strongly recommended for both laboratory characterizations and practical large-scale applications to achieve consistent and optimal material properties. Second, it is important to establish specific protocols for discharge methods in international jurisdictions. This ensures uniformity in tensile strength characterization and compliant characteristics of UHPFRC in practical structural applications.

While specialized devices have been developed to facilitate UHPFRC casting, their practicality in large-scale, on-site applications remains limited. The rapid setting time of UHPFRC necessitates swift casting processes; any delays introduced by such devices can compromise material integrity, particularly under variable environmental conditions. Moreover, employing multiple stationary discharge points may disrupt the fibre network, leading to inconsistent mechanical properties. Therefore, a straightforward casting approach—utilizing a single stationary discharge point from one end—is advocated to maintain the material's structural performance and to streamline the casting process in real-world applications.

Nonetheless, it is essential to recognize that each construction project presents unique challenges and requirements. Engineers must exercise professional judgment to assess and determine the most suitable casting method on a case-by-case basis. Factors such as the volume of UHPFRC to be cast, the dimensions of the structural element (including its depth and length), and the intended function of the member (e.g., structural or non-structural) should be carefully evaluated to select the most appropriate casting strategy. This tailored approach ensures that the casting method supports optimal fibre orientation and distribution, thereby yielding enhanced and consistent UHPFRC performance.

6. Conclusion

Two types of concrete discharge methods were assessed in this study in terms of tensile performance. The findings underscore the importance of selecting appropriate casting techniques to optimize fibre alignment and, consequently, the mechanical properties of UHPFRC elements. Key conclusions drawn from the research include:

- The concrete discharge method significantly affects the tensile strength of UHPFRC. Establishing specific protocols for discharge methods in international jurisdictions is crucial to ensure uniformity in tensile strength characterization and compliance in practical structural applications.
- Discharge from a single stationary point- one end was found to be the most optimal as it promotes better fibre alignment at the critical section. Fibre analysis at the failure location showed that fibres in this specimen had the closest average diameter to the value provided by the manufacturer, leading to superior tensile strength and strain capacity. This method is recommended for practical applications.
- Discharge from a central stationary point results in less aligned fibres at the critical location (discharge location), leading to less effective fibre bridging capabilities and, therefore, a reduced tensile strength.

Further research is needed to develop standardized guidelines for casting procedures, considering factors such as UHPFRC volume, structural element dimensions, and the intended function of the member to ensure optimal fibre orientation and distribution. This way, UHPFRC applications in the construction industry can be advanced, ensuring that the enhanced performance and durability of UHPFRC structural elements are fully realized.

The integrated VS30 maps and soil classification for Sakarya province

Elif Toplu[1], Osman Kırtel*[1]

[1] *Sakarya University of Applied Sciences, Department of Civil Engineering, 54000 Sakarya, Türkiye*

Abstract. This study focuses on the development of an up-to-date and integrated VS30 map for Sakarya province, combining local seismic measurements with raster data provided by the United States Geological Survey (USGS). The USGS employs advanced techniques to generate VS30 maps, which include regression analyses to determine relationships between topographic slope, elevation, and VS30 values. In this research, 2044 seismic data points collected from the region were digitized using QGIS software, followed by interpolation analyses to create density maps. These local seismic data were then integrated with the USGS raster data, resulting in an integrated VS30 map for the province. To validate the map's accuracy, it was calibrated with field measurements, enhancing its reliability. The study's findings include the spatial distribution of the measured VS30 values, the USGS raster data clipped to the boundaries of the province, the integrated VS30 map, and ground classifications in accordance with the TBDY 2018 standards. The integration of local seismic data with global datasets significantly improves the accuracy of geotechnical assessments and enhances the reliability of seismic risk models.

Keywords: VS30 map; QGIS; Geographic information systems; Soil classification; Seismic risk; TBDY 2018.

1. Introduction

Local soil conditions have a significant impact on the magnitude, frequency, and duration of seismic waves. This effect varies depending on the material properties of the ground that seismic waves pass through before reaching the surface (Borcherdt, 1994). Particularly in areas with soft sediments near the surface, significant increases in the intensity of ground shaking may be observed. This phenomenon highlights the importance of the site effect, a factor that directly influences the vulnerability of structures. Vs is used to determine the dynamic response of the soil, liquefaction potential, and soil profile. Vs30, which represents the average shear wave velocity in the upper 30 meters of the soil, is critical for determining dynamic responses (Boore, 2004; Pokhrel et al., 2013; Seed et al., 1983). Vs30 has become a fundamental parameter representing site conditions and is widely used in engineering seismology. Proposed by Borcherdt (1994), this parameter has been made mandatory in the building and seismic design codes of many countries. For example, Eurocode 8 (CEN, 2004), the International Building Code (IBC, 2021), and the Turkish Earthquake Regulation (AFAD, 2018) use this parameter for site classification (Table 1). Additionally, Vs30 values are employed in ground motion prediction equations (GMPEs), playing a direct role in the creation of seismic hazard maps (Abrahamson et al., 2014; Boore & Atkinson, 2008; Bozorgnia et al., 2014; Chiou & Youngs, 2014).

Table 1. Soil Classification (AFAD, 2018)

Soil Classification	ZA	ZB	ZC	ZD	ZE	ZF
Vs30	1500>	760-1500	360-760	180-360	<180	-

However, the direct measurement of Vs30 values is quite costly and time-consuming. Measurements taken using methods such as MASW, SASW, SCPT, and SPT-N involve complex procedures that need to be implemented in the field, making it difficult to perform Vs30 mapping for large areas. As a result, many researchers have developed surrogate parameter-based methods for estimating Vs30. The most prominent of these surrogate parameters is topographic slope. Wald & Allen (2007) established a correlation between slope and Vs30 using data from the Shuttle Radar Topography Mission (SRTM) (Anon n.d.) and demonstrated that this method is applicable in active tectonic regions. Allen & Wald (2009) emphasized that topographic slope-based models yield more successful results when combined with higher-resolution DEM (digital elevation model) data. However, it has also

*Corresponding author, E-mail: okirtel@subu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_432

been noted that these methods achieve limited success in stable tectonic regions (Allen and Wald, 2009). Representing site conditions solely with topographic data can lead to erroneous results in certain regions. In areas with solid bedrock and flat terrain, high Vs30 values are expected, but slope-based models may fail to represent these conditions adequately. Therefore, hybrid models that combine geological data and topographic slope offer a more reliable approach (Thompson et al., 2014; Wills, 2008). Studies by Wills & Clahan (2006), Wills & Gutierrez (2008), and Wills et al. (2015) have shown that approaches that assess both geological units and topography lead to more accurate site classifications. Similarly, Thompson et al. (2010, 2014) and Heath et al. (2020) emphasized the success of hybrid models and enhanced model quality with spatial regression methods like trend kriging. Many Vs30 maps have been developed for various regions in the international literature (Abbasnejadfard et al., 2023; Boyd et al., 2024).

In Turkey, within the framework of studies conducted by AFAD, Vs30 data are collected using seismic methods such as MASW for accelerometer stations and are utilized in applications like ShakeMap (Wald et al., 2022). However, the lack of a detailed Vs30 distribution across the country creates uncertainty, especially in post-earthquake loss estimation and risk analysis. In this context, detailed and up-to-date Vs30 maps, developed using geological maps, digital elevation data, and slope-based surrogate models, are of critical importance in determining site effects. Consequently, to accurately predict the effect of site conditions on ground motions, topographic slope alone is insufficient; hybrid approaches integrating geological knowledge provide more accurate results. This is a fundamental requirement for enhancing the reliability of seismic hazard and risk assessments in countries with active fault zones, such as Turkey (Sahin et al., 2024).

The slope distribution of Sakarya Province not only reflects the topographic and geomorphological segmentation of the region but also illustrates the intensity of deposition and erosion processes and the influence of young tectonics. The study area contains large plains. It is made up of the Samanlı Mountains and Çamdağ elevations, and when examining the settlement patterns of Sakarya Province, it can be observed that the urban centers are widespread in flat areas formed by river-borne sediments and shaped by river influences, characterized by highly fertile land. According to the suitability analysis for settlement, areas with a steep slope (≥ 45%), consisting of magmatic, metamorphic, and sedimentary rocks, which are prone to rockfalls and landslide hazards, as well as alluvial units with marshes, make up the third priority areas for settlement, most of which are located in the southern part of the province. The second priority areas for settlement, which include non-marsh parts of alluvial, alluvial fan, and slope debris areas with slopes up to 10%, contain areas where the groundwater level is close to the surface and consist mostly of alluvial units carried by the Sakarya River, where "liquefaction" is expected during an earthquake. These areas include the city center and the majority of the population. The main morphological units in the newly developed areas in the city center of Adapazarı and to the northwest of the existing city center, which underwent reconstruction after the 1999 earthquakes, are the Kocaeli Peninsula, the KAF Zone (Sapanca Depression), and the Samanlı Mountain Elevation (Sakar, Taga, and Zorlu, 2023).

QGIS, an open-source Geographic Information System (GIS) software, provides capabilities for visualizing, editing, analyzing, and mapping spatial data. With its user-friendly interface and extensive tool support, it is frequently used for spatial analysis and modeling tasks. QGIS software also offers various methods for spatial interpolation. Two main interpolation methods commonly used in QGIS are Inverse Distance Weighting (IDW) and Triangulated Irregular Network (TIN) interpolation. In IDW interpolation, the values of unknown points are estimated based on the distances to surrounding known sample points, with the influence of these points decreasing as the distance increases. This method is effective for cases where the data exhibit spatially continuous variation. The TIN method, on the other hand, involves constructing triangles between sample points to model the surface, but it may lead to sharp transitions and irregular slopes on the surface, creating limitations in representing continuously varying parameters (QGIS, 2022). In this study, the Inverse Distance Weighting (IDW) interpolation method was used to obtain a smoother and more realistic surface for the spatial distribution of Vs30 values.

2. Methodology

In this study, a Geographic Information System (GIS)-based method was employed to determine the spatial distribution of Vs30 (the average shear wave velocity to a depth of 30 meters from the surface) values reflecting local ground conditions within the boundaries of Sakarya Province. In this context, both the globally prepared USGS (United States Geological Survey) Vs30 raster data and the Vs30 point data obtained through on-site measurements at various locations by the Sakarya Metropolitan Municipality (SBB) (Şahvelet, 2022) were utilized.

In the first phase of the study, both datasets were imported into the QGIS software environment. The USGS data was incorporated in raster format, while the SBB Vs30 data, representing point data, was loaded according to the appropriate map coordinate system. The SBB data corresponds to locations that represent different ground properties across the province, providing highly accurate local information.

Subsequently, a continuous Vs30 surface map was created using the "Inverse Distance Weighting" (IDW) interpolation method in QGIS, utilizing the SBB point data. In this process, weighting was applied based on the distance to each measurement point, and Vs30 values in the intermediate areas were estimated. The resulting interpolation map was overlaid with the existing USGS raster data, allowing for the spatial compatibility of the two datasets to be assessed and enhancing the precision of the local map.

3. Data processing and analysis

The map of Vs30 measurements taken within the boundaries of Sakarya Province is presented in Figure 1. Figure 2, on the other hand, shows the USGS Vs30 raster data clipped to the boundaries of Sakarya Province. In Figure 3, an integrated Vs30 map has been generated by combining the measured Vs30 data with the USGS Vs30 data. Additionally, in Figure 5, soil classification has been carried out based on these datasets in accordance with the 2018 Turkish Seismic Design Code (TBEC).

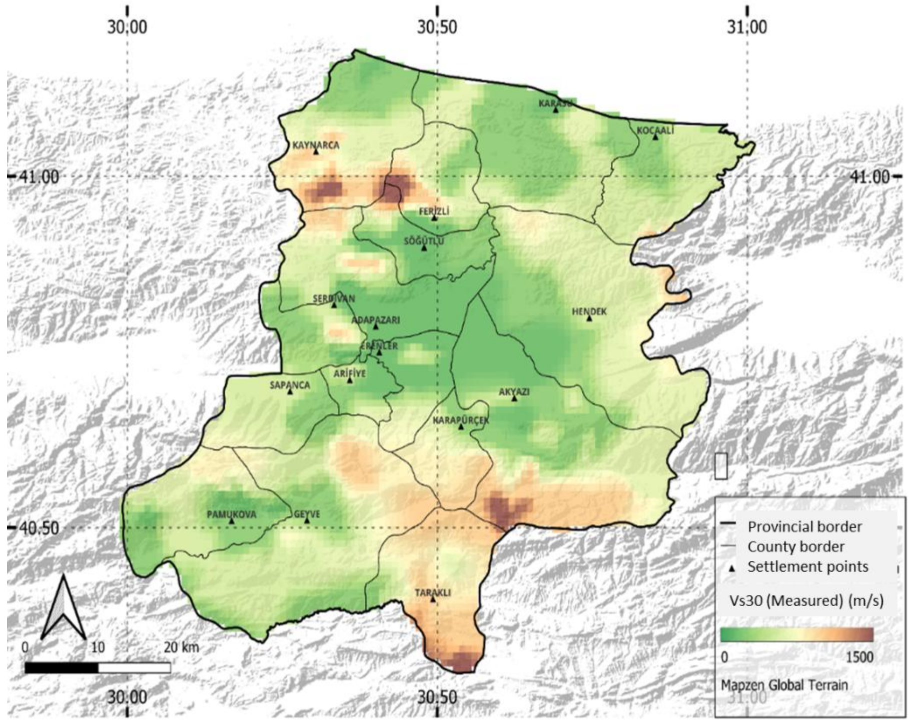

Fig. 1 Measaured Vs30 Map

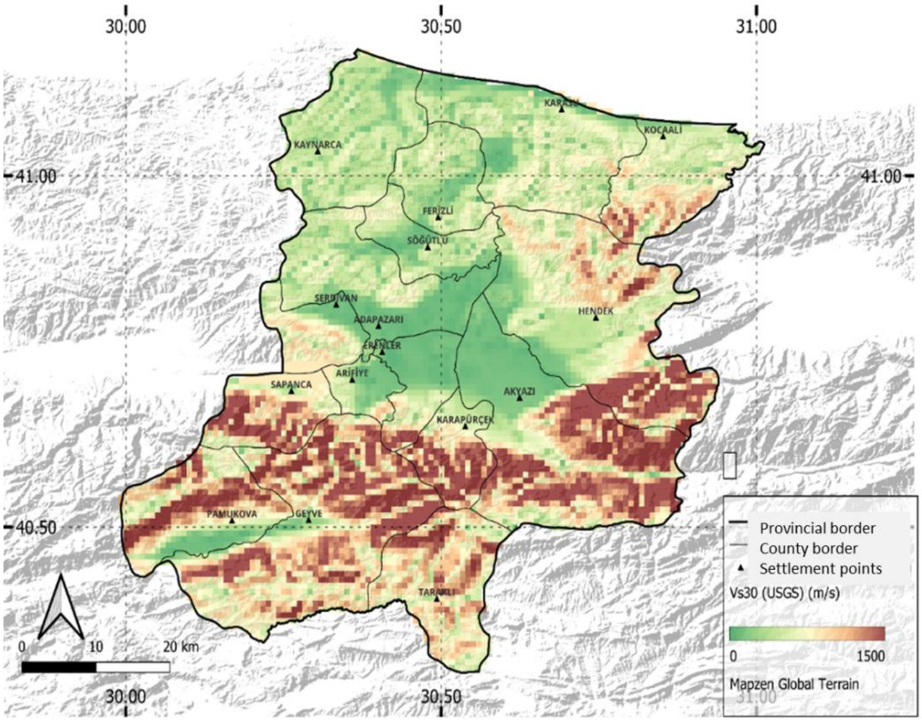

Fig. 2 USGS Vs30 map

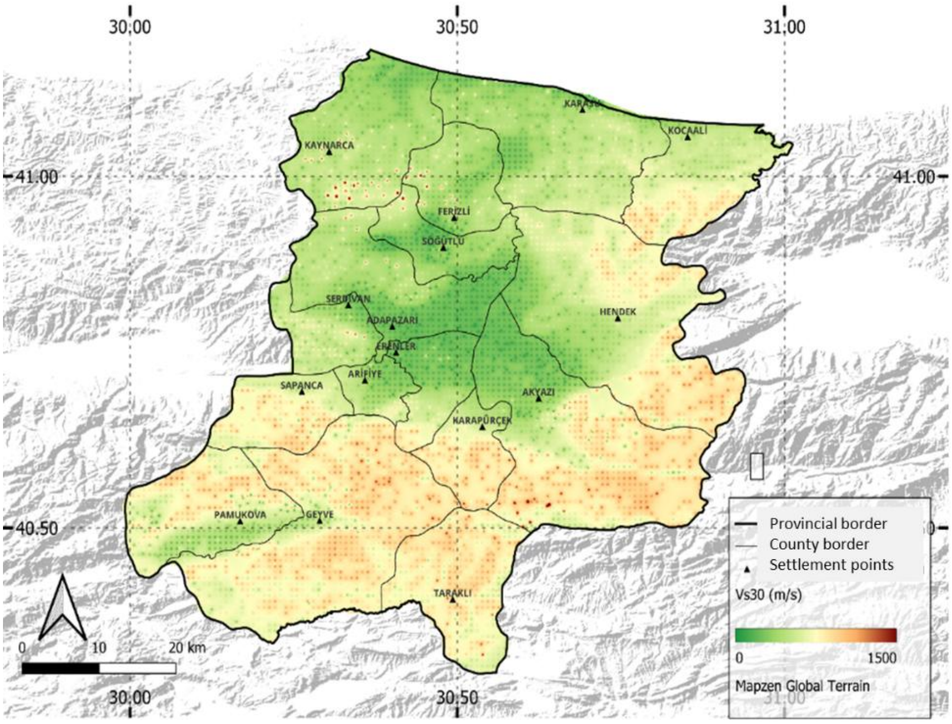

Fig. 3 Integrated Vs30 map

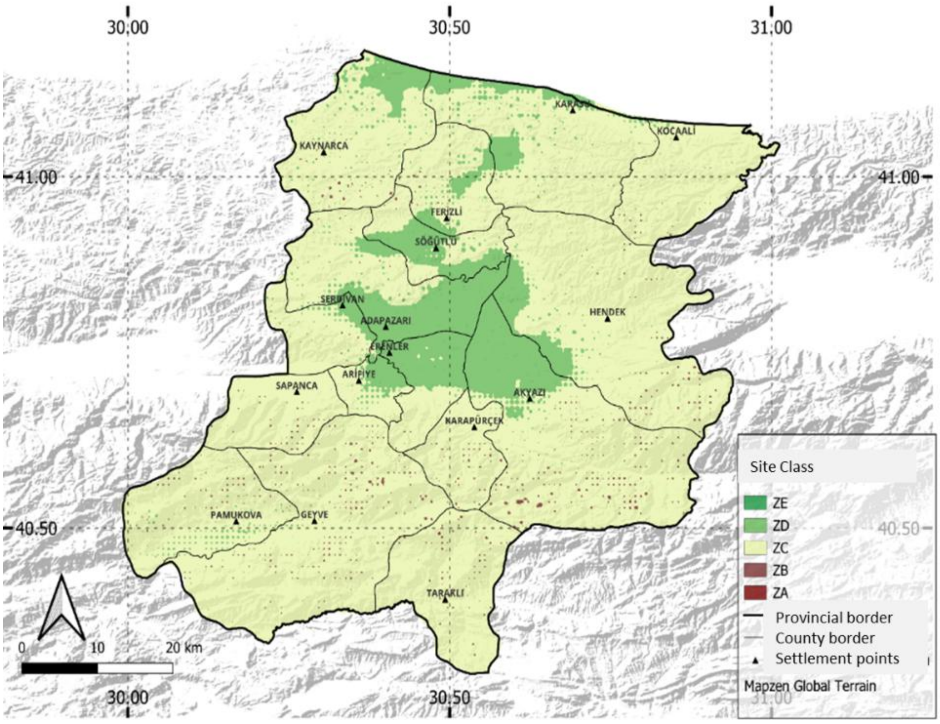

Fig. 4 Site class map

Fig. 3 presents the integrated Vs30 (shear wave velocity) distribution for Sakarya province. The Vs30 value provides information about soil type and stiffness: Low Vs30 values (green tones) are typically associated with soft soils and alluvial units, while high Vs30 values (orange-red tones) are related to firmer, rocky areas. The central and major urban areas of Sakarya (Adapazarı, Serdivan, Erenler, Arifiye) are situated on extensive alluvial plains. These plains, primarily formed by the alluvium deposited by the Sakarya River, are characterized by a high groundwater table, making them susceptible to liquefaction. Areas in the south and southwest of Sakarya (around Pamukova, Geyve, Taraklı) and the western part of Sapanca are represented by orange-red tones. In these regions, the Vs30 values increase (ranging from 1000–1500 m/s), indicating the presence of sloped, rocky terrains.

4. Conclusions

In this study, a spatially continuous Vs30 map has been developed to serve as a foundation for soil classification and seismic risk analyses specific to Sakarya province. The point measurement data provided by the local authority (SBB) were processed in the QGIS environment using interpolation techniques, and the resulting surface was overlaid with USGS data to enhance the map's accuracy. This approach integrated local data with global-scale information, yielding a more reliable soil profile.

As a result, a high-resolution Vs30 distribution map has been generated, which more accurately represents the soil characteristics of the region based on in-situ measurements. This map can be used as a critical data layer for soil classification and for future seismic hazard analysis, damage prediction, and risk assessment studies. In this regard, the study provides a va”luable source of updated, locally supported data that can be used in disaster management planning by local authorities and in engineering applications.

Abstract. Understanding the dynamic behavior of structures is crucial, especially for evaluating their performance under seismic dynamic loads. Dynamic characteristics, such as natural frequencies, mode shapes, and damping ratios, define how structures respond to variable loads. Accurately identifying these parameters is essential for assessing seismic performance and ensuring structural safety. Modal analysis methods are widely used to understand and characterize dynamic behavior. This study investigates the dynamic behavior of a building model created using the finite element method (FEM). The goal is to calculate the building's dynamic characteristics through experimental modal analysis (EMA) using displacement data from selected points on one face of the building and validate these results by comparing them with finite element modal analysis outcomes. A dynamic load with sweeping frequency was applied to the base of the building model in order to induce torsional effects and reveal its response at various frequencies. Displacement responses at specific points on each floor were measured over time, providing essential data for understanding the structure's behavior. The displacement data were processed using MATLAB to generate transfer functions, which characterized the building's dynamic behavior and identified its modal parameters. The analysis revealed bending and torsional modal frequencies on the building's front face, and corresponding mode shapes were constructed using amplitude calculations. The results showed strong agreement between the finite element and experimental modal analysis methods, confirming the accuracy and reliability of the proposed approach for determining dynamic characteristics under loading conditions.

Keywords: Experimental modal analysis method; Dynamic behavior; Dynamic characteristics.

1. Introduction

Structures are evaluated based on their dynamic responses to external influences, particularly under seismic loading. One of the fundamental parameters in characterizing these dynamic responses is the natural frequency, which reflects the characteristic oscillatory behavior of engineering structures under free vibration conditions. The natural frequency is determined by the geometric and mechanical properties of the structure, and it serves as a critical indicator of dynamic stability, energy transmission, and resonance behavior. Since this parameter can vary over time due to damage phenomena such as stiffness degradation, it is extensively employed in structural health monitoring and performance assessment (Salawu, 1997). Environmental effects, material aging, and operational conditions can alter structural stiffness over time, thereby inducing variations in the dominant modal periods and mode shapes. Earthquake loadings constitute some of the most critical dynamic actions that structures may encounter during their service life. During such events, energy is dissipated predominantly in regions of reduced stiffness, and the resulting damage in these areas has a direct impact on the global dynamic characteristics of the structure.

Within this framework, structural vibrations are not only a matter of safety but are also critical in terms of serviceability and user comfort. Uncontrolled increases in vibration levels can lead to failures, fatigue damage, or user discomfort in various engineering systems, such as turbine blades, suspension bridges, and high-rise buildings. Therefore, accurate identification of natural frequencies, mode shapes, and damping ratios is essential to ensure that vibration levels remain within acceptable limits during the design phase (Ewins, 2000). Modal analysis techniques, which are used to identify the dynamic parameters of structures, have found widespread application in both analytical and experimental domains. Experimental Modal Analysis (EMA), in conjunction with analytical modeling, is widely used in structural health monitoring, damage detection, and model calibration. However, since

https://doi.org/10.31462/icearc2025_ce_eqe_440

golden light publishing

modal parameters are influenced by environmental and operational factors, the reliability of these techniques requires carefully designed testing protocols and the application of statistical validation methods. For example, the studies conducted by Alampalli et al. (1995) on bridges demonstrated that modal parameters could be employed to identify structural damage, although their localization capabilities may be limited.

Modal analysis defines the vibration modes of a structure through eigenvalue and eigenvector solutions (Zuming, 2018). Modal testing and analysis techniques have rapidly advanced since the 1960s. The development of the Fast Fourier Transform (FFT) algorithm by Cooley and Tukey in 1965 enabled the analysis of experimental data in the frequency domain. Subsequently, the Structural Dynamics Research Laboratory (SDRL) established at the University of Cincinnati played a pioneering role in systematizing experimental modal testing. General-purpose finite element software such as NASTRAN, developed in 1968, standardized modal solutions in engineering analysis. Since the 1980s, modal analysis methods have become applicable to multi-input multi-output (MIMO) systems, and advanced algorithms such as PolyMAX, the HV estimator, and MLMM have provided high accuracy in distinguishing closely spaced modes (Siemens, 2021).

Nevertheless, the evaluation of modal parameters should not be limited to frequency and mode shapes alone. Due to the influence of environmental variability and operational conditions, these parameters must be supported by cross-validation and statistical analysis method (Alampalli, 2000). Moreover, the dynamic behavior of structures can be examined across three frequency regions: low, mid, and high frequencies. At low frequencies, resonance responses are more prominent; as the frequency increases, damping ratios increase, modal density rises, and resonance distinctiveness diminishes. At this point, the resolution capability of conventional modal analysis decreases, necessitating the application of high-resolution techniques such as wavelet transform and time-frequency analysis (Ege et al., 2009).

More recently, Operational Modal Analysis (OMA) has emerged as a significant technique, enabling the identification of modal parameters by utilizing ambient excitations without requiring external input forces. Magalhães and Cunha (2011), for instance, demonstrated the applicability of OMA under field conditions through its implementation on a 280-meter-long concrete arch bridge. Similarly, the vibro-acoustic modal analysis approach proposed by Liu et al. (2022) offers high-accuracy modal parameter estimation using fewer input parameters. Furthermore, studies focusing on the retrofitting of historical structures have diversified methodological approaches in this area. For example, Kocaman et al. (2025) observed, in their analysis of the Kabasakal Mosque in Gaziantep, that reinforced concrete elements added post-construction enhanced structural stiffness but provided limited protection against large-magnitude earthquakes.

In this study, the dynamic characteristics of a four-story reinforced concrete frame system are investigated through a numerically conducted Experimental Modal Analysis (EMA) procedure. Time-dependent displacement data obtained from controlled base angular acceleration excitation were transformed into the frequency domain. The natural frequencies and mode shapes derived from these data were then compared with the eigenvalue solutions obtained via the Finite Element Method (FEM). The results revealed a high level of consistency between both approaches in terms of modal parameters, indicating the reliability of this methodology for model validation purposes. In this context, the study contributes to structural dynamic characterization by integrating EMA principles within a numerical framework and validating them through FEM-based analysis.

2. Material and method

2.1. Benchmark building model

In this study, the structural model was developed using the finite element analysis software SAP2000 (v21.1.0). The model represents a four-story reinforced concrete moment-resisting frame system. In plan view, the structure spans 32 meters in the X-direction and 24 meters in the Y-direction, with equal bay lengths of 8 meters. The story heights were assumed to be 3.5 meters. Figure 1(a) presents the overall structural geometry, while Figure 1(b) illustrates the location and labeling of observation points. The cross-sectional dimensions of structural members were kept constant throughout the height of the structure. Column sections were defined as 60×60 cm, and beam sections as 30×60 cm. The floor system was modeled with the rigid diaphragm assumption, and the foundation system was idealized using fixed support boundary conditions. Dead and live loads were applied as 2000 N/m² on slabs and an additional continuous wall load of 1500 N/m on beams. The material properties used in the model correspond to C35-grade concrete and B420C reinforcing steel.

2.2. Dynamic excitation and data acquisition

In the Experimental Modal Analysis (EMA) method, two primary excitation techniques are employed to determine the modal parameters of structural systems: impulse hammer testing and continuous vibrational forcing (shaker test). In this study, the continuous excitation method was selected to identify the natural frequencies and mode shapes of the numerically modeled structural system. A virtual shaker was used to apply a sinusoidal acceleration input at the base of the structure. This excitation was designed to simulate seismic effects originating from the ground and to effectively excite both translational and torsional modes of vibration.

To reveal the torsional modal behavior, an angular acceleration was applied at the base of the structure, generating a moment about the Z-axis (Figure 2). This approach enabled the identification of both translational and torsional components in the structural response. The applied dynamic loading consisted of a sinusoidal acceleration signal with a frequency range increasing from 0.01 Hz to 6 Hz, sustained over a total simulation period of 1000 seconds. The maximum angular acceleration was set to 100 rad/s² (CSI America, 2025), resulting in the acquisition of approximately 1,000,000 data points. These parameters were selected to ensure the excitation of the structural modes within the 0–10 Hz bandwidth.

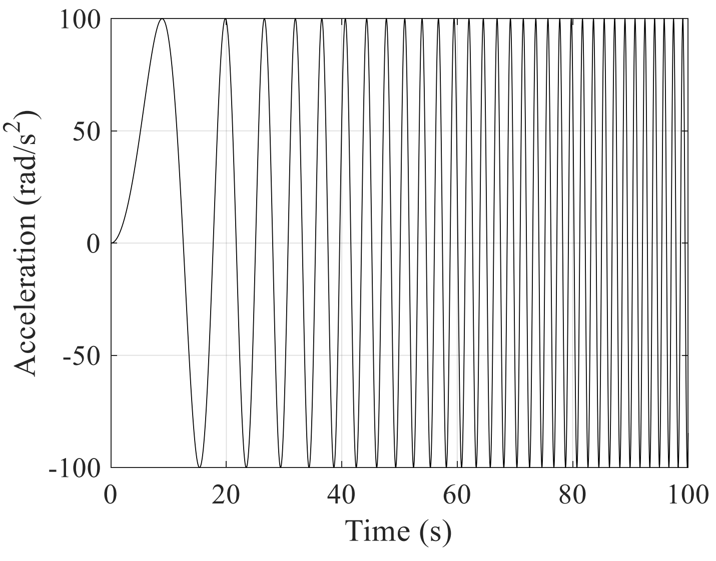

Fig. 2. Applied angular acceleration input used for base excitation

The structural response under forced vibration was analyzed using the direct integration method in the linear time-domain. Time-dependent displacement data were extracted in both the X and Y directions from predefined observation points. These observation points correspond to selected nodal locations in the numerical model, where structural response data were extracted virtually for subsequent modal analysis. These time-series data were subsequently transformed into the frequency domain and processed to identify the modal characteristics of the structural system in accordance with the EMA framework. Frequency analyses were conducted based on the Fast Fourier Transform (FFT), and Frequency Response Functions (FRFs) were generated to characterize the dynamic behavior of the system. The relationship between the input (applied acceleration signal) and the output (obtained displacements) was analyzed, and resonance frequencies were identified by examining amplitude variations along the frequency axis.

A sampling frequency of 1000 Hz was adopted for the analyses. To enhance spectral resolution, the signals were segmented and processed using a windowing technique with 50% overlap. A Hanning window was applied to minimize spectral leakage. Mode shapes corresponding to the identified resonance frequencies were extracted from the frequency response functions, enabling the interpretation of the structure's vibration modes. Furthermore, the system's linearity and time-invariance were evaluated through a consistency analysis. The degree of correlation between the input and output signals across the frequency band served as an indicator for assessing the system's linear behavior. Amplitude and phase characteristics in the frequency domain provided clear insight into the modal properties of the structural system.

All numerical analyses and signal processing steps were conducted within the MATLAB computing environment. The findings demonstrate that both translational and torsional modes of the structure were successfully isolated. Moreover, the modal parameters identified in the frequency domain were rendered suitable for comparison with those obtained through finite element analysis (Avitable, 2000).

3. Results and discussion

Following the application of sinusoidal excitation to the structure, the time-dependent displacement data were transformed into the frequency domain for both directions, and corresponding transfer functions were obtained. Figures 3 and 4 present the computed transfer functions for all observation points in the X and Y directions, respectively. The prominent peaks observed in the amplitude spectra of these plots indicate the resonance frequencies of the structural system and served as primary data for the identification of modal frequencies. The relevant frequency values are summarized in Table 1.

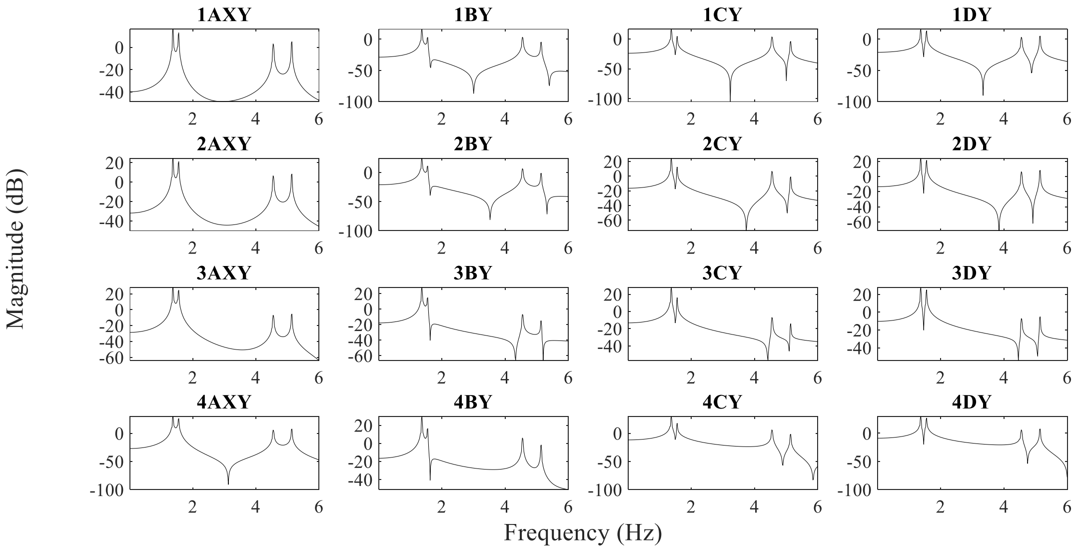

Fig. 3. Frequency response functions (FRFs) in the X-direction obtained from all observation points

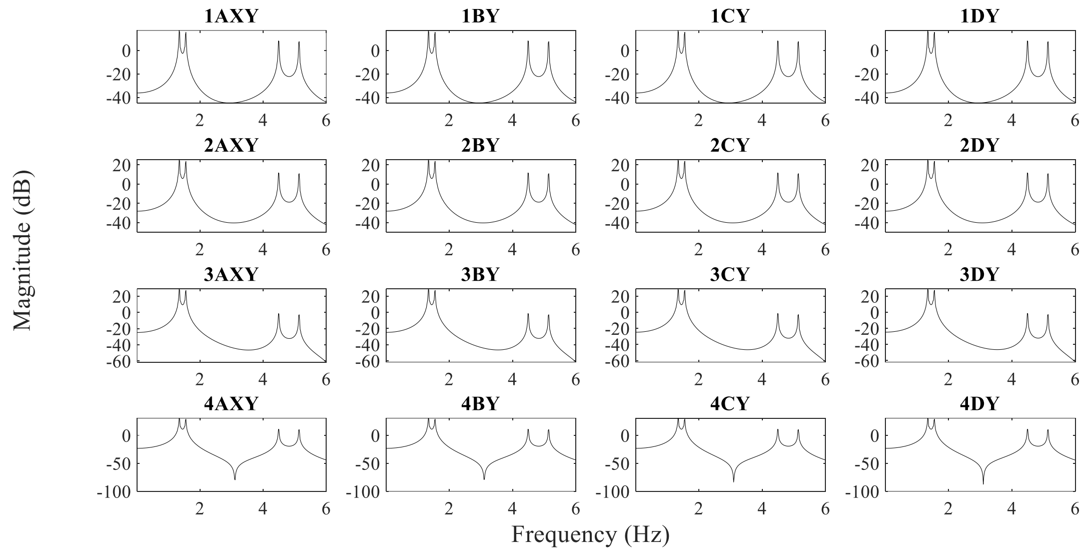

Fig. 4. Frequency response functions (FRFs) in the Y-direction obtained from all observation points

Table 1. Modal frequencies identified from transfer function analysis

Direciton	Frequency			
X	1.3733	1.5546*	4.5471	5.1422**
Y	1.3428	1.5546*	4.4861	5.1422**

* 1st torsional mode and ** 2 nd torsional mode

To assess whether the system exhibits linear and time-invariant behavior, a coherence analysis was conducted between the input (applied dynamic excitation) and the output (measured displacement) signals. Figures 5 and 6 present the calculated coherence spectra in the X and Y directions, respectively. In these plots, the coherence values within the frequency range corresponding to the first six modes of the structure are observed to be very close to 1 (or 100%), indicating strong input-output correlation. This result confirms that the system possesses linear characteristics and that the input-output relationships are represented with high accuracy.

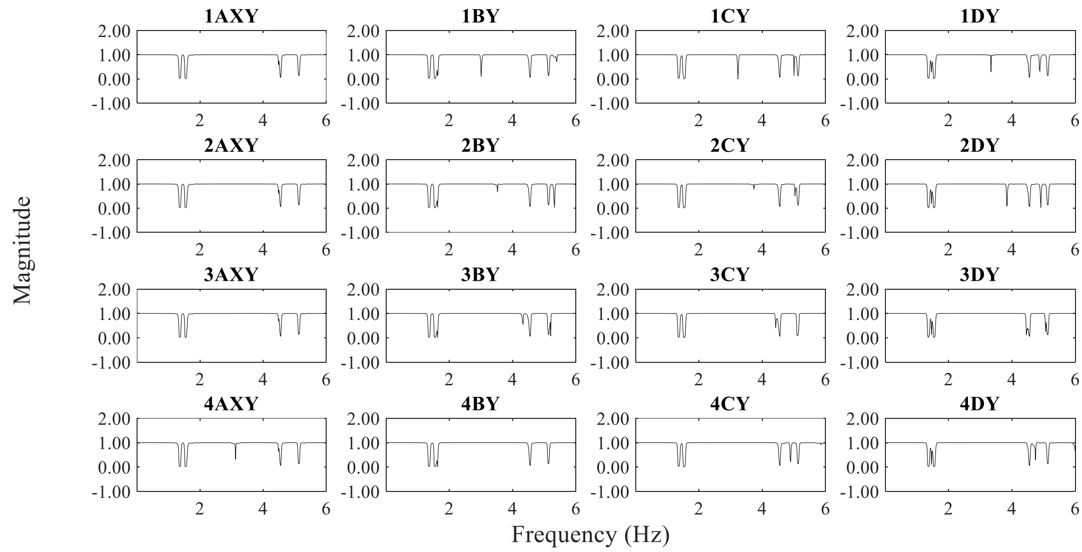

Fig. 5. Coherence function in the X-direction

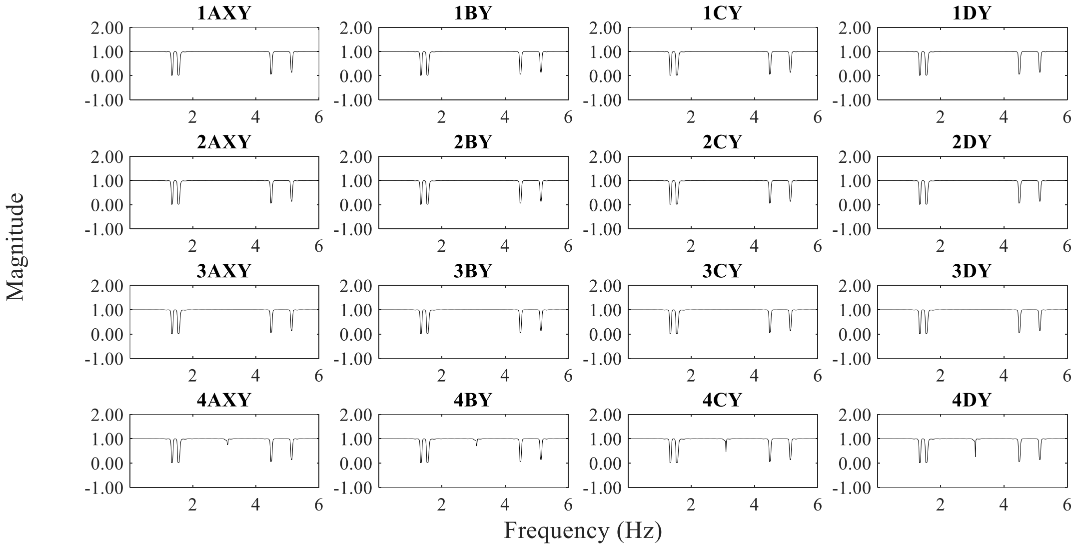

Fig. 6. Coherence function in the Y-direction

The frequencies of 1.549 Hz and 5.137 Hz, identified from the transfer functions presented in Table 1 and observed in both directions, indicate that these modes exhibit torsional characteristics. In contrast, the other frequencies correspond to direction-dependent bending modes. The fact that the lowest frequency was detected in the Y-direction suggests that the flexural stiffness in this direction is lower than that in the X-direction, indicating that the fundamental mode occurs in the Y-direction.

The data used in the computation of the transfer functions are in complex form, and the magnitude profiles corresponding to the mode shapes were derived from the imaginary components of these functions. Figures 7 and 8 present the extracted mode amplitude distributions for the X and Y directions, respectively. The peak points in these graphs correspond to the resonance frequencies listed in Table 1 and identify the characteristic regions of the associated mode shapes.

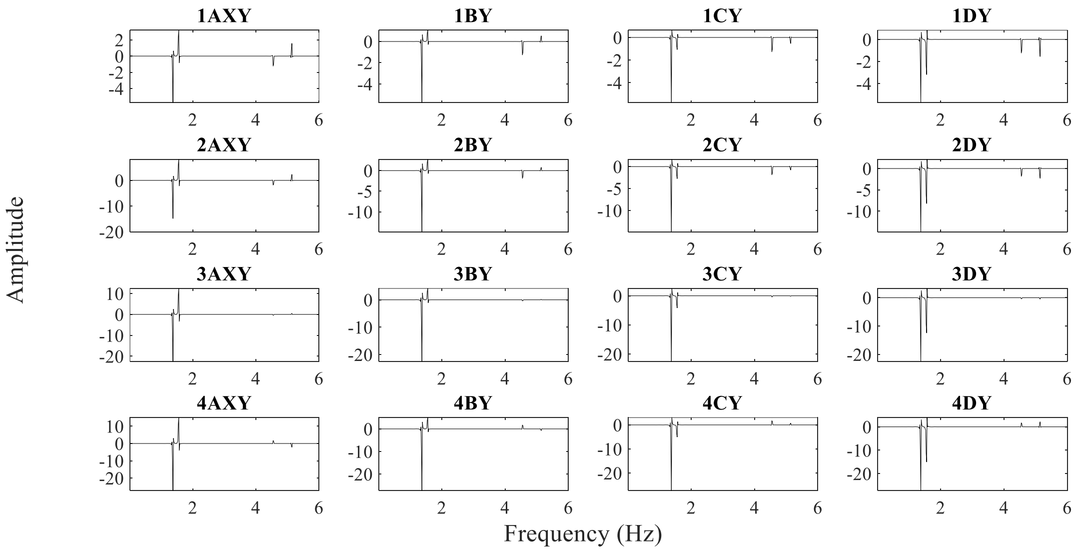

Fig. 7. Frequency-dependent mode shape amplitudes in the X-direction

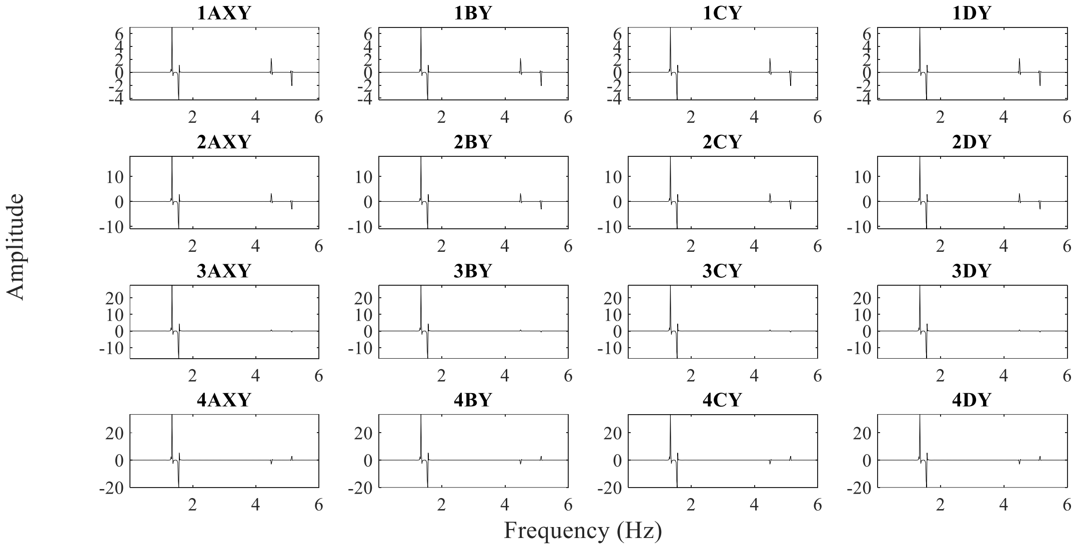

Fig. 8. Frequency-dependent mode shape amplitudes in the Y-direction

The obtained mode amplitudes were normalized with respect to the structural geometry and scaled to more clearly illustrate the relative displacement distribution along the structural axes. Within this scope, a three-dimensional mode shape was graphically constructed based on the amplitude data of the observation points located on the A-axis plane (Figure 9). This visualization provides a spatial representation of the structural system's modal vibration behavior and enables the identification of deformation modes under resonance conditions.

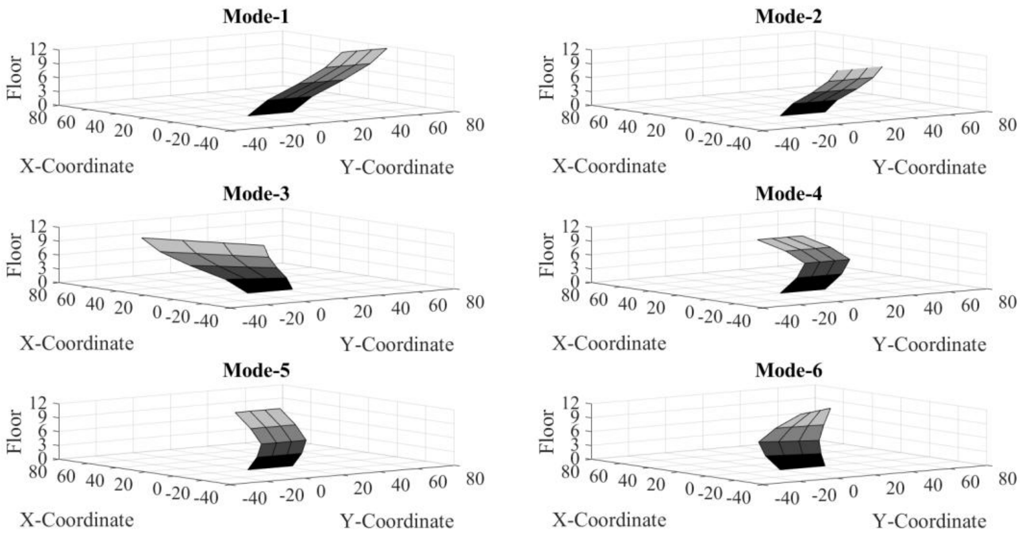

Fig. 8. Three-dimensional representation of mode shapes along the A-axis plane

The modal frequencies obtained through the experimental modal analysis (EMA) procedure conducted on the numerical model were compared with the eigenvalue solutions derived from the finite element analysis (FEA) software. The comparison considered both the modal frequencies and the mass participation ratios in the X and Y directions, as well as about the Z-axis. The corresponding values are presented in Table 2. A high level of agreement was observed between the frequencies identified via EMA simulation and those obtained from FEM results, with the frequency differences for the first six modes remaining below 1%. This outcome supports the applicability of virtual EMA outputs in the model validation process and confirms the reliability of the method.

Table 2. Comparison of modal properties obtained from FEM and EMA results

Mode	Period with FEM	Frequency with FEM	Load Participtaion at X	Load Participation at Y	Load Participation at RZ	Frequency with EMA
1	0.7436	1.3447	0	0.82	0	1.3428
2	0.730537	1.3688	0.82	0	0	1.3733
3	0.645477	1.5492	0	0	0.82	1.5546
4	0.222629	4.4918	0	0.12	0	4.4861
5	0.219598	4.5538	0.12	0	0	4.5471
6	0.194659	5.1372	0	0	0.12	5.1422

4. Conclusions

In this study, the dynamic characteristics of a four-story reinforced concrete frame structure were evaluated through an experimentally simulated modal analysis (EMA) procedure conducted in a numerical environment. By applying a sinusoidal base acceleration with increasing frequency content, both translational and torsional modes were effectively excited. The resulting time-domain displacement data were transformed into the frequency domain to identify the natural frequencies and mode shapes. Analyses based on frequency response functions (FRFs) revealed a high degree of consistency between the modal frequencies obtained through EMA and those calculated via the finite element method (FEM). Additionally, comparisons of the mode shapes demonstrated that both methods were able to identify the same vibration modes.

The findings indicate that the dynamic parameters of structural systems can be estimated through the numerical implementation of experimental modal analysis procedures. Particularly in cases where physical measurement capabilities are limited or inaccessible, such numerical EMA applications may serve as a valuable tool for the preliminary assessment of structural modal properties. The comparison between the extracted modal parameters and FEM results confirmed a consistent level of agreement between the two approaches. In this regard, the numerical EMA framework can be considered a potential engineering tool when in-situ experimental testing is not feasible. However, to enhance the validity of this method, further comprehensive comparison studies supported by physical experimental data on real structures are required.

The effect of non-uniform scour in transverse direction on seismic behavior of ordinary highway bridges

Serenay Ateş*[1], Özgür Avşar[1]

[1] *Eskisehir Technical University, Department of Civil Engineering, 26555 Eskisehir, Türkiye*

Abstract. The seismic behavior of ordinary highway bridges during earthquakes is significantly influenced by the scour around bridge piles. The process of erosion of the soil surrounding bridge foundations due to water flow causes scour, which becomes particularly critical during seismic events. This study investigates the effect of both uniform (Case-1) and non-uniform scour (Case-2) cases, which take place in transverse direction, on the seismic performance of ordinary highway bridges. Using a combination of analytical models created in the OpenSees program, the effect of scour-induced soil degradation on pile behavior and bridge response during earthquakes was examined by conducting nonlinear response history analyses. Scour depth was supposed to be the same around all piles and varied uniformly in the first scouring type, known as Case-1. In Case-2, two different non-uniform scouring types with linearly varying scour depth around the piles were investigated. In addition, various incidence angles of ground motion pairs were taken into consideration while examining the uncertainty in the excitation direction of the two horizontal components of the earthquake ground motion. The maximum seismic demands of members were assessed for different ground motion incidence angles for each scour cases at the specified scour depth. The results highlight how uniform and non-uniform scour cases can alter the seismic demands in engineering demand parameters such as superstructure displacement, curvature demands of bridge column and shear force demands of piles. The non-uniform scour can increase the shear force demands of pile elements during earthquakes, which can cause a brittle type of shear damage mechanism in the downstream piles.

Keywords: Non-uniform scour; Highway bridges; Incidence angle; Nonlinear response history analysis

1. Introduction

Highway bridges are susceptible to structural damage from a range of external factors, such as scour around bridge supports due to the erosive effects of flowing water. Moreover, the scour effects may come together with the earthquake, and it may lead to increased seismic demands on the bridge elements. The effect of scour around substructure elements on the seismic performance of highway bridges have been the subject of numerous studies in recent years. Bridge-type structures are frequently analyzed under a multi-hazard framework using finite element software and fragility curves was used for seismic vulnerability assessment (Guo & Chen, 2016; He et al., 2020; Prasad & Banerjee, 2013; Wang et al., 2019; Wei et al., 2021). There are several relevant experimental investigations about bridges subjected to earthquake and scour effects in the literature. Shake table tests were conducted by Wang et al. (2015) to examine the seismic behavior of a scouring bridge pier with a pile foundation. The experimental results show that while the demand for the bridge pier decreases as the scour depth increases, the flexural moment and shear demand of the pile increases. This may cause the bridge failure mechanism to shift from the pier to the pile. Zhou et al. (2021) conducted an experimental investigation of the vertical load carrying capacity of reinforced concrete bridge pile group exposed to scouring. Experimental results indicate that corner pile was more vulnerable to seismic damage, because it was the initial location of both the first aboveground and first belowground plastic hinges. Additionally, some studies have been conducted to examine the impacts of an earthquake and scour on existing bridges. Yilmaz et al. (2016) investigated two actual bridges in California in a multi-hazard scenario. For various flood cases, fragility curves and surfaces were obtained. The research results indicate that floods make bridges seismically vulnerable. Avsar et al. (2017) examined the Bahçeli Bridge, which is situated on Lapseki-Biga highway in Türkiye. When comparing the full scour scenario to the no scour case, it was found that the horizontal superstructure displacements under earthquake loads were approximately doubled. There are a few research studies that consider non-uniform scour in bridges. Fioklou and Alipour (2019) calculated the non-uniform scour depth using two different scour scenarios, namely Case 1 and Case 2 corresponding to 25% and 50% more scour in the upstream of bridge's transverse direction, respectively. The results show that, in

golden light publishing

comparison to the demands derived from non-uniform scour situations, the seismic displacement demand of bridges is underestimated when a uniform variation in scour depth is taken into account. Ateş and Avşar (2024b) used straight and skewed bridge models to perform a series of nonlinear time history analyses while considering non-uniform scour in the transverse direction of the bridge. The outcomes show that in cases of non-uniform scour, shear force demands of piles exceed their shear capacity, resulting in a brittle damage mechanism.

When evaluating the seismic performance of bridges, nonlinear response history analyses are often used. During the analysis, the horizontal components of ground motion are generally applied to the global axis of the structures. However, the exact direction at which an earthquake affects a structure in real life is unknown. Therefore, researchers have been recently concentrating on studies that examine the effects of the earthquake incidence angle on analysis results and bridge performance (Atak et al., 2014; Bhatnagar & Banerjee, 2014; Moschonas & Kappos, 2011; Noori et al., 2019). In the literature, two distinct approaches are used to consider the angle θ, known as the earthquake incidence angle. The first method rotates the horizontal ground motion components while keeping the bridge principal axes constant using linear formation equations, while the second method rotates the bridge's main axes while keeping the horizontal ground motion components constant. According to Ates and Avsar (2024a), seismic demands derived from both approaches give the same outcome. In order to perform a multi-hazard framework, this study uses the first approach to take the earthquake ground motion excitation angle into account.

The objective of this study is to determine the seismic demands of ordinary highway bridges by taking into account two distinct non-uniform scour scenarios in addition to uniform scour. Within the parameters of the study, three distinct scour cases were examined. The scour depth in the first scenario, known as Case-1, was equal across all piles and changed uniformly. On the other hand, a non-uniform scour scenario in the bridge's transverse direction was examined in Case-2 and it was further separated into two distinct categories. In Case 2-1, non-uniform scour occurred in the transverse direction around bridge piles with a scour depth angle of γ=0.6 between upstream and downstream piles. In the second non-uniform scour scenario (Case 2-2), the scour depth angle is γ=1.0. 6 scour depth levels were taken into consideration, ranging from 0 m to 5 m with 1 m increment. During the analysis, horizontal ground motion pairs rotated by using linear transformation equations from 0° to 180° with 15° increments. This study focuses on three engineering demand parameters; superstructure displacement, shear force demand of piles, and curvature demand of bridge pier column.

2. Materials and method

2.1. Bridge model

This study examines a reinforced concrete highway bridge previously analyzed by Atak et al. (2014). The bridge superstructure consists of four spans, each measuring 35 m in length and 12 m in width as seen in Fig. 1. It is composed of 8 prestressed concrete I-section beams supporting a continuous reinforced concrete deck that is 0.22 m thick. Expansion joints are present between the abutments and the bridge deck in both longitudinal and transverse directions. The prestressed beams are made of C40 grade concrete (f_c = 40 MPa), while the remaining RC components have C25 grade concrete (f_c=25 MPa). The steel reinforcement grade is S420 (f_y=420 MPa). The substructure consists of abutments, cap beams, and single-column piers supported by pile foundations. Each column pier features an oblong cross-section with a diameter (D) of 4 m, a width (B_c) of 1.2 m, and a height (H) of 8.7 m. The cap beam has a rectangular cross-section with a width of 1.2 m and a depth of 1.75 m. Each prestressed beam is supported by an elastomeric bearing measuring 450 × 250 × 40 mm, ensuring effective load transfer from the superstructure to the substructure. The bridge superstructure is elastic during an earthquake because of their low lateral stiffness (Caltrans, 2019). Additionally, the pile cap has a rectangular geometry with a width (B_{cap}) of 2.5 m, a length (L_{cap}) of 5 m, and a height (H_{cap}) of 1.5 m. It is supported by six circular piles, each has a diameter (D_{pile}) of 1 m and a height (H_{pile}) of 20 m.

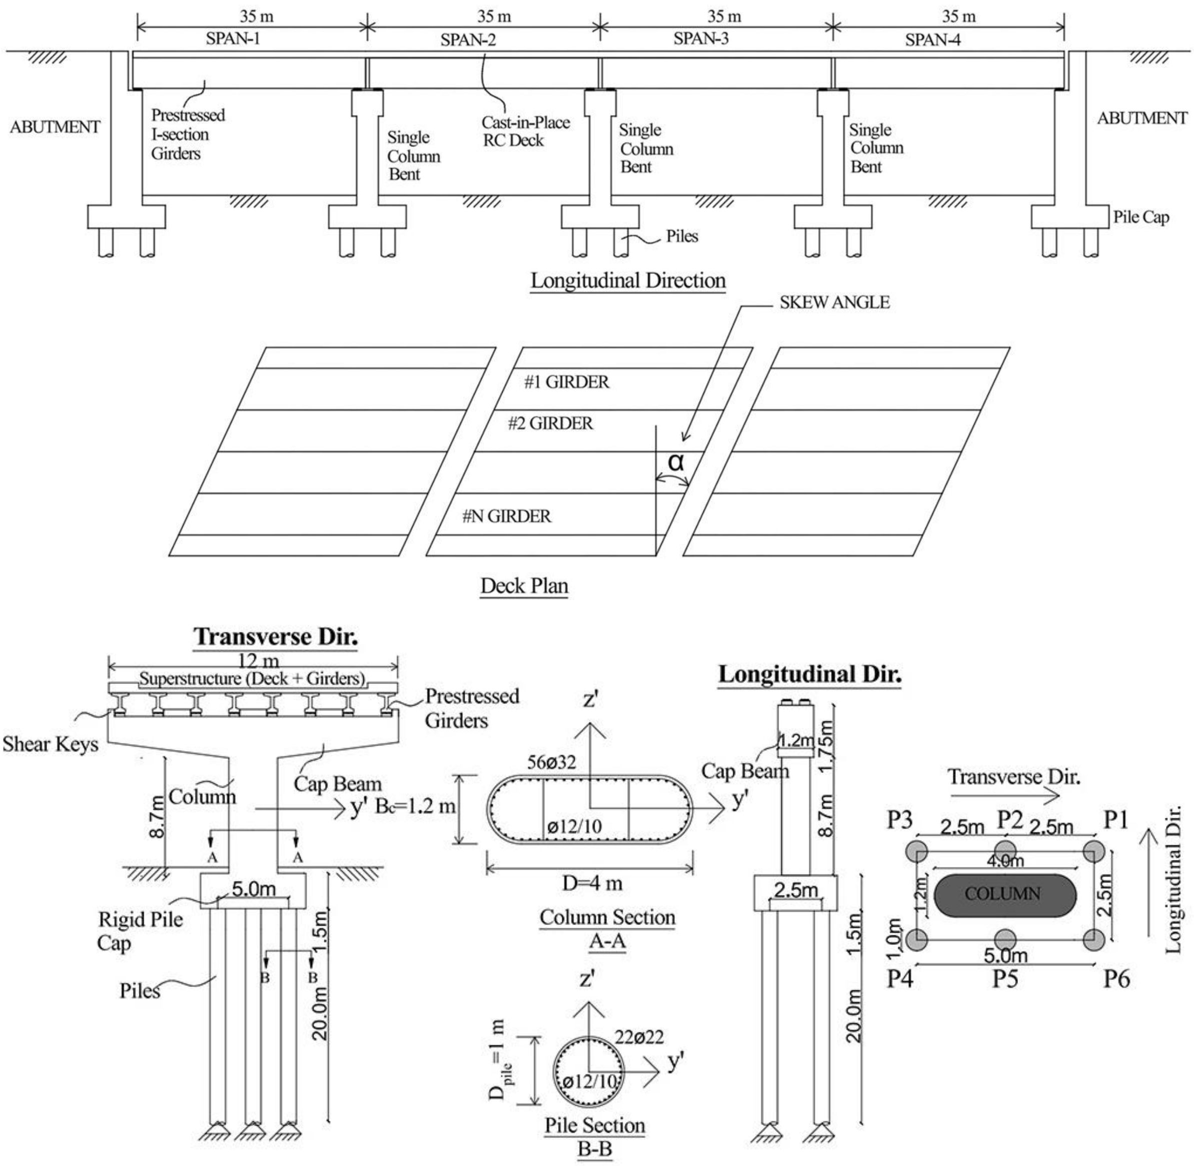

Fig. 1. Properties of bridge members

2.2. Numerical modelling of the bridge

The OpenSees program was adopted to create the three-dimensional numerical model of the reinforced concrete highway bridge in this study as shown in Fig. 2. Superstructure elements are defined as elastic beam column elements because it is expected that the presence of elastomer bearings will keep the bridge superstructure within elastic limits during an earthquake. Moreover, elastic beam column elements are utilized to model cap beams since their load capacity is sufficient to withstand forces of gravity. Nonlinear fiber elements were used to represent the bridge column piers during severe seismic events as they reach their flexural capacity and respond in the inelastic range. Three different material definitions, unconfined concrete, confined concrete, and reinforcement steel were used to model the nonlinear response of columns. At integration points along the length of the column, a distributed plasticity approach was utilized. For unconfined concrete, the crushing strain is ε_{cu} = 0.005, the strain corresponding to peak stress is ε_{co} = 0.002, and the maximum compressive stress is f_{co}= 25 MPa. For confined concrete, the material model presented by Kent and Park (1971) is used. The Concrete 01 material model is used to define confined and unconfined concrete. The S420 reinforcement grade has a 200 GPa modulus of elasticity with a characteristic yield strength of 420 MPa, the ultimate strength of 550 MPa, and the ultimate strain of 0.1. The Steel 01 material model was used to define the reinforcement steel in the OpenSees program. In order to simulate abutment backwall-deck pounding and deck-shear key pounding, nonlinear pounding elements are used in the bridge's longitudinal and transverse directions, respectively. Deck-shear key pounding takes place at the bents as well as the abutments. Between the pounding bridge components, there are 2.5 cm and 5 cm transverse and longitudinal gaps, respectively. Rigid elastic beam column elements were used in OpenSees program to define the pile cap. In the numerical model, piles were defined using elastic beam column elements. It was shown that piles stayed within their elastic limits during the nonlinear response history analyses under various seismic ground motions, based on sensitivity analyses carried out during the construction of numerical modeling of the examined bridges. This is compatible with Caltrans's design specifications (Caltrans, 2019). On the other hand, shear damage may occur when pile elements reach their shear capacity during earthquakes. Therefore, the shear capacity of the pile elements was calculated as 735 kN according to ASCE-ACI 426 (1973) explained in detail in Ateş and Avşar (2024b).

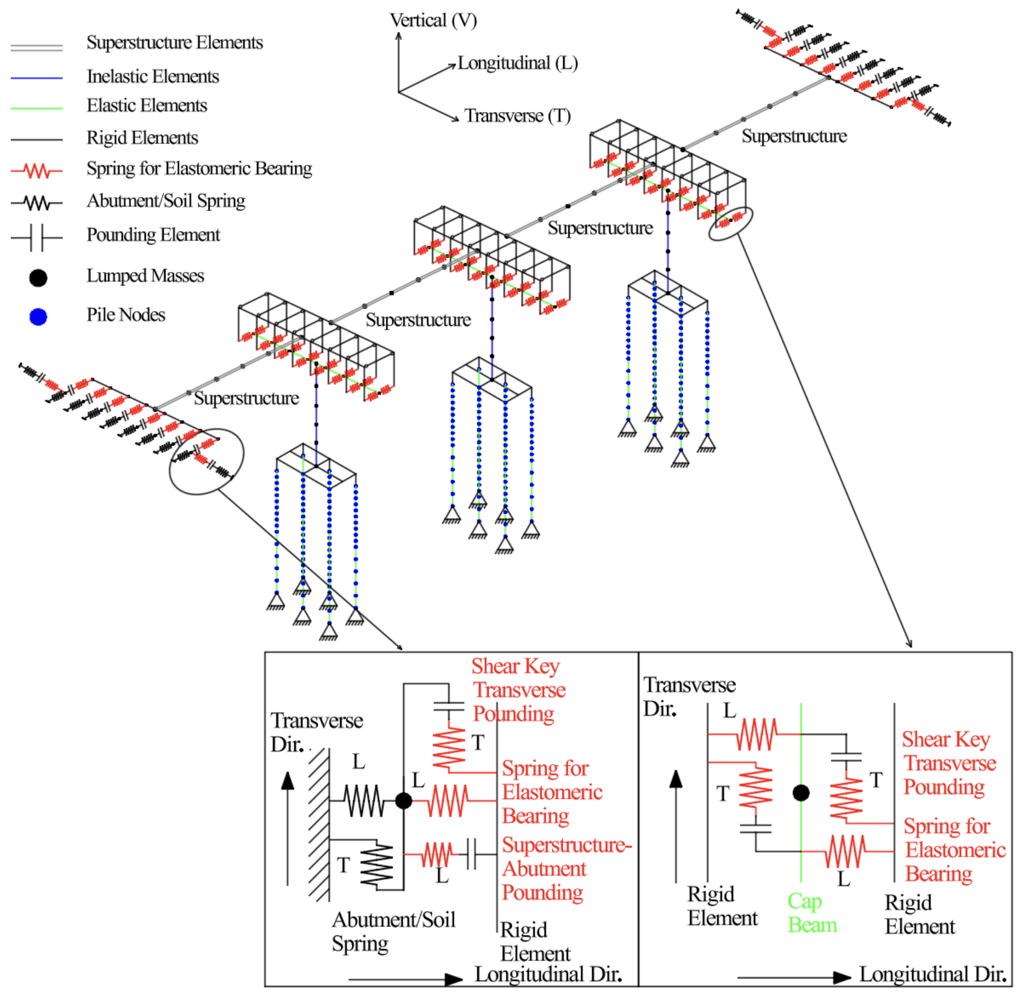

Fig. 2. Numerical bridge model created in OpenSees

The "Py Simple1" material model for lateral soil resistance and the "Tz Simple1" material model for axial resistance were used in the OpenSees program to model the soil structure interaction (SSI) between the piles and the surrounding soil. For the first 10 meters below the pile cap, the pile elements were separated into segments of 0.5 m length, and for the last 10 meters, they were separated into segments of 1 m length. The soil springs were assigned to pile segment nodes. As shown in Fig. 3, t-z springs were formed vertically, whereas p-y springs were defined horizontally (both longitudinally and transversely) along the bridge. Sand, which has an angle of internal friction of 25° and a unit weight of 18 kN/m^3, is the type of soil that has been selected to surround the piles. The calculation of the uniaxial material properties of p-y springs was done in accordance with the American Petroleum Institute (2000). For sand-type soil, the uniaxial material properties of the t-z spring were calculated in compliance with Kulhawy (1991). Finally, the end nodes of the piles were assumed to be restrained by simple support.

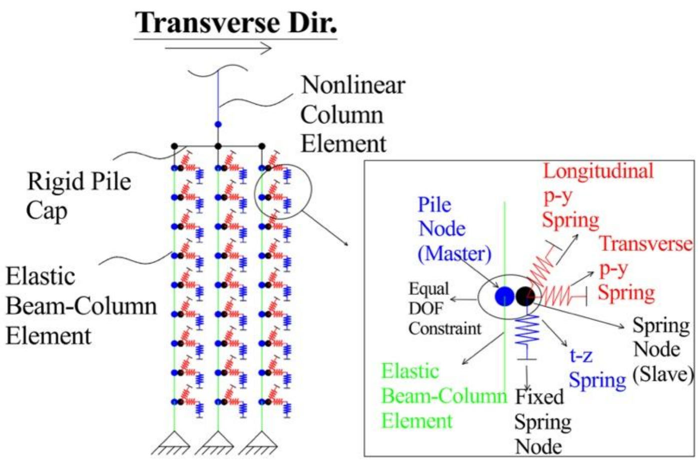

Fig. 3. Properties of the nonlinear soil springs on the piles

2.3. Uniform and non-uniform scour modelling

Seismic effects on the structural elements of water crossing bridges can be increased by scour-induced soil material loss, which reduces the lateral support surrounding the foundation piles. In many previous studies, the impact of scour on bridges was examined by response history analysis by considering uniformly varying scour depth around bridge substructure members. However, the scour depth variation might be non-uniform, resulting in irregularities in the supporting soil surrounding the piles, depending on the riverbed conditions and water flow. The study's objective is to investigate two distinct scour case scenarios for the SSI-modeled bridge with piling base. In the first scenario, shown in Fig. 4 and referred to Case-1, the scour depth is uniformly increased. The uneven scour in the bridge's transverse direction in Case-2 reflects the irregularity in the scour depth variations surrounding the substructure components (Fig. 5). Depending on the flow direction, piles near the upstream are subjected to greater scour than those in the downstream. Additionally, Case-2 is separated into two categories. According to Case-2-1, the scour depth angle (γ) between the upstream and downstream piles is equal to 0.6. In the second subgroup, which is called as Case-2-2, a steeper angle (γ) is taken into consideration by taking γ=1.0. For uniform scour case (Case-1), scour depth is changed starting from 0 m to 5 m with a 1 m increment. Also, for non-uniform scour scenarios, the scour depth for the piles on the downstream side was changed starting from 0 m to 5 m with an increment of 1 m as illustrated in Fig. 5(a) and Fig. 5(b), respectively. OpenSees program was used to create numerical models of non-skewed bridges with uniformly and non-uniformly increasing scour depth. For each scour depth and scenario, nonlinear soil springs were removed from the pile nodes above the scour level. To account for flood-induced soil loss, the nonlinear soil spring parameters were updated at each scour depth.

(a) (b)

Fig. 5. Representation of non-uniform scour (Case-2) and the change in scour depth from downstream pile (a) when angle is γ=0.6 (b) when angle is γ=1.0

2.4. Earthquake ground motion data

7 ground motion pairs were chosen from the Pacific Earthquake Engineering Research Center (PEER) database and scaled in compliance with the Principles for the Design of Highway and Railroad Bridges and Viaducts Under the Impact of Earthquakes (2020) in order to perform nonlinear response history analyses. The properties of the horizontal components of the selected ground motion recordings are listed in Table 1. The bridge under examination is assumed in Eskisehir, Turkey, and having the soil type ZD with an average shear wave velocity (V_{s30}) of less than 180 m/s. The Turkish Earthquake Hazard Map (TEHM, n.d.) web interface was used to obtain a target elastic response spectrum for 5% damping ratio as represented in Fig. 6 for the ZD soil class and DD-2 earthquake level (earthquake ground motion level with a 10% probability of exceedance in 50 years) of this location. The SRSS (square root of the sum of the squares) of the spectra of the two horizontal ground motion components is used to determine the response spectrum that results for each chosen ground motion record. The Principles for the Design of Highway and Railroad Bridges and Viaducts Under the Impact of Earthquakes (2020) state that the ratio of the amplitudes of the design acceleration spectrum in the same period range to the average amplitudes of the resultant spectra of all selected records between the period ranges of $0.2xT_p$ and $1.5xT_p$ should not be less than 1.3, where T_p is fundamental period of the bridge. For every given ground motion record, the scale factor of 1.0 satisfies the scaling requirements. The horizontal ground motion component with the largest PGV was applied in the transverse direction of the bridge, whereas the other horizontal component was applied in the longitudinal direction, as the effect of scour is being studied in the transverse direction.

3. Results and discussion

3.1. Superstructure displacement

Superstructure displacement is a significant engineering demand parameter for evaluating the seismic performance of highway bridges. During an earthquake, large superstructure displacements may cause pounding with the abutment backwall in the longitudinal direction or with the shear keys in the transverse direction. The peak displacement demands of the deck midpoint were assessed for each ground motion in both longitudinal and transverse directions. For each scour case and scour depth, the average of the peak displacement demands derived from the response history analysis results of seven ground motions are presented in Fig. 7. The provided graphs show that superstructure displacement demands increase as scour depth increases for all scour scenarios in both longitudinal and transverse directions of bridges, with the transverse direction showing a more noticeable increase. Additionally, a change in non-uniform scour depth has a greater impact on displacement demands than when scour depth varies uniformly.

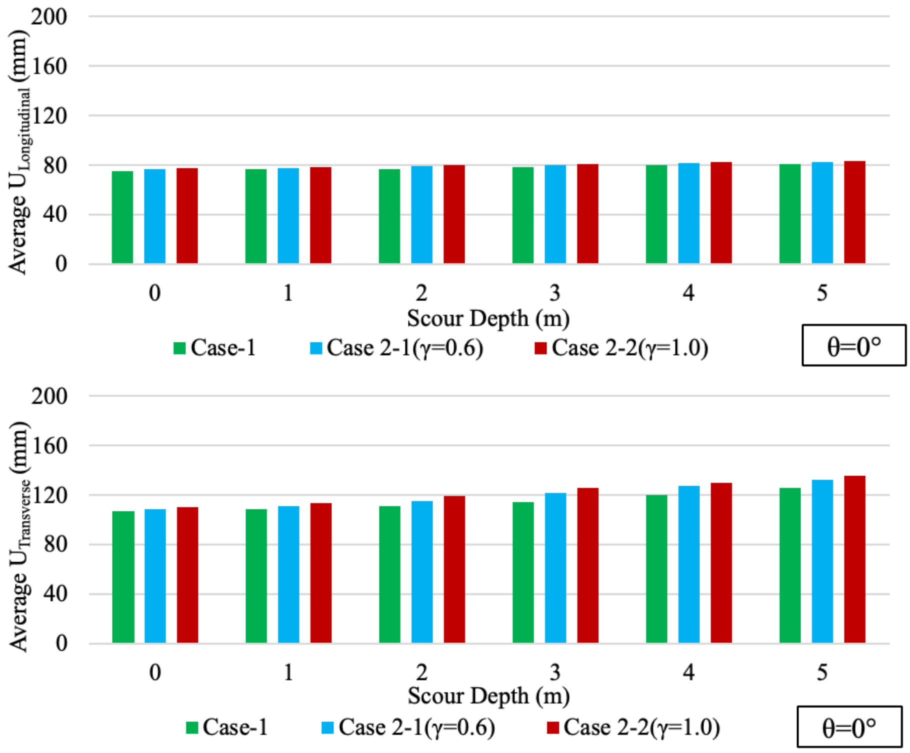

Fig. 7. Average of the peak superstructure displacements for different scour cases and scour depths

In this study, the most critical ground motion incidence angle for bridge-type structures was also examined. OpenSees program was used to assess the ordinary highway bridges by taking Case-1 and Case-2 scour situations into account. Only the analyses results belong to the scour depth of 5 m, which resulted in the largest superstructure displacement demands, were investigated in this part of the study. During the analysis, horizontal ground motion pairs rotated by using linear transformation equations from 0° to 180° with 15° increments. For various scour scenarios and ground motion incidence angles, the average of the peak displacement demands in longitudinal and transverse directions are shown in Fig. 8. According to that, for all scour cases, average displacement demands increase when the ground motion incidence angle shifts from 0° to 90° in the longitudinal direction. On the other hand, the transverse direction of the bridge exhibits the opposite response.

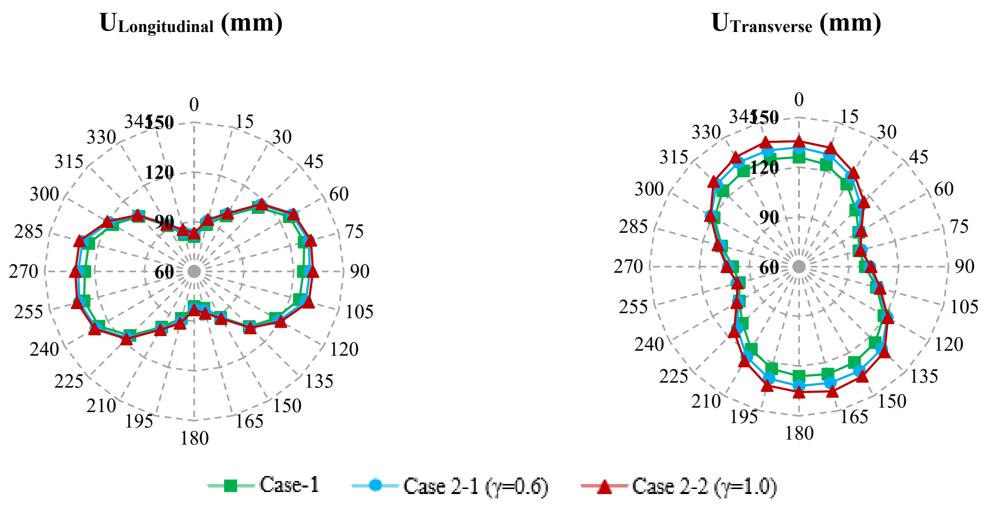

Fig. 8. Average of the peak superstructure displacements for different scour cases and ground motion incidence angles at 5 m scour depth

3.2. Curvature demands of pier column

Although the superstructure, joints, pile shafts, and cap beams of the bridge should all remain to be fundamentally elastic, the pier column is permitted to attain its flexural capacity in compliance with the capacity design principles, according to Caltrans (2019). In order to determine the force and deformation capacity of the bridge column section for both weak and strong axes, section analysis was performed using the XTRACT program. The yield curvature was calculated as $\Phi_{y'}$=0,0033 (1/m) for the weak axis and $\Phi_{z'}$=0,0011 (1/m) for the strong axis of the column section as seen in Fig. 1. Fig. 9 represents the average of the peak curvature demand of the middle bent column's weak and strong axis for each scour scenario and scour depth. Additionally, the graphs included the column yield curvature for each axis as a red dashed line. For each scour scenario and scour depth, the column curvature demands for weak axis are less than the yield curvature. In the strong axis of the column, curvature demands are greater than the yield curvature when scour depth is equal to 0 m (no scour case). For each axis, column curvature demands show a declining trend as the scour depth increases. The substructure, whose lateral stiffness is made up of the stiffness of the piers and piles with supporting soil, has an unsupported clear height that increases as the scour depth increases. As a result, the bridge became more flexible, and the seismic loads placed on the columns were reduced. Additionally, Case-1 (uniform scour) has larger column curvature demands than Case-2 (non-uniform scour). Regardless of the scour depth, Case 2-2 consistently created lower column curvature demands when comparing the demands of the two non-uniform scour scenarios (Case 2-1 and Case 2-2).

Moreover, for different scour scenarios and ground motion incidence angles, Fig. 10 shows the average of the peak curvature demands in the weak and strong axes of the bridge column at 5 m scour depth. For all scour scenarios, the demands on column curvature increase when the ground motion incidence angle shifts from 0° to 120° in both the weak and strong axes of the column. Column curvature demands are lower than their yield capacity in all scour scenarios for a 5 m scour depth as seen in Fig. 9. On the other hand, column curvature demands in the local y' axis can reach its yield curvature when the horizontal ground motion pairs are applied at varied incidence angles. In local z' axis, column curvature demands are below the yield curvature for all incidence angles and scour cases. This result shows the importance of considering various incidence angles in nonlinear response history analyses to achieve the most critical seismic demands for the column deformations.

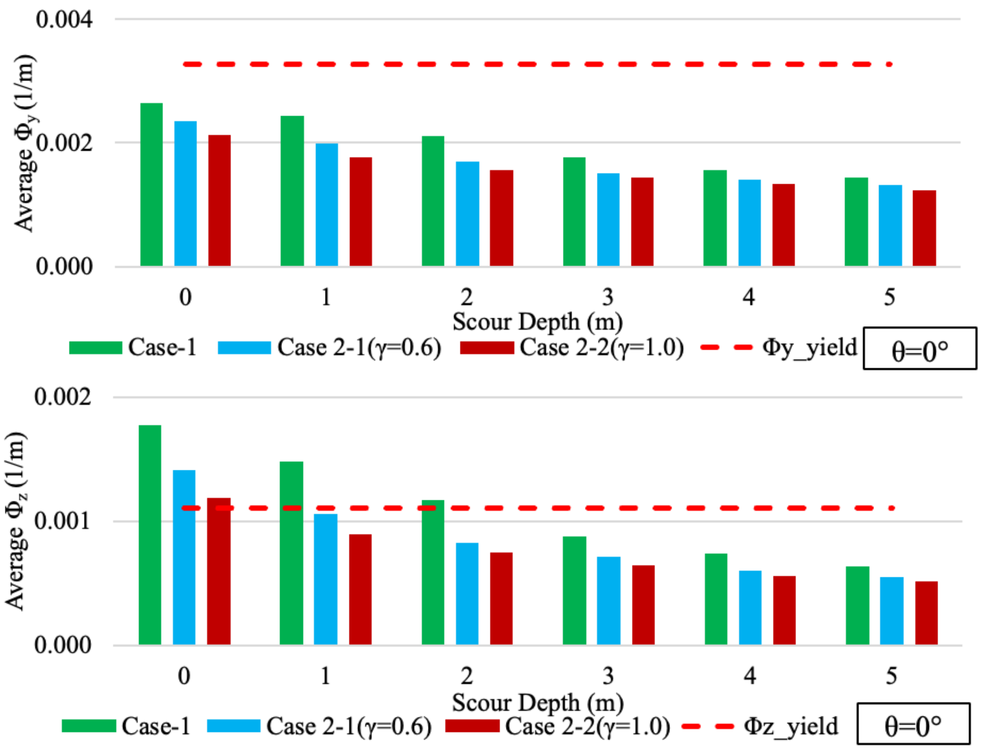

Fig. 9. Average of the peak column curvature demands for different scour cases and scour depths

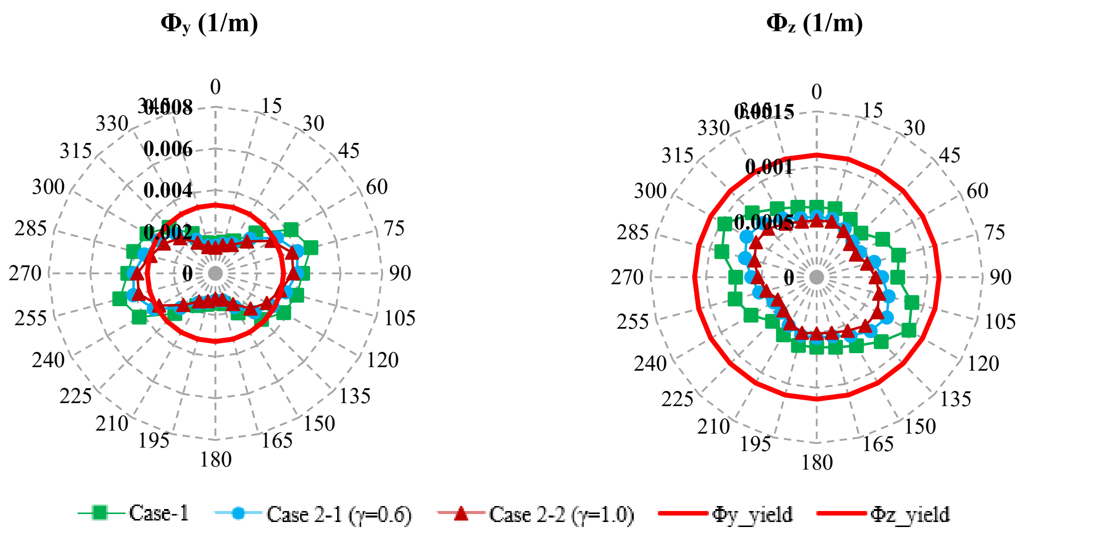

Fig. 10. Average of the peak column curvature demands for different scour cases and ground motion incidence angles at 5 m scour depth

3.2. Shear force demands of piles

Sensitivity analyses were conducted before the response history analyses and pile elements were found to be in their elastic range. However, especially in conditions of scour, it is crucial to verify the shear demands of pile elements. Consequently, the shear force demands of P4 pile, as depicted in Fig. 11 were examined. Similar to pile P3 in the case of non-uniform scour, pile P4 is situated downstream of the bridge and has the lowest clear height. The average of the peak shear force demands obtained from each response history analysis was shown in Fig. 11 for each scour scenario and scour depth. Consequently, when the scour depth increases for each scour situation, the pile P4's shear force demands decrease. The average of the P4 pile's peak shear force in non-uniform scour cases is larger than in uniform scour, when outcomes are compared based on the scour cases. The distribution of shear force demands among the piles is not uniform in the non-uniform scour situation because of the variations in the piles' clear height and, consequently, their stiffness. Higher shear demands are placed on piles with the smallest clear heights than on piles with greater clear heights. The shear capacity of P4 pile was determined as 735 kN using ASCE-ACI 426 (1973), as seen by the red dashed line in Fig. 11. P4 piles were not subjected to any shear damage in the uniform scour scenario when demands and shear capacity were examined. However, P4 had the highest shear demands, particularly in Case 2-2 where the scour depth surrounding the pile was comparatively lower than that of the piles upstream.

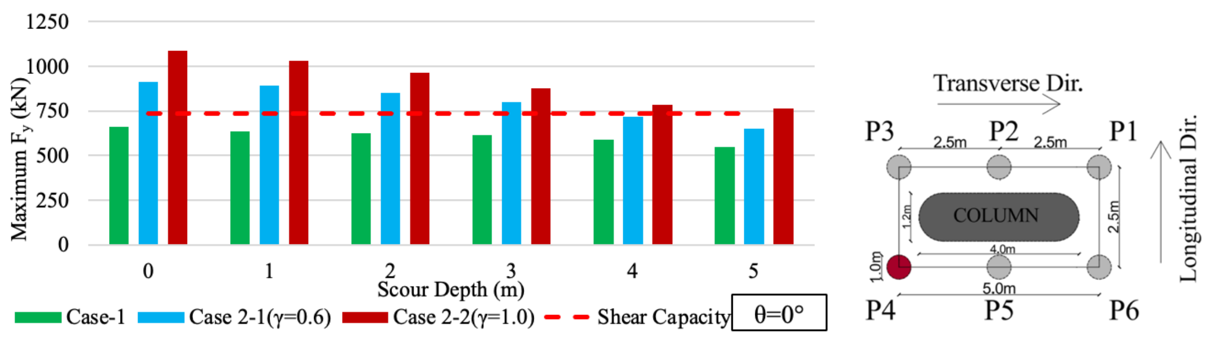

Fig. 11. Average of the peak shear force demands of P4 pile for different scour cases and scour depths

For various scour scenarios and ground motion incidence angles, Fig. 12 shows the average of the peak shear force demands in the local y' axis of the P4 pile for a 5 m scour depth. According to the results, changes in the ground motion incidence angle have an impact on pile shear demands. In contrast to uniform scour case, non-uniform scour cases have higher demands. The P4 pile experiences shear damage when scour is non-uniform and γ=1.0 (Case 2-2), and shear force demands in some incidence angles above the shear capacity of 735 kN.

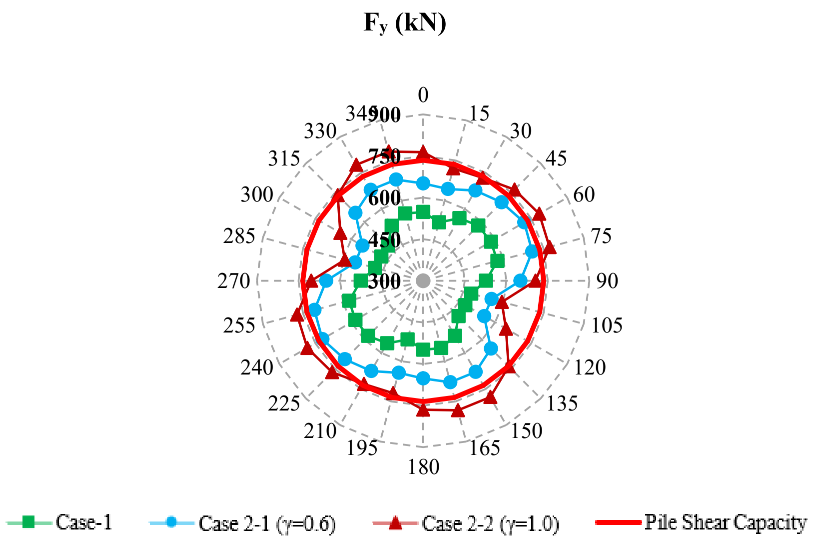

Fig. 12. Average of the peak shear force demands of P4 pile for different scour cases and ground motion incidence angles at 5 m scour depth

4. Conclusions

The safety of lifeline networks depends on the combined impact of earthquakes and flood-induced deterioration on highway bridges. Additionally, one of the key factors affecting a bridge's seismic performance is the ground motion incidence angle. In order to determine the maximum seismic demands of bridge members, a parametric research was carried out, taking into account the uniform or non-uniform scour situation. 7strong ground motion recordings were chosen, and nonlinear response history analyses were performed. The engineering demand parameters for this study are superstructure displacement, shear force demand of piles, and curvature demand of bridge pier columns. The following conclusions can be made in light of the outcomes of the nonlinear response history analyses:

- In all scour scenarios, superstructure demands increase as scour depth increases and this increase is more noticeable in the bridge's transverse direction. Additionally, compared to the case where the scour depth changes uniformly, the displacement demands are more affected by variations in the non-uniform scour depth. For all scour scenarios, displacement demands increase when the ground motion incidence angle shifts from 0° to 90° in the longitudinal direction. On the other hand, the transverse direction of the bridge exhibits an opposite response.
- For each column axis, the curvature demands show a declining trend as the scour depth increases. Additionally, Case-1 (uniform scour) has larger demands than Case-2 (non-uniform scour). In conclusion, the curvature demands of bridge columns are positively impacted by non-uniform scour. For all scour scenarios, curvature demands increase when the ground motion incidence angle shifts from 0° to 120° in both the weak and strong axis of the column. Furthermore, it has been demonstrated that while the column curvature demands are less than the yield curvature at certain incidence angles, the demands are greater at other incidence angles, causing the column to behave nonlinearly during earthquakes.
- As the depth of scour increases, pile P4's shear force demands decrease for all scour cases. The average maximum shear force in non-uniform scour situations is larger than in uniform scour when the results are compared for various scour cases. Additionally, when the scour situation becomes uniform for all depths, pile P4 does not sustain shear damage. However, like in the case of the short column phenomenon, the shear force demands in the case of non-uniform scour exceed the shear capacity and result in a brittle damage mechanism. The variation in the ground motion incidence angle also affects the pile shear demands. When scour is non-uniform and γ=1.0 (Case 2-2), shear damage occurs in the P4 pile because shear force demands in some incidence angles are greater than shear capacity. These findings demonstrate that different earthquake incidence angles should be taken into account in nonlinear response history analysis in order to achieve the most unfavourable seismic demands.

Abstract. Precast concrete provides a construction method using durable and quickly erectable prefabricated elements to create sustainable and high-quality structures. The seismic behavior of precast buildings is highly dependent on the characteristics of the precast floors. A precast concrete diaphragm is defined as a diaphragm comprising precast concrete components, with the option of incorporating specialized connections along some or all boundaries. Additionally, it may be constructed with or without cast-in-place concrete topping slabs. The most common practice, particularly in the case of the building stock of Türkiye, is to use cast-in-place concrete slabs to provide the diaphragm. Furthermore, according to the seismic code of Türkiye, the use of untopped floors in seismic zones is not permitted. Another commonly employed methodology, particularly within the USA in the context of this study, is the provision of a diaphragm with connections on untopped floors. This is an area that requires further investigation and development in Türkiye. Design requirements were established for untopped diaphragms intended for use in buildings assigned to high seismic zones. In order to satisfy these requirements, it is essential to guarantee that the diaphragms remain elastic throughout the design seismic event, even with the highly conservative diaphragm design forces. The aim of this study is to examine and contrast the behavior of the diaphragm in the building during a seismic event, with particular attention paid to the effects of not having a topping. The design methodology employs a Finite Element Model (FEM) of the subject building to examine the code requirements and the behavior of the floors.

1.Introduction

Lateral resisting systems are critically important for buildings made of steel, concrete, or precast concrete, regardless of whether they are in a high seismic zone or not. The lateral loads must be transferred to the foundation following the correct load pattern, and diaphragms are the first step in this process. It is essential to understand that diaphragms can behave in three different ways: rigid, semi-rigid, or flexible. Moreover, it should be noted that due to structural irregularities or construction errors, a diaphragm may not behave as expected. Therefore, before starting the design of a building, it is crucial to first determine the diaphragm behavior, as this decision will guide the selection of the appropriate lateral resisting system.

For a common usage, it is mostly preferred to use topped floors for precast buildings. Precast floors could be hollow-core slabs, double-tees, t-slabs and other precast components. After the erection of the floors is completed, cast-in-place concrete is placed on top of them. So, this cast-in-place concrete which is called also topping concrete provides diaphragm behavior. According to the Turkish Seismic Code (2018) a minimum of 7 cm topping concrete is required. Furthermore, the Turkish Seismic Code (2018) does not allow the use of untopped precast floors in any part of Türkiye. So, this study tries to summarize behavior of untopped precast floors at high seismic regions like Türkiye even it is not allowed by the code.

1.1. Behavior of topped floors

It is important to understand the behavior of topped precast systems in relation to the behavior of untopped floors, as both systems can act very similar when special connection details are applied. Figure 1 shows a basic precast system with or without a cast-in-place concrete topping. As seen, the shear walls at the ends of the system act as support against diaphragm forces. In this case, the diaphragm behaves as a deep beam, which is why the diagrams for both systems are similar to a simply supported beam. That is why it is mandatory to take precautions against shear forces, moments, and support connections in order to maintain the rigidity of diaphragm.

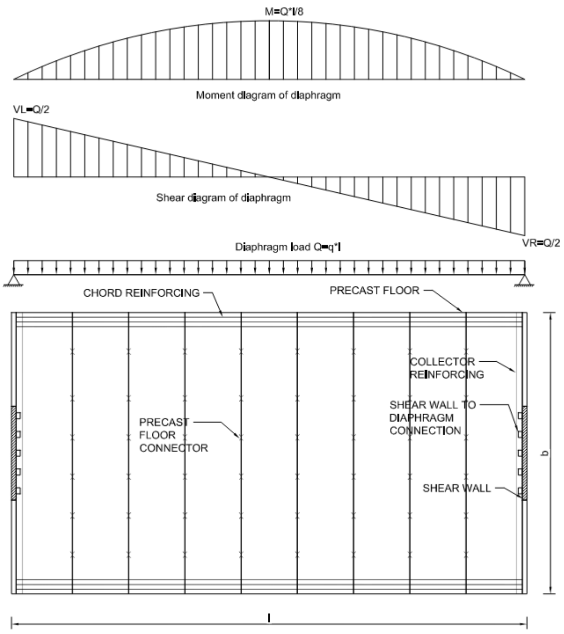

Fig. 1. Topped precast diaphragm system

Fig. 2. Precast slab-to-slab connection (Example of a ceg project application)

As shown in Fig. 1, the first step is to ensure that the precast floors are connected properly to resist shear forces. According to the shear force diagram, shear forces occur between the precast floors. A typical connection type can be seen in Fig. 2. However, when there is a cast-in-place concrete topping, the connection shown in Fig. 2 is necessary only for the erection process. The cast-in-place concrete itself is expected to be capable of resisting all the shear forces and moments.

Given the potential for seismic forces to act in both directions of the diaphragm, it is essential that reinforcement is applied to both sides. Simply, when the moment is divided by the moment arm (denoted as "b" in Fig. 1), it becomes easy to calculate the chord reinforcement. A typical application for chord reinforcement into cast-in-place topping is shown in Figure 3.

As described in Fig. 1, the floor-to-shear wall connections are critical. Since shear walls provide support feature in the diaphragm, it is a matter of designing the connections between the floor and the walls properly. These connections can be as simple as rebar embedded in the topping concrete or more complex welded connections, as shown in Fig. 4. When designing the welded connections, special care must be taken to meet seismic requirements. These connections, which should transfer the diaphragm shear forces to the shear walls, are essential according to the deep beam analogy. Thus, shear walls can transfer lateral loads to foundation with the load path. In most structures, it is not possible to place shear walls along the entire length of the floor. As shown in Fig. 1, shear walls are generally used as partial. In such cases, collector members are used to transferring the residual shear forces to the shear walls. The collector members typically consist of rebars that extend beyond the shear walls in areas without shear walls. The rebars collect the shear forces through their capacity and transfer the forces to the ends of the shear walls.

Fig. 3. Chord reinforcement

Fig. 4. Welded floor connection

1.2. Behavior of untopped floors

Untopped floors demonstrate a comparable behavior to that of topped precast systems. The main advantage of topped systems is that they can act monolithically, which helps to address many construction challenges. However, there may be instances where pouring concrete is not feasible. This can present a particular challenge when the project site is located remotely from a concrete batching plant. In such situations, the use of untopped precast floors can be a key advantage, especially in terms of reducing the amount of on-site work required, which can be crucial for meeting project schedules.

The most significant challenge associated with untopped systems is ensuring the integrity of the floor. In the context of this issue, connection details become very critical. Basically, the primary aim is connecting double-tees to accommodate the lateral shear forces. Regarding this situation, most of the connections are provided by welded connections between double-tee members, as shown in Fig. 5. The connections perform as chord reinforcing. They are standardized products which can be provided by different producers.

Provide chord reinforcement at the ends as shown in Fig. 6. For untopped systems, there are two options for implementing chord connections. The first option is to produce double-tees with recesses at the ends and place the chord reinforcement into the recess with cast-in-place concrete, like the method used in topped systems. The second option is to eliminate all the cast-in-place concrete and use certificated mechanical connections instead, as shown in Fig. 7.

Fig. 6. DT recess for placing chord and collector reinforcements

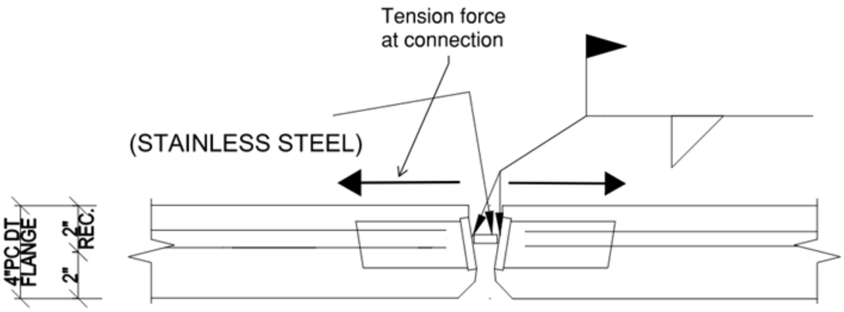

Fig. 7. Chord connection at untopped precast slab (side view)

2. Components and methods

In this research, the diaphragm behavior in the Y direction is observed. In order to examine this behavior, a generic single-storey structure was designed specifically for this study. Information about this structure is summarized in the following section.

2.1. Structure features

The structure has 10 grids in the X direction and 2 grids in the Y direction. The distance between X direction grids is 12ft (~3.66m) and the distance between the Y direction grids is 48ft (~14.6m). The height of the structure is 12ft (~3.66m) and there are 2 shear walls with a section thickness of 1ft (~30.5cm) on the side grids along the Y direction. 4 square columns (2ft~61cm) are located on the middle grids. Beams are extending between the columns and the shear walls. Nine double-tees are positioned from Grid-A to Grid-J. These slabs carrying 1-way loads are connected to each other by connection components.

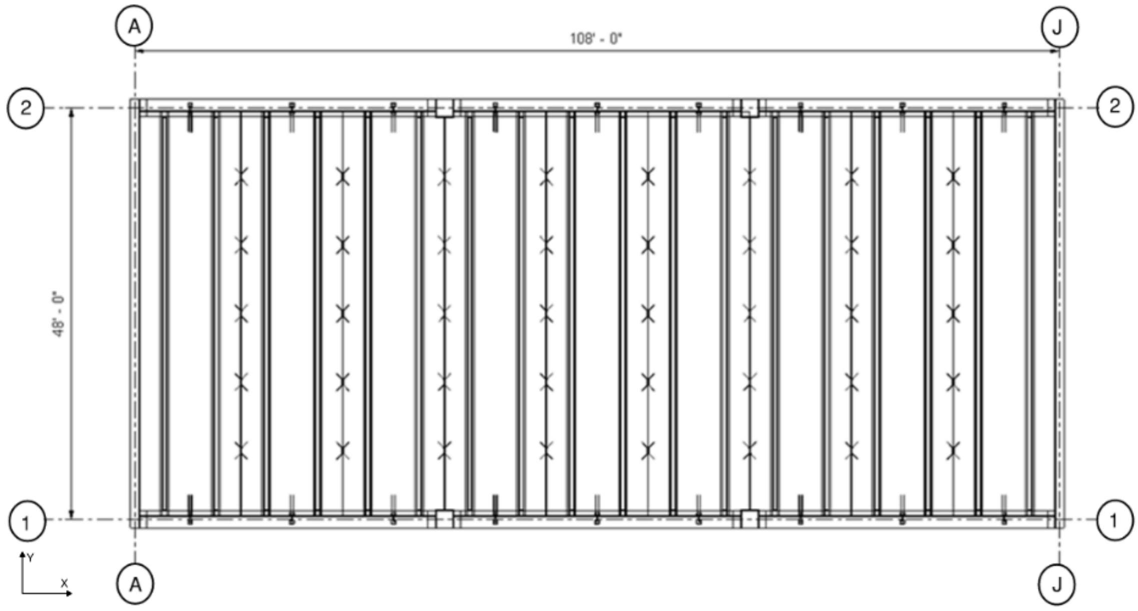

Fig. 8. Typical measured plan

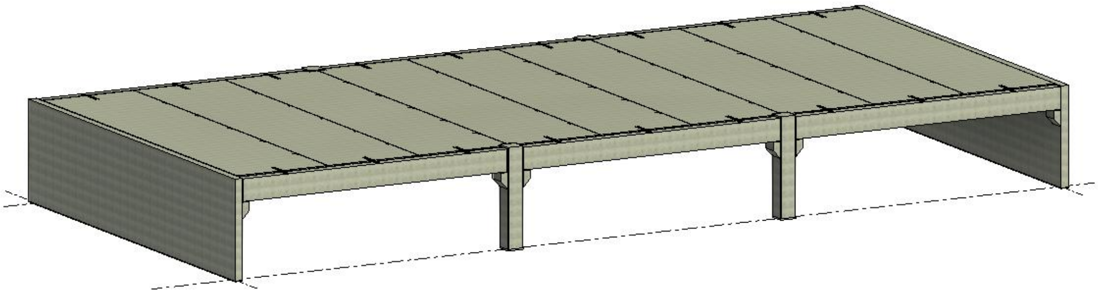

Fig.9. Shaded 3D view

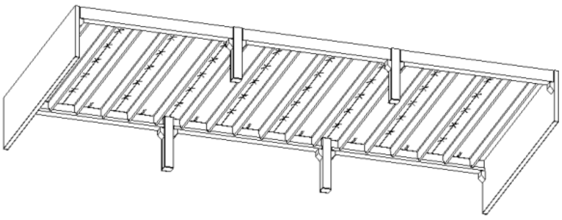

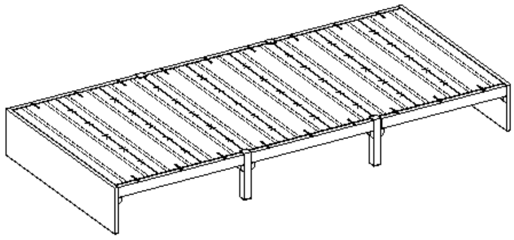

Fig. 10. 3D view from below

Fig. 10a. 3D view from above

The mathematical model was created via SAP2000_V24, and the imperial system was used for units. At this stage, the structure information specified above was used. Release definitions were done at the beam ends. Link components were assigned for the connections. For the link properties, previously researched tables published in PCI Journal were used (Klein and Lindenberg, 2009). Since only the Y-direction diaphragm behavior of the structure was examined in the modeling, only the tensile properties of the link components were used. 5 rows of chord connectors were placed on the sides of the structure and V-shape connectors were placed in the middle part. The mechanical properties of these elements are summarized below. Tensile Capacity and stiffness of diaphragm connections in Table 1.

Table 1. Mechanical properties

Connection Type	Ultimate Capacity [(kips)-(kN)]	Secant Stiffness [(kip/in)-(kN/m)]
V-Shape Connector	(9.7)- (43.1)	(58)-(10157)
Chord Connector (Plate-Edge)	(36.4)-(161.9)	(297)-(52012)

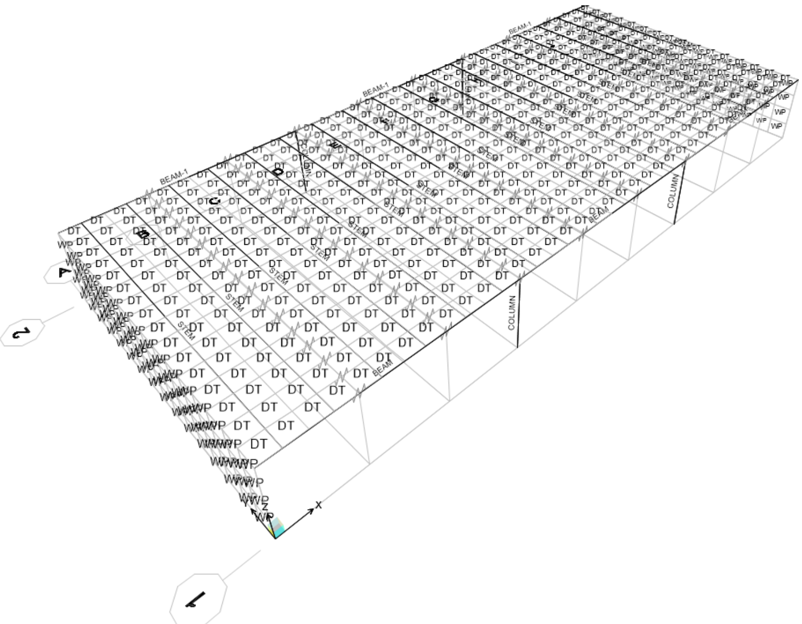

Fig. 11. Frame and area sections

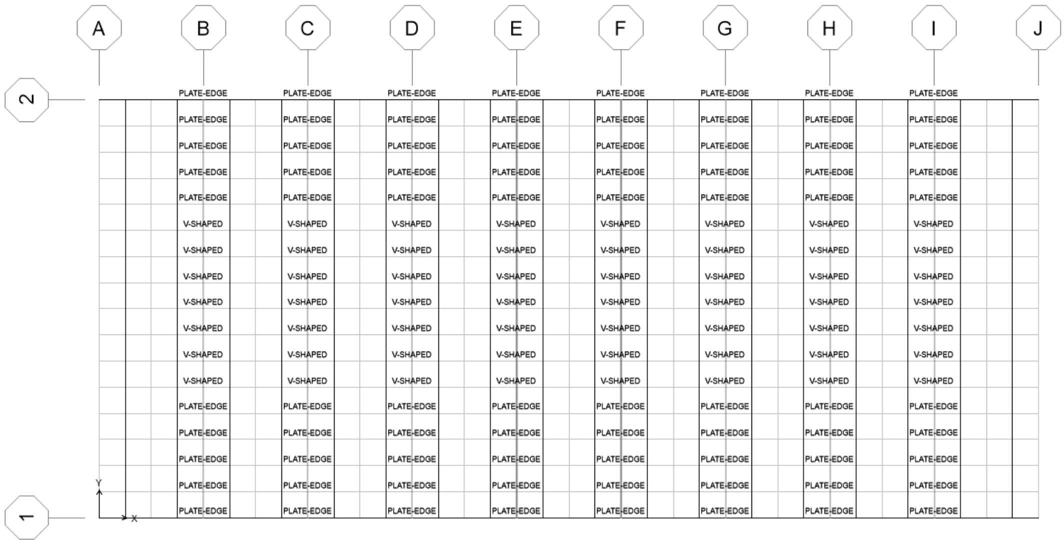

Fig. 12. Defined link properties (SAP2000 V24)

The main structure is created with link components as mentioned above. Link capacities, structure behavior, and incoming forces will be examined through this model. A monolithic model was also created to understand to what extent this modeling represents the diaphragm behavior. There are no connection elements in the monolithic model. It is assumed that a typical topping of concrete is placed. For convenience, the main structure model with the connection elements is named as "MODEL-1" and the model with the topping concrete is named as "MODEL-2".

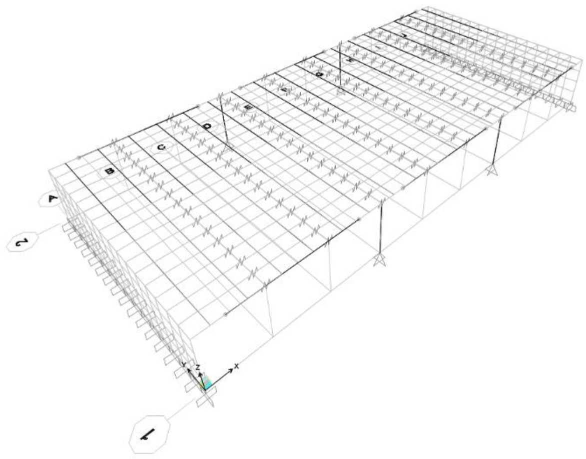

Fig. 13. Model 1-with link components

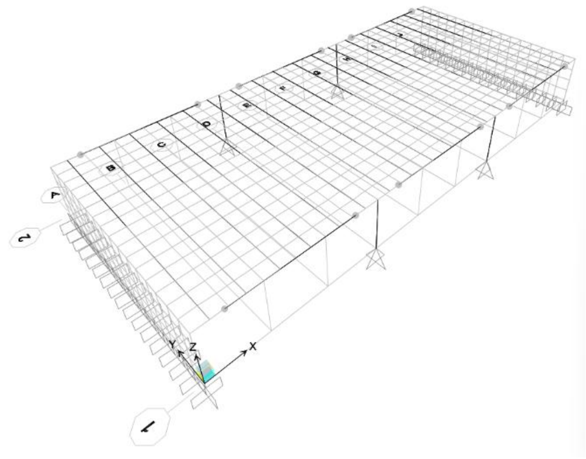

Fig. 13a. Model 2- monolithic

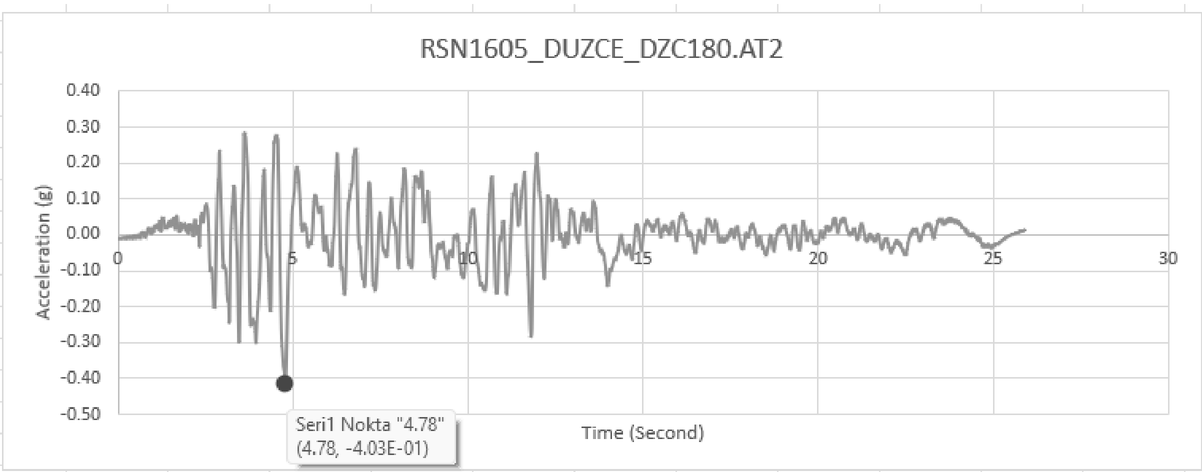

Fig.14. 1999 Düzce earthquake record (PEER)

In order to focus on the horizontal behavior of the diaphragm in the structure, as typical 15 psf (0.71 kN/m2) load definition was assigned for the whole floor as vertical load. This load, which was defined in addition to the loads of the structural components, was taken into account in the earthquake load calculation.

A linear time history analysis was performed for the earthquake loading. For this analysis, the 1999 Düzce Earthquake data was used. The PGA value of this earthquake data, which is preferred in earthquake analyses performed in high seismic regions, is 0.404g.

2.3. Structure seismic results and analysis of the results

As a result of the earthquake analysis, the maximum forces on the link elements in MODEL-1 are given in Fig. 15 below.

It is seen that the link components defined with the information that the tensile capacity of the edge-plate elements (chord connectors) is 36.4k (161.9kN) and the tensile capacity of the V-shaped connector elements is 9.7k (43.1kN) remain under the limit values and can carry the seismic load.

The base shear forces are very close to each other in both models. It is understood that this convergence supports the modeling approaches. The deformed shapes of the monolithic model (MODEL-2) with diaphragm behavior and the linked model (MODEL-1) are compared and these images are given in Fig. 17 above.

The difference in displacements between the two models (MODEL-1 and MODEL-2) is due to the link components being defined as having the ability to move in the direction of the axial load. As a matter of fact, since the maximum displacements are still quite small, it has been observed that they do not create any disadvantages in carrying horizontal loads. Since diaphragm behavior is examined in the structures, the limiting effect of the beams on the movement is also neglected.

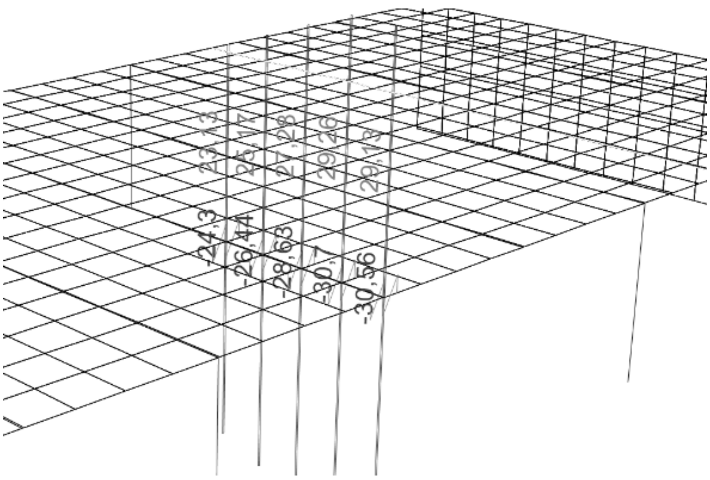

Fig. 15. Maximum link (chord connector) forces

Table 2. Base reactions and displacements

	Base Reactions [(kips)-(kN)]	Maximum Displacement [(in)-(mm)]
MODEL-1	495- 2201.8	0.26- 6.8
MODEL-2	465- 2068.4	0.06- 1.6

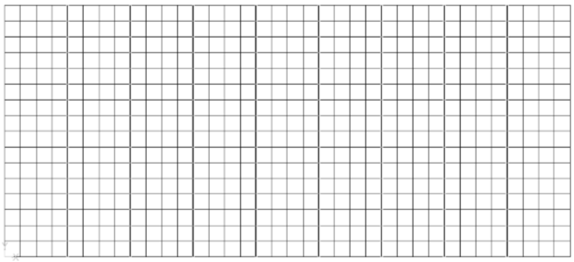

Fig. 16. Undeformed shape for Model-1

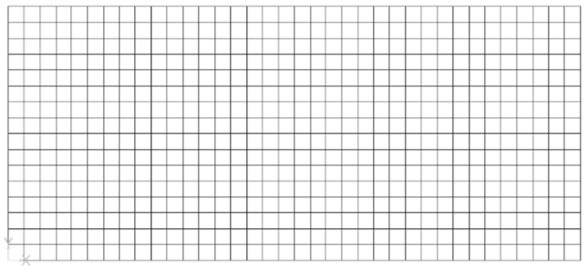

Fig. 16a. Undeformed shape for Model-2

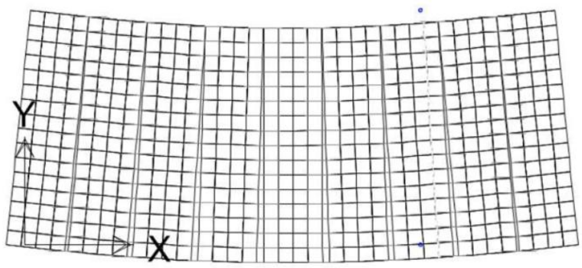

Fig. 17. Deformed shape for Model-1

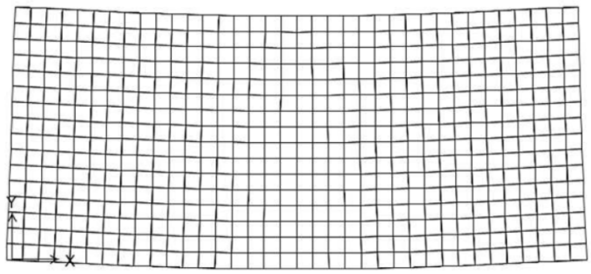

Fig. 17a. Deformed shape for Model-2

3. Conclusions

- Extensive experimental and practical evidence from past studies has demonstrated that adequate diaphragm action in precast structures can be achieved using topping concrete with sufficient thickness.
- Beyond the topping concrete approach, which is currently incorporated into the Turkish Seismic Code (2018), this study indicates that the use of reinforced chord plates—positioned along the sides of precast double-tee slabs, within both tension and compression zones—can perform effectively under high seismic demands, exhibiting structural behavior comparable to that of monolithic systems.
- The findings of this study emphasize the necessity for structure-specific design strategies, including the careful placement of a sufficient number of chord plates with appropriate capacity at strategically critical locations.

- The structural performance afforded by these additional components is highly dependent on the geometric configuration of the building, particularly the width-to-length ratio of the floor diaphragm.
- Given the inherent complexity of seismic ground motion and the variability in fault-specific characteristics, it is evident that further experimental investigations and application-oriented research are essential to validate this method—especially considering its current prohibition in Türkiye.

Structural damage and transportation closure analyses based on earthquake performance

Zeynep Demirel*[1], Seda Selçuk[1]

[1] Çankaya University, Department of Civil Engineering, 06790 Ankara, Türkiye

Abstract. Earthquakes are complex natural disasters with sudden and unpredictable impacts, posing significant threats to human life, structural safety, and transportation networks. Located on active fault lines, Türkiye faces a high earthquake risk, which can lead to multidimensional issues such as structural damage and disruptions in transportation systems in the affected regions. The effects of an earthquake are expected to vary depending on the seismic parameters, soil conditions, and structural characteristics of the affected area. The primary aim of this study is to comprehensively analyse the structural collapses caused by earthquakes, and the resulting road closures. The study examines the effects of an earthquake within the framework of seismic, structural, and geotechnical parameters, it focuses on the determination of the areas covered by collapse of the buildings. In this context, the situations that may lead to potential interruptions in transportation functionality due to the damage that occurred will be available for analysis. In order to determine the level of these potential interruptions, seismic and geotechnical data were analysed to determine road closures due to building collapses within the studied region. This analysis paved the way for reliable predictions regarding the post-earthquake functionality of roads and has the potential to make significant contributions to strategic planning in disaster management processes.

Keywords: Earthquakes parameters; Structural collapses; Road closures; Disaster management; Seismic parameters

1. Introduction

Developing seismology increasingly emphasizes the need to assess the safety of road networks worldwide, especially in countries with high seismic activity. Turkey, one of the countries with high earthquake risk, has been severely affected by the collapse of numerous structures during major earthquakes in the past, and the resulting debris on the road system has seriously affected the functionality of transportation networks and caused widespread congestion (Bakırcı & Aydoğdu, 2023). The dysfunction of transportation systems after earthquakes is a serious problem that disrupts emergency response (McCullough, 1994). Therefore, the accurate assessment of the functionality of transportation networks after earthquakes is necessary for the sound development of emergency response plans and rescue strategies.

Over the years, studies have been conducted to assess the functionality of transportation networks after earthquakes. In these studies, road closures due to building collapse have generally been estimated through probabilistic models; parameters such as seismic intensity, building location, and road typology have been used. Yu and Gardoni (2022) analysed the closure risk in different types of roads by creating fragility curves with a Bayesian approach. Hosseini and Mohammadi (2023) evaluated the opening time of closed roads and the network re-operability of the network with a scenario-based resilience model. In another study conducted in Thessaloniki, the vulnerability of the network was analysed depending on the building location and road geometry; however, in this study, the network closures were evaluated predefined scenarios with fixed plan dimensions and heights for all buildings (Argyroudis et al., 2015). Although these studies provide important contributions in terms of post-earthquake transportation functionality, they are largely based on theoretical assumptions.

Theoretical equations derived to predict debris-covered areas after building collapses are based on probabilistic approaches using Gaussian distribution, which can estimate various collapse scenarios. In this study, using real field data obtained from the regions affected by the February 6, 2023 Kahramanmaraş earthquakes, different scenario estimates of the probabilistic models were compared with the observed data.

Within the scope of the study, the effects of building collapse debris after the February 6, 2023 Kahramanmaraş earthquakes on road closures were analysed using spatial and structural data obtained from the field. Unlike similar studies in the literature, seismic and geotechnical parameters affecting the spread area of collapsed building debris

* Corresponding author, E-mail: c2019017@student.cankaya.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_498

were examined comprehensively. In this respect, the study presents an original approach that evaluates expected spread area of the collapsed buildings based on both seismic and geotechnical parameters which would pave the way to assess functionality of transportation networks with much higher precision.

2. Materials and methods

On February 6, 2023, two major earthquakes with magnitudes of Mw = 7.7 and Mw = 7.6 occurred one after the other in Kahramanmaraş, Türkiye. These earthquakes directly affected 10 provinces in the southeast of Türkiye; many structures in these regions were seriously damaged or completely destroyed. In this study, data on the spatial and physical characteristics of the structures affected by these earthquakes were obtained from various sources.

Parameters such as location, number of floors, building plan dimensions (width), proximity of the building to the neighbouring structures and damage status were determined through detailed visual analyses performed on Google Earth (Google, n.d.). In order to evaluate the effect of seismic parameters on the intensity and debris spread area, regional Peak Ground Acceleration (PGA_{475}) and Peak Ground Velocity (PGV_{475}) data of earthquakes with a return period of 475 years, together with the distance to the fault line, were obtained from the AFAD Türkiye Earthquake Hazard Map (TDTH) platform (AFAD, 2019). In addition, in order to analyse the effects of geotechnical parameters; soil class information was obtained from the AFAD Türkiye Acceleration Database and Analysis System (TADAS) (AFAD, n.d.) and data on liquefaction potential were obtained from United States Geological Survey (USGS) sources (United States Geological Survey [USGS], 2023).

2.1. Methods

In this study, the debris spread width (Wd) resulting from building collapse was calculated based on a probability-based model proposed in the literature by Argyroudis et al. (Argyroudis et al., 2015). In this model, Wd is defined under the Gaussian distribution assumption, and the main reason for this assumption is the existence of a correlation between the building geometry and the debris width.

The model indicates that the variability in debris spread for a single building depends on two basic parameters: collapse angle (c) and volume loss rate (kv). These parameters represent the slope of collapse debris and the amount of debris produced, respectively, and are the main sources of uncertainty on the debris spread width. The model allows estimating the probabilities of different debris area scenarios which directly affects level of road functionality.

In addition to these parameters a collapse scenario proposed by Argyroudis et al. was selected for the estimation of debris spread area. The selected scenario is considered more suitable for urban structures constructed in adjacent arrangements and continuous building facade forms (Argyroudis et al., 2015). As shown in Fig. 1, in the Thessaloniki study, building height (Y) was calculated as low, medium and high-rise average values; The building width (W) is assumed as a fixed parameter of 15 m. In addition, the expected value for the volume loss rate is taken as E[kv] = 0.50 and for the collapse angle as E[c] = 45°. The coefficient of variation for both parameters is determined as 30%.

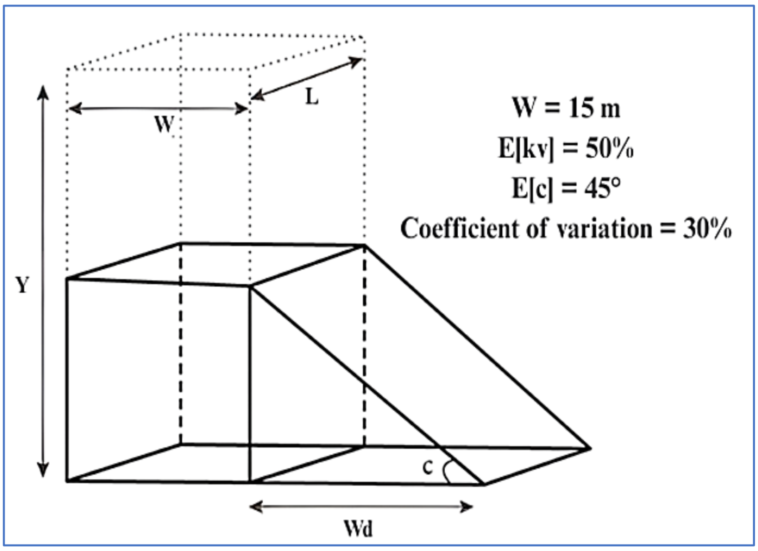

Fig. 1. Selected Scenario and Used Parameters Proposed by Argyroudis et al.

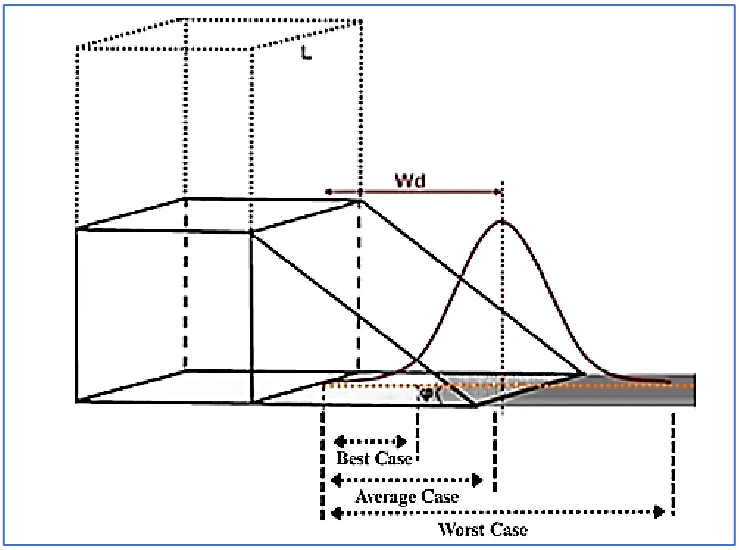

Fig. 2. Different Debris Spreading Cases (Best - Average – Worst) (Argyroudis et al., 2015)

In our study, we modified this approach by assessing building height (Y) and building width (W) separately for each building. The building height was calculated approximately based on the number of floors for each building; while the average floor height was taken as 3 meters, a height of 3.5 meters was used as ground floor height. Thus, the total height of each building was calculated uniquely. Similarly, the building plan geometry was measured for each building via Google to be used in the calculations. Due to the uncertainties inherent in the collapse angle (c) and volume loss ratio (kv) parameters, three different scenarios for the debris spreading width (Wd) are defined based on the variations of these two parameters, as shown in Fig. 2. These scenario parameters allow how the road closure situations may change within the probability distribution according to the collapse type of the buildings and the amount of debris they produce.

- Best Case: The case represents a situation where slope of collapse debris is steeper and the volumetric loss is less. In this case, the structure produces less debris and the road closure level is minimal because the collapse occurs in a narrower area.
- Average Case: The case represents a situation where slope of collapse debris and volumetric loss rate are the mean of the probabilistic distribution . This reflects the amount of road closure most expected to occur if the parameter ranges are following a typical gaussian distribution.
- Worst Case: The case represents a situation where the slope of collapse debris is more horizontal and the volumetric loss is greater. In this scenario, the structure produces more debris and spreads over a wider area, thus the road closure level reaches the maximum level among the three cases.

In each case, the building width and height were taken into account specifically for the building and calculations were performed in accordance with the formula of the relevant model. The obtained theoretical debris spread values were then compared with real data obtained from Google Earth images.

$$Wd = \sqrt{W^2 + \frac{2.kv.W.Y}{tan\ c}} - W \tag{1}$$

In this context, the lateral debris spread (Wd) value for each building was calculated using Equation (1) (Argyroudis et al., 2015). In the equation, the square of the building width (W^2) and the volume loss ratio (kv) multiplied by the building width (W) and the building height (Y) times twice the product divided by the tangent of the collapse angle (tan(c)) are added; the building width (W) is subtracted after the square root of this sum is taken. In addition, the volume loss ratio (kv) and collapse angle (c) parameters used in the model were not kept constant and were determined according to the characteristics of each scenario.

In the Best Case scenario, the minimum road closure was calculated by using a steeper collapse angle and a lower volume loss. The Average Case scenario represented the average values of the probabilistic distribution for volume loss and collapse angle and reflected the expected typical road closure level. In the Worst Case scenario, the maximum road closure level was calculated by using a flatter collapse angle and a higher volume loss.

3. Results and discussion

As can be seen in Fig. 3, the theoretical debris spread widths of the “best”, “average” and “worst” scenarios calculated for each building were compared graphically with the observed (actual) values of these buildings. Following these comparisons, the general distribution percentages showing which scenario is closer to the actual data are presented in Fig. 4. Accordingly, while the debris spread values observed in 75.5% of the 94 buildings examined showed higher compliance with the "worst" scenario, 23.4% gave results closer to the "average" scenario. These findings reveal that our model can be compatible with the conditions specific to the study region and can successfully represent the actual situation in the field.

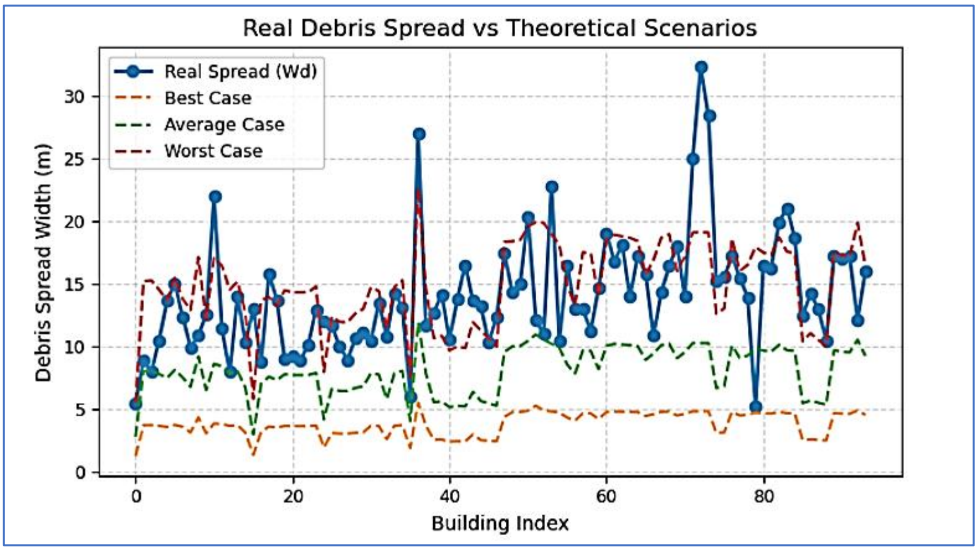

Fig. 3. Comparison of Observed and Model Debris Spread Widths for Each Building

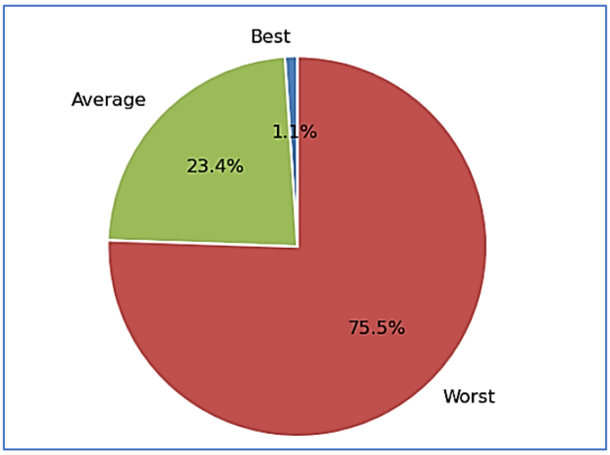

Fig. 4. Percentage of Buildings Closest to Each Collapse Scenario

Approximately 49.3% of the buildings that were compatible with the "worst case", the actual debris spread exceeded the value predicted by the model. The worst value was exceeded by 2.94 meters on average in these buildings. This finding is closely related to the local structural features such as the fact that the examined buildings were mostly built next to each other without space in the form of a continuous facade.

In addition, it has been evaluated that due to the high magnitude and intensity of the earthquake, the debris spread widths may depend not only on structural factors but also on the geotechnical and seismic parameters. Therefore, in order to examine the effects on W_d in more depth, comparative analyses were made according to geotechnical and seismic parameters and the role of these parameters on debris spread was examined.

3.1. Effect of geotechnical parameters on debris dispersion

The binary relationships between debris spreading width (Wd) and geotechnical parameters, namely liquefaction status and soil class, were evaluated separately. Additionally, multiple regression analysis was performed to examine the joint effect of Wd and both parameters. In these analyses, the t-test, one of the basic statistical tests, was used to evaluate whether statistical differences are significant. The t-test is applied to test whether there is a statistically significant difference between the means of two groups. In this evaluation, a criterion called the p-value was used. According to the generally accepted approach, a p-value less than 0.05 indicates that the null hypothesis should be rejected and that the observed difference is very unlikely to have occurred by chance; therefore, the difference is statistically significant. Before applying the t-test, it was checked whether the data used in the study met the necessary conditions to ensure the applicability of this test. These conditions are; the data being in the interval or ratio scale, the data being normally distributed, and the variances between the groups being homogeneous. Since the sample size used in the study was n>30, it was accepted that the distribution of the data was approximately normal within the framework of the Central Limit Theorem (CLT) and thus the assumption of normality was met.

3.1.1. Liquefaction status

The liquefaction status in the soils of the buildings examined in the study was defined as a binary variable as "present" and "absent" and the difference between the average Wd values of these two groups was compared with the independent sample t-test. As a result of the analysis, the t-statistic was found to be -4.8244 and the p-value was found to be 0.000005546. These results show that there is a statistically significant relationship between the liquefaction status and Wd. However, as can be seen in Fig. 5, it was determined that the average Wd values of the buildings located in non-liquefied soils were higher. Contrary to the general expectation, the debris spread was unexpectedly higher in non-liquefied soils. Therefore, this unexpected result may be due to the limited sample size or the fact that the effects of other structural, seismic and geotechnical parameters were not controlled.

3.1.2. Soil class

In the study, since there is only data for ZC and ZD soil classes in the areas where the collapsed buildings are located, the average difference between the soil classes, the Wd averages of these two classes, were also compared with the independent sample t-test. As a result of the analysis, the t-statistic was found to be 4.8244 and the p-value was 0.00001. These results show that there is a statistically significant relationship between the soil class and Wd. However, as can be seen in Fig. 6, it was determined that the average Wd values of the structures in the ZC soil class were higher. This result reflects a situation contrary to expectations; because the ZD class represents a softer soil type and is theoretically expected to cause more debris spread. It is thought that this unexpected difference obtained may be related to the effects of other structural parameters.

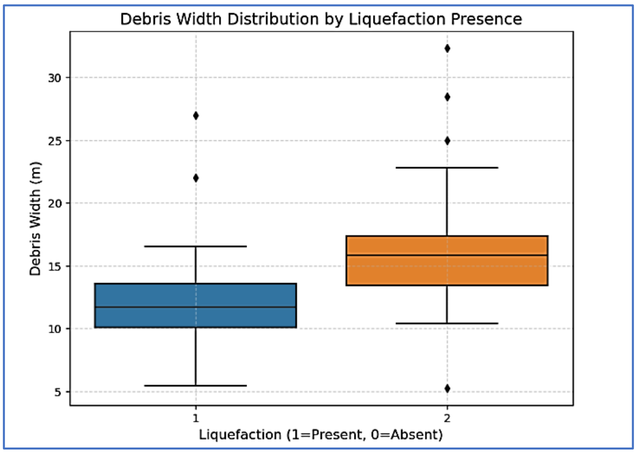

Fig. 5. Effect of Liquefaction Status on Debris Spread (Wd)

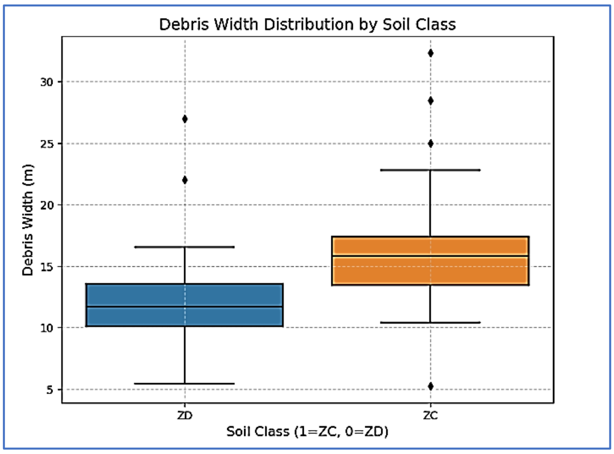

Fig. 6. Effect of Soil Class on Debris Spread (Wd).

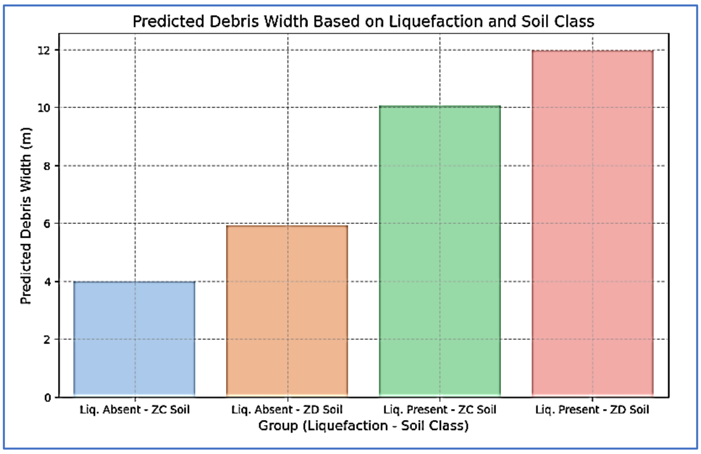

Fig. 7. Combined Debris Spread Effect of Liquefaction Condition and Soil Class on Debris Spread (Wd)

3.1.3. Multiple regression analysis (Liquefaction & Soil Class)

In order to better understand the contradictory findings in the above individual analyses, liquefaction and soil class variables were analysed together with a multiple linear regression model. Multiple regression analysis aims to measure the relationship between the dependent variable and more than one independent variable.

According to the multiple regression results obtained, a significant relationship was found between the presence of liquefaction and the width of the debris spread (Wd) ($p < 0.0001$) and it was determined that liquefaction increased the Wd value by an average of 6.05 meters. Similarly, a significant relationship was found between the soil class variable and Wd ($p = 0.002$) and it was observed that the Wd values of buildings located on ZC class soils were 1.92 meters higher on average compared to ZD class. The overall explanatory power of the model was calculated as $R^2 = 0.202$, indicating that approximately 20% of the change in Wd could be explained by liquefaction and soil class variables.

The results of this analysis allowed a regression equation to be obtained by establishing significant relationships between dependent and independent variables. The graphical comparison of the obtained equation is presented in Fig. 7. According to the graphical results, it was observed that debris spreading was higher under the presence of liquefaction and ZD soil class conditions. This situation reveals that some contradictory findings observed in individual analyses can be explained under the combined effect of the variables.

The multiple regression results generally provide a framework compatible with the literature. In other words, when liquefaction and soil properties are considered together, it is expected that debris will spread over a wider area. However, when individual parameters are examined separately, effects in different directions can be observed, which reveals the importance of evaluating the parameters together.

As a result, the fact that p-values were below 0.05 in all three separate analyses showed that the differences between the variables were statistically significant. However, instead of focusing only on p-values, the context of the analysis, the combined effects of the variables and the explanatory level of the model should also be taken into consideration. Therefore, multiple regression analysis revealed the effects of geotechnical conditions on Wd to be statistically significant but with limited explanatory power, indicating that the contradictory results seen in individual analyses could be explained more by the combined effect of the variables.

3.2. Effect of seismic parameters on debris dispersion

The relationship between debris spread width (Wd) and seismic parameters was investigated using three variables: PGA (Peak Ground Acceleration), PGV (Peak Ground Velocity) and the distance of buildings to the fault. Data characteristics were taken into account in the selection of the statistical test to be used in the evaluation of the relationships. In the preliminary analyses, it was determined that there was no normal distribution and linear relationship between the data. Therefore, the Spearman correlation test was used in the analyses to measure the strength of the sequential (monotonic) relationship between the two variables. In this evaluation, the p-value criterion was used to determine statistical significance. According to the generally accepted approach, if the p-value is less than 0.05, the null hypothesis (H_0) is rejected and it is accepted that the probability of the observed relationship occurring by chance is very low.

3.2.1. Peak ground acceleration (PGA)

PGA refers to the highest acceleration reached by the ground during an earthquake and represents the intensity at which structures are subjected to sudden strain. Since no measurements were made specifically for the buildings in this study, the PGA_{475} value (the regional standard value for the design earthquake expected to occur once in 475 years) was used in all analyses. The relationship between PGA and debris spread width (Wd) was analysed with the Spearman correlation test to measure the monotonic relationship between two continuous variables. As a result of the analysis, Spearman correlation coefficient was found as 0.4150 and p-value was found as 0.0000319.

These results show that there is a moderate positive and statistically significant relationship between PGA and Wd. In other words, as the PGA value increases, debris spread width also increases. This relationship is also visually supported in Fig. 8, where the Debris Width distributions grouped according to the average PGA values are presented.

3.2.2. Peak ground velocity (PGV)

PGV is the highest ground velocity reached during an earthquake and represents the structures subjected to discontinuous deformations. In this study, PGV_{475} value (belonging to the regional design earthquake) was used instead of building-based data. The relationship between PGV and debris spreading width (Wd) was evaluated with the Spearman correlation test. As a result of the analysis, the Spearman correlation coefficient was found to be 0.4245 and the p-value was 0.0000201.

These findings show that there is a moderately positive and statistically significant relationship between PGV and Wd. This relationship is also visually supported in Fig. 9, where Debris Width distributions are presented grouped according to average PGV values.

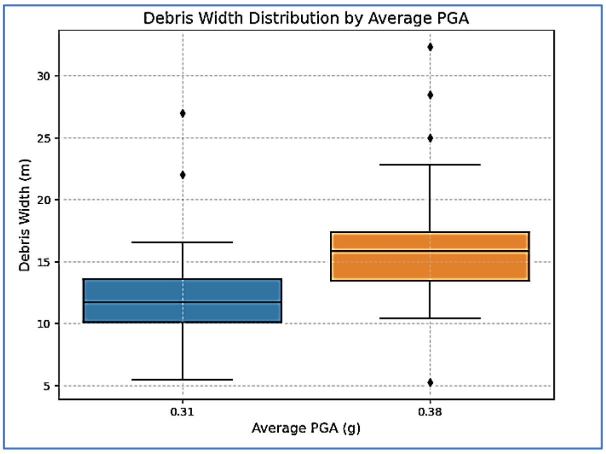

Fig. 8. Relationship Between Average PGA and Debris Spread (Wd)

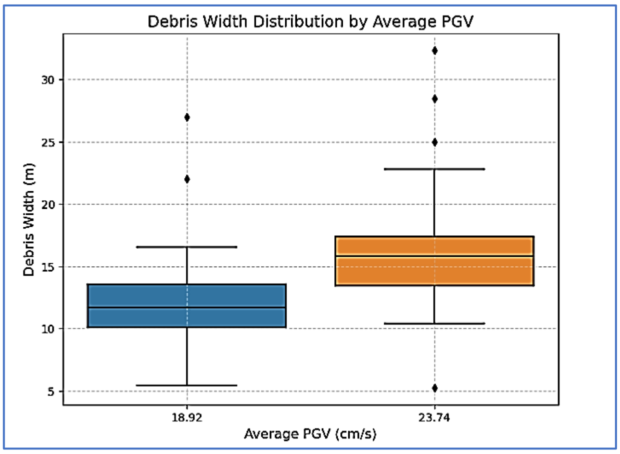

Fig. 9. Relationship Between Average PGV and Debris Spread (Wd)

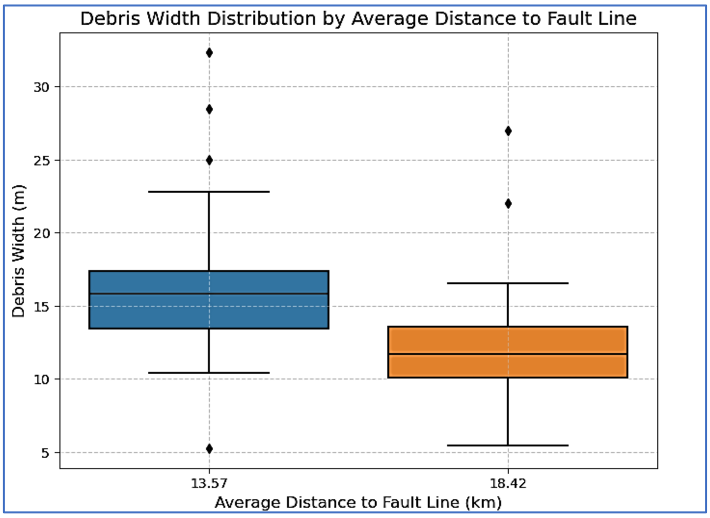

Fig. 10. Effect of average distance to fault line on debris spread (Wd)

3.2.3. Distance to fault line

The relationship between the distance of the structure to the fault line and Wd was also evaluated with the Spearman correlation test. The test result was found to be the correlation coefficient $r = -0.417$ and the p-value 0.00003. These results show that there is a moderately negative and statistically significant relationship between the distance to the fault and Wd. In other words, debris dispersion occurs at a higher level in buildings closer to the fault. This relationship is also visually supported in Fig. 10, where Debris Width distributions are presented grouped according to the average distance to the fault line values.

As a result of the analysis, it was determined that the parameters PGA, PGV and distance to the fault had statistically significant and directional effects on debris dispersion (Wd). As an important limitation, the fact that the PGA and PGV values were not calculated separately for each building but were taken from the standard design data of the region, limited the accuracy of the model, but still provided a sufficient basis for understanding the general trends. Therefore, it was evaluated that seismic effects should definitely be taken into account in the modelling of debris spread from building collapse.

The findings obtained in this study have shown that the debris dispersion (Wd) phenomenon cannot be explained only by structural parameters; more meaningful and realistic results can be achieved when evaluated together with soil properties and seismic effects. A striking finding is that the actual debris dispersion exceeded the theoretical “worst” scenario in approximately 49.3% of the buildings belonging to the worst case scenario. The debris spread width in these buildings was exceeded between a minimum value of 0.07 meters to as much as 13.23 meters.

In the analyses related to geotechnical parameters, when each of the liquefaction and soil class variables were evaluated independently, they yielded statistically significant results that were not consistent with the general expectations. When examined together in the multiple regression model, the effects of these variables were found to be statistically significant but had low explanatory power. These findings reveal that soil behaviour should be evaluated not with single parameters but by considering the soil properties together in interaction. In addition, the fact that both parameters became significant together emphasizes the importance of contextual multivariate approaches in collapse scenarios.

It was observed that seismic parameters have significant effects on debris dispersion (Wd). The statistical analyses revealed that both PGA (Peak Ground Acceleration) and PGV (Peak Ground Velocity) variables are positively correlated with Wd. Especially, the higher explanatory power of PGV suggests that velocity-based ground motion parameters may be more effective in determining the dispersion behaviour compared to acceleration-based parameters. A negative and significant relationship was found between the distance to the fault and Wd. This situation reveals that proximity to the source point is effective on debris dispersion, however, the limited explanatory power of this variable alone shows that debris dispersion is shaped by the combined effect of multiple factors. In this context, evaluating the structure-soil-seismic interaction together will provide a more accurate interpretation of seismic effects.

4. Conclusion

This study aimed to evaluate debris dispersion (Wd) due to building collapses, which is one of the most critical factors causing disruption of transportation infrastructure after an earthquake, from a multidimensional perspective. Analyses based on real field data revealed that debris dispersion should be considered not only through structural features but also together with ground characteristics and seismic effects.

It was observed that probability-based theoretical models were compatible with field observations to a certain extent; however, it was understood that these models should be interpreted flexibly within the framework of local urban morphology, construction patterns and demolition dynamics. Especially in regions with irregular, adjacent and dense building stock, the limitations of theoretical approaches drew attention and the need for recalibration of the model in the local context arose.

It was observed that geotechnical variables can produce meaningful results on debris dispersion when considered in interaction with each other. This finding shows that ground behaviour should be interpreted within the framework of relationships between parameters, not only based on classification in engineering analyses.

When geotechnical variables were evaluated together, they had a statistically significant but limited explanatory effect on debris dispersion. This situation indicates that not only structural damage data but also seismic parameters should be taken into account when assessing post-earthquake transportation risks.

Although structural parameters were evaluated to a limited extent within the scope of the study, the potential effects of these variables on debris distribution are clearly known. Therefore, it is recommended that the subject be examined in more depth with multivariate analyses to be conducted using larger sample groups in the future. In addition, re-conducting the study with larger data sets may provide a more meaningful demonstration of the relationships between the parameters.

In conclusion, this study not only analysed the spatial and physical dimensions of debris dispersion; it also proposed an applicable and holistic method for modelling post-disaster road closure risks, determining intervention priorities and developing urban resilience strategies. The findings provide a multidisciplinary contribution that will guide disaster management and urban planning processes.

Abstract. One of the reasons for the damages or collapses observed in reinforced concrete structures in recent earthquakes is due to the different forms of beam arrangement. The aim of this study is to verify the observed damage reasons with numerical analyses. Nonlinear analyses were performed in the time history domain in three different reinforced concrete structures with the same column application plan, normal4 beam arrangement (RC1), flat beam and hollow block slab arrangement (RC2), square column arrangement (RC3) and deep beam arrangement (RC4). In the numerical analyzes, moment-rotation curves and load-displacement curves were taken into account as analysis parameters. At the end of the study, it was determined that collapse prevention (CP) occurred in RC2 and RC4 reinforced concrete models and limited damage levels (IO) occurred in RC1 and RC3 model. It has been suggested that sufficient horizontal stiffness and damping mechanism should be provided in load-bearing elements such as columns and shear walls in order to be able to perform deep beam or flat beam applications.

Keywords: Deep beams; Earthquake behaviour; Flat beams; Nonlinear time history analysis; RC structures

1. Introduction

It is known that structures should have properties such as stiffness, strength, adaptability, stability, damping and ductility in order to be earthquake resistant (ASCE 41-17; FEMA 356). The arrangement of the structural system is of great importance in order to provide the properties stated in the design of structures against earthquakes. Vertical loads coming from slabs and beams under the effect of earthquake should be carried by columns and then safely transferred to the foundation. In the absence of this stable behavior, it is obvious that the earthquake effect will have destructive effects on the structures (Yenidoğan 2023). As a result of the earthquakes experienced in recent years, the design of deep beams has caused heavy damages and even collapses as a result of the formation of strong beams and weak columns (Erdem et al. 2024). In addition, it is known that the arrangement of the structural system in the form of flat beams causes surrounded column irregularity and causes heavy damages. Especially in the February 06, 2023 Maraş earthquakes, it was observed that there were significant heavy damages and collapses in structures with flat beams and hollow slabs and structures with deep beams (Erdem et al. 2024;Yenidoğan 2023). Turkey Building Earthquake Code 2018 and other relevant regulations limit the use of deep beams and hollow slabs (TBEC 2018, FEMA 356). In reinforced concrete building systems with high ductility level, the principle of strong columns and weak beams is adopted. Therefore, the deep beam arrangement is also contrary to the principle of strong columns and weak beams.

Deep beams are defined as beams in which the ratio of shear span to depth is less than 2 (ACI 318-19 2019; CEB-FIP Model Code 1990). In the literature, many experimental and numerical analysis studies have been conducted on the performance evaluation of deep beams (Husem et al. 2022; Saleh et al. 2023). In these studies, shear span/depth ratios are usually given as parameters (Kim et al. 2017). In these studies, load-displacement curves and stress-strain diagrams of the beams were obtained and interpreted (Husem et al. 2022, Chen 2018, Demir 2019). In addition, shear capacities of deep beams were also determined by numerical and experimental studies (Ismail et al. 2024). In order to prevent brittle fracture of deep beams, reinforcements were made with FRP (Fiber Reinforcement Polymer), CFRP (Carbon Fiber Reinforcement Polymer) and basalt fibers (Ahmad et al. 2021; Song et al. 2023). Deep beams were also tested in an experimental environment by changing the longitudinal and transverse donate ratios under different bearing conditions (Hamoda et al. 2024). The experimental studies

* Corresponding author, E-mail: celebioguzhan@atauni.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_501

were verified by finite element analysis (Hamoda and Hossain 2019). Similarly, the load-displacement curve of flat beams with weak axis in axial loading has been studied in terms of shear capacity and rotational capacities (Rayan et al. 2021;Feng et al. 2024). An analytical model was developed for the effective width value required to increase the bending capacity of flat beams (Jiang et al. 2023). Garg et al. (2021) conducted a field study on retrofitting methods to prevent collapse in RC beamless slab buildings (Garg et al. 2021). At the end of the study, it was confirmed in static and dynamic analyses that column arrangement and reinforced concrete shear wall placement should be required in such structures.

The current study is aimed at evaluating the effects of deep beam and flat beam arrangement on the seismic behavior of structures separately. The effects of column arrangement in flat beam and hollow slab applications are also investigated. Based on the literature, instead of element-based experimental and numerical studies, the effectiveness of flat beam and deep beam applications in direct buildings is investigated in time domain.

2. Numerical study

In this study, it is evaluated how the seismic behavior of the reinforced concrete structure changes in flat beam and deep beam alignment and some measures to be taken in this case. In this context, nonlinear time domain analysis was applied to 4 different reinforced concrete structural systems. The plan dimensions and storey heights in both directions of the four different reinforced concrete building systems are considered to be the same. Material class C25/30 concrete and B420C reinforcement class were used in the building systems in accordance with the standard (TS498). RC1 model is considered as a beam slab slab type and slab thickness is 15 cm (Fig. 1a). The corner columns were designed as 30x50 cm, the facade columns on the balcony section as 30x90 cm, the other two facade columns as 70x30 cm and the central column as 40x60 cm. Longitudinal and transverse freezes corresponding to these dimensions are designed according to the standard (TS 500; TBEC 2018). Beams were selected in 30x70 cm size. In the RC2 model with the same column and corresponding longitudinal reinforcements, the beams were arranged in a flat form with a size of 70x30 cm (Fig. 1b). In the building system where the hollow slab type is used, the rib beams are 10x30 cm in size and the slab thickness is 7 cm. In RC3 model, only the columns were selected with square cross-section by keeping the flat beam and hollow slab form of RC2 model (Fig. 1c). In RC3 model, the corner columns are designed as 40x40 cm, the facade columns in the middle of the axis are designed as 50x50 cm and the columns in the balcony section are designed as 60x60 cm. In the RC4 model, unlike the RC1 model, a deep beam was applied. The deep beam is arranged in 30x120 cm size (Fig. 1d). The moment of inertia of the deep beam in one direction is greater than the moment of inertia of the column. The finite element model of the reinforced concrete structural systems designed according to TBEC 2018 was created as shown in Fig. 2. The slabs were subjected to 0.212 t/m^2 pavement load and 0.2 t/m^2 live load (TS498). In the walls, 0.625 t/m load was applied.

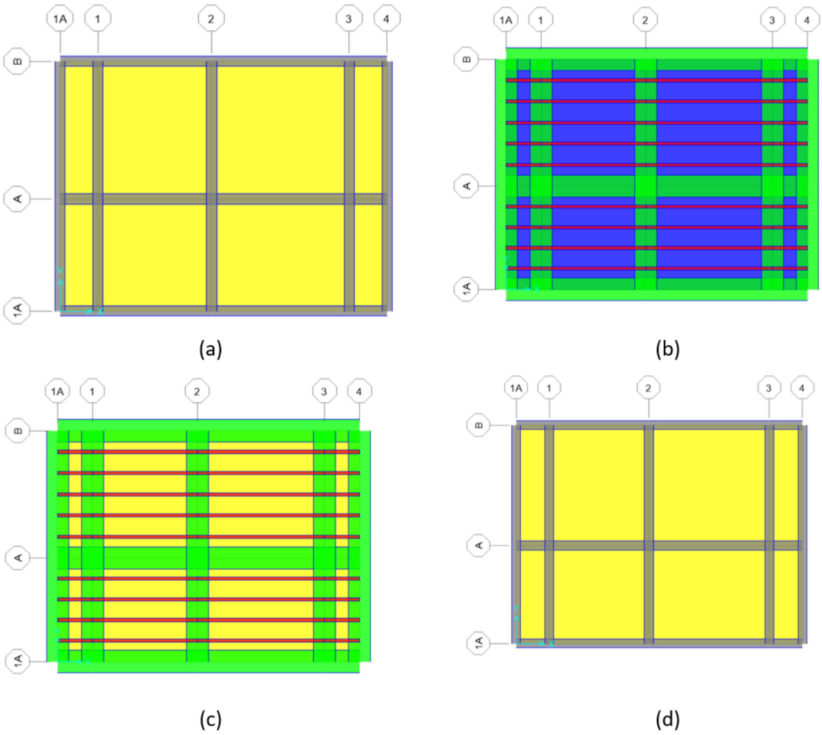

Fig. 1. Slab plans; a) RC1, b) RC2, c) RC3, d) RC4

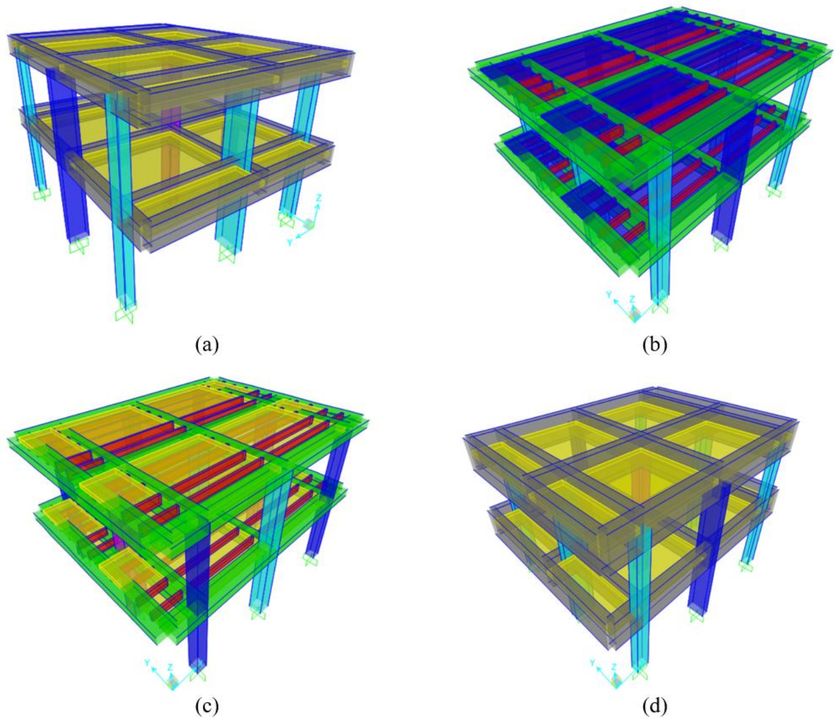

Figure 2. Finite element models; a) RC1, b) RC2, c) RC3, d) RC4

Nonlinear analyses in time domain were applied to reinforced concrete structural systems. In nonlinear analyses, damping ratios of 0.05 are assumed for all modes in reinforced concrete structural systems. Numerical analysis is based on Taylor iteration model. Nonlinear material models are defined in the related structures. For columns, plastic joints (P-M2-M3) including axial compressive force and compound bending are defined at the column end zones. For beams, simple bending (M3) plastic joints are defined in the end zones. The effective stiffnesses of the structural elements are defined in TBEC 2018 (TBEC 2018). For the time domain analyses, the acceleration data of the Elbistan earthquake that occurred on February 6, 2023, centered in Maras, whose characteristics are given in Table 1, were used. The acceleration data of the Elbistan earthquake were scaled as structure-specific within the scope of TBEC 2018 and used in the analysis. Analyses were performed using the horizontal and vertical acceleration components of the Elbistan earthquake. Since it is known that flat beam and deep beam building systems have damages caused by the vertical component of Maraş earthquakes, evaluations were made under the influence of vertical and horizontal acceleration components.

Table 1. Earthquake charecteristics (AFAD 2024)

Earthquake	Date	Latitude	Longitude	Station	Depth (km)	Magnitude (Mw)	PGA (g)-EW*	PGA (g)-UD*
Elbistan (el)	06.02.2023	38.089	37.239	Göksun	7	7,6	0,648	0,501

EW: East-west (horizontal) component of the earthquake*
UD: Vertical component of the earthquake*

Fig. 3 shows the scaled acceleration spectra of the Elbistan earthquake according to TBEC 2018 and the horizontal elastic acceleration spectrum of the structure plotted together for horizontal and vertical components. Fig. 4 shows the scaled and unscaled acceleration-time plots. Spectrally, approximately 1.4 g horizontal acceleration and 0.9 g vertical acceleration were used in the analysis. In addition, 0.5 g horizontal acceleration and 0.45 g vertical acceleration were taken into account in the analysis. The peak ground acceleration value of the structure in question was assumed to be 0.5g according to Turkey Earthquake Hazard Maps (AFAD 2024).

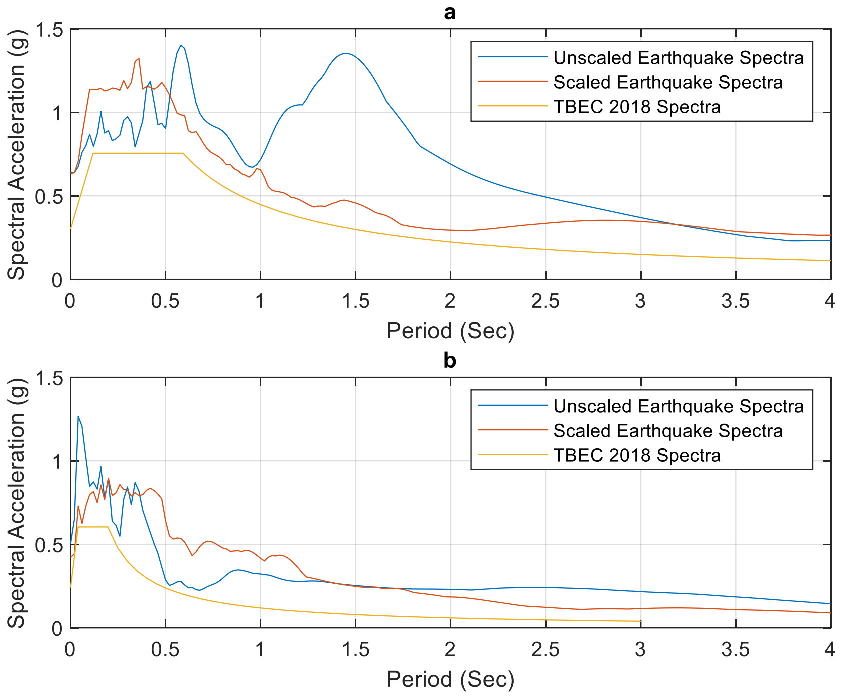

Fig. 3. Earthquake spepectrum acceleration; a) yatay ivme,b) düşey ivme

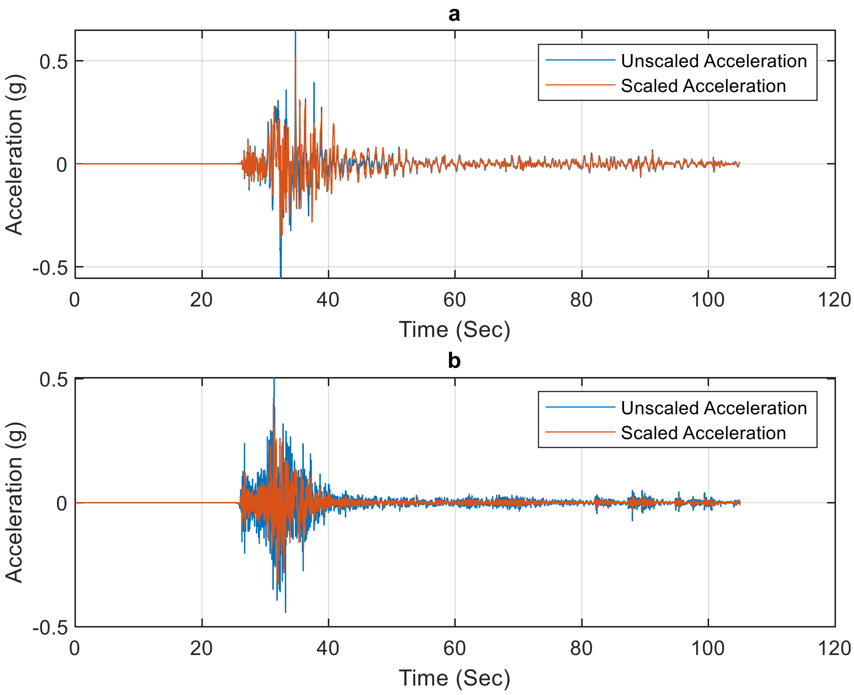

Fig. 4. Acceleration-time graphs; a) yatay ivme,b) düşey ivme

Reinforced concrete structural systems were analyzed in time domain under the influence of Elbistan earthquake acceleration values. The reference points and columns shown in Fig. 5 were taken into consideration in the analysis results. Horizontal displacements, vertical displacements and storey acceleration values were taken at the reference points. Moment-rotation capacities and axial load capacities were evaluated in two columns, one corner and one center. In addition, load-displacement curves were obtained and compared in all building models.

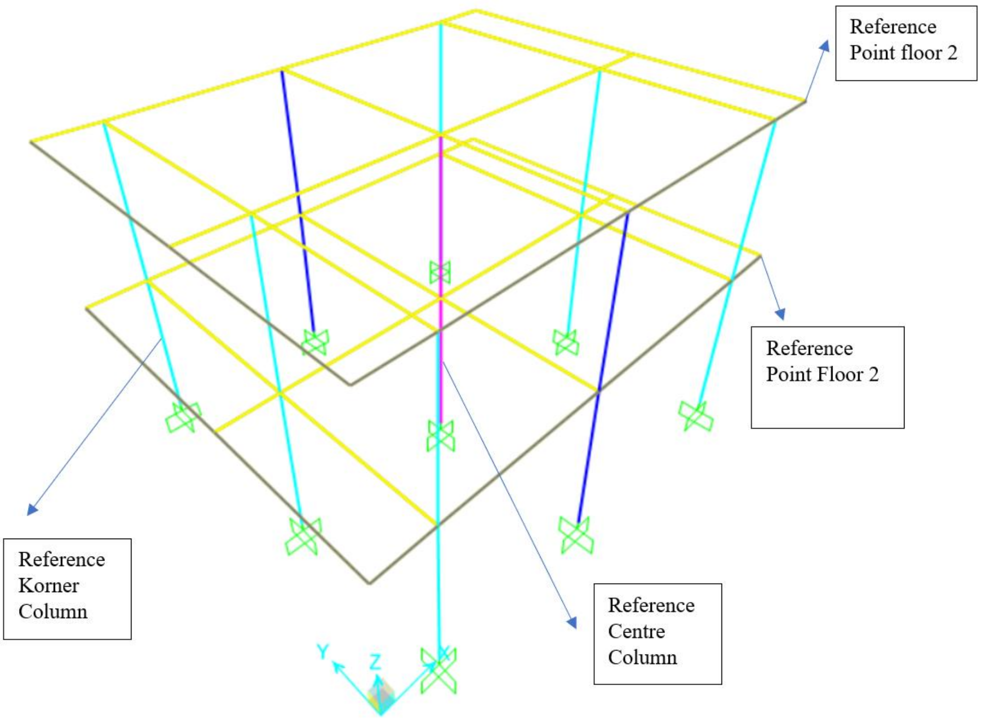

Fig. 5. Points and members taken as reference in the analysis

3. Numerical analysis results

Firstly, the period values (T) and mass participation rates (U) of the structural models were evaluated in the analysis results (Table 2). It was found that the X-direction mass participation ratios (UX) and Y-direction mass participation ratios (UY) were approximately the same in all models. RC2 and RC4 models were found to have higher mass participation ratios (UZ) in torsional mode. It was determined that the dominant mode in all structures was 1st mode. Especially in RC2 model, 1st mode, 2nd mode and 3rd mode period values were found to be close to each other. It is understood from the period values that RC1 model behaves more rigid structurally than the other models. The largest period value was observed in RC2 model.

Table 2. Period values and mass partification ratio

Buildings	T1 (sec)	T2 (sec)	T3 (sec)	UX (%)	UY (%)	UZ (%)
RC1	0.326	0.298	0.251	99.99	100	65.36
RC2	0.391	0.367	0.331	99.99	99.99	72.76
RC3	0.314	0.303	0.294	99.99	99.99	65.61
RC4	0.321	0.288	0.234	99.99	100	66.74

The values of base shear forces, peak displacement and vertical displacement in time domain are obtained and given in Table 3. It was found that the base shear force in RC4 model was 8.47%, 30.39% and 12.40% higher than the base shear forces in RC1, RC2 and RC3 models, respectively. It was determined that the deep beam arrangement increased the base shear force value most effectively. Hollow slab and flat beam arrangement effectively decreased the base shear force. Flat beam and hollow slab arrangement increased the peak displacement, earthquake induced vertical displacement and displacement due to vertical loads by 44.48%, 16.33% and 50% respectively. However, square column arrangement decreased the peak displacement, earthquake induced vertical displacement and displacement due to vertical loads by 15.38%, 18.06% and 30% respectively. The lowest values were observed in RC1 model for peak displacement, RC3 model for earthquake induced vertical displacement and RC4 model for vertical displacement due to vertical loads.

Table 3. Base shear force, roof displacement and vertical displacement values

Buildings	Base Shear Force (kN)	Roof Displacement (m)	Displacement (Z axis) (EQ)(m)	Displacement (Z Axis) (NLoad) (m)
RC1	2096	0.0166	0.000338	0.0005
RC2	1594	0.0299	0.000404	0.001
RC3	2006	0.0253	0.000331	0.0007
RC4	2290	0.0185	0.000349	0.0004

In the analysis results, the acceleration values at the top of the reinforced concrete building models are given in Fig. 6 and the acceleration values at the first floors are given in Fig. 7.

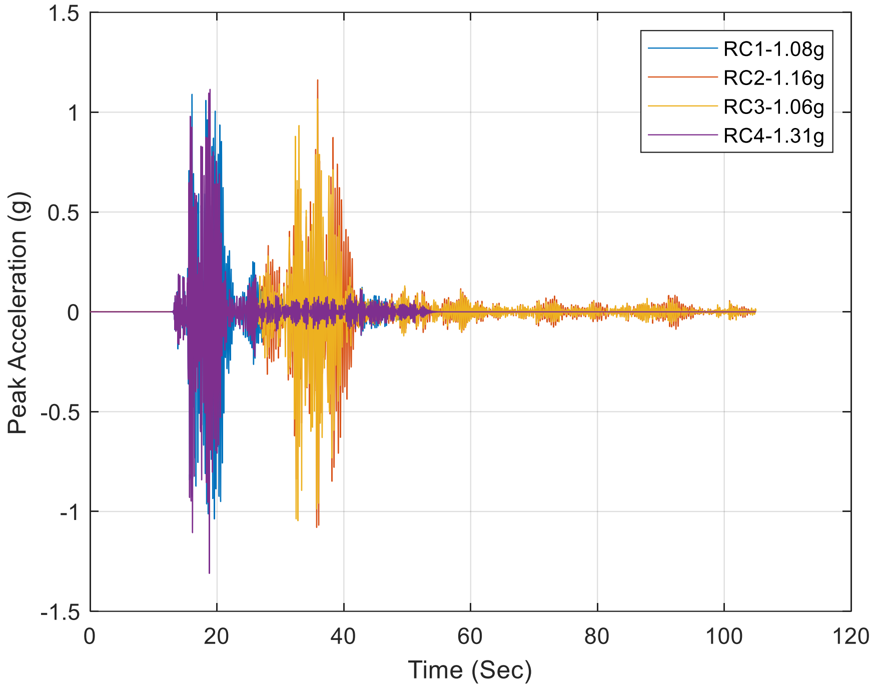

Fig. 6. Peak acceleration values

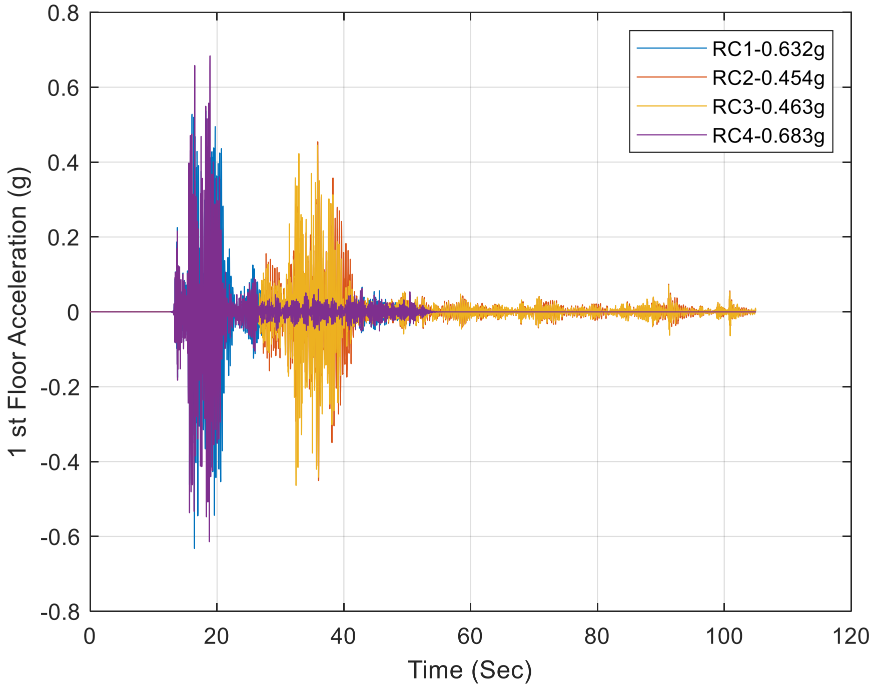

Fig. 7. 1st floor peak acceleration values

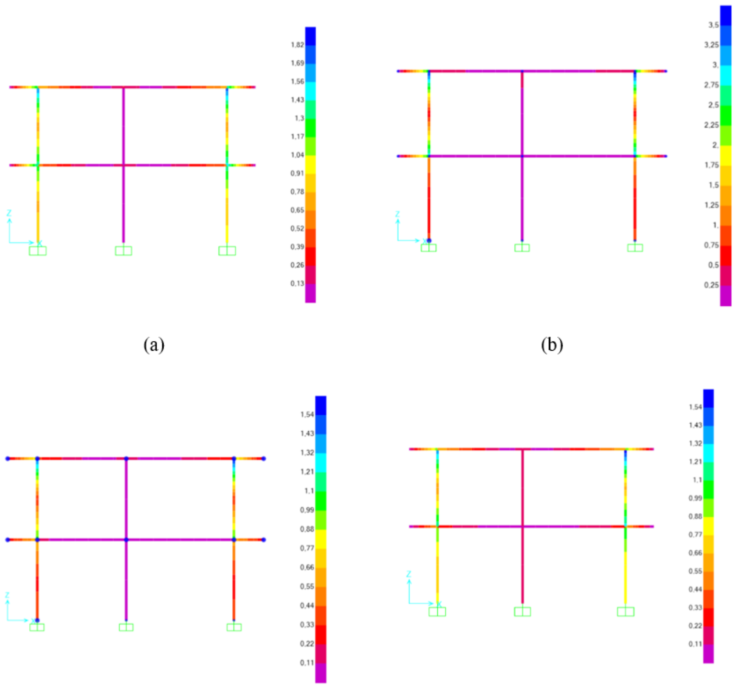
The peak and first floor earthquake acceleration values are generally less in the model with square column arrangement (RC3). The peak acceleration values in RC3 model were 1.85%, 8.62% and 19.08% less than the peak acceleration values in RC1, RC2 and RC4 models, respectively. At the first floor, the acceleration values of RC2 model were found to be 1.94% less than RC3 model. It was concluded that the acceleration values of RC3 model at the first floor were 26.74% and 32.21% lower than RC1 and RC4 models, respectively.

Normal stress distributions in the X-Z plane as a result of vertical earthquake loading in time domain are given in Fig. 8. It is observed that RC2 and RC4 models have higher stresses especially at the column beam joints. The square column arrangement was not as effective in reducing the normal stresses as the beamed slab slab. It was determined that the stress values in RC2 model were approximately 47.72% higher.



(a) (b)

(c) (d)

Fig. 8. Distributipn of normal stresses

The load-displacement curves obtained at performance acceleration and displacement values in time domain are given in Fig. 9. It is concluded that RC1 model behaves more ductile and RC3 model shows high elasticity. RC4 model was found to have reached the advanced damage level due to the permanent displacements. It was determined that brittle fractures occurred in RC2 model. In RC1 model, it was observed that lower loads occurred and high plastic displacements occurred. It was calculated that 0.0481 m plastic displacement capacity was reached for 488.95 kN shear force in RC1 model, 0.0116 m plastic displacement capacity for 1544.15 kN shear force in RC2 model, 0.0116 m plastic displacement capacity for 1652.47 kN shear force in RC3 model, and 0.0712 m plastic displacement capacity for 500.21 kN shear force in RC4 model. It is determined that higher permanent displacement demands occur for lower load t-values in RC1 and RC4 models. However, RC4 model reached the advanced damage level by making higher permanent deformation. RC2 model could not exhibit sufficiently ductile behavior according to force-displacement values. RC3 model, on the other hand, showed ductile behavior by showing resistance against higher loads and making sufficient permanent displacement.

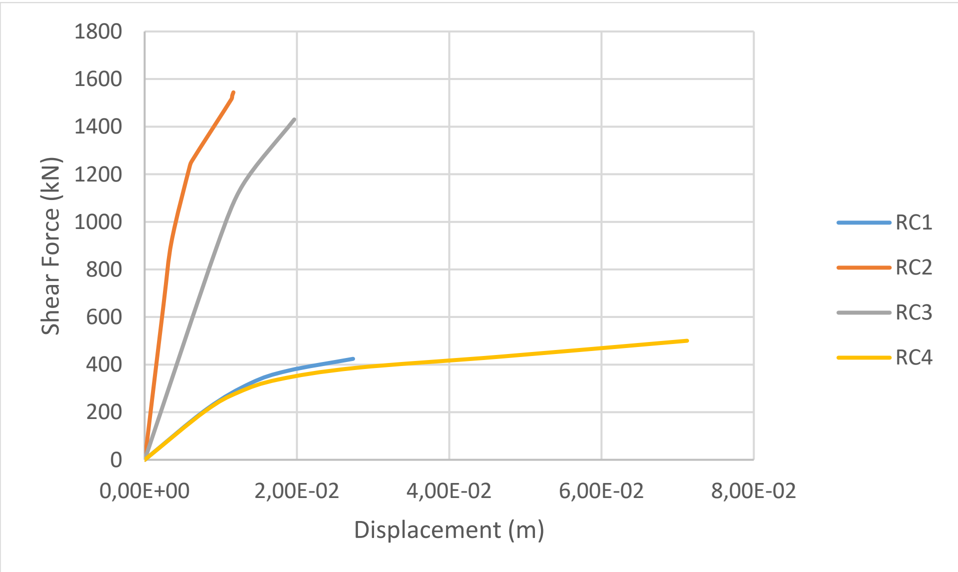


Fig. 9. Load-displacement curves

Fig. 10 shows the moment rotation capacities of the corner columns. It is determined that the moment capacity of RC3 model is 4.89%, 55.29% and 14.47% higher than the moment capacity of RC1, RC2 and RC4 models respectively. Rotation values of RC4 model were calculated to be 81.20%, 91.25% and 95.85% higher than RC1, RC2 and RC3 models, respectively. The RC4 model was at the significant damage level (LS) due to its high rotation value, RC1 model was at the immediate use level (IO) due to its high moment capacity and corresponding rotation, RC2 model was at the collapse prevention damage level (CP) and RC3 model was at the immediate use level (IO). Figure 11 shows the damage types at the joints of the corner column.

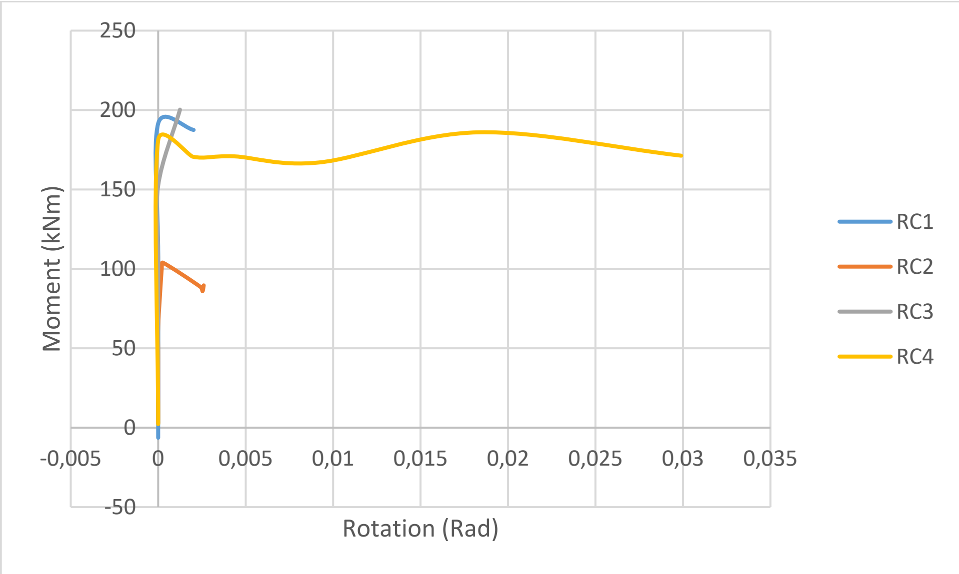

Fig. 10. Moment-rotation values in the corner column

The moment-rotation capacities of the center column taken as reference in the analysis results are given in Fig. 12. It is determined that the moment capacity of RC4 model is 87.42%, 88.89% and 21.88% higher than the moment capacity of RC1, RC2 and RC3 models, respectively. The rotation in RC4 model was calculated to be 79.94% more than RC2 model, while RC1 and RC3 models did not have any rotation. RC4 model entered the collapse zone due to its high rotation value. RC1 and RC3 models remained in immediate use. RC2 model was determined to have entered the collapse zone. Fig. 13 shows the damage types at the joints of the center column.

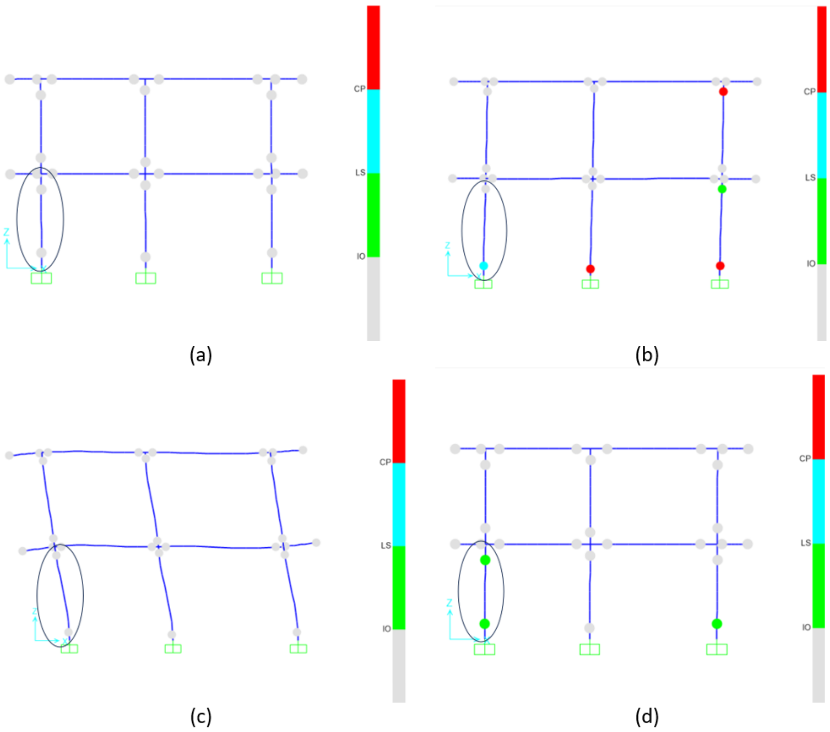

Fig. 11. Hinges in the corner column; a) RC1, b) RC2, c) RC3, d) RC4

As can be shown in Fig. 11, the columns and beams of RC1 and RC3 models remained at immediate use level, some columns of RC2 model collapsed, some columns remained at significant damage level and some columns remained at immediate use level. In the RC4 model, it was observed that some columns were significantly damaged and some columns remained at the immediate use level. It was determined that the beams of RC2 and RC4 models remained at the immediate use level.

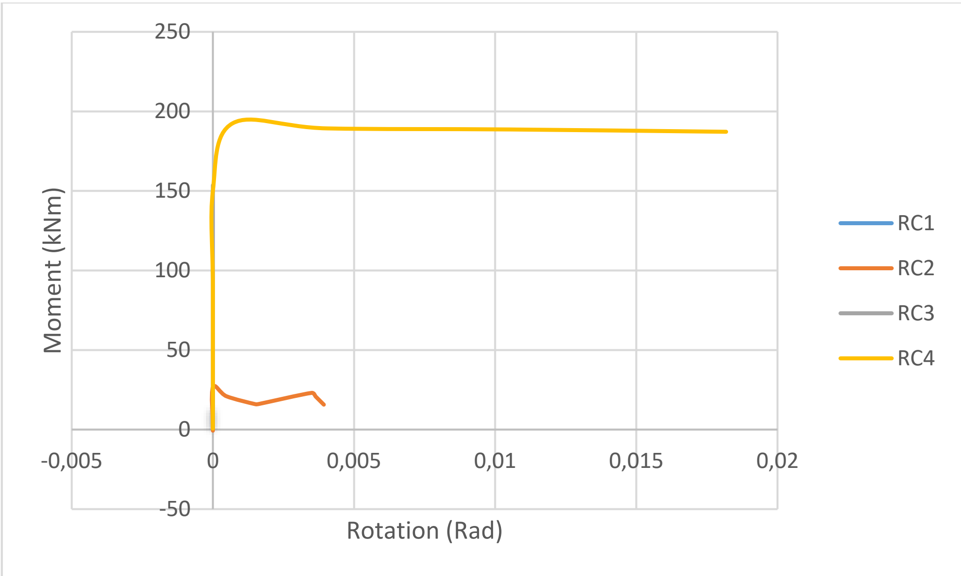

Fig. 12. Moment-rotation values in the center column; a) RC1, b) RC2, c) RC3, d) RC4

As shown in Fig. 13, it is observed that the columns and beams of RC3 model remained at the immediate use level, while some columns of RC1 model reached the significant damage level. Some columns of RC2 model collapsed, some columns remained at significant damage level and some columns remained at immediate use level. In the RC4 model, it was observed that some columns of RC2 and RC4 model were collapsed and some columns remained at the level of significant damage and some columns remained at the level of immediate use. It was determined that the beams of RC2 and RC4 models remained at the immediate use level.

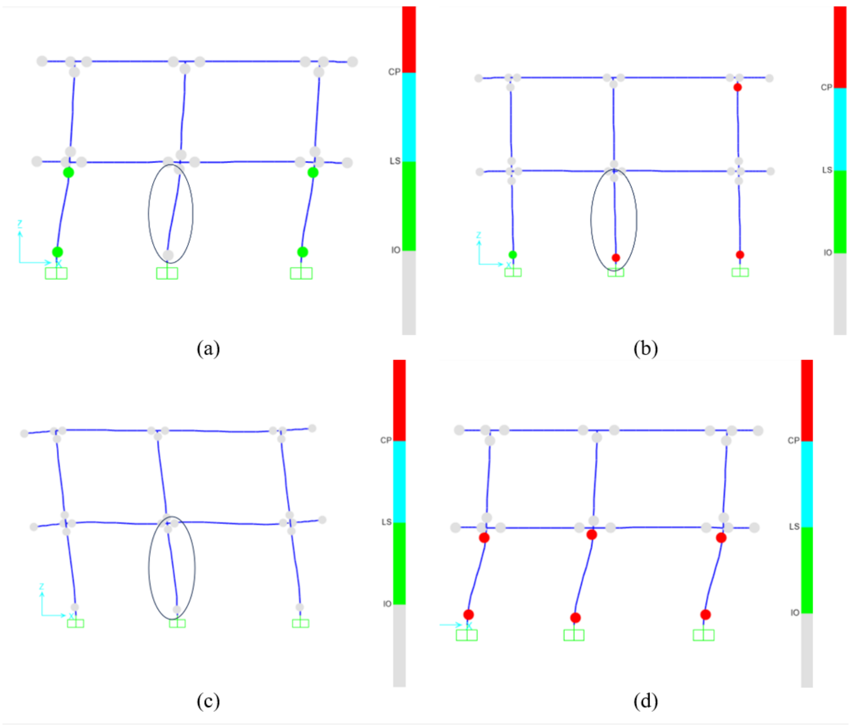

Fig. 13. Hinges in the center column; a) RC1, b) RC2, c) RC3, d) RC4

4. Conclusions

In this paper, the effects of flat beam and deep beam arrangements on the performance of reinforced concrete structural systems are investigated. In four different reinforced concrete structural systems with approximately the same cost, it is emphasized that the brittle fracture problem caused by the flat beam can be eliminated with the square column arrangement and at the same time, instead of deep beams, main beams with a b/d ratio less than 3, which do not create too much weight in the structure, should be used. The results obtained as a result of the analyses applied to reinforced concrete building models in the time domain are briefly summarized below.

- It is concluded that flat and deep beam arrangement increases the dominant period value of the structure and also the mass participation ratio in torsion mode. The square column arrangement decreased the mass participation ratio and the values of the period in torsion mode.
- It was determined that the flat and deep beam arrangement increased the horizontal and vertical displacements due to earthquake and vertical load combinations by approximately 45% and 40%, respectively. It is concluded that the square column arrangement effectively reduces these values in horizontal and vertical.
- Peak acceleration values were found to be the lowest in RC3 model. It was determined that the square column arrangement reduced the peak acceleration values of the system with hollow slab and flat beams by approximately 9%.
- It was observed that the normal stresses due to vertical earthquakes reached the highest values (3.54 MPa) in RC2 model. It was determined that the stress values decreased by approximately 50% with the square column arrangement.
- The results of the nonlinear analysis showed that the use of the deep beam increases the degree of damage due to excessive permanent deformations and the flat beam arrangement increases the risk of brittle fracture.
- It is concluded that RC1 and RC3 models exhibit ductile behavior and have the most ideal moment-rotation capacity.
- RC1 and RC3 were generally found to remain at the immediate use level (IO) and RC2 and RC4 at the collapse prevention performance level (CP).

At the end of this study, it was concluded that the arrangement of the load-bearing columns is very important in order to prevent further damage to the flat beam and hollow slab models under earthquake effects. It is concluded that the column widths and section heights should be chosen close to each other and no weak axis should be created. It is also confirmed that when deep beams should be used, strengthening methods that can reduce permanent deformations should be applied.

Ground motion simulation of the 1859 Erzurum Earthquake

Dursun Burak Özdoğan*[1], Dilek Okuyucu[1], Ayşegül Askan[2]

[1] ErzurumTechnical University, Department of Civil Engineering, 25100 Erzurum, Türkiye
[2] Middle East Technical University, Department of Civil Engineering, 06800 Ankara, Türkiye

Abstract: The earthquake that occurred on June 2, 1859, was recorded as one of the most destructive earthquakes in the history of Erzurum. The magnitude of this earthquake of the pre-instrumental period is evaluated approximately as 6.1, and the intensity value on the MMI scale is IX. Historical documents and publications contain evidence on the fact that the earthquake of June 2, 1859 caused great destruction and loss of life in the residential areas in the center of Erzurum. Understanding the seismicity of the region and reflecting the findings on structural performance is possible with ground acceleration values and spectral acceleration data calculated accordingly. In this context, the importance and necessity of ground motion simulations for pre-instrumental earthquakes become evident. Based on this issue, the presented study aims to produce a synthetic earthquake record of the June 2, 1859 Erzurum earthquake using the stochastic modeling technique. For the acceleration record of the June 2, 1859 Erzurum earthquake simulated at a point of interest in terms of historic stuctures using the stochastic finite fault method, PGA is calculated as 0.19g and PGV as 8.8 cm/sec.

Keywords: Ground motion simulation; Stochastic finite-fault model; Erzurum; 1859 Earthquake.

1. Introduction

Earthquakes affect different fields, from civil engineering to earth sciences and from the economy to health. In the design phase in terms of civil engineering, the main objective is to ensure that the building can survive against possible earthquake loads that the building may be exposed to. The possible earthquake loads must be reliably estimated. Ground motion prediction equations help for this purpose. However, to evaluate the safety and performance of structures, not only the maximum ground motion intensity but also the frequency content of the seismic excitation is of great importance. Therefore, it may be necessary to obtain the full ground motion time series of a past earthquake or a scenario earthquake predicted in the future. In regions where ground motion data are inadequate, recordings from areas with similar seismotectonic characteristics are often used in dynamic analyses, and their averages are calculated. However, in cases where there are no active seismic stations or where historical earthquake records are limited, ground motion simulations are a reliable alternative. Especially in events where instrumental measurement data are not available, such as historical earthquakes, these simulations provide valuable information for earthquake engineering. Ground motion simulation approaches are divided into three main groups: deterministic, stochastic, and hybrid approaches. Deterministic methods are usually based on numerical solutions of the wave equations, and although they offer high accuracy, they are only applicable in certain frequency ranges due to computational costs and physical constraints related to wavelength (e.g.: Frankel 1993,; Frankel et al., 1994; Olsen et al., 1995; Komatitsch et al., 2004). In contrast, stochastic methods provide a lower cost and practical alternative by taking into account the random nature of ground motions (e.g: Boore 1983; Hanks and Boore, 1984; Beresnev and Atkinson, 1997). Hybrid methods combine deterministic and stochastic approaches to produce broadband ground motion simulations. The simulated acceleration records obtained by alternative approaches are validated with active seismic stations or past earthquake records. If there are unrecorded earthquakes, the validation process cannot be performed. In this case, the valdiation of simulations is performed by indirect methods such as earthquake intensity, damage distribution, and empirical ground motion prediction equations (Karimzadeh and Askan, 2018).

Erzurum, which is located in a seismicly hazardous region, has experienced major earthquakes in the history. In extensive literature studies, it has been determined that the city has been exposed to many large earthquakes and substantially damaged at different times (e.g.: Tozlu, 2000; Ambraseys and Finkel, 2006). In particular, the earthquake that occurred on June 2, 1859, was recorded as the most destructive earthquake in the history of Erzurum. The 6.1 magnitude earthquake had a magnitude of IX according to the Mercalli Intensity Measure (MMI) (Özer et al., 2019). The damage caused by the earthquake in the city was frightening. Although the certainty

* Corresponding author, E-mail: bozdoganitu@gmail.com

https://doi.org/10.31462/icearc2025_ce_eqe_520

is not clear, 360 people were reported to have died in the reports written to the capital of that time, Istanbul. In terms of damage, 1462 houses were destroyed, about 3500 houses were severely damaged, 6 mosques were destroyed, and about 20 mosques and masjids were partially destroyed (Tozlu 2000; Sağlam 2021). This study aims to produce a synthetic acceleration record of the 1859 earthquake using a stochastic method.

2. Materials and methods

2.1. Stochastic finite fault methodology

Basically, the complex character of high-frequency ground motion records with frequencies greater than 1 Hz have been inadequate for modeling ground motion simulations. The reason for this inadequacy is the phase inconsistencies resulting from the complex character structures. These phase inconsistencies coupled with computational costs and lack of velocity models for higher frequencies have led to dificulty in analytical or numerical seismic wave equation solutions for modeling simulations of high-frequency ground motions. As a result, the stochastic point source model was developed and used for modeling high frequencies (Boore, 1983). Stochastic techniques are based on the principle of combining an arbitrary phase spectrum with the spectral amplitude of the ground motion. This method has its inherent limitations, as it does not fully reflect the effects of wave propagation, but it is widely used due to its ability to obtain high- and medium-frequency ground motions.However, this point source method is no longer a suitable method to be used in cases where the fault fracture width is larger than the distance between the source and the site because it cannot fully model the near-field effects. In the following years, Beresnev and Atkinson (1998) developed a method to overcome this deficiency in the point source method by modeling the fault as a rectangle and dividing this large fault into small fault segments and considering each segment as a point fault. They called this method the stochastic finite fault element method. These small faults are considered as point sources with an ω-2 spectrum. In this method, an earthquake hypocenter is placed on any of the sub-faults, and waves start to propagate from this hypocenter at a constant speed. While propagating, the waves move similar to rupture motion, and the waves propagating from each fault trigger the other fault. In time, the rupture motions on the sub-faults affect the main fault, and all these effects are summed up. The total acceleration from the fault is obtained as follows:

$$A(t) = \sum_{i=1}^{nl} \sum_{i=1}^{nw} Aij(t + \Delta tj) \tag{1}$$

A(t) is the acceleration record obtained from the whole fault, Aij is the acceleration contribution of the ijth subfault, nl and nw are the number of subfaults along the length and width of the fault, Δtij is the delay time calculated for each subfault. This time is the sum of the time for the rupture surface to reach each subfault and the time for the wave to reach the observation point as shown in Fig. 1. (e.g.: Ünal and Askan 2015; Askan and Karimzadeh 2019).

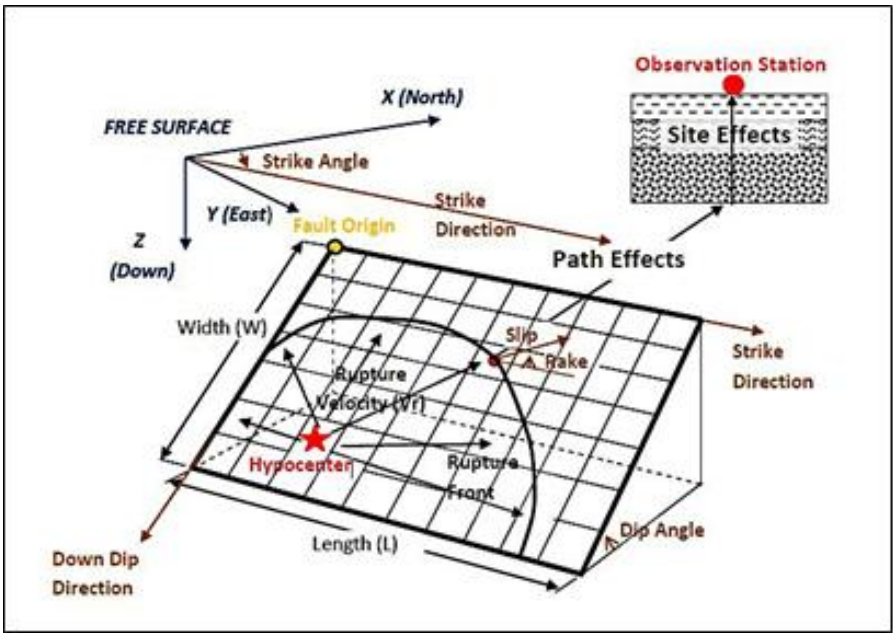

Fig. 1. Stochastic Finite Fault Method (adopted from Uğurhan 2010)

This model had some issues due to the limitation on the total number of subfaults and the direct dependence of the energy in the fault on the subfault dimensions. This limitation was overcome by Motazedian and Atkinson (2005) with a new approach called dynamic corner frequency model, the total energy is no longer dependent on the sub-fault size.

With this update in the stochastic finite fault method, this method is based on the concepts of deterministic spectrum for subfaults, and stochastic phase angles. For any subfault ij, the spectral acceleration relation at frequency f is given as follows:

$$A_{ij}(f) = CM_{0ij}H_{ij}\frac{(2\pi f)^2}{\left[1+\left(\frac{f}{f_{cij}}\right)^2\right]}e^{-\frac{\pi f R_{ij}}{Q(f)\beta}}G\left(R_{ij}\right)A\left(f\right)e^{-\pi kf} \tag{2}$$

$C = \Re^{\theta\varphi}\sqrt{2}\big/4\pi\rho\beta^3$ is the scaling coefficient expressed by the relation., $\Re^{\theta\varphi}$, radiation cover, ρ density, β S wave velocity, $M_{0ij}=\frac{M_0 S_{ij}}{\sum_{k=1}^{nl}\sum_{l=1}^{mw}S_{kl}}$ is theseismic moment of the sub fault, S_{ij} relative shear weights,

$f_{cji}\left(t\right) = N_R\left(t\right)^{-1/3} 4.9x10^6\beta\left(\frac{\Delta_\sigma}{M_{0ave}}\right)$ is the dynamic corner frequency of the sub fault. $\Delta\sigma$ stress drop, N_R (t) is nthe total number of sub-fractures that have broken at any time t ve $M_{0ave} = M_0\big/N$ is the average seismic moment of the sub-faults. Rij distance from observation point, Q(f) is the quality factor, $G(R_{ij})$ is the geometric spreading factor, $A(f)$ is the site amplification factor, $e^{-\pi kf}$ is a high-cut filter to include the spectral decayat high frequencies described with eden Kappa factor of soils (Anderson and Hough, 1984). Hij is the high frequency filter and is expressed as:

$$H_{ij} = \left\{N\frac{\sum\left[\frac{f^2}{1+f_c^2}\right]}{\sum\left[\frac{f^2}{1+f_{ij}^2}\right]}\right\}^{1/2} \tag{3}$$

2.2. June 2, 1859 Erzurum earthquake

The June 2, 1859 earthquake is stated to be the most severe in Erzurum's history. It was the last and most destructive event in a sequence of earthquakes that began at midnight on June 1. Although the initial tremor was not severe and was felt in the western part of the city, it was followed by a series of 12 successive earthquakes that culminated in a major quake around 4:00 a.m. on June 2, impacting the northern and southern parts of the city. A second powerful earthquake struck 15 minutes later, effectively leveling the city. Despite lasting only about 15 seconds, the earthquake had a devastating impact due to its intensity (Tozlu,2000) The magnitude of the earthquake is reported in sources as Mw = 6.1 to the Modified Mercalli Intensity (MMI) scale, the intensity level was IX (Özer et al., 2019).

There are different opinions regarding the affected area of the earthquake. The most well-known of these is the report by German geologist Hermann von Abich (1896), a member of the Russian Academy of Sciences. According to Abich’s report, the epicenter of the earthquake was located somewhere between Palandöken and Eğerlidağ. Waves were especially intense on the northern and eastern slopes of Mount Palandöken, which lies to the south of Erzurum’s city center. The seismic waves did not reach Pasinler to the east of the city or its western parts, and the earthquake was not felt beyond a 60 km radius. Muffled sounds were reportedly heard during the quake (Küçükuğurlu, 2024). The earthquake caused varying degrees of damage across different parts of the city. According to Abich, the southern section of the city, where Erzurum Castle is located, and the Turkish neighborhoods to the east of the castle suffered the most damage. One-third of the city was destroyed. The fact that the damage was more severe in some parts of the city is attributed to differing soil characteristics across the region. In reports sent to the capital, Istanbul—though not entirely verified—it was stated that 360 people died (Tozlu, 2000; Sağlam, 2011). In the 1859 earthquake, 1,462 houses were completely destroyed, around 3,500 were severely damaged, six mosques were entirely demolished, and approximately 20 other mosques and prayer halls were also damaged.(Özdoğan,2024). The location of the 1859 earthquake and the Erzurum fault lines are shown in Fig. 2.

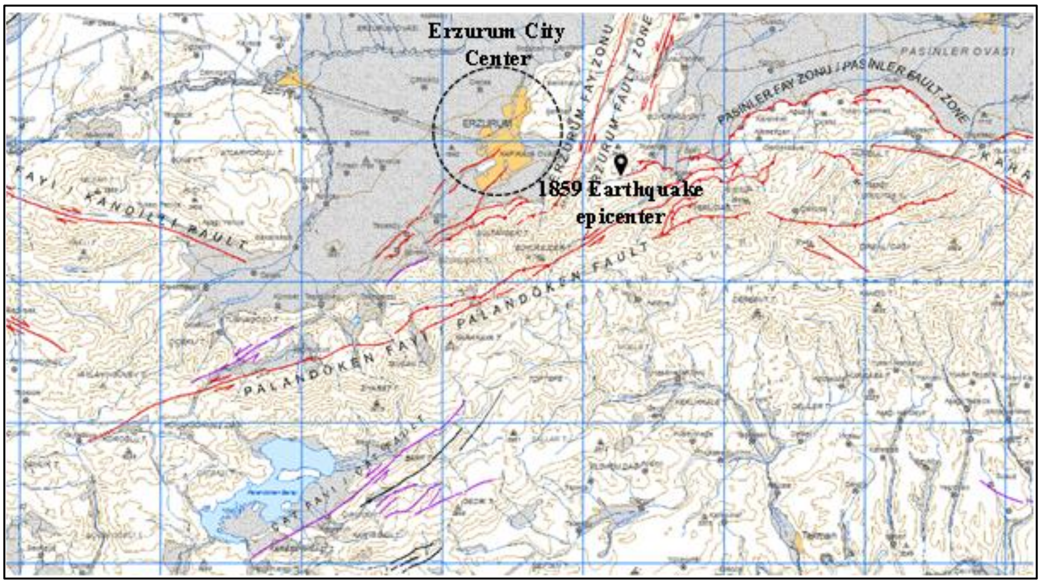

Fig 2. Erzurum faults and 1859 Earthquake center (MTA, 2021).

3. Simulation of June 2, 1859 Erzurum earthquake

Simulation of earthquake records is primarily driven by event-specific parameters, which are crucial in simulating ground motion. In this study, synthetic records for the June 2, 1859 Erzurum earthquake were created using the EXSIM open source code (Motazedian and Atkinson,2005). EXSIM allows users to simulate ground motion by inputting key seismic characteristics (Özdoğan,2024).

Main parameters involved in simulating records include earthquake magnitude, fault coordinates, rupture width, stress drop, faulting mechanism, fault dimensions and depth, wave propagation geometry, crustal density, rupture velocity, shear wave velocity of the crust, the size and number of sub-faults, the earthquake's geographic location, and the local kappa factor. A major challenge in generating synthetic acceleration records for thesimulating the 1859 Erzurum earthquake is the scarcity of historical data, as the event occurred before instrumental recording began. As a result, some parameters could not be directly observed and were instead sourced from prior research. Based on existing literature, the moment magnitude (Mw) of the 1859 earthquake is estimated at 6.1 (BOUN, 2023), and the event is assumed to have occurred near the Erzurum Fault.

The upper edge of the fault coordinates used were 39°94'N and 41°397'E, as reported in the literature. The fault is characterized as a left-lateral strike-slip fault, spanning approximately 38 km in length and 23 km in width, located between the eastern and northern areas of Erzurum. Although direct data on the rupture dimensions are unavailable due to the earthquake's historical nature, studies suggest the Erzurum Fault could extend up to 35 km eastward. For this study, the rupture was assumed to cover a 15 km segment.

Given the earthquake magnitude and fault type, the rupture width was calculated using Equation 3:

$$log(RW) = a + b \times M \tag{3}$$

Where M is the magnitude, and empirical constants a and b are -0.76 and 0.14, respectively, for a left-lateral strike-slip fault (Wells and Coppersmith, 1994). This resulted in a rupture width of 7.5 km, which was input into EXSIM.The dip angle was approximated at 25°, based on the fault's length and calculated width. Since this fault type typically has a vertical dip, a dip angle of 90° was ultimately adopted in the code.

In the stochastic finite-fault model, sub-faults of 1.5 km × 1.5 km were defined. One sub-fault, identified as (5, 3) in the (i, j) grid system, was designated as the earthquake's hypocenter. The stress drop (Δσ) was estimated using Equation 4:

$$\Delta\sigma\left(SS\right) = 8.9xW^{0.8} \tag{4}$$

where W is the fault width (Mohammediun and Serva,2001). Substituting the 7.5 km width into the equation yielded a stress drop of approximately 45 bar. The absence of exact numerical data meant some input parameters were constrained and supplemented using findings from previous studies. To fill data gaps, results from earlier simulations of earthquakes in Erzincan were referenced (Uğurhan,2010; Karimzadeh et al, 2018). Based on these sources, the focal depth of the 1859 Erzurum earthquake was set at 3 km. The quality factor for anelastic attenuation (Q*f*) was defined using the equation:

$$Q = 122xf^{0.68} \tag{5}$$

Geometrical spreading was modeled using:

- R^{-1} for R ≤ 25 km (6a)
- $R^{-0.5}$ for R > 25 km (6b)

The time duration model was expressed as:

$$T = T_0 + 0.05R \tag{7}$$

where T is the total duration, T_0 is the source duration, and R is the hypocentral distance. These values were incorporated into the simulation.

To classify the local site conditions, Vs30 shear wave velocity values were used. According to Turkish seismic code (TBDY, 2018) central Erzurum has Vs30 values between 200–240 m/s, corresponding to local soil class ZD (NEHRP-D site class). This classification and corresponding amplification factors were used in EXSIM. The kappa factor (κ_0), which accounts for local site effects, was also adjusted. The minimum recommended κ_0 for ZD-class soils in eastern Turkey is 0.0365. Previous simulations used values of 0.045 and 0.066 for the 1992 and 1939 Erzincan earthquakes, respectively. In initial simulations for the 1859 event, a κ_0 of 0.040 was used, but this did not yield the expected damage levels for mosques. To address this, the value was gradually lowered. Ultimately, based on the recommendation by Altındal and Askan (2022) and considering the rugged topography of the region, a κ_0 value of 0.025 was adopted using a kappa value corresponding to mean minus one standard deviation. This adjusted value was used to generate the final synthetic acceleration record. The values of 3600 m/s for crustal shear wave velocity and 2800 kg/m³ for crustal density were employed. Once all parameter inputs were finalized, the target location for applying the simulated record was obtained. The parameters of the simulation are shown in Table 1.

Table 1. Simulation parameters of the 1859 earthquake

Parameter	Values
Fault	Dip angle: 25° Depth angle: 90°
Fault Dimensions	15 x 7.5 km
Earthquake Magnitude	6.1
Fault Depth	3.0 km
Sub-fault Dimensions	1.5 x 1.5 km
Stress Drop	45 bar
Crustal Shear Wave Velocity	3.600 m/s
Crustal Density	2.800 kg/m^3
Slip Area Percentage	% 50
κ_0	0.025
Time Duration Model	0.05*R
Attenuation Factor Q(f)	122 $f^{0.68}$
Geometrical Spreading	$R^{-1.1}$, R≤25 km $R^{-0.5}$, R>25 km
Windowing Function	Saragoni- Hart
Local Site Class	ZD

The simulated ground motion record for the 1859 earthquake has a duration of almost 8 seconds. The calculated hypocentral distance is 17.94 km, while the R_{JB} distance is around 11.48 km. The peak ground acceleration (PGA) of the simulated motion is 190 gal, and the peak ground velocity (PGV) is 8.8 cm/sec. The acceleration and velocity time histories are given in Fig. 3.

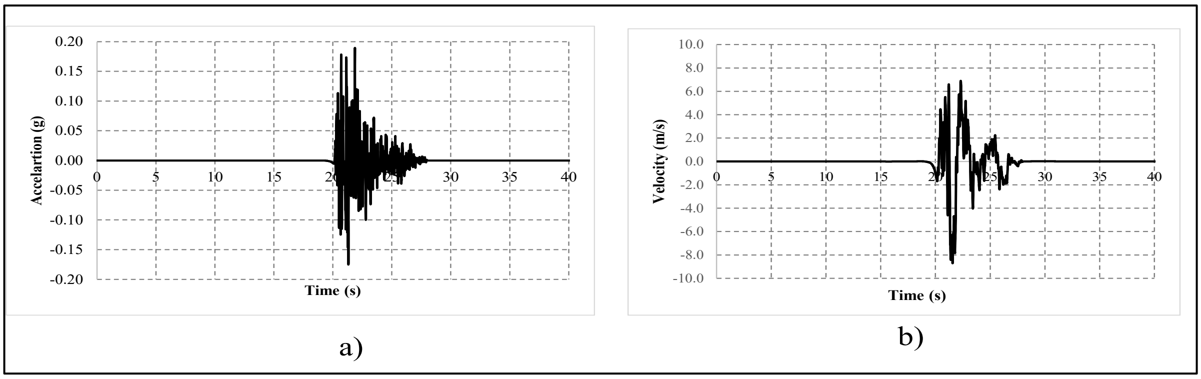

Fig. 3. Simulated a) acceleration, b) velocity graphs generated for the June 2, 1859 Erzurum earthquake.

One of the most crucial steps in generating synthetic earthquake records is the validation phase. For earthquakes that occurred during the instrumental era, the acceleration records simulated using stochastic methods are assessed by comparing them with actual recorded ground motions. Numerous studies in the literature have followed this approach, validating synthetic records of major historical events—such as the 1999 Düzce, 2009 L'Aquila, and 1992 Erzincan earthquakes—by comparing them to the corresponding real acceleration data (Uğurhan, 2010).

The validation process extends beyond the comparison of a single earthquake record at a specific site. It also involves referencing databases that compile records from multiple relevant seismic events in the region. This broader approach allows for adjustments and improvements to the simulated acceleration records as needed (Tsiolou et al., 2019) However, for earthquakes that occurred before the development of seismic instrumentation, direct validation using recorded ground motion data is not possible. In such cases, earthquake intensity has been proposed as an alternative method for validation. Bilal and Askan (2015) stated that when the peak ground acceleration (PGA) is available, the Modified Mercalli Intensity (MMI) can be estimated using Equation 8:

$$MMI = 0.132 + 3.884 \times log(PGA) \tag{8}$$

In this equation, PGA must be provided in units of gal. It is noted that this method has been applied to validate the simulated acceleration record of the 1939 Erzincan Earthquake, which predates instrumental recordings (Karimzadeh and Askan, 2018).

For the June 2, 1859 earthquake, no instrumental acceleration data are available. As a result, the initial validation was carried out by estimating the earthquake intensity based on the simulated record. Historical sources report that the intensity of this earthquake, which affected Erzurum, was level IX on the MMI scale (Özer et al., 2019).Using the PGA value of 190 gal derived from the synthetic record, the calculated intensity from Equation 8 is 9.33. This estimated value aligns closely with the historically reported intensity of IX, supporting the validity of the synthetic data.

A second validation method is to comapre the simulated peaks with those from ampirical ground motion models (GMMS). Among various ground motion models, the models proposed by Akkar and Çağnan (2010) and Kale et al. (2015), which yield results closely matching the recorded data in this region of the country, were selected for analysis. In Table 2 the peak ground acceleration values of the simulated ground motions are compared with the mean predictions and ±1 standard deviation ranges obtained from these models. In these comparisons, the empirical ground motion equations were applied using a moment magnitude (Mw) of 6.1, a Joyner–Boore distance (Rjb) of 11 km, and site conditions corresponding to Vs30 = 240 m/s, consistent with the characteristics of the simulated earthquake

Table 2. Table of Peak Ground Acceleration Values

	Average Peak Ground Acceleration (g) – One Standard Deviation"	Average Peak Ground Acceleration (g)	Average Peak Ground Acceleration (g) + One Standard Deviation"
Akkar and Çağnan (2010)	0.06	0.138	0.317
Kale et al. (2015)	0.07	0.140	0.281
Simulated Peak Ground Acceleration (g)		0.190	

Upon examination of Table 2, it is observed that the peak ground acceleration value obtained from the simulation for the June 2, 1859 earthquake falls within the range of limit acceleration values reported for real earthquakes that occurred under similar conditions. It has been concluded that the peak ground acceleration values corresponding to both the raw and the scaled ground motion records lie within the boundary values specified in both references. Through this study, the peak ground acceleration value obtained from the simulation has been validated.

4. Conclusions

In this study, to enhance the understanding of seismic activity in Erzurum, a strong ground motion record at a point of interest in terms of historic stuctures was simulated and validated for the 2 June 1859 Erzurum earthquake—one of the most devastating events in the region's history—using a stochastic approache. Alongside estimating the earthquake's intensity empirically through the PGA value of the generated record, the reliability of the synthetic data was also assessed by comparing with empirical estimated from groun motion models The following conclusions were drawn from the simulation of this acceleration record:

- For the 1859 Erzurum earthquake, the simulated ground motion record has a peak ground acceleration (PGA) of 0.19g, a peak ground velocity (PGV) of 8.8 cm/s, and a peak ground displacement (PGD) of 2.5 cm. The PGA value is validated against an empirical MMI value obtained from historical damage reports.

- Based on the PGA value, reported shaking experiences, and historical damage data, the earthquake's intensity was classified as IX on the Modified Mercalli Intensity (MMI) scale. Given the nature of Erzurum's building stock at the time, the event was deemed highly destructive.
- Although the PGA value was relatively low, Erzurum experienced substantial damage, which may be attributed more to poor soil conditions and inadequate construction quality rather than to the earthquake's magnitude itself.
- The stochastic modeling technique takes researchers back to the pre-instrument era when earthquake recorders were not available, and allows for the subsequent recording of an earthquake that occurred in the past. Generating records of pre-instrumental earthquakes in our country with this method and validating them against any empirical data with studies similar to this thesis will contribute to a better understanding of the seismicity and earthquake hazard of our country.

Abstract. The detection of structural anomalies is essential for safeguarding the integrity and longevity of buildings with cultural and historical significance, such as masonry minarets. This study explores the use of Convolutional Neural Networks (CNNs) for forecasting vibration responses and identifying patterns indicative of potential structural damage. Vibration data collected from a minaret under both undamaged and controlled damage scenarios are used to train and evaluate a CNN model designed to extract spatial features from time-series signals. The model demonstrates strong performance in distinguishing normal structural behavior from anomalous patterns, offering high accuracy and sensitivity in damage detection. In addition to its predictive capabilities, the CNN approach proves to be computationally efficient and suitable for real-time monitoring applications. The findings highlight the potential of deep learning–based methods, particularly CNNs, to enhance non-contact structural health monitoring strategies, providing a reliable and scalable solution for the preservation of historic structures.

Keywords: Historic masonry structures; Optical flow; Convolutional Neural Networks (CNN); Anomaly detection; Non-contact measurement

1. Introduction

Historic masonry structures, such as minarets, are significant cultural heritage assets that often experience deterioration over time due to aging, environmental conditions, and dynamic forces such as earthquakes (Sabia, Demarie et al., 2022). Maintaining their structural integrity is essential due to their historical and cultural importance. Traditional structural health monitoring (SHM) methods are often invasive and limited by practical challenges and the risk of further damage (Dong and Catbas, 2021). As a result, non-contact and non-intrusive methods, especially video-based SHM, have become increasingly popular for being safe, cost-effective, and efficient (Shariati, Schumacher et al., 2014).

Video-based SHM uses advanced computer vision, image processing, and machine learning (ML) techniques to detect structural damage by analyzing video data. This method provides significant benefits in scalability, accuracy, and safety, allowing continuous monitoring without physical contact (Ghandil, Dabanli et al., 2021; Xiong, 2021). Although video-based SHM has been widely studied, research focused specifically on historic masonry minarets are limited. These structures present unique challenges for monitoring due to their complex geometry, varied materials, and cultural significance.

Recent progress in video-based SHM has highlighted its effectiveness in monitoring structural dynamics and detecting gradual damage in historic buildings. Digital video imaging, in particular, has proven suitable for non-contact dynamic assessment, offering a practical solution for historic masonry structures where traditional sensors are often impractical or pose a risk to the structure (Ghandil, Dabanli et al., 2021). Graph-based video processing techniques have emerged as effective tools for early warning systems in historic masonry structures. By analyzing key deformation patterns, these methods can help predict potential structural failures, offering a means to protect valuable heritage sites from severe damage (Fioriti, Cataldo et al., 2024).

Automated damage detection in masonry using video imaging shortens inspection times and improves safety by removing the need for inspectors to enter hazardous areas (Sangirardi, Altomare et al., 2022). Moreover, advancements in machine learning have greatly enhanced the effectiveness of video-based SHM. Sophisticated algorithms that detect subtle structural changes in video data support long-term monitoring and predictive

*Corresponding author, E-mail: kemalhaciefendioglu@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_529

maintenance, which are especially important for historic masonry buildings exposed to seismic activity and other dynamic forces (Aktürk, Aras et al., 2022; Farrar, Dervilis et al., 2025). Although video-based methods have advanced significantly, their use in monitoring historic masonry minarets has received limited attention. This study aims to bridge that gap by presenting a tailored video-based monitoring framework that considers the unique structural traits and preservation demands of minarets.

This study presents a novel integration of advanced optical flow techniques with deep learning (DL) architectures, specifically CNN model, to capture the distinctive structural behavior of masonry minarets and detect anomalies. The key contributions are: (a) directly addressing the monitoring challenges arising from the complex geometry and material variability of historic masonry minarets, (b) introducing a hybrid Autoencoder-PCA method to efficiently reduce dimensionality and improve anomaly detection by isolating dominant patterns in displacement time-series data, and (c) conducting a detailed analysis of CNN model to evaluate its performance and suitability for video-based monitoring of heritage structures.

2. Theoretical background

2.1. Optical flow methods

Optical flow refers to the apparent motion of objects or surfaces in a scene due to movement between the camera and the environment. In structural health monitoring (SHM), it enables real-time, non-contact tracking of displacements, deformations, and vibrations.

The Lucas-Kanade method is well-suited for tracking small displacements, whereas its extension through the pyramid approach improves reliability in cases involving larger movements (Lucas and Kanade, 1981; Bouguet, 2001; Baker and Matthews, 2004).

2.2. Hybrid autoencoder-PCA

Autoencoders (AEs) are neural networks that use unsupervised learning to extract efficient, lower-dimensional representations of data. They consist of two main parts: an encoder that compresses the input and a decoder that reconstructs it, enabling meaningful features learning from the original data.

2.3. Convolutional neural networks (CNNs)

Convolutional Neural Networks (CNNs) play a pivotal role in deep learning, especially for analyzing visual data such as images and videos. Unlike conventional neural networks that rely on manually selected features, CNNs automatically learn spatial hierarchies of features from raw input, enabling efficient processing of high-dimensional and complex datasets. Their architecture, inspired by the structure of the visual cortex, consists of multiple layers that progressively extract informative patterns relevant to tasks like classification and detection (Fig. 1). The process begins with a convolutional layer that applies learnable filters (kernels) to the input data, extracting features that range from basic edges and textures to more abstract patterns in deeper layers. An activation function—typically the Rectified Linear Unit (ReLU)—is then used to introduce nonlinearity, allowing the network to model complex relationships. Pooling layers follow this step, reducing the spatial dimensions of the feature maps while retaining essential information, which helps lower computational cost and control overfitting. After several convolution and pooling operations, fully connected layers flatten and integrate the extracted features for classification or regression. Each neuron in these layers connects to all neurons in the next layer, enabling high-level reasoning. A SoftMax layer is typically used at the output to convert raw scores into class probabilities, allowing the model to produce interpretable predictions in visual recognition tasks (Simonyan and Zisserman, 2014). CNNs are particularly well-suited for image processing and pattern recognition tasks. Their primary strength lies in their ability to automatically extract hierarchical features from raw data, eliminating the need for manual feature engineering. This makes CNNs highly effective in domains that involve complex visual data.

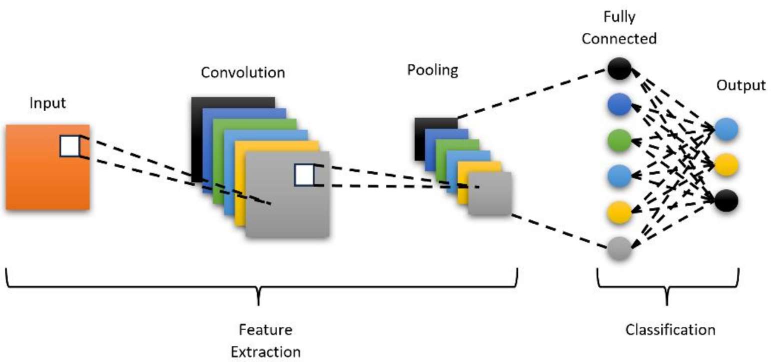

Fig. 1. The structure of a CNN

CNNs have revolutionized many fields, especially those that require the analysis of complex visual data. Their ability to automatically learn features from raw data has made them indispensable in tasks such as image classification, object detection, and medical image analysis. As technology continues to evolve, the applications of CNNs will likely expand even further, playing a critical role in innovations across a wide range of industries. Their effectiveness in understanding complex patterns, coupled with their efficiency, ensures that CNNs will remain a foundational tool in the field of deep learning (Szegedy, Liu et al. 2015).

3. Anomaly assessment methodology

The proposed approach combines advanced image processing with unsupervised learning to evaluate the structural condition of a portable minaret model. Four cameras, positioned at key locations, record high-resolution video of markers placed on the minaret's surface, allowing accurate measurement of both horizontal and vertical displacements under intact and damaged states. Optical flow techniques are used to calculate these displacements, which are then translated from pixel units into real-world values through calibration using known marker dimensions. The resulting displacement time series is used for feature extraction, where a hybrid Autoencoder-PCA model captures the latent patterns of healthy behavior. In parallel CNN architecture leverage both spatial and temporal features to improve anomaly detection. A reconstruction error-based damage index, computed in an unsupervised manner, identifies anomalies by comparing original and reconstructed signals, with detection refined through thresholding and segment-level analysis. This integrated framework enables continuous monitoring and clear visualization of structural damage progression over time.

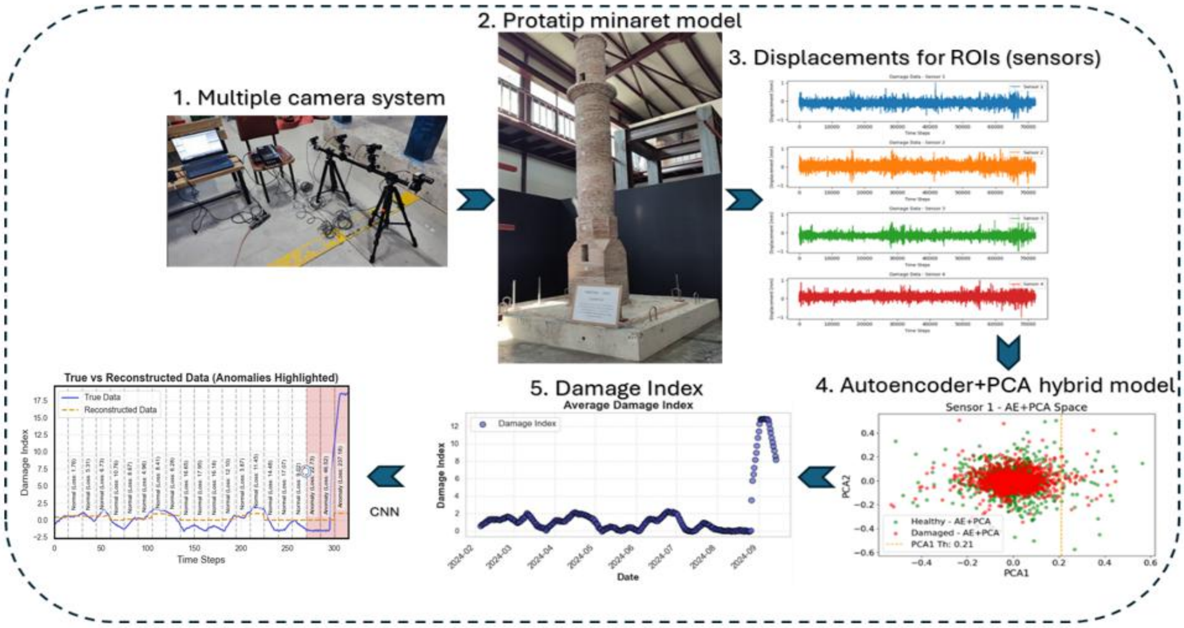

Fig. 2. Steps of proposed damage strategy

Figure 2 illustrates the workflow of the proposed methodology, with each step outlined as follows:

Step 1: Multi-Camera System and Prototype Minaret Model: A portable minaret model was equipped with four cameras positioned strategically to focus on specific markers placed on the surface of the structure. This setup enabled each camera to independently record video data, resulting in four separate and complementary data streams.

Step 2: Displacements for ROI. Each video stream is processed using the optical flow method to compute pixel movements between consecutive frames, capturing horizontal displacements of the minaret. Marker positions and their motion patterns are analysed to distinguish displacements at different locations on the structure. The resulting pixel-based motion vectors are extracted and stored, creating a raw dataset for further analysis.

The pixel-based motion vectors derived from optical flow are then converted into real-world units, such as millimeters or centimeters. This conversion relies on scaling factors determined through the known dimensions of the markers used in the experimental setup, combined with camera calibration parameters to ensure accurate spatial measurements.

These parameters allow for precise conversion of pixel displacements into actual physical distances. The resulting horizontal and vertical displacement values are recorded as time series data for multiple points on the minaret, creating a detailed dataset for subsequent analysis.

Step 3: Feature extraction and model training. To facilitate damage detection, the displacement time series data are transformed into a more compact and informative representation using a hybrid Autoencoder-PCA model. The autoencoder compresses and reconstructs the input signals, capturing their key characteristics. PCA is then applied to further reduce dimensionality and highlight dominant patterns. Importantly, only data from the undamaged (healthy) state are used during training, enabling the model to learn a latent representation that characterizes normal structural behaviour.

Step 4: Unsupervised reconstruction error-based structural damage index. The model is initially trained on the undamaged (reference) dataset of the minaret. Once trained, it is applied to new measurements to calculate a damage index based on reconstruction error. By comparing how well the model reconstructs current data relative to the reference state, deviations indicating potential damage are identified. Tracking these indices over time allows for visualization of damage progression throughout the monitoring period.

DL models are designed to compress input data and reconstruct it with minimal loss. The reconstruction error quantifies how effectively the model can reproduce the input.

4. Experimental implementation

4.1. Controlled damage scenarios

The damage was introduced by selectively removing bricks, a method chosen to observe changes in the structure's dynamic behavior. The targeted damage area was located on the brick wall section aligned with the lowest-level accelerometer, where seven bricks were removed to enable effective 2D displacement measurement. This damage zone was situated roughly 35 cm above the transition section, at a height of 145 cm from the base of the minaret. The procedure used for brick removal is illustrated in Figure 3 and detailed in the following paragraphs:

- Step 1 (Damage-1). The initial damage phase involved the removal of two out of the seven designated bricks, as shown in Figure 3a.
- Step 2 (Damage-2). In the next phase, four additional bricks located next to the initially removed ones were taken out, with two on each side. This resulted in a damaged region measuring approximately 30 cm in width and 3 cm in height, as shown in Figure 3b.
- Step 3 (Damage-3). As in the previous steps, one additional brick was removed from the upper brick layer, bringing the total number of removed bricks to five. Displacement measurements using the camera system were performed after each removal, as shown in Figure 3c.
- Step 4 (Damage-4). In the final stage, three additional bricks were removed from the upper brick layer, resulting in a total of seven bricks being extracted. After each removal, camera-based displacement measurements were repeated, as illustrated in Figure 3d.

Throughout the damage induction process, camera-based measurements were consistently recorded to monitor and evaluate the structural response of the minaret model.

Fig. 3. Controlled damage scenarios considered in the experimental study

4.2. Data collection and analysis
The monitoring was carried out using predefined regions of interest (ROIs) on the scaled minaret model. A template-matching-based sensing system continuously tracked the motion of selected points to collect displacement data. Measurements were performed using a multi-camera setup, and the data from each camera were analyzed comparatively. Figure 4 illustrates the placement of the template markers and the camera configuration. In this setup, the most distant camera was aimed at the top section of the model, specifically the honeycomb structure, while the other cameras were directed toward the podium, transition zone, and shaft at predefined angles. This arrangement ensured complete high-resolution coverage of all critical regions. The structured positioning allowed each camera to capture motion at different levels, ensuring synchronized and consistent data collection, and enabling accurate analysis of structural behavior and dynamic response.

Fig. 4. Template markers on the minaret and camera layout

During the monitoring process, periodic displacement measurements were analyzed to identify variations in the structure's dynamic behavior. The reference dataset, representing the undamaged state, includes 216,433 data points collected from four distinct measurement locations, as shown in Figure 5. This figure also displays the time-dependent displacement trends for both the training and test sets under undamaged conditions. After introducing controlled damage to the minaret model, measurements were repeated at the same four locations. For instance, the displacement data corresponding to the Damage-4 condition are detailed in Figure 6. These evaluations offer valuable insights into the model's dynamic response following damage and support the assessment of its structural stability.

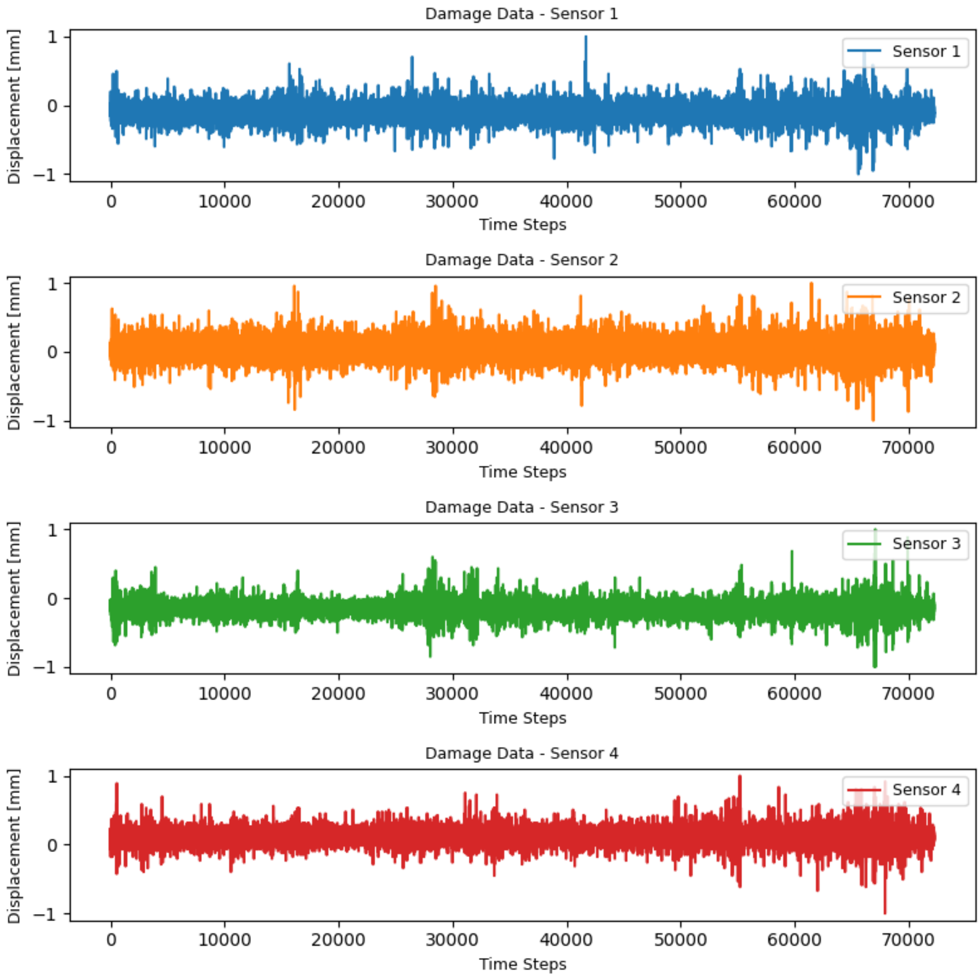

Fig. 6. Displacement-time graphs obtained for Damage-4 after controlled damage a) Sensor-1 horizontal and vertical displacement b) Sensor-2 horizontal and vertical displacement c) Sensor-3 horizontal and vertical displacement d) Sensor-4 horizontal and vertical displacement

5. Results

5.1. CNN model

The CNN model is designed to compress and reconstruct time series data. In the encoder section, sequential 1D convolutional (Conv1D) and max pooling (MaxPooling1D) layers are used to extract and reduce features. The first Conv1D layer applies 64 filters with a kernel size of 3 to capture low-level patterns in the input. This is followed by a MaxPooling1D layer that reduces the temporal resolution by half. The second Conv1D layer uses 128 filters to learn more abstract features, and another pooling layer further compresses the data. By the end of the encoder, the input time series is transformed into a compact latent representation for reconstruction.

The decoder section reconstructs the compressed time series using Conv1DTranspose and UpSampling1D layers. The first transpose convolution layer, with 128 filters, begins expanding the latent representation, followed by an upsampling layer that doubles its size. A second Conv1DTranspose layer with 64 filters further refines the reconstruction, again followed by upsampling. Finally, a third transpose convolution layer with a sigmoid activation restores the time series to its original dimensions, completing the reconstruction process.

The model comprises 99,073 trainable parameters and is optimized using the Mean Absolute Error (MAE) loss function. The Adam optimizer is employed to ensure efficient training. This CNN autoencoder architecture is well-suited for tasks such as feature extraction, anomaly detection, and noise reduction in time series data (Fig. 7). Its structure demonstrates the capability of deep learning models to handle complex temporal patterns, making it a valuable tool for both research and practical applications.

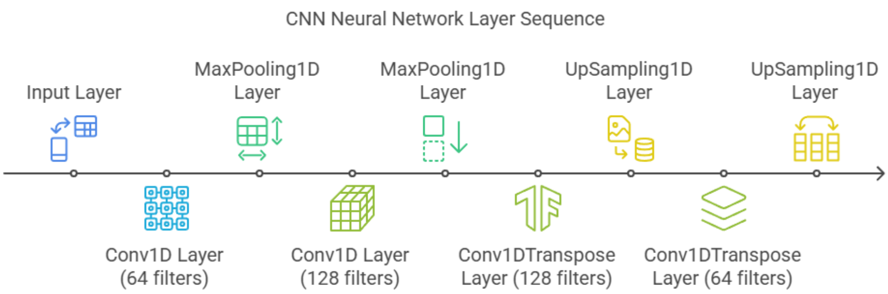

Fig. 7. CNN neural network layer sequence

Fig. 8 shows the training and validation losses of the CNN model. The training loss stabilized at around 0.80, while the validation loss initially decreased from 1.10 to 0.75, then fluctuated between 0.75 and 0.85 during later epochs. The stable training loss suggests that overfitting is not an issue, although the fluctuations in the validation loss might indicate some instability in the model's generalization performance. Overall, the model performs effectively with low loss values. Fig. 9 displays the distribution of MAE losses during training. The losses are predominantly clustered in the 0.4 to 0.6 range, with high loss values being rare. The fact that there are very few samples exceeding the 1.42 threshold indicates that the model performs well on normal data and is effective in anomaly detection. In general, the model has achieved successful learning with low losses. Fig. 10 presents the MAE losses on the CNN model's test data. Most loss values are concentrated below 2, and only a very few samples exceed the threshold of 16.89. This demonstrates that the model successfully reconstructs normal data with low error and is effective in detecting anomalies. Fig. 11 illustrates the CNN model's ability to distinguish between normal and anomalous data. During the time steps 0–250, the model accurately reconstructs normal data with low losses. After the 250th step, it correctly identifies anomalies with high losses (e.g., 46.52 and 237.18). The divergence between the blue and orange lines underscores the model's effective anomaly detection performance.

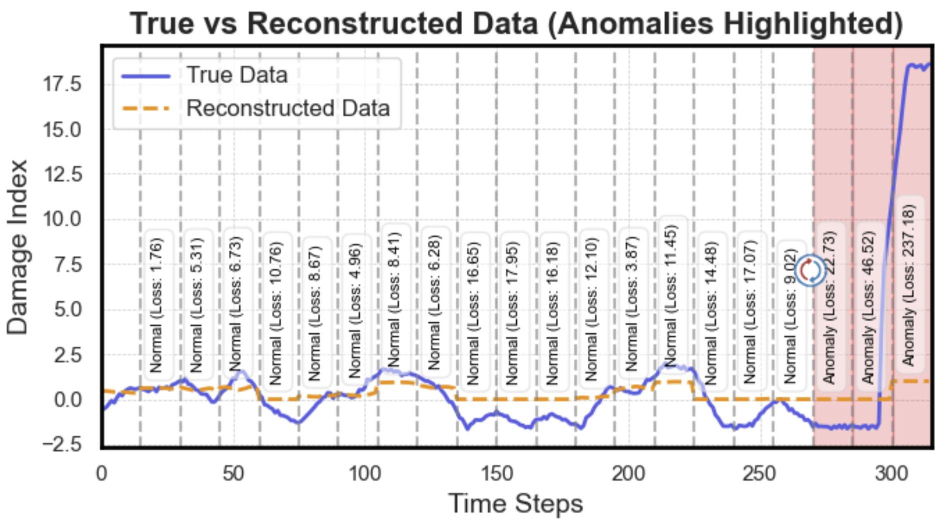

Fig. 11. Anomalies for CNN model

6. Discussion

The proposed video-based structural health monitoring (SHM) system demonstrated considerable promise in assessing the condition of historic masonry minarets through precise, non-contact displacement measurements. By applying advanced optical flow techniques—particularly the pyramidal approach—the system effectively tracked both small and large motions, enabling accurate real-time monitoring of structural dynamics. The conversion of pixel displacements into real-world measurements further confirmed the system's applicability in practical scenarios, especially where traditional sensor-based methods are limited or invasive.

Controlled damage scenarios provided critical insight into the CNN model's performance in anomaly detection. The model exhibited strong spatial feature extraction capabilities, accurately identifying localized damage patterns in the structure. Despite minor fluctuations in validation loss, the CNN maintained stable performance and avoided overfitting, which attests to its reliability for real-world deployment. Its ability to distinguish between normal and anomalous structural conditions underscores the potential of convolutional architectures in video-based SHM applications.

Overall, the findings support the effectiveness of CNNs for spatial anomaly detection in video-based monitoring frameworks. The experimental results validate this approach as a cost-effective, scalable, and non-intrusive tool for continuous structural health assessment, particularly suited for preserving the integrity of historic masonry minarets.

7. Conclusions

This study developed a video-based SHM framework tailored to historic masonry minarets, integrating optical flow techniques with a convolutional neural network (CNN) to achieve accurate, non-invasive anomaly detection. The main findings are as follows:

- Optical flow methods provided reliable, non-contact displacement measurements, enabling structural assessment in areas where direct instrumentation is impractical.
- The CNN model demonstrated strong spatial feature learning capabilities, effectively distinguishing between damaged and undamaged structural states with high accuracy.
- The system's ability to operate under real-time conditions and deliver robust performance under varying damage levels highlights its suitability for long-term structural monitoring.
- The reconstruction-error-based anomaly detection approach enabled the model to generalize from healthy-state data and detect deviations indicative of structural damage.

In conclusion, the proposed video-based SHM system presents a practical and effective approach for monitoring and preserving historic masonry minarets. Its non-invasive nature, combined with the analytical power of CNNs, makes it a valuable contribution to heritage conservation efforts.

Acknowledgments

This study was conducted as part of the research project titled "Video Camera-Based Structural Health Monitoring of Historical Masonry Minarets and Development of a Long-Term Decision-Making Model Based on Deep Learning Method" (Project No: 222M140), supported by the TÜBİTAK 1001 – Scientific and Technological Research Projects Support Program I would like to express my sincere appreciation to the General and Regional Directorates of Foundations for their valuable collaboration and logistical support throughout the research process.

Innovative housing solutions: Integrating ultra-high-performance concrete in modular construction for sustainability and efficiency

Oumaima Awassa [1], Raafat El-Hacha*[1]

[1] University of Calgary, Department of Civil Engineering, 2500 University Drive NW, Calgary, Alberta, Canada

Abstract. The global housing crisis presents an urgent challenge, exacerbated by rapid urbanization, affordability issues, and environmental concerns. Traditional construction methods struggle to meet demand due to high costs, inefficiency, and substantial environmental impact, contributing to over 34% of global energy consumption and nearly 37% of CO_2 emissions. In response, this paper explores the integration of Ultra-High-Performance Concrete (UHPC) in modular construction as a transformative approach to addressing these challenges.
UHPC, recognized for its superior mechanical properties, durability, and sustainability, offers a compelling alternative to conventional construction materials. Its high compressive and tensile strength, combined with its resistance to harsh environmental conditions, makes it an ideal choice for prefabricated modular housing. By leveraging prefabrication techniques, UHPC enables the rapid production of robust and lightweight structural elements, reducing construction timelines, material waste, and overall costs. This study highlights the structural benefits of UHPC sandwich wall panels (SWPs) and waffle slab systems, focusing on their implementation in modular housing. A key aspect of this research is the evaluation of shear connectors used in the SWPs, providing essential data on their mechanical behaviour. The findings contribute to optimizing UHPC modular construction, ensuring efficient load transfer and long-term resilience. Beyond its technical advantages, UHPC modular construction presents a sustainable pathway for urban development. Minimizing embodied carbon, enhancing energy efficiency, and reducing maintenance requirements align with global efforts to achieve net-zero emissions in the built environment. This paper discusses how adopting UHPC in modular housing can significantly enhance construction efficiency while addressing pressing housing shortages in urban and remote regions. The research findings pave the way for a scalable, cost-effective, and environmentally responsible solution to modern housing challenges.

Keywords: Prefabricated modular houses; Sustainability; Ultra high-performance concrete; Sandwich wall panels; Energy efficiency.

---

1. Introduction

Access to safe, affordable, and sustainable housing is foundational to healthy communities and individual well-being. Globally, housing insecurity is reaching critical levels, with 1.6 billion people—roughly 20% of the global population—lacking adequate housing. This includes not only those who are homeless but also millions living in overcrowded, unsafe, or insecure conditions (UN-Habitat, 2024). The housing crisis manifests in various ways across different regions, from urban affordability pressures to post-conflict destruction and climatic extremes As urbanization accelerates—projected to reach 68% of the global population by 2050 (UN-DESA, 2018)—this crisis is poised to deepen unless comprehensive and sustainable strategies are adopted.

In Canada, the housing shortage has intensified, especially in urban centers such as Toronto and Vancouver, where demand consistently outpaces supply. Factors such as rapid immigration-driven population growth, limited land availability, and sluggish construction timelines contribute to surging property and rental prices (Government of Canada, 2023; CBS News, 2023). The Canada Mortgage and Housing Corporation estimates that the country needs an additional 3.5 million housing units by 2030 to restore pre-2004 affordability levels (CMHC, 2024). Although the federal government has committed more than $9 billion since 2013–14 (CHI, 2024), including the $4 billion Housing Accelerator Fund, to streamline approvals and stimulate construction, these measures alone may be insufficient to meet escalating demand (CBS News, 2023).

The Canadian housing crisis also disproportionately impacts remote and northern communities, where geographic remoteness, logistical hurdles, and extreme weather inflate construction costs. In the Northern Territories, where temperatures can drop below -40°C, nearly 26% of households face overcrowding or require

* Corresponding author, E-mail: relhacha@ucalgary.ca

https://doi.org/10.31462/icearc2025_ce_eqe_532

major repairs (CBC News, 2024). The high costs of material transport and the need for specialized, climate-resilient construction exacerbate these issues. A house in northern Canada may cost up to three times more than in southern regions (CMHC, 2024). This national housing crisis reflects a broader global trend. Conflict zones such as Ukraine and Syria have seen catastrophic destruction of residential infrastructure. In Ukraine, nearly 40% of housing in war-affected areas has been damaged or destroyed, displacing millions (IDMC, 2022). Syria, enduring over a decade of civil war, has over 6 million internally displaced citizens, many in inadequate shelters (UNHCR, 2025). These examples underscore the urgent need for rapid, resilient, and adaptable housing solutions.

Climate and environmental pressures add another layer of complexity. Cold-climate regions like Russia and Scandinavia face similar construction and durability challenges. Simultaneously, traditional construction practices significantly contribute to environmental degradation. In 2021, the construction and operation of buildings accounted for 34% of global energy consumption and 37% of CO_2 emissions (IEA, 2022). The embodied carbon in construction materials like cement and steel, alongside lifecycle emissions, intensifies the ecological footprint of the built environment. These environmental concerns have galvanized the construction industry to seek more sustainable alternatives. The World Green Building Council's "Advancing Net-Zero" initiative and other global efforts aim to achieve net-zero carbon buildings by 2050 and reduce embodied carbon by at least 40% by 2030 (WGBC, 2025). McKinsey & Company projects that green construction will represent 60% of new buildings by 2030, and nearly half of the construction firms have already integrated green practices into at least half of their project (McKinsey & Company, 2020).

Innovative technologies such as Ultra-High-Performance Concrete (UHPC) and Carbon Nanofiber-reinforced UHPC (CNF-UHPC) are emerging as promising solutions. These materials offer unparalleled strength, durability, and sustainability. Coupled with modular construction techniques, they present a viable strategy for building resilient, cost-effective, and environmentally conscious housing. Prefabricated modular construction can expedite housing delivery while reducing waste and emissions, making it a compelling alternative to traditional methods. However, to fully assess the viability of modular UHPC-based housing, a life-cycle evaluation is critical to quantify its sustainability benefits relative to conventional construction.

This paper explores the application of UHPC and CNF-UHPC in modular construction as a strategic response to the global housing crisis. It investigates the social, environmental, and economic impacts of these technologies and highlights their role in fostering a more equitable and sustainable future.

2. Modular construction: global perspectives on opportunity and challenges

Modular construction, also known as off-site construction, is rapidly transforming the global construction landscape by providing a compelling alternative to traditional on-site methods. Built-in controlled factory settings using the same materials and regulatory standards as conventional buildings, modular structures can be assembled in significantly shorter timeframes, improving efficiency and sustainability. While the method has demonstrated substantial benefits—including reduced construction time, lower environmental impact, and improved quality—several challenges still hinder its widespread adoption. This integrated overview explores modular construction's advantages, challenges, and real-world applications.

2.1. Distinction between precast and prefabricated construction

Precast construction refers to producing components in reusable molds and transporting them to the site for assembly. Prefabricated construction, however, involves off-site manufacturing of entire building modules—including structural, mechanical, and architectural systems—that are delivered nearly complete. While both methods aim to improve efficiency and quality, modular prefabrication supports faster project delivery and greater environmental and cost savings when implemented at scale (NI, 2025; Quora, 2025; Patyal, 2019; MBI, 2025).

2.2. Key advantages of modular construction

Modular construction offers numerous advantages that span across project performance, sustainability, and user experience:

- Time and Cost Efficiency: Modular projects allow simultaneous off-site fabrication and on-site preparation, resulting in timeline reductions of up to 50% and cost savings of up to 25% (Ferdous et al., 2019; O'Connor et al., 2014; Salama et al., 2017; Becker, 2003; Pan, 2007). Case studies in Melbourne, Australia, demonstrated the construction of high-rise modular buildings—including a 9-story apartment built in 5 days and a 25-story tower completed in 27 weeks—achieved 30% faster completion rates (Ferdous et al., 2019; Gunawardena et al., 2014).
- Sustainability and Environmental Impact: Modular systems can reduce material waste by 65%, CO_2 emissions by 36%, and delivery trips by 70% (Lawson et al., 2012). Other studies report reductions in timber and water usage by 71% and 22%, respectively, along with a 6.6% decrease in human health impacts and 3.5% in ecosystem damage (Cao, 2015).

- Improved Quality Control: Controlled environments facilitate rigorous testing, better tolerance control, and minimized defects. The repetitive nature of factory processes also fosters continuous improvement and reduces variability (Pan, 2007; NRC, 2009).
- Safety: Factory-based production improves worker safety, reducing on-site accidents by up to 80% (Peñaloza, 2017).
- Flexibility and Adaptability: Modular units can be reconfigured, relocated, or expanded easily, making them suitable for evolving demands in housing, healthcare, and disaster relief (Ferdous et al., 2019; Chourasia et al., 2023; Shahzad et al., 2022; Chen et al., 2022).

2.3. Current limitations and implementation challenges

Although modular construction provides substantial benefits—including accelerated project delivery, enhanced quality control, and notable environmental performance—it is not without significant challenges. Despite its growing recognition as a viable approach to meeting the construction industry's evolving demands for efficiency and sustainability, several barriers hinder its broader implementation. These challenges encompass the entire project lifecycle, beginning with the high initial capital investment required to establish prefabrication facilities. Further complexities arise in the logistics of transporting large volumetric modules, as well as in navigating regulatory frameworks that are often tailored to conventional construction methods. Additionally, modular construction is subject to inherent design constraints that may limit architectural flexibility and customization. Market uptake is further constrained by persistent skepticism regarding the structural integrity and long-term performance of modular buildings, underscoring the need for greater public awareness and industry education. The following external factors restrain the widespread adoption of modular construction.

2.3.1. Inadequate design codes and standards

The lack of modular-specific design codes impedes performance prediction and quality assurance. Traditional codes often fail to address unique load paths, connection details, and short-term stresses from transport and lifting. Modular guidelines such as Lawson's *Design in Modular Construction* and region-specific codes like the IRC/IBC/IECC in the U.S. are emerging to bridge this gap (Bogenstätter, 2000; Lacey et al., 2018; Murray-Parkes et al., 2017; Mao et al., 2015; Blagojevich & Whitaker, 2007; Lu et al., 2017 ; Lawson et al., 2014).

2.3.2. Skilled labour shortage

Modular construction requires trained personnel in digital design, precision manufacturing, and hybrid assembly techniques. China and Australia have identified workforce development as a strategic need, prompting collaborations between academia and industry to upskill labour (Lu et al., 2017; Iacovidou et al., 2021).

2.3.3. Transportation and logistics constraints

Large modules are challenging to transport due to size, height, and weight restrictions. Damage during transit and long-distance delivery contribute to delays and cost overruns. To mitigate this, compact module design and factory-site proximity strategies are increasingly employed (Lacey et al., 2018; Godbole et al., 2018; Nester et al., 2003).

2.3.4. High initial investment

Establishing a modular factory demands significant upfront capital, particularly in urban centers with high land values. While long-term gains are evident, the initial barrier discourages small developers. Public incentives and shared investment models are helping reduce this threshold (Rahman, 2014; Chiang et al., 2006; Pan et al., 2012; Ribeiro et al., 2022).

2.3.5. Communication and integration complexity

Successful modular projects demand close collaboration among architects, engineers, manufacturers, and contractors—often working from dispersed locations. Communication lapses can lead to assembly issues, delays, and increased costs. Integrated project delivery (IPD), BIM tools, and regular stakeholder meetings are crucial mitigation strategies (Ribeiro et al., 2022; Ezzeddine & de Soto, 2021; Thurairajah et al., 2023).

Modular construction presents considerable advantages in terms of sustainability, operational efficiency, and cost optimization when executed under appropriate conditions. However, the full realization of these benefits is contingent upon resolving persistent logistical constraints. As the sector advances, developing and implementing long-term, system-level strategies that enhance the logistical infrastructure supporting modular construction is imperative. Such advancements are essential to enable the widespread deployment of modular systems as an efficient, sustainable, and scalable solution to the global housing demand.

2.4. Global Case studies and applications

Modular construction has been applied worldwide in residential towers, emergency hospitals, educational buildings, and military facilities. It is positioned as a strategy to accelerate urban development while aligning with sustainability goals. The COVID-19 pandemic further underscored its utility, with modular hospitals erected in record time (Chen et al., 2022).

Queen Elizabeth University Hospital-Glasgow, Scotland (Multiplex, 2015)

- Queen Elizabeth University Hospital in Glasgow is a state-of-the-art facility, and modular construction was employed to construct certain areas, including plant rooms and support services. The use of prefabricated modular components allowed for faster installation of critical building systems

Mount Sinai Medical Center Expansion – New York City, USA (NK Architects, 2016)

- Mount Sinai Medical Center in New York utilized modular construction techniques for the expansion of certain sections of the hospital. Prefabricated components such as bathroom pods and mechanical systems were manufactured off-site and assembled on-site, allowing for more efficient and less disruptive construction

Dalston Works – London, UK (Waugh Thistleton Architects, 2017)

- Dalston Works is a 10-story modular residential and commercial building in East London. It is constructed entirely from cross-laminated timber, making it one of the tallest timber modular buildings in the world

Clement Canopy – Singapore (dezeen, 2019)

- Clement Canopy is one of the tallest modular buildings in the world, consisting of two 40-story residential towers. The project utilized volumetric modular construction, with each module fully finished and assembled off-site before being stacked on-site

Wuhan Emergency Modular Hospitals – Wuhan, China (Miller, 2020)

- In response to the COVID-19 pandemic, Wuhan built several emergency hospitals using modular construction. One of the most notable examples is the Huoshenshan Hospital, constructed in just 10 days using prefabricated modules. This 1,000-bed hospital was built to treat COVID-19 patients and was one of the fastest examples of healthcare infrastructure being delivered during a crisis

101 George Street – Croydon, London, UK (CTBUH, 2021)

- 101 George Street in Croydon, London, is the tallest modular building in the world, consisting of two towers. The project features 546 units and was developed using volumetric modular construction.

Smith's Garden: 26-Storey Modular Residential Tower–Birmingham, UK (Ongoing) (Goodstone, 2025)

- Smith's Garden is a modular residential development currently under construction in Birmingham, UK. The project includes a 26-story tower constructed using volumetric modular construction techniques. This method enables faster assembly, improved quality control, and reduced environmental impact, offering an efficient solution to meet growing urban housing demands

Horizon North Modular Housing – Various Locations, Canada (ongoing) (Housing Innovation Collaborative, 2025)

- Horizon North is building modular housing units in multiple Canadian cities, including Calgary and Edmonton, as part of a nationwide effort to provide affordable housing.

Fig. 1: Global modular construction projects

3. Ultra-high-performance concrete (UHPC): comparative developments and applications

3.1. Evolution and fundamentals of ultra-high-performance concrete (UHPC)

Ultra-High-Performance Concrete (UHPC) represents a paradigm shift in cementitious composite materials, addressing the limitations of conventional concrete systems by offering superior mechanical performance and exceptional durability under aggressive environmental conditions. Characterized by a water-to-binder ratio ≤ 0.25, compressive strengths exceeding 120 MPa, and post-cracking tensile strengths of at least 5 MPa, UHPC combines optimized granular packing, absence of coarse aggregates, and the inclusion of high-performance pozzolanic admixtures such as silica fume to form a dense, discontinuous pore structure (Ahmed Sbia et al., 2014; Norhasri et al., 2016; Russell & Graybeal, 2013; Al-Osta, 2018; CSA, 2019).

Early advancements in UHPC can be traced to pre-1980s research that emphasized vacuum mixing and thermal curing to densify the matrix and enhance mechanical properties (Roy et al., 1972). Subsequent innovations in the 1980s led to Micro-Defect-Free (MDF) cement and Densified Systems with Ultra-fine Particles (DSP). However, challenges in workability and placement due to the absence of adequate superplasticizers hindered large-scale adoption (Birchall et al., 1981; Bache,1981).

A breakthrough occurred in the 1990s with the development of Reactive Powder Concrete (RPC) by Richard and Cheyrezy, culminating in commercial UHPC products such as Ductal® (Richard & Cheyrezy, 1995). The material was first deployed in the Sherbrooke Pedestrian Bridge in Quebec, Canada, in 1997, showcasing a pioneering use of 3D precast UHPC trusses post-tensioned on-site (Azmee & Shafiq, 2018; Blais & Couture, 1999). Despite the innovation, widespread use remained limited due to RPC's high cost, specialized curing requirements, and the lack of unified design standards.

Post-2000s, the field has witnessed a marked shift toward sustainability and scalability. UHPC formulations now often incorporate supplementary cementitious materials (SCMs) like fly ash, ground granulated blast furnace slag (GGBFS), silica fume, and rice husk ash to reduce environmental impact and energy consumption while enabling ambient curing methods (van Nguyen et al., 2010; Yu et al., 2015). Several design guidelines now offer technical frameworks supporting UHPC's structural applications (CSA, 2019; ACI 239, 2018; PCI (Sim et al., 2020); FHWA (Graybeal & El-Helou 2023); AASHTO, 2024; AFNOR (NF, 2016).

3.2. Mechanical properties and durability characteristics of UHPC

UHPC exhibits a combination of ultra-high compressive strength, enhanced tensile performance, and unparalleled durability, distinguishing it from normal-strength concrete (NSC) and even high-performance concrete (HPC). Typical compressive strengths range from 120 to 150 MPa, with some formulations exceeding 200 MPa depending on curing protocols and mix optimization (Russell & Graybeal, 2013). This exceptional performance is achieved through a highly optimized particle gradation, elimination of coarse aggregates, a very low water-to-binder ratio, and the incorporation of high-range water reducers and silica-based pozzolanic materials (Al-Osta, 2018).

A defining characteristic of UHPC is its post-cracking tensile strength, typically ≥5 MPa, enabled by including steel or synthetic fibres. These fibres enhance the strain-hardening behaviour by bridging micro-cracks and arresting crack propagation, thereby converting a traditionally brittle failure mode into a more ductile response. For example, adding 2% steel fibre volume can lead to tensile strength improvements of up to 228% and flexural strength gains of 180% relative to fibre-free UHPC (El-Abbasy, 2023). This transformation in behaviour is critical in structural applications requiring enhanced energy absorption and impact resistance.

In terms of durability, UHPC's ultra-dense matrix—with minimal capillary porosity and discontinuous pore structure—yields extremely low permeability. Water and chloride ion ingress are significantly curtailed, with the chloride diffusion coefficient up to 50 times lower than that of NSC (Chuang & Huang, 2013). This makes UHPC particularly advantageous for marine and de-icing salt environments where reinforcement corrosion is a major concern.

Carbonation resistance is another critical attribute. While carbonation in conventional concrete reduces alkalinity and depassivates steel reinforcement, UHPC's refined microstructure dramatically retards this process, preserving internal pH and prolonging service life (Li et al., 2020; Andrade & Torres, 2013; Kono et al., 2013; Piérard et al., 2013).

UHPC also demonstrates superior freeze-thaw resistance. The tightly packed microstructure limits internal water movement, mitigating internal stresses induced by freezing cycles. Studies indicate UHPC retains >95% durability factor after 300–600 cycles with negligible mass loss (Li et al., 2020; Zhong & Wille, 2015), and in some cases, performance remains unaffected even after 800 cycles (Wang, 2011). In contrast, NSC commonly suffers deterioration after just 300–400 cycles (ASTM C666, 2008). Furthermore, UHPC's abrasion resistance, fatigue life, and resistance to alkali-silica reaction (ASR) are considerably superior, contributing to its increasingly widespread use in critical infrastructure such as bridges, tunnels, and precast façade systems (van Nguyen et al., 2010; Yu et al., 2015).

3.3. Carbon nanofibre (CNF) innovations in UHPC

Recent advancements in nanotechnology have led to a transformative enhancement in UHPC by incorporating carbon nanofibres (CNFs), ushering in a new generation of high-performance, multifunctional cementitious composites. CNFs are nanoscale carbon-based materials known for their extraordinary tensile strength, elastic modulus, electrical and thermal conductivity, chemical inertness, and low density (Sharon, 2021).

Including CNFs in UHPC matrices has improved fresh and hardened properties. In the fresh state, CNFs act as nucleation sites during the hydration process, facilitating a more uniform and accelerated hydration reaction. Each cubic meter of CNF-UHPC contains approximately 7×10^{19} individual CNFs—equivalent to about eight nanofibres per cement grain—contributing to a more homogeneous internal structure and reduced differential stress during early-age curing. These microstructural refinements offer substantial performance benefits. CNF-reinforced UHPC achieves high early-age compressive strengths—exceeding 80 MPa within 10 hours and surpassing 100 MPa at 24 hours—making it suitable for time-sensitive construction scenarios. The nanofibres also serve as crack arrestors at the micro- and nano-scale, delaying the initiation and growth of tensile cracks and enhancing the modulus of rupture and post-cracking strength. Additionally, CNFs help reduce autogenous shrinkage by forming a nanoscale mesh that counteracts internal tensile stresses. Their presence also densifies the interfacial transition zones (ITZs) between cement paste and aggregates or embedded steel fibres. This densification leads to improved bond strength, particularly the pull-out resistance of steel fibres, thereby enhancing the composite's overall tensile ductility and energy absorption capacity (Sharon, 2021; Yıldırım et al., 2018; Morsy et al., 2010; Patil & Deshpande, 2012; El-Gamal et al., 2017; Shi et al., 2019).

From a sustainability standpoint, CNF-enhanced UHPC (CNF-UHPC) offers a route to reduce the required steel fibre volume while maintaining or improving mechanical performance. This reduction translates into lower embodied energy and carbon emissions. Notably, CNF-UHPC manufactured by ceEntek Pte Ltd achieves compressive strengths up to 160 MPa and tensile strengths near 10 MPa while remaining compatible with standard mixing and placement techniques at precast plants or in-field applications (CeEntek, 2020).

As the industry advances toward low-carbon construction, CNF-UHPC emerges as a robust, resilient, and environmentally conscious alternative to traditional cementitious materials—particularly in regions with extreme weather conditions, seismic risk, or limited infrastructure access.

3.4. Field applications and practical implementation of UHPC

The global deployment of UHPC has grown substantially over the past two decades, driven by its outstanding mechanical performance, durability, and potential for architectural innovation. Initially adopted in bridge construction, UHPC has evolved into a multipurpose material suitable for complex structural and aesthetic applications in precast and cast-in-place formats.

The first landmark application of UHPC occurred in 1997, when the Sherbrooke Pedestrian Bridge was constructed in Quebec, Canada. The bridge comprised six precast UHPC space truss elements post-tensioned on site, marking a turning point in structural precast technology (Corvez, 2011). This innovation was followed by the Mars Hill Bridge in Iowa, USA, completed in 2006, which reinforced UHPC's suitability for accelerated bridge construction and long-span solutions (Azmee & Shafiq, 2018).

In Europe and Asia, UHPC has been employed in pedestrian and vehicular bridges, showcasing slender geometries and extended service life with minimal maintenance. Examples include the Horikoshi C-ramp Bridge in Japan and the Shepherd's Gully Bridge in Australia, where UHPC's high strength-to-weight ratio enabled reduced structural depth and material consumption (Amran et al., 2022).

UHPC's architectural potential has been equally significant. Projects such as the Museum of European and Mediterranean Civilizations (MuCEM) in Marseille (2013), the Fondation Louis Vuitton in Paris (2014), and the roof of the Jean Bouin Stadium illustrate UHPC's capability to form thin, complex geometries with exceptional durability (Azmee & Shafiq, 2018). Similarly, the Olympic Museum in Lausanne employed UHPC to realize elegant, lightweight roofing systems, exemplifying the synergy of form and function (Muttoni et al., 2013). In 2019, the National Museum of Qatar showcased UHPC's versatility by featuring it in its façade design (Azmee & Shafiq, 2018).

In North America, Lafarge Canada, the University of Calgary, and DIALOG Consulting pioneered one of the first ultra-thin UHPC architectural façade systems, used in "The Atrium" project in Victoria, British Columbia. These façade panels, validated through rigorous testing, offered structural integrity and thermal performance. Their success led to subsequent implementations at the Rotman School of Management (Toronto) and Ornan's Infant School in France (Seibert et al. 2012).

The development of standardized design and construction guidelines has also facilitated the practical implementation of UHPC. Organizations such as CSA (2019), ACI 239 (2018), PCI (Sim et al., 2020), FHWA (Graybeal & El-Helou 2023), AASHTO (2024), and AFNOR (NF, 2016) now provide prescriptive guidance for UHPC's structural use, including material characterization, detailing requirements, and durability design. These codified practices are essential to ensuring quality control and broader industry adoption.

Notably, CNF-enhanced UHPC is being investigated for modular construction, seismic retrofitting, and impact-resistant structures. With its extended service life (often exceeding 100 years), reduced section size, and minimal need for passive reinforcement, CNF-UHPC is poised to reshape the landscape of sustainable and resilient infrastructure (CeEntek, 2020).

4. Benefit of integrating UHPC in modular construction

The expected benefits of integrating UHPC into modular housing systems are multi-dimensional:

- Alleviating Housing Shortages: The speed and scalability of modular construction using UHPC systems make them ideal for addressing housing crises in developed and developing regions, especially where onsite construction is impeded by weather, terrain, or socio-political constraints.
- Improved Affordability and Lifecycle Economics: Although the initial material and fabrication costs may be higher than conventional methods, these are offset by savings in construction time, energy consumption, maintenance, and transportation logistics due to lighter elements and faster installation cycles.
- Resilience and Disaster Resistance: UHPC-based modular units exhibit high resistance to impact, freeze-thaw cycles, chloride penetration, and other environmental deteriorations, making them well-suited for disaster-prone and climate-vulnerable areas.
- Architectural and Functional Flexibility: UHPC's rheological properties allow for intricate mouldings and customized finishes without additional treatments, addressing aesthetic considerations while maintaining strength. This opens new avenues in modular design, where standardization and customization often compete.
- Development of Standardized Guidelines: There is a growing need to formalize design frameworks and construction specifications for UHPC modular systems. Establishing comprehensive codes and guidelines will support broader adoption by engineers and practitioners, fostering economic and environmentally conscious practices.

5. Design challenges in UHPC-based modular construction

5.1. Absence of standardized design guidelines

Integrating UHPC into modular construction presents significant challenges due to the lack of standardized design guidelines tailored to UHPC, which is a primary challenge in the structural design of modular housing systems. While UHPC offers substantial benefits such as reduced member thickness, enhanced durability, and lower self-weight, its application in modular systems such as ribbed floor slabs and lightweight roofing panels is constrained by the limited availability of codified methodologies. In particular, although structurally efficient, the slenderness of UHPC floor systems may introduce serviceability concerns related to vibrations, potentially affecting occupant comfort and satisfaction. Studies have highlighted that high-strength slender floor elements can exhibit vibration issues that impact user comfort.

5. 2. Connection detailing and structural continuity

Another significant design consideration involves the performance and detailing of connections. Ensuring effective load transfer across prefabricated components is crucial for structural integrity. However, the behaviour of connections, especially under dynamic and long-term loading conditions, especially for UHPC elements, remains insufficiently documented in existing codes. This lack of information poses reliability concerns during the assembly and service of UHPC elements. UHPC connections require careful detailing to maintain structural continuity and performance.

5.3. Performance under extreme loading conditions

Furthermore, desiginig for structural safety under extreme loading conditions—such as seismic events, wind loads, and fire exposure—remains a design grey area for UHPC applications and is challenging due to the lack of well-established predictive models or design provisions for UHPC in current standards (Graybeal, 2011). This is particularly problematic for modular buildings where structural redundancies are minimized. Studies have emphasized the need for comprehensive guidelines to address UHPC behaviour under such extreme conditions (Jabbar et al., 2022).

5.4. Thermal performance and airtightness

Similarly, thermal performance and airtightness—especially in wall and roof assemblies using thinner UHPC sections—necessitate detailed consideration to meet energy efficiency targets. Thermal performance and airtightness are critical factors, especially in modular construction, where energy efficiency is a priority. Research has shown that UHPC sandwich panels can be designed to improve energy efficiency while maintaining structural performance (Ghazy et al., 2025).

5.5. Foundation systems for lightweight modular construction

Developing foundation systems compatible with lightweight modular construction and adaptable to variable geotechnical conditions is essential. The reduced weight of UHPC elements requires foundations that can accommodate these characteristics without compromising stability. Innovative foundation solutions are needed to support the unique demands of UHPC modular systems.

5.6. Sandwich wall panels (swps) design complexity
Among the most complex components from a structural and thermal design perspective are Sandwich Wall Panels (SWPs). These elements simultaneously serve as load-bearing components and as integral parts of the thermal envelope. Typically composed of two concrete wythes separated by a rigid insulation core, SWPs must achieve adequate shear transfer between layers while minimizing thermal bridging. Careful detailing of connectors and embedment strategies is necessary to balance structural and thermal performance (Ghazy et al., 2025).

6. UHPC in modular housing development at the University of Calgary

6.1 Proposed UHPC modular hourse
Integrating UHPC, particularly CNF-UHPC developed by ceEntek Pte Ltd, into modular construction systems represents a pivotal advancement in modern construction technologies. UHPC is recognized for its exceptional mechanical and durability properties, including ultra-high compressive and tensile strengths, improved fire resistance, and superior resistance to environmental degradation. These characteristics significantly reduce the thickness and weight of structural components, optimizing material use and improving logistics, especially in volumetric modular housing systems.

Prefabricated modular homes, often constructed using volumetric three-dimensional units manufactured off-site, benefit extensively from UHPC's performance. These modules are especially suitable for applications such as multi-unit residential buildings, hotels, dormitories, and single-family housing. The lightweight nature of UHPC structural components allows for more efficient transportation and erection, minimizing on-site construction time and enabling rapid deployment in both urban and remote contexts. This is particularly beneficial in regions facing urgent housing needs due to conflict, natural disasters, or climate-related challenges.

The modular system under development, showcased in ongoing research at the University of Calgary, utilizes insulated CNF-UHPC sandwich wall panels (SWPs), CNF-UHPC waffle floor slabs, and CNF-UHPC roof components (Figure 2). The SWPs incorporate thin inner and outer UHPC wythes (typically 15–50 mm thick), separated by high-performance insulation up to 150 mm in thickness. These wythes are interconnected using non-metallic Glass Fiber Reinforced Polymer (GFRP) shear connectors, chosen for their corrosion resistance, low thermal conductivity, and cost-effectiveness compared to other FRP types. All elements are wet-cast in a controlled factory environment using CNF-UHPC mix designs optimized for flowability and strength retention across interfaces.

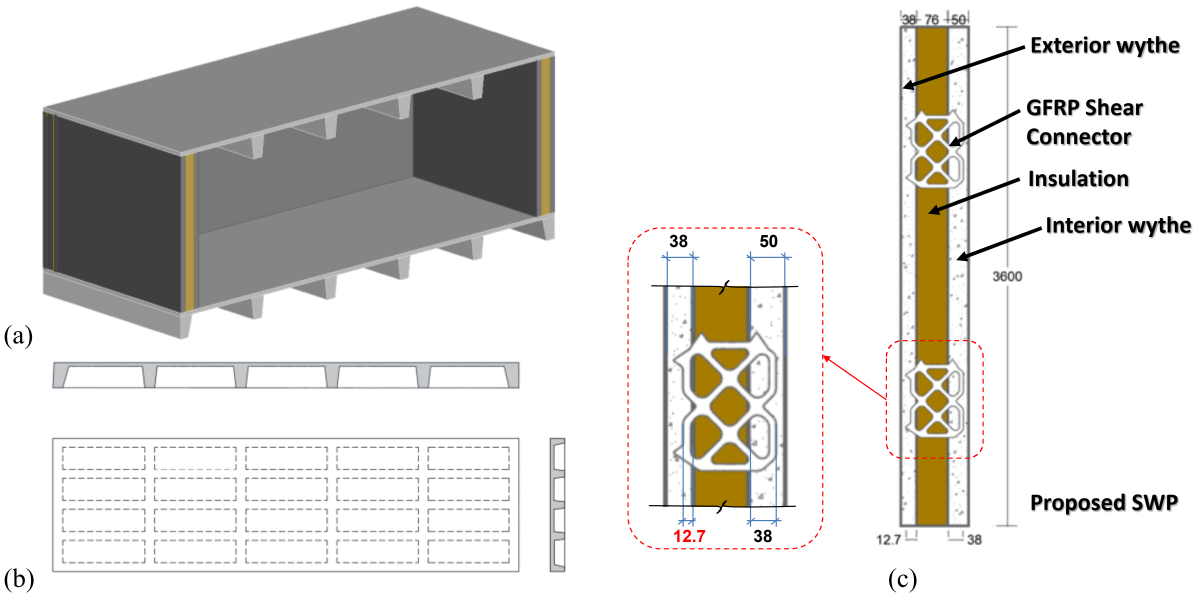

Fig. 2: (a) Prefabricated UHPC modular house, (b) waffle floor/roof element, and (c) proposed insulated sandwich wall panel

The structural system's reduced mass—often under 20 tonnes for an entire modular unit—allows for deployment with smaller cranes and transport vehicles, cutting overall construction and installation costs. Moreover, integrating waffle slabs for floors and roofs enhances load distribution efficiency and system robustness while maintaining minimal weight. The result is a resilient, high-performance building envelope capable of enduring dynamic and static loads, seismic activity, high winds, and fire exposure.

Beyond structural benefits, using CNF-UHPC in modular housing aligns with global sustainability goals. Its high durability and resistance to degradation extend service life and reduce maintenance requirements, thus lowering life cycle costs and environmental impacts. Adopting CNF-UHPC in modular housing promotes sustainable construction practices by reducing material use, minimizing construction waste, and improving energy efficiency. Such systems are especially suited for sustainable development in areas facing logistical or climatic constraints. The thermal efficiency and reduced mass of UHPC panels contribute significantly to reducing heating and cooling loads, constituting the largest share of energy consumption in residential buildings.

A critical element in validating this innovative construction system involves extensive performance evaluations at both the material and structural levels. At the material level, CNF-UHPC's mechanical properties, including tensile ductility, compressive strength, and long-term durability, are being thoroughly investigated. At the structural level, tests on full-scale SWPs, waffle slabs, and roof elements under varying loading conditions are being conducted. Special focus is given to evaluating air-tightness, thermal performance, and lifecycle cost metrics to assess the modular system's competitiveness against conventional alternatives. Testing is ongoing to confirm CNF-UHPC's capacity to deliver superior thermal insulation and airtightness, thereby reducing operational energy consumption and greenhouse gas emissions throughout the building's life cycle.

6.2 Experimental validation of GFRP shear connectors

A comprehensive experimental program was initiated to validate the mechanical performance of UHPC modular elements under realistic conditions. One particular design constraint arose from the need to utilize thinner panel sections, which precluded the use of the manufacturer-recommended minimum embedment length of 1.5 inches for GFRP shear connectors (Figure 2c). Thus, the 1.5 inches minimum embedment length for GFRP shear connectors could not be achieved. Instead, panels were fabricated with a reduced embedment length of 0.5 inches, necessitating experimental verification of their shear transfer capacity.

6.2.1 Double shear test setup and results

A double shear test was conducted to assess the structural performance of the GFRP connectors under these modified conditions (refer to Figure 3). The average shear capacity was determined to be 9.18 kN, closely aligning with the manufacturer's reported capacity of 7.94 kN, despite the latter being based on normal-strength concrete and longer embedment. These findings suggest that the used GFRPshear connectors retain robust mechanical performance even with reduced embedment in UHPC, likely due to the superior bond characteristics and matrix strength of UHPC compared to conventional concrete (Yoo & Yoon, 2017). All specimens showed the same failure mode, indicating rupture of the GFRP shear connectors (Figure 4).

This outcome validates the use of shorter embedment lengths in thin UHPC wall panels and reinforces the feasibility of efficient and structurally sound SWP designs within modular construction frameworks. The improved understanding of connector behaviour under constrained embedment conditions offers valuable flexibility in the geometric and architectural design of UHPC-based modular systems.

7. Executive summary and conclusion

Modular construction is no longer a niche approach—it is an innovative paradigm with a proven ability to deliver quality, speed, and sustainability in the built environment. Although challenges remain—particularly in logistics, standards, and labour—the rapid evolution of digital tools, manufacturing technologies, and collaborative project delivery models are paving the way for broader adoption. A coordinated global effort in training, regulation, and innovation is essential to unlocking its full potential as a resilient and adaptable construction methodology for the future.

Incorporating Carbon Nanofiber Ultra-High-Performance Concrete (CNF-UHPC) into modular housing systems presents a significant advancement in pursuing high-performance, durable, sustainable and resilient residential construction. These advanced cementitious materials combine superior mechanical and durability properties with eco-efficient features, enabling the fabrication of thin, lightweight yet high-strength components, resulting in modular units with reduced material consumption and embodied energy while maintaining structural integrity and resilience under extreme conditions, including high wind loads, seismic activity, and aggressive environments. The high mechanical properties of UHPC allow for the creation of thinner elements, which facilitate easier transportation and rapid onsite assembly, thus aligning with the core principles of modular construction.

From a sustainability standpoint, UHPC-based systems significantly minimize construction waste and carbon emissions while offering service lives exceeding 100 years with minimal maintenance and repair interventions, especially in severe environments. These properties address critical demands in contemporary housing, particularly in regions facing shortages, harsh environmental constraints, or rapid urbanization pressures. Furthermore, UHPC modules exhibit enhanced resistance to natural disasters such as floods, high winds, and extreme temperatures, making them highly suitable for deployment in climate-vulnerable and disaster-prone areas. Such longevity reduces lifecycle costs and alleviates the burden on landfills, particularly in regions with limited waste-processing infrastructure. Despite higher initial material and production costs, the long-term economic benefits of UHPC—through reduced maintenance, extended service life, and operational energy savings—render them cost-effective over the building lifecycle. In addition, the aesthetic versatility of UHPC allows for the replication of detailed architectural textures and finishes, expanding the design possibilities for modular housing without compromising structural integrity.

The SWPs utilized in the modular construction comprised two CNF-UHPC wythes with an insulating core. The design aimed to ensure effective load transfer between the layers while minimizing thermal bridging. Experimental results from double shear tests conducted on sandwich wall panels (SWPs) utilizing CNF-UHPC and GFRP shear connectors confirmed that even with reduced embedment lengths, effective shear transfer between the two wythes can be achieved. The successful performance of GFRP shear connectors with reduced embedment lengths supports the feasibility of efficient and structurally sound SWP designs within modular construction frameworks. These findings support the development of lighter and thinner prefabricated modules without compromising mechanical reliability and structural performance, thereby enhancing transportability and onsite assembly. CNF-UHPC further expands the performance envelope of UHPC and, in particular, augments these benefits by incorporating nanofiber reinforcement within its matrix that enhances the ductility, thermal performance, and fracture resistance. The dense microstructure of CNF-UHPC results in lower thermal conductivity, which contributes to decreased energy consumption in extreme climate conditions and improved building envelope efficiency. This contributes significantly to lower operational energy demands, especially in climates requiring intensive heating or cooling. Combined with SWP systems, CNF-UHPC modules have the potential to become net-zero-ready units, aligning with global decarbonization and sustainability goals.

The findings presented herein underscore the importance of continuing efforts to standardize design and construction practices for UHPC-based modular systems. Developing comprehensive design guidelines and construction specifications is necessary to facilitate the wider adoption of CNF-UHPC in modular housing applications, ensuring consistency in performance, safety, and economic viability. As the construction industry seeks innovative solutions for affordable, resilient, and environmentally conscious housing, CNF-UHPC modular technologies are prepared to play a pivotal role in shaping the future of sustainable residential infrastructure. In summary, the convergence of UHPC technologies and modular construction offers a promising pathway toward rapid deployment of next-generation housing solutions that are durable and environmentally responsible. Future work should focus on scaling production methods, optimizing thermal and acoustic insulation of composite panels, and harmonizing international design standards to accelerate the global adoption of UHPC modular housing systems.

In conclusion, the synergy between CNF-UHPC and modular construction presents an innovative path toward rapid, sustainable, and cost-effective housing solutions. The potential for immediate deployment, combined with long-term durability and reduced environmental impact, underscores CNF-UHPC's transformative role in the evolution of prefabricated building systems. As testing and development progress, these systems are poised to become central to addressing the global housing crisis and advancing sustainable infrastructure development.

Timber as the sustainable building material of the 21st Century: key advantages and facts

Ahmet Turer*[1]

[1] *Middle East Technical University, Department of Civil Engineering, 06800 Ankara, Türkiye*

Abstract. Timber is a natural and sustainable construction material with several advantages, including its negative carbon footprint, high strength-to-weight ratio comparable to steel, and characteristic bending, compressive, and tensile strength of 15 to 30 MPa. It is also five times lighter than reinforced concrete structures, reducing foundation loads, while offering faster construction and lower costs, making it a highly cost-effective option. Seismic performance is the primary advantage of timber buildings, as earthquake forces are directly correlated to building mass. Lighter structures experience lower seismic forces, and timber's combination of strength and lightweight properties provides a significant advantage over heavy and brittle materials like concrete. Fire safety in timber structures can be significantly enhanced through impregnation technologies and intumescent paints. Additionally, timber's slow-burning characteristics and natural heat insulation allow for 60-90 minutes of fire resistance, making it a viable choice when properly designed. Protective covers would further improve its fire performance. The new Turkish Timber Building Regulation (TABY-2024) introduces key structural design provisions, covering tension, bending, compression, shear, lateral-torsional buckling, and column buckling, along with guidelines for connection design and various member types such as glulam, CLT, and spaced columns. It also includes important considerations for serviceability, vibrations, creep, thermal, water, and sound insulation, as well as fire resistance calculations. As a conclusion, the lightweight properties, superior earthquake resistance, and sustainable production of timber, establishes it as the construction material of the 21st century.

Keywords: Timber; Regulation; Sustainable; Building; Design

1. Introduction

Timber is a renewable and biodegradable material which is dominantly used as the main structural engineering material in USA and Canada, where more than 90% of the houses are built using timber. For countries like Turkey, timber is recently gaining recognition as the sustainable building material of the 21st century. The initiation is largely by the pioneering efforts of TORID (Türkiye Orman İş Adamları Derneği) and UAB (Ulusal Ahşap Birliği), who have strongly advocated for timber's structural use in modern construction. Complementing these institutional efforts, the Department of Civil Engineering at Middle East Technical University has offered a dedicated timber engineering course (CE4008) since 2016, helping educate a new generation of engineers. Similarly, Kocaeli University, Van Yüzüncü Yıl University, and Mimar Sinan Fine Arts University have taught timber design for many years, establishing themselves as academic leaders in timber design in Türkiye.

A critical milestone was achieved in 2020 when the General Directorate of Forestry (OGM) initiated the classification of national coniferous timber species for structural applications, aligning them with international standards (OGM, 2020). Studies conducted in 4 universities, in accordance with TS 1265 (Sawn timber Coniferous - For building construction / Kereste İğne Yapraklı Ağaç Keresteleri - Yapılarda Kullanım için) have enabled classification of Turkish timber in European standards and now listed under TS EN 1912 (Structural timber - Strength classes - Assignment of visual grades and species / Yapı kerestesi - Mukavemet sınıfları - Ağaç türleri ve görsel sınıfların tasnifi). This study provided the strength classification for main tree species produced in Türkiye (Table 1).

The availability of these high-quality native species now enables structural usage of timber in Türkiye, as well as also compete structurally with concrete and steel considering traditional materials. Unlike concrete and steel, timber requires low processing energy, stores carbon, and enables faster and lighter construction. In order to further encourage use of timber in buildings, the Ministry of Environment, Urbanization and Climate Change has founded The Turkish Timber Building Regulation (TABY-2024) for a inter university large executed by Middle East Technical University (METU), Kocaeli University, Van Yüzüncü Yıl University, and Mimar Sinan Fine Arts University which is now in effect since January 1st, 2025; as the product of a three year intense work and provides

* Corresponding author, E-mail: aturer@metu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_551

a modern engineering framework for timber buildings, accelerating its acceptance. The Turkish Timber Building Regulation (TABY-2024) provides detailed provisions for mainly for a) strength-oriented member design (tension, compression, bending, shear, buckling lateral-torsional, column, connection design, glulam, CLT, and similar), b) Serviceability: deflection, vibration, creep, c) Fire design, and d) Insulation design (thermal, moisture, acoustic). Consistency was satisfied with Eurocode 5 was satisfied by building it upon EN 1995 with many improvements such as buckling, rigid vs flexible diaphragm action of slabs, and vibration performance calculations.

Table 1. The strength classification for main tree species

Tree Species	Grade I	Grade II	Grade III
Black Pine (Karaçam)	C35	C24	C18
Fir (Göknar)	C27	C24	C18
Scots Pine (Sarıçam)	C35	C27	C20
Red Pine (Kızılçam)	C35	C24	C18
Cedar (Sedir)	C24	C20	C16
Spruce (Ladin)	C27	C22	C20

2. Earthquake resistance of timber structures

One of timber's most crucial advantages is its seismic performance. Since earthquake forces are proportional to mass, timber having about 1/5th mass of reinforced concrete but having similar characteristic strength significantly reduces seismic demand. For example, native Turkish timbers, such as black pine, scoots pine, and red pine, achieve characteristic strengths up to C35 (i.e., 35 MPa 5% characteristic bending strength per EN 338). This strength to weight ratio is comparable to steel even exceeding mild and ordinary steel (Fig. 1). The relatively low strength of C35 concrete normalized with density can be clearly seen; when the tensile strength of concrete is taken as about 1/10th of compressive strength, the difference is more pronounced. Since normalized strength by density are similar but timber density is more than 15 times lighter than steel, sections have about similar total mass but timber sections are relatively larger mostly eliminating buckling related problems. Lightweight construction using timber also enables smaller and less costly foundations, benefiting weak soil conditions.

In seismic design, flexibility and energy dissipation are the major concerns. Timber structures, especially when connected using nailed systems, can exhibit ductile behavior. Nails have superior energy dissipation properties compared to screws due to their ability to deform plastically under cyclic loads also move in and out of their holes dissipating energy via friction.

Usage of timber especially after earthquakes has additional advantages: aftershocks can adversely affect concrete curing and damage fresh RC elements; whereas, timber structures are prefabricated (dry-assembled) and can be rapidly constructed even in post-disaster areas for rapid housing.

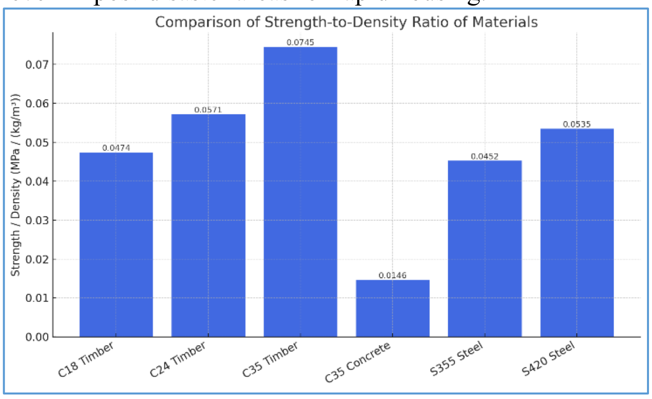

Fig. 1. Comparison of Strength-to-Density Ratio of Construction Materials

3. Environmental benefits

Timber is produced naturally as the trunk of trees which is made by mostly the carbon absorbed as CO_2 from the atmosphere. On average, 1 ton of dry timber uses about 1.7 to 2 tons of CO_2 positively effecting in reduction of CO_2 levels in the atmosphere. In contrast, producing 1 ton of cement emits 0.9 ton CO_2 for 1 ton of cement, 1 m^3 concrete production emits about 0.159 ton CO_2 (typically 10 to 15% of cement), and 1 ton of steel production emits about 1.89 tons CO_2 [2], The production of cement and steel also emits CO_2 during chemical process (Eqn. 1) other than burning fuel.

$$CaCO_3 + heat \rightarrow CaO + CO_2 \tag{1}$$

Timber grows naturally, powered by solar energy, without the need for high-temperature industrial processes used for steel or cement. Furthermore, forests contribute to preventing erosion, maintaining humidity, regulating microclimates, and hosting biodiversity. When sustainably harvested, most pine forests in Turkey takes about 60 to 80 years to regenerate to harvesting size, depending on climate and region. Thus, timber is not only carbon-negative but also contributes to broader ecological balance.

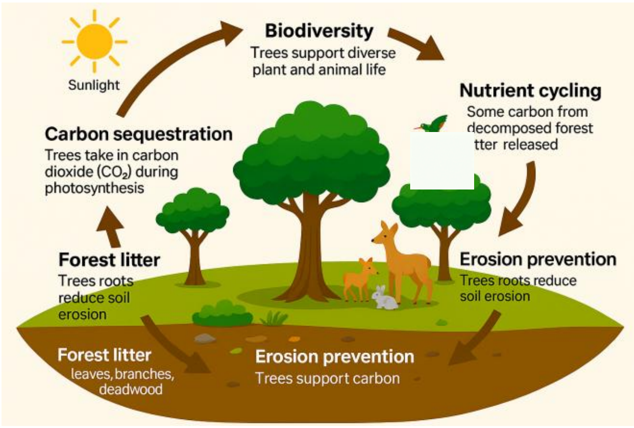

Fig. 2. The role of trees in CO_2 sequestration

4. Economic and constructional advantages

Timber construction offers numerous economic advantages that make it a better alternative to conventional building materials. One of the best known benefits is the speed of construction; prefabricated timber systems enable rapid on-site assembly, significantly reducing project timelines. Floors can be finished in a week's time or less without any requirement to wait strength gain to remove forms or scaffolding. In addition, construction of timber structures requires less labor and equipment, as they eliminate the need for steel reinforcement, formwork, and curing processes typical of reinforced concrete. The lightweight nature of timber also allows for the use of smaller cranes or even manual handling in certain cases, which further lowers construction costs. Transportation expenses are minimized due to the reduced material weight, leading to decreased fuel consumption and associated CO_2 emissions. These factors collectively result in a faster use of the building either by rent or use, as buildings can become operational and income-generating more quickly. The survivors can start using their homes much faster than reinforced concrete buildings, literally in one or two months' time eliminating costly and uncomfortable container homes or tents. In North America, timber buildings have been shown to be up to 13% more economical than reinforced concrete buildings [6]. Moreover, the reduced dead load simplifies seismic design requirements and leads to smaller, more cost-effective foundations. Soil improvement studies such as piles or deep mixing are usually not necessary due to the reduced overall weight of the building.

5. Timber construction techniques

Timber construction has evolved to include a variety of structural systems, many of which developed independently in different parts of the world but are now globally categorized into distinct structural types. Timber-based load-bearing systems are adapted to suit various architectural needs, performance criteria, and levels of prefabrication. One of the most widespread methods is light frame construction (Fig. 3), which is especially common in low to mid-rise residential buildings. In fact, this system has been used for buildings up to ten stories high in the United States. It utilizes small cross-section members, such as studs and joists, arranged in a repiting pattern to form walls. Floors are also similarly constructed with small but frequent beams and again board connecting all beams together. The popularity of light frame construction stems from its cost-efficiency, speed of assembly, and layout flexibility.

Although the term "frame" is used, when the studs are covered with plywood or oriented strand board (OSB), the system behaves like a shear wall, creating a rigid and strong structural element. In this way, the structural behavior resembles that of "tunnel-form reinforced concrete buildings" rather than a typical light frame. These systems are relatively easy to construct, resistant to lateral loads, and the wall cavities can be filled with insulation materials such as glass wool, stone wool, wood wool, or polyurethane expanding foam. Not all walls are load-bearing; some are used mainly for partitioning purposes where gypsum boards can be used, which are not load bearing members.

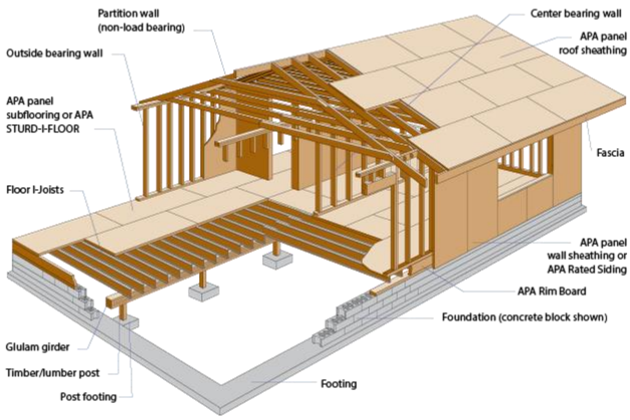

Fig. 3. Light frame construction - Labeled house construction diagram (CleanPNG, 2025).

Another traditionally used method is the “post-and-beam” system, which is quite similar to the reinforced concrete frame structures in Türkiye, as beams and columns form the load-bearing frames. Nevertheless, the connections of beam and columns require special attention and may not be the best solution for seismically active regions. The connections require to transmit bending moment and shear, which may be difficult for 3D beam and column connections. Traditional Japanese connections involve major cutting and grooving which would reduce the cross section and make the members vulnerable at the most critical load transfer location. Although energy dissipation properties and introduced additional flexibility may bring advantages, a frame system has to transfer moment and shear properly. Just like reinforced concrete structures require shear walls, post and beam buildings would require a sound way to transfer inertial forces. Although wooden slabs are relatively much lighter compared to reinforced concrete slabs, the “flexible slab” vs “rigid slab” behavior differences also play an important role for the diaphragm action. Structural designer must be extremely careful when designing post-and beam load carrying system in earthquake prone regions since this system may not be suitable for seismically regions unless shear walls or proper cross-bracing is introduced.

A relatively more modern system is Cross-Laminated Timber (CLT), which involves bonding layers of lumber at right angles to form large, dimensionally stable panels. The number of layers is mostly defined as odd integer numbers and the direction with most fibers are usually used in the vertical direction. These CLT panels may serve as structural walls, floors, and roofs, offering high strength in both directions and excellent seismic and fire performance. CLT enables rapid construction and is increasingly used in mid to high-rise buildings due to its rigidity and mass. Best examples can be found in buildings such as the 86-meter-tall Mjøstårnet in Norway and the Ascent tower in the USA as they illustrate how CLT can be applied at demanding high structures. Nevertheless, the rolling shear of CLT panels is their weakest point. Most of the times, the shear acting perpendicular to the fibers without cutting them causes rolling action and failure. Another weakness of CLT panels may the metal connectors between walls to the ground or slab to slab connections. These connections and connectors must be carefully planned and designed to prevent any premature failures.

Panelized construction offers a fast and high quality “prefabricated” solution, where wall and floor elements are manufactured off-site in the factory and assembled on location using light cranes. This method speeds up construction timelines and ensures better quality control since most of the manufacturing is completed in the factory, while maintaining architectural adaptability. The panels often times have the windows and doors installed on them during pieces are combined on the site. Sandwich panels are also considered as panelized construction since exterior timber plates are combined using foam that sticks to both timber panels, fill the void, and transfer shear force between the exterior panels.

Finally, hybrid systems combine timber with reinforced concrete or steel cores. A common configuration includes a reinforced concrete core to house stairwells and elevators, which attracts almost all of the seismic loads, while the remaining structural framework is composed of timber. The system relies on the lateral load carrying capability of the core(s), which are always preferred to be symmetrically placed and present more than one core. The most critical and important aspect of hybrid system in earthquake prone regions is 1) make sure the connection between slab and core(s) are successfully maintained 2) the timber slabs connecting to cores are a) form a rigid diagram and b) slabs are light weight to minimize the earthquake forces. However, the slabs should not be overly light weight since “serviceability” becomes a major concern for light weight and flexible slabs. Many people may feel uncomfortable if too much and low frequency vibration is present in the slabs. Sometimes, the slab may be constructed unnecessarily stiff and stronger than it should be from a strength point of view. The hybrid systems provide seismic resilience and lightness of timber since timber is already a light weight material and the columns would only carry vertical loads during an earthquake. The rigid cores would be the major horizontal load carrying system. The cores are not only active during earthquakes, but they are also active during high wind conditions especially for taller buildings.

The civil engineer to perform the structural design should be careful to select the most appropriate load carrying system and be very careful with the connections. The members may be very strong and high quality, but the connections play a very important role in the load carrying mechanism during an earthquake. Connections are often times form the weakest link of load resisting chain.

Structural design of a building cannot be complete by only checking “strength” criteria though. Additionally, “serviceability”, “fire safety”, and “humidity, heat insulation, and “sound insulation” are the other key issues in timber building design.

6. Current seismic code limitations and suggestions

As per Turkey's current seismic code (2018), Table 4.1 limits timber buildings to Building Height Classes BYS 7 and 8 (up to 7 m and 10.5 m respectively in high seismic zones). The height limits are increased to 10.5m and 17.5 m respectively for low seismic zones but the performance advantage of timber buildings is the most dominant at earthquake prone regions.

Addition of “hybrid structures” were proposed, which would incorporate symmetrically placed core towers with rigid diaphragm action and proper deck to core connections. In this way, BYS=6 may be introduced to Türkiye, where engineered timber buildings can rise up to 17.5 m, about 5 floors, in highly seismic zones as well. The reduced seismic force due to timber’s low mass would enable safe and economical designs.

7. Fire safety considerations

Contrary to common perceptions, timber can be a fire-safe material when properly designed. One of the key mechanisms that make timber behave reliably in fire is the formation of a char layer on the surface of exposed wood. As the timber burns, a blackened char not only generates a thermal barrier, but also blocks the oxygen significantly to slow down the burning process. This predictable charring process insulates the unburned core and allows timber members to retain their load-bearing capacity for a prolonged time, often sufficient for the fire department to arrive and extinguish the fire. According to Eurocode 5 (EN 1995-1-2), the design charring rate for softwood is typically taken as 0.65 mm/min in standard fire exposure (ISO 834), though 0.8 mm/min is often used as a conservative and practical approximation in preliminary design. This rate implies that a structural timber member with a sacrificial outer layer can survive fire exposure of 60–90 minutes while still supporting its load, which is in line with many code requirements for medium-rise buildings. If the cross sections are selected to be 72 mm thicker in the fire exposed regions considering 0.8 mm/min and 90 mins, the members would be immune to fire for 90 minutes.

Timber's fire resistance can be further enhanced through the use of impregnation treatments and intumescent coatings, which either chemically slow the combustion process or expand to form an insulating black foam-like barrier when exposed to heat. In building practice, massive timber elements such as glulam and CLT panels outperform unprotected steel, which loses its strength rapidly at high temperatures. While steel may reach critical failure temperatures (around 550°C) within minutes, timber’s gradual degradation provides crucial time for evacuation and firefighting efforts.

In modern construction, additional fire protection measures are routinely taken for timber buildings. These include multi-layer gypsum board cladding for internal faces and non-combustible surface finishes like magnesium panels to delay ignition and heat transfer. Other major fire protection technique that must be mentioned is the simple sprinkler systems. Recently, new springers of water mist and/or gas based firefighting strategies are also being used. As a result, timber buildings (especially those designed under contemporary codes and fire engineering principles) can safely meet or exceed the 60–90 minute fire resistance thresholds required for structural elements in most low to mid-rise applications.

8. Conclusions

Timber was not an unfamiliar construction material to Ottomans and Turkish Republic since “yalılar ve konaklar” which can be translated as waterside and inland mansions of Ottoman-Turkish architecture as well as “Hımış”, “Bağdadi”, “Şamdolma” type of construction in Black Sea (Safranbolu specifically) and Anatolia regions are very common. The large Istanbul earthquake occurred on 10 September 1509, often referred to as “The Lesser Judgment Day” (Küçük Kıyamet) in Ottoman chronicles has been the point of dominantly timber usage in buildings since the timber buildings performed well during the earthquake. Timber material in building construction has reemerged as a powerful structural material, offering a compelling combination of sustainability, strength, and seismic resilience. The warm looks and many health benefits has been the major decision making of modern timber buildings. The structural safety, resilience, earthquake performance, being light weight, and economically compelling; timber buildings are dominantly used in North America for low and mid-rise construction.

Timber’s coming back in Türkiye after reinforced concrete structures’ dominance (starting with early 20th century until now) was initiated and accelerated through the efforts of institutions such as TORID, UAB, and leading universities, along with the support of the General Directorate of Forestry and the introduction of the Turkish Timber Building Regulation (TABY-2024) by Urbanization and Climate Change (CSIB). The structural classification of Turkish softwoods in accordance with international standards such as EN 338 and EN 1912 and registration to TS 1265 has made it feasible to use nationally produced structural timber in timber building construction with confidence.

Timber's strength-to-weight ratio, especially in species like black, red, and scots pine, is comparable to or exceeds that of mild steel on a density-normalized basis. Structural timber's lightweight character not only reduces seismic demand, soil requirements, and foundation costs but also enhances constructability and post-earthquake resilience. Timber members can be prefabricated and dry-assembled rapidly, avoiding delays otherwise due to concrete curing or too cold, too hot, rainy weather.

From an environmental and life-cycle perspective, timber stands out as a carbon-negative material, absorbing more CO_2 during its growth than it emits during processing. It helps mitigate the 38% share of global CO_2 emissions attributed to the construction sector, while also contributing positively to the forest ecosystems through erosion control, biodiversity support, and climate regulation. Timber also allows for fast and cost-effective construction, with studies confirming up to 13% cost savings compared to reinforced concrete in mid-rise buildings. The adaptability of timber construction systems, considering light-frame, CLT, post and beam, or hybrid core configurations, ensures architectural and structural flexibility. Fire safety, often misunderstood aspect, can be easily and effectively addressed with proper design, accounting for predictable charring rates, and protective strategies such as intumescent coatings, gypsum cladding, and sprinkler systems. As Türkiye continues to face the dual challenges of seismic risk and climate responsibility, engineered timber stands out as main construction material for the buildings of the 21st century.

Acknowledgments

The author would like to express his sincere appreciation to Assoc. Prof. Dr. Barış Erdil, Asst. Prof. Dr. Erkan Akpınar, and Assoc. Prof. Dr. Mehmet Selim Ökten, along with their dedicated team members, for their valuable contributions to the development of timber engineering in Türkiye. Gratitude is also extended to the General Directorate of Forestry (OGM), the Türkiye Orman İş Adamları Derneği (TORID), the Ulusal Ahşap Birliği (UAB), and the Ministry of Environment, Urbanization and Climate Change (CSIB) mainly Dr. Mustafa Tekin for their ongoing support and leadership in promoting sustainable timber construction.

Numerical and analytical study of the dynamic behaviour of Tokat Clock Tower

Muhammed M. Öztürk[1], Emre Alpaslan[2], Şahin Sözen[*1]

[1] *Tokat Gaziosmanpaşa University, Department of Civil Engineering, 60010 Tokat, Türkiye*
[2] *Ondokuz Mayıs University, Department of Civil Engineering, 55100 Samsun, Türkiye*

Abstract. It is very important to determine the dynamic behavior of historical buildings, which are a part of cultural heritage. The dynamic behavior of structures is obtained depending on parameters such as material properties, boundary conditions, and damage conditions of the existing structure. The modal analysis method is used to solve dynamic problems in many fields, especially in civil engineering. In this method, dynamic parameters such as natural frequency, mode shape and damping ratio of the structure are obtained. Slenderness is a very important problem in tall, thin masonry structures such as towers and minarets which are sensitive to lateral loads. Damages may occur in such engineering structures due to severe earthquakes. In this study, the linear dynamic analysis of the historical masonry Tokat Clock Tower located in the central district of Tokat province was carried out. Built in 1902, the clock tower was replaced and modernised in 1917. Finally, the dimensions of the building, which underwent a restoration process in 2019, were obtained by using the technical drawings in the restoration report. The dynamic characteristics of the historical building in question were obtained numerically and analytically. In the numerical study performed using ANSYS software, response spectrum analysis was performed according to 2007 and 2018 Turkish Earthquake Codes (TEC 2007 and TEC 2018). The results of the analyses according to both regulations are compared. In the analytical study, the fundamental period of the clock tower was determined by using an approach based on the Rayleigh method. At the end of the study, the dominant period of the clock tower obtained by the finite element method was found to be very close to the result obtained by the Rayleigh method. In addition, it was determined that the forces and displacements obtained according to the TEC 2007 have larger values compared to the TEC 2018.

Keywords: Masonry structure; Dynamic behaviour; Finite element method; Rayleigh method.

1. Introduction

The preservation of historical buildings is of paramount importance, as they constitute a significant component of our cultural heritage, and it is imperative to ensure their transmission to future generations. It is an established fact that throughout their existence, historical edifices are susceptible to damage or complete destruction as a result of natural disasters such as earthquakes, floods, wars, and fires. Consequently, a comprehensive investigation into the structural integrity of historical edifices is imperative, followed by the implementation of requisite measures to ensure the preservation of these structures for posterity. In this context, in order to ascertain the current behaviour of historical buildings, it is necessary to determine the properties of the materials used in their construction.

Tall and fragile structures such as clock towers, mosque minarets and bell towers, which are among the historical buildings, exhibit a more sensitive behaviour, especially against seismic effects. Numerous studies have been conducted to ascertain the dynamic behaviour of such structures (El-Attar et al., 2005; Beyan, 2007; Livaoğlu et al., 2016; Gökdemir & Baki, 2024). In the majority of studies, the existing behaviour of structures is modelled using the finite element method (Akan & Özen, 2005; Mortezaei et al., 2012; Sözen, 2022). The finite element method facilitates the development of numerical models of structures and the investigation of their static and dynamic behaviours through analyses conducted on these models.

The dynamic behaviour of structures is represented by parameters such as mode shape, natural frequency and damping ratio. The aforementioned parameters can be obtained either numerically by theoretical modal analysis method or experimentally by operational modal analysis method (Serhatoğlu et al., 2015; Hacıefendioğlu et al., 2016; Altunışık et al., 2023).

golden light publishing

In this study, the structural behaviour of the historical Tokat Clock Tower, located in the centre of Tokat province, is investigated by both numerical and analytical methods. The results obtained are intended to make a contribution to the studies on earthquake protection of masonry historical buildings with similar characteristics. The distinguishing feature of this study is that the linear analysis of the Tokat Clock Tower is conducted by taking into account both the 2007 and 2018 Turkish Earthquake Regulations, and the fundamental period of the structure is analytically determined using the Rayleigh method. The accuracy of the analytical approach is evaluated by comparing the results obtained from finite element analysis and Rayleigh method.

2. Architectural and structural features of the Historic Tokat Clock Tower

The Tokat Clock Tower, erected in 1902 in the Behzat neighbourhood in the city centre, was constructed with the intention of being visible from all parts of the city. The tower, constructed from cut stone, features an octagonal design that narrows towards the top from a square base, with a total height of 33 metres. The main entrance of the building is situated on the south side. Current photographs of the building are shown in Fig. 1.

Fig 1. Current photos of the clock tower

In 2019, Seka Architecture was responsible for the technical drawings of the Clock Tower, which had just undergone restoration. The tower is composed of four distinct octagonal sections, which rise from a square base. The 5.8-meter-high pedestal measures 5.6 meters in length and width. The lateral dimensions of the octagonal blocks, which vary in size, range from 1.5 to 2 meters. The stairs within the tower are composed of monolithic cut stone. These stones are supported by a 20-centimeter-thick hollow circular core. The plan view and height of the tower at +20.10 m are illustrated in Fig. 2.

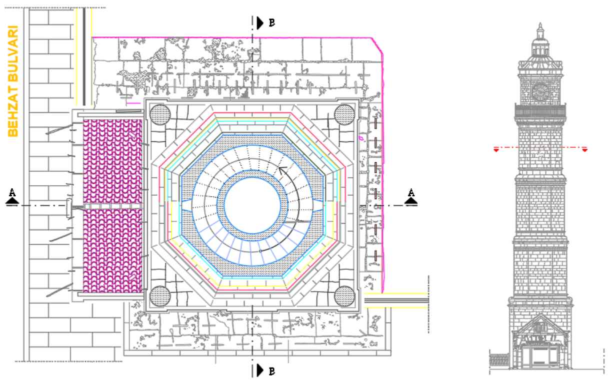

Fig. 2. Plan and height of the clock tower

3. Material and method

The objective of the study was to ascertain the dynamic behavior of the Tokat Clock Tower under earthquake loads. In order to perform the structural analysis, it is necessary to determine the material properties. The materials of historical buildings may deteriorate due to exposure to various environmental conditions over extended periods.

It is important to note that natural stone samples extracted from the same quarry may exhibit different mechanical properties. Consequently, ascertaining the mechanical properties of materials utilized in historical edifices poses a considerable challenge. A plethora of test methods, both destructive and non-destructive, have been documented in the extant literature for the purpose of determining material properties. However, due to the historical nature of the tower, it was not possible to perform a destructive test by taking a material sample. Consequently, the non-destructive test method and the material properties documented in the extant literature were employed to develop the material model for the analysis.

In a study of the Tokat Clock Tower, an N-type Schmidt hammer—a non-destructive testing device—was utilized to ascertain the compressive strength of the cut stone employed in the tower's construction. The mean compressive strength of the stone was found to be 31.67 MPa. Subsequently, the compressive strength and modulus of elasticity of the wall were determined using empirical formulas from the extant literature. The resulting values were 4.52 MPa and 3390 MPa, respectively (Sözen, 2022).

The tensile strength of masonry walls has been observed to range from 5% to 20% of the compressive strength (Gönen & Soyöz, 2021). In this study, the tensile strength of the wall was set at 0.3 MPa.

The unit volume weight and Poisson's ratio employed in the analysis of the tower were 2650 kg/m^3 and 0.2, respectively, in accordance with the values reported in the extant literature (Ertek & Fahjan, 2007; Gönen & Soyöz, 2021; Sözen, 2022).

4. Dynamic Analysis of the Tower

The dynamic analysis of the Tokat Clock Tower was performed according to the widely used mode coupling method, which yields results that are close to those of time domain analysis. ANSYS software was utilized in the analysis. Subsequently, response spectrum analysis was executed in accordance with both TEC 2007 and TEC 2018 regulations. The resulting data were then subjected to comparative analysis.

As indicated by the geotechnical analyses carried out by the Tokat Municipality, the shear wave velocity in the upper 30 meters was determined to be $2(V_s)_{30} = 225\ m/sn$. According to the regulations outlined in TEC 2007 and TEC 2018, the soil class of the building was determined to be Z3 and ZD, respectively.

The parameters employed in the spectrum analysis of the tower, as outlined in the TEC 2007 and TEC 2018 Regulations, are enumerated in Table 1.

Table 1. Parameters for spectral analysis

Regulation	TEC 2007	TEC 2018
Classification of Soil	Z3	ZD
Effective Acceleration Coefficient (A_o)	0.4	-
Structural Importance Factor (I)	1	-
Map Spectral Acceleration Coefficient for Short Period Region (SS)	-	0.749
Map Spectral Acceleration Coefficient for 1.0 Second Period Region (S1)	-	0.258
Peak Ground Acceleration (PGA)	-	0.316
Local Soil Effect Coefficient for Short Period Region (FS)	-	1.2
Local Soil Effect Coefficient for 1.0 Second Period Region (F1)	-	2.1
Design Spectral Acceleration Coefficient for Short Period Region (SDS)	-	0.899
Design Spectral Acceleration Coefficient for 1.0 Second Period Region (SD1)	-	0.542

In the context of the study, the analysis is confined to the horizontal response spectrum, as the effect of the vertical response spectrum is deemed negligible. The elastic design spectra of the TEC 2007 and TEC 2018 earthquake codes are presented in Fig. 3.

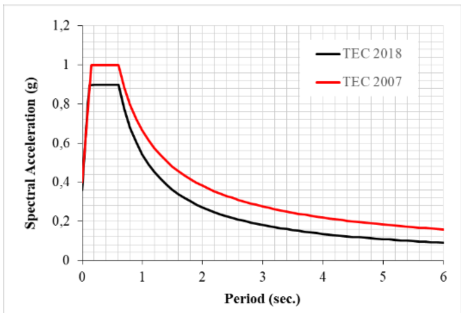

Fig. 3. Elastic design spectrums according to TEC 2007 and TEC 2018

4.1. Finite Element Analysis

In the linear analysis of the tower, all elements of the structure (including the stair treads) were modeled as solid. The SOLID187 element was utilized in the modeling process. The element is defined by 10 nodes having three degrees of freedom at each node: translations in the nodal x, y, and z directions. The element has plasticity, hyperelasticity, creep, stress stiffening, large deflection, and large strain capabilities (Ansys, 2025). The structure was subdivided into a total of 206,446 elements, and the total weight of the structure was calculated as 7,930 kN. As illustrated in Fig. 4, the finite element model and mesh network of the structure are presented.

The mode shape and frequency values, which are dynamic characteristics of the structure, were obtained as a result of performing a modal analysis on the finite element model. The frequency and period values of the first five modes of Tokat Clock Tower are enumerated in Table 2, while the mode shapes are illustrated in Fig. 5.

Spectrum analysis was performed on the tower, with separate analyses conducted for the x and z directions. These analyses were conducted in accordance with the elastic design spectra presented in Fig. 3. The peak displacement, base shear force, and equivalent (von-Mises) stress values obtained as a result of the analysis are given in Table 3.

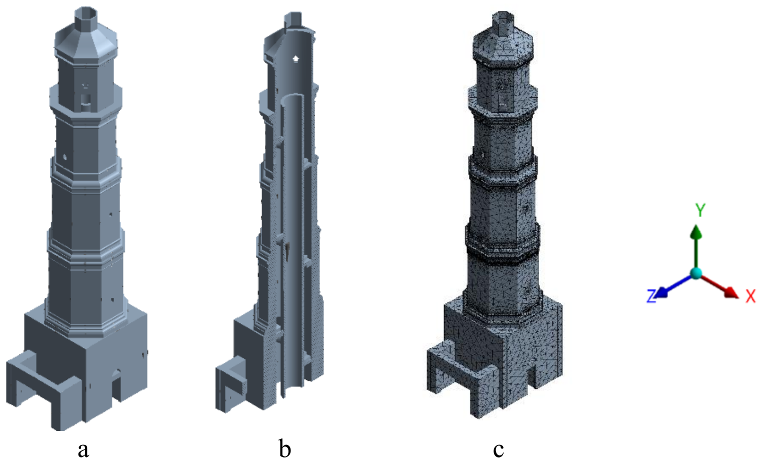

Fig. 4. Finite element model (a-b) and mesh network (c) of Tokat Clock Tower

Table 2. The initial five periods of the Tokat Clock Tower

Mode	Direction	Characteristics	Frequency, *Hz*	Period, *sec.*
1	x	Translational	2.41	0.41
2	z	Translational	2.47	0.40
3	x	Translational	7.89	0.13
4	z	Translational	8.01	0.12
5	-	Torsion	11.2	0.09

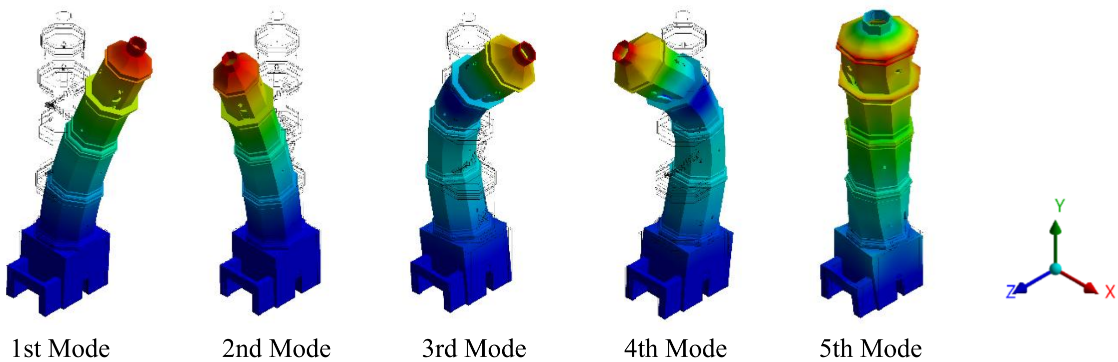

Fig. 5. Mode shapes of Tokat Clock Tower

Table 3. Spectrum analysis results obtained for X and Z direction according to TEC 2007 and TEC 2018 regulations

	X direction		Z direction	
	TEC 2007	TEC 2018	TEC 2007	TEC 2018
Displacement of the top point, *mm*	92	83	88	79
Shear force of the base, *kN*	3420	2970	3370	2910
Equivalent (von-mises) stress, *MPa*	9.02	8.13	8.90	7.99

4.2. Determination of Fundamental Period Using the Rayleigh Method

The Rayleigh method is a mathematical technique used to calculate the dominant period of a tower (Kılıç et al., 2019). This calculation is performed by utilizing equation 1, which is derived from the Rayleigh method. In this instance, the tower is modeled as an equivalent Timoshenko beam, as outlined in the extant literature. In this case, Equation 2-11 can be written as follows (Dym & Williams, 2012):

$$T_1 = \frac{2\pi}{\omega} \tag{1}$$

In this equation, ω denotes angular frequency, which is calculated using the provided Equation 2.

$$\omega^2 = \frac{\omega_e^2 \omega_k^2}{\omega_e^2 + \omega_k^2} \tag{2}$$

Here, ω_e is the angular frequency calculated from pure bending deformations and ω_k is the angular frequency calculated from pure shear deformations and can be calculated by Equations 3 and 4:

$$\omega_e^2 = \frac{\int_0^1 EI(\varepsilon)\left(\frac{d^2 y_e}{d\varepsilon^2}\right)^2}{H^4 \int_0^1 \rho A(\varepsilon)\, {y_e}^2} \tag{1}$$

$$\omega_k^2 = \frac{\int_0^1 kGA(\varepsilon)\left(\frac{dy_k}{d\varepsilon}\right)^2}{H^2 \int_0^1 \rho A(\varepsilon)\, {y_k}^2} \tag{4}$$

Where E is the modulus of elasticity, G is the shear modulus, $I(\varepsilon)$ is the moment of inertia function, $A(\varepsilon)$ is the cross-sectional area and k is the shear deformation factor. The mode 1 shape consisting of pure bending and pure shear deformations y_e and y_k, respectively, can be approximated as in Equations 5 and 6:

$$y_e = 1 - \cos\left(\frac{\pi\varepsilon}{2}\right) \tag{5}$$

$$y_k = \sin\left(\frac{\pi\varepsilon}{2}\right) \tag{6}$$

Here ε is defined by Equation 7:

$$\varepsilon = \frac{z}{H} \tag{7}$$

Where z is the variation along the height of the tower and H is the total height of the tower. In this study, parabolic and cubic variations of moment of inertia and cross-sectional area along the height of the structure are considered and presented in Equations 8-11:

$$I(\varepsilon) = I(O)\left[1 - \left(1 - \frac{I(H)}{I(O)}\right)\varepsilon^2\right] \tag{8}$$

$$A(\varepsilon) = A(O)\left[1 - \left(1 - \frac{A(H)}{A(O)}\right)\varepsilon^2\right] \tag{9}$$

$$I(\varepsilon) = I(O)\left[1 - \left(1 - \frac{I(H)}{I(O)}\right)\varepsilon^3\right] \tag{10}$$

$$A(\varepsilon) = A(O)\left[1 - \left(1 - \frac{A(H)}{A(O)}\right)\varepsilon^3\right] \tag{11}$$

Where $I(O)$ and $A(O)$ are the inertia and cross-sectional area at the base, and $I(H)$ and $A(H)$ are the moment of inertia and cross-sectional area at the peak. The fundamental period values were calculated for parabolic and cubic variation assumptions using Equations 1-11. Uncracked and cracked section fundamental period values for parabolic and cubic variations of moment of inertia and cross-sectional area by Rayleigh method are given in Table 4.

Table 4. Fundamental period obtained using Rayleigh method

Change Acceptance	Parabolic	Cubic
Period, *sec.*	0.35	0.38

5. Conclusions

In this study, the dynamic parameters of the historical clock tower in Tokat Province were determined using ANSYS software. The results obtained by using solid element type in finite element analysis were evaluated. The tower was subjected to an analysis in accordance with TEC 2007 and TEC 2018 using the response spectrum analysis method.

- It was concluded that the peak displacement, base shear force and equivalent stress values obtained as a result of the response spectrum analyses performed in the X and Z directions differ due to the geometry of the structure. In addition, the values obtained in the X direction were found to be larger.
- When the results of 2007 and 2018 earthquake code analyses are compared, it is seen that the values obtained from 2007 earthquake code have higher values.
- The maximum peak displacement obtained was 92 mm, base shear force was 3420 kN and equivalent stress values were 9.02 MPa. These values were obtained as a result of the analysis carried out in the x direction according to TEC 2007 regulations.
- In the context of the study, a methodology is proposed for the practical determination of the fundamental period, employing the Rayleigh method as a means to achieve this objective. The fundamental period value obtained by the proposed approach is found to be in close agreement with the fundamental period value obtained by finite element analysis.

Consequently, the analyses conducted in this study are predicated on linear behavior. To ensure the integrity and safety of the tower in the event of a major seismic event, nonlinear analyses must be conducted to assess its behavior during such an event.

The design of multi-story steel industrial building with various equipment

Samet Kılıç*[1]

[1] *Star Yazılım Mühendislik ve Danışmanlık, Ataşehir, Türkiye*

Abstract. In industrial facilities, multi-story steel structures contain many non-structural elements; These are components whose design is crucial under earthquake and wind loads. The interaction of these elements with the main structure is critical. Silos, tanks, vessels, mills, filters, pipes, solar panels, monorails and cranes are examples of them. Besides their mass and inertia, the material loads inside the tank; operating frequencies of equipment like mill, crusher etc., should be observed. Fluid dynamics and thermal expansion effects in pipes; brake loads in cranes must be considered. With these technical difficulties, there are problems like lack of clarity of design responsibility, especially with mechanical discipline, the conflict of design codes and the limitations of numerical analysis tools. In this study, the design and detailing of a multi-story steel structure containing various solution methods against these problems, is mentioned. Finite element method is applied with SAP2000® software. In detailing, fiber bolts, slotted holes, special pipe supports, and dampers are used. Thermal insulations and compensators are used for thermal expansions. Possible non-structural elements can be modeled together with the main structure. The building vibration modes are compared with frequencies of equipment causing resonance. Special polymers and isolators are other solutions. Grounding is for electrical effects and cathodic protection is used against corrosion. This study may be helpful for structural engineers at designing steel structures with different instruments and equipment.

Keywords: Multi-story steel structures; Solar energy panels; Seismic design of industrial structures; Cranes and monorail design; Machinery foundations

1. Introduction

A careful balance between structural integrity, operational efficiency, and adaptability is necessary in the intricate and diverse process of designing multi-story industrial buildings. These buildings are being used more and more in urban and space-constrained locations where a variety of industrial operations require vertical development. A comprehensive approach to design that incorporates engineering, architectural, and operational issues is required when integrating different machines and equipment into a multi-story structure. Important design factors of multi-story industrial structures are made to support heavy loads from operational procedures, machinery, and equipment. A mix of static and dynamic loads must be handled by the structural system.

The structure's self-weight is referred to as a dead load, whilst the weights of workers, materials, machinery, and equipment are referred to as live loads. To provide load distribution without overloading any particular structural member, the design must take into account the various weights and positions of the equipment (McCormac & Brown, 2015). Environmental elements including wind and seismic forces, operating loads, and vibrations caused by equipment all contribute to dynamic loading. Under these circumstances, structural performance is analyzed and optimized using sophisticated computer techniques like finite element analysis (FEA) (Chopra, 2011). Multi-story industrial buildings frequently use materials like structural steel and reinforced concrete. Steel is frequently chosen because of its excellent strength-to-weight ratio, high ductility, ease of building, and adaptability when designing open floor layouts to fit huge machinery. Composite materials provide increased structural efficiency by integrating steel and concrete (Chung, 2019).

Effective spatial planning is necessary when integrating different pieces of equipment into a multi-story structure in order to maximize efficiency and save material handling expenses. One of the elements affecting layout design is equipment location. To reduce structural stresses and vibration transmission, heavy machinery is usually positioned on lower floors. To preserve operational efficiency and balance weight distribution, lighter equipment and administrative areas are situated on upper levels. Another parameter is vibration control. Specialized slab systems, calibrated mass dampers, or isolation pads must be installed in order to reduce vibrations in sensitive

*Corresponding author, E-mail: kilicsamet123@gmail.com

https://doi.org/10.31462/icearc2025_ce_eqe_575

equipment. These characteristics prolong the life of machinery and provide steady operations (Den Hartog, 1956). Flexibility for the future is one of the most important issues in industrial design. Flexible floor layouts and modular construction enable flexibility in response to change industry demands. Effective retrofitting and modifications are made possible by this method without seriously interfering with continuing business operations.

To guarantee functionality and safety, multi-story industrial buildings must abide by national and international construction norms and standards (ASCE, 2022; ÇYTHYE, 2016; TBDY, 2019). Important things to think about are codes of structure, fire safety and environmental sustainability. Guidelines for load combinations, structural integrity, and material specifications are provided by standards like the International Building Code (IBC). The building's ability to endure expected operational and environmental stressors is guaranteed by compliance (International Code Council, 2021). To reduce the dangers connected with industrial processes, design includes sprinkler systems, emergency evacuation routes, and fire-resistant materials for fire safety. Maintaining compliance and preparedness requires routine fire safety audits (NFPA, 2020). Energy-efficient systems, such light-emitting diode (LED) lighting and renewable energy sources, lower operating costs and support sustainability objectives. Eco-friendly techniques in industrial construction are promoted by green certifications like LEED (USGBC, 2020).

The main difficulties in constructing multi-story industrial buildings are balancing the interaction of large loads, vibrations, and spatial limitations. These structures' structural capacities have been improved by advancements in building materials, such as high-performance concrete and sophisticated steel materials. Building Information Modeling (BIM) also makes it easier for stakeholders to collaborate, which guarantees accuracy in design and implementation.

Designing multi-story industrial structures with a variety of equipment is a very specialized task that calls for advanced engineering solutions and interdisciplinary collaboration. Designers are able to produce robust and flexible facilities that satisfy the needs of contemporary businesses by taking structural, operational, and regulatory factors into account. The efficiency and utility of these structures will be further improved by upcoming advancements in materials, technologies, and sustainable practices, guaranteeing their continued relevance in an industrial world that is changing quickly.

2. Design of highrise industrial structure with precautions

2.1. Nonstructural design precautions

The most important reason for the construction of high-rise steel industrial structures is the need to place many equipment such as silos, filters, pumps, fans, mills, solar panels, etc. in a way that they will go down from a certain height within the process. For this reason, the presence of equipment in such structures is one of the most important criteria in design. Equipment is not only weight, but also special precautions must be taken in structures according to their characteristics. For example, solar panels have been used in many structures in recent years. These panels increase seismic loads and cause the dominant periods shift of the structure to some extent. In addition, snow cleaning must be done manually or with automation on the roofs so that the solar panels are always in working order. It is very important to have work safety railings on the outer lines for the use of ropes etc. for roof works. Due to the height of the structures, it is important to have warning signs and lighting for unmanned aerial vehicles such as helicopters, drones, etc. Drainage must be designed for rainwater drainage as shown in Figure 1. In order to prevent rainwater from seeping through the roof and electrical equipment from being damaged, the roof cladding and insulation must be proper. It is recommended to use cathodic protection and effective insulation to protect structures from corrosion. In addition, lightning rods are an indispensable part of the design to protect against lightning. Similarly, grounding, which supplies energy-efficient and environmentally sustainable systems, is a priority in electrical design.

It is essential for possible disassembly that the roof elements are not welded. Especially silos and tanks are located at the highest elevations of such structures. It is very important to arrange the steel elements and their connections in such a way that they can be removed from the structure with a tower crane from the top in case of any failure. Also, it is crucial for future expansion. In general, all elements including the railings should be connected with bolts to facilitate the disassembly of the equipment in the entire structure, and field welding should be avoided as much as possible. Monorails or cranes should be designed for easy movement of equipment within the structure. Cranes such as monorail are preferred more than cranes in high-rise structures. In addition, doorways should be left on the facades for exits from many floors. Since the structures are high-rise structures, it is important for them to have fire escape engineering, to have fire escapes and to have elevators for vertical human circulation. It is inevitable to arrange mini platforms to provide access to each equipment. Sufficient thermal insulation of the hot air lines (pipes and pipe supports) passing through the structure will prevent excessive thermal load from passing to the structural elements.

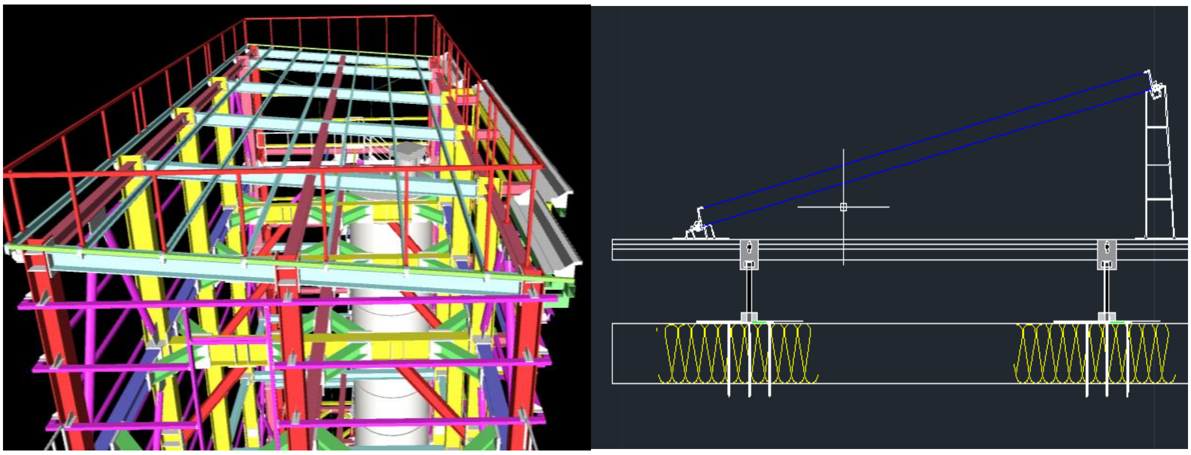

Fig. 1. Solar Panels and Roof Design (Navisworks, 2022)

2.2. Structural design precautions

The most important structural design problem in high-rise buildings compared to hangar-type structures is the limitation of lateral drift. While it is possible to choose a direction moment frame, a direction center or eccentric brace in hangar-type structures, it is not possible for moment frames to solve the displacement problem, especially as the structure rises. For this reason, it is necessary to use dual systems (Kılıç, 2015) where braces are used together with moment frames instead of moment frames. It is also very important to limit lateral drifts caused by wind loads in high-rise structures. The increase in the width of the facade and the height of the structure increases the wind load exposed. A drift limitation is made in a way that does not allow non-linear behavior under wind loads (ASCE, 2022). The analysis of the panels used for solar energy under wind and dead loads should be made by the supplier companies and should be added to the finite element models.

Elements such as silos, tanks or bunkers in high-rise steel structures are generally evaluated under the discipline of mechanical design, therefore only the support loads are affected in structural models. Often, the designs of such non-structural elements are out of scope and their rigidity is neglected in the models. As shown in Figure 2, silos were considered in the finite element model. In addition (BIM) is used in 3D models to prevent any clashing.

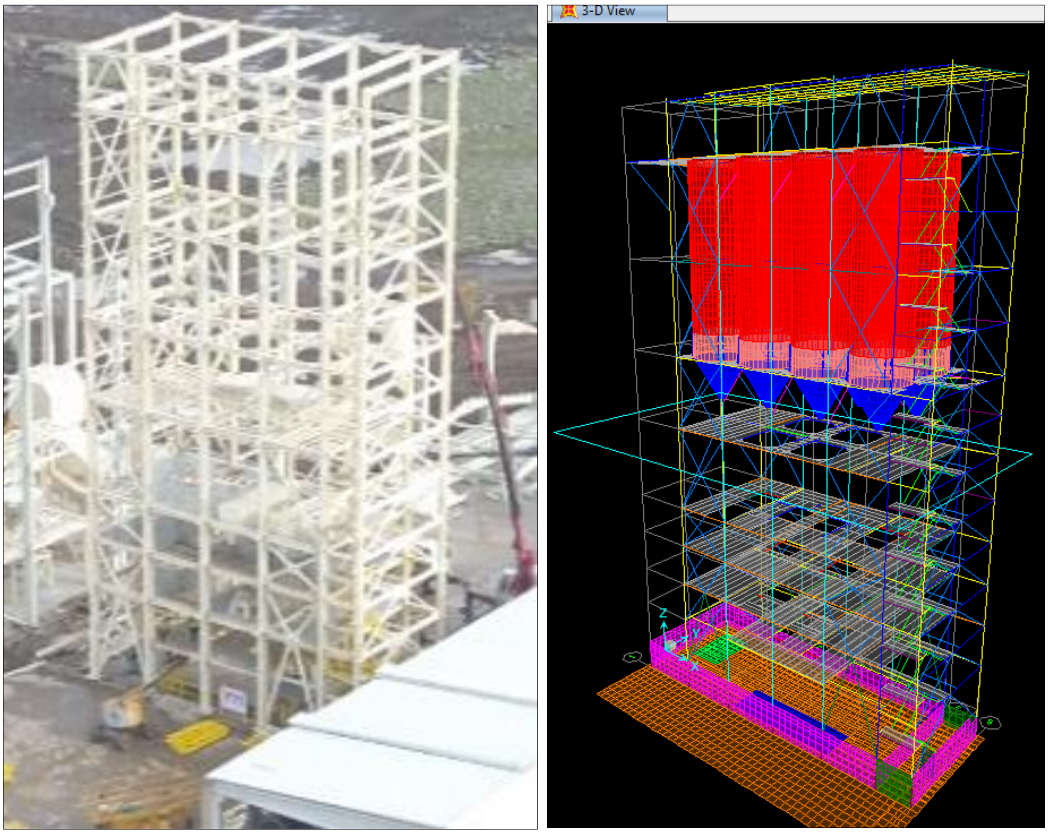

Fig. 2. Real view and FEM Model of Industrial Building (SAP2000, 2021)

In addition, pipes with large diameters and therefore high rigidity located within the structure are only affected as a load on the system. It is possible to model pipes in advanced finite element programs used today. It will be possible to add pipes to the system isostatically with the help of one roller and one fixed support. In addition, even if we cut off the heat transfer of the pipes to the outside with the necessary insulation, it is not possible to prevent thermal extension within them. For this reason, as seen in Figure 3 below, expansion joints with sufficient distance should be used and the extension should be absorbed here. The necessary strength should be provided in piping with pipe stress analyses. Reservoirs such as silos should also be added to the system and additional effects such as overturning moments on the structure should be taken into account. When the models in which such equipment is processed or continued with support reactions without processing are compared, it has been determined that some additional forces are seen especially in steel columns extending towards the top level of the silo due to the movement of the top of the silo. Apart from this, silos, tanks, etc. whether the equipment meets the earthquake loads and material, wall stress under liquid pressures, buckling resistance, lateral displacement limits should be checked externally, and coarse thicknesses from other disciplines should be checked (Kılıç, 2024; Kılıç et al., 2022; Kılıç et al., 2021).

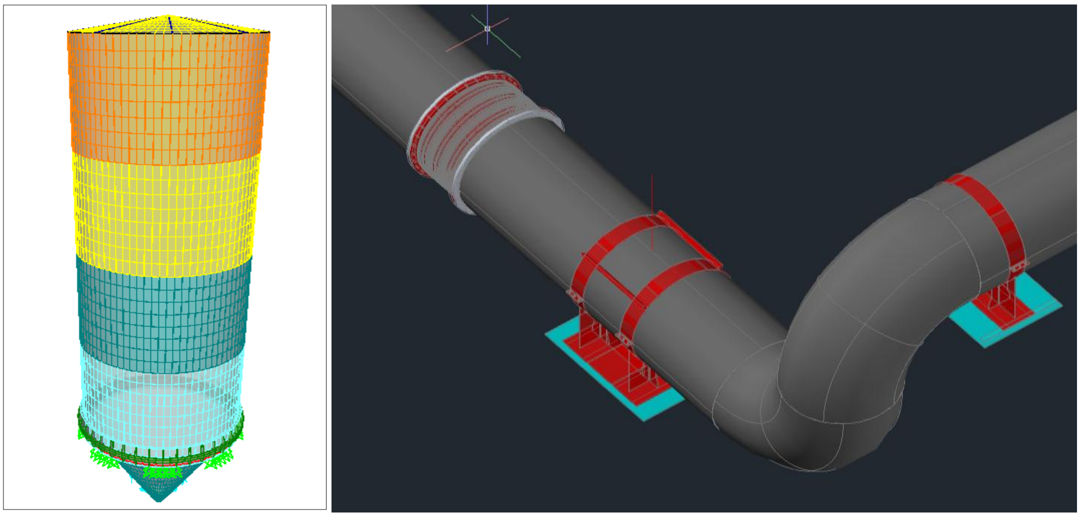

Fig. 3. Independent Solutions for Silos and Pipes (Navisworks, 2022)

In the case of presence of pressure vessels in the structures or equipment with computational fluid dynamics and support reactions, it is very important to continue with the data and loads received from technology companies.

3. Vibration control of structure

3.1 Steady state analysis and vertical modal analysis check

It is very important to provide vibration comfort in all steel structures. As seen in Figure 4 below, it is desired for the frequency to remain within certain vibration limits depending on the acceleration and load in structures such as residences, shopping malls, etc. In steel structures, diamond-patterned sheet metal etc. claddings are made on the floors. It is possible to limit vibration by switching to composite slabs. In high-rise industrial structures, the presence of machines operating at higher vibrations compared to human walking excitation. These machines cause large vibrations in the entire structure. As a result of vibrations, fatigue occurs in the structural elements and various comfort problems occur in the long term. One of the ways to prevent these problems is to find the vibration frequency of the machine and move away from the dominant vibration frequencies of the structure that will cause resonance. Here, the level where the equipment causing vibration is located in the building is very important. Simply, it is important whether it is on the foundation of the building, on the first floor or on higher floors other than the first floor. If it is on the foundation level of the building, the ideal solution is to separate the building foundation from the machinery foundation. Afterwards, a steady state analysis should be performed on the equipment foundation to try to separate the equipment vibration frequency from the fundamental frequency. This process is implemented as described below. Firstly, the steady state function was defined in related software SAP 2000 (SAP2000, 2021) as described in CSI Analysis Reference Manual, chapter "Frequency Domain Analyses", section "Steady-State Analysis". Steady-State function was introduced to software with the equation (1) below. "w" and "f" refer to angular velocity and frequency.

$$w^2 = (2\pi f)^2 \quad (1)$$

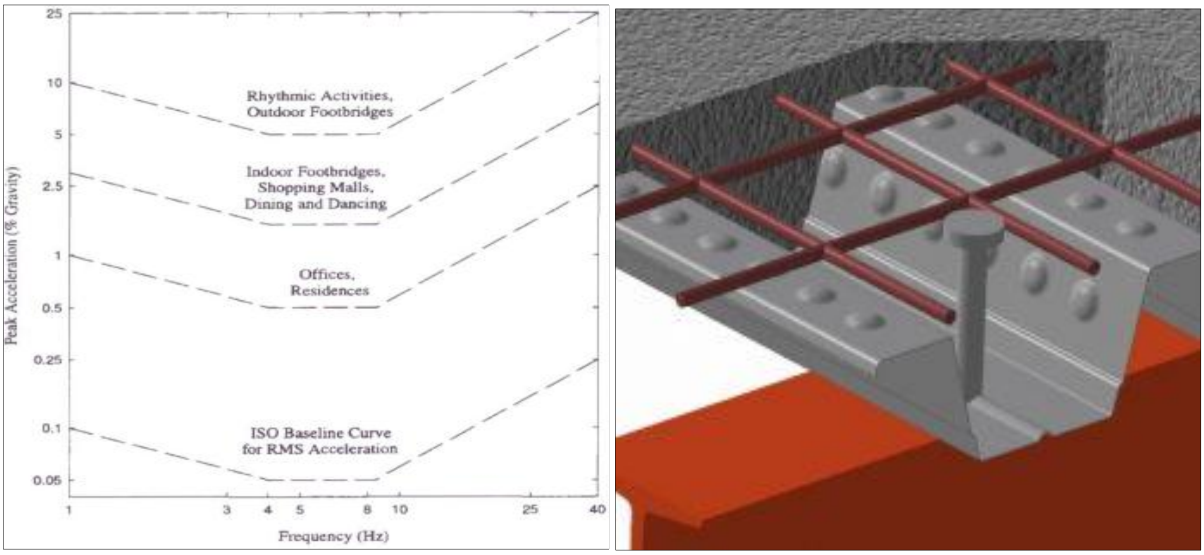

Fig. 4. Walking Excitation and Composite Slab Design (Composite Slab, 2025)

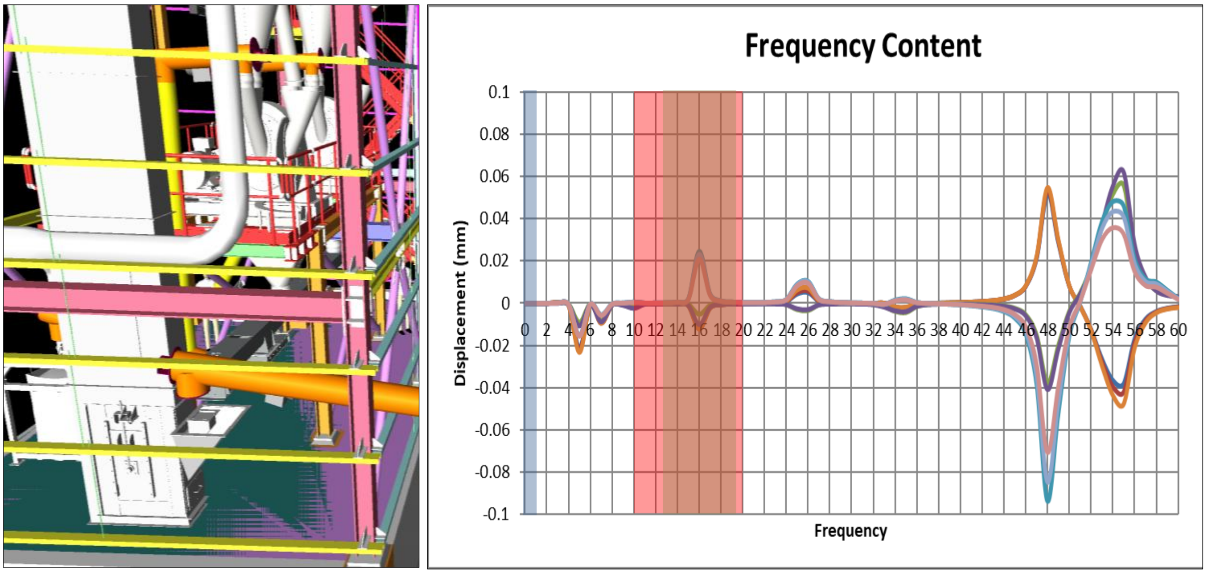

Fig. 5. Different Level of Equipment Platforms and Frequency Content Check (Navisworks, 2022; Excel 2022)

After the steady state analysis, the values and the graph are illustrated above. It is expected that the structure resonates for frequencies of mode which is vertical. After finishing analysis, the frequencies and the maximum displacement places are compared. For this reason, initially the values' unit is converted from rpm to Hz. Then to be on the safe side, the resonance frequency should be different at least %20 percent of operational frequencies (Siyahi, 2012). So, calculated the values of frequencies multiplied coefficients "1, 2" and "0, 8" are shown in Figure 5. It is impossible to show every joint displacement in excel graph. So, only a few of the joints are shown in Figure 5 which is not in the operational frequency borders as indicated. The resonance occurs in the mode where the highest mass participation exists, as expected (Kılıç, 2023).

3.2 Measures against resonance

Despite such measures, it is not possible to eliminate the vibration felt in the structure. There are additional solutions that claim to reduce vibrations by half. An example is sylomer. This unique polymer was added to the system in a bundling manner. Figure 6 shows the force-deflection and damping curves following the application of a particular polymer. Equipment vibrations are absorbed by this unique polymer (Getzner, 2022).

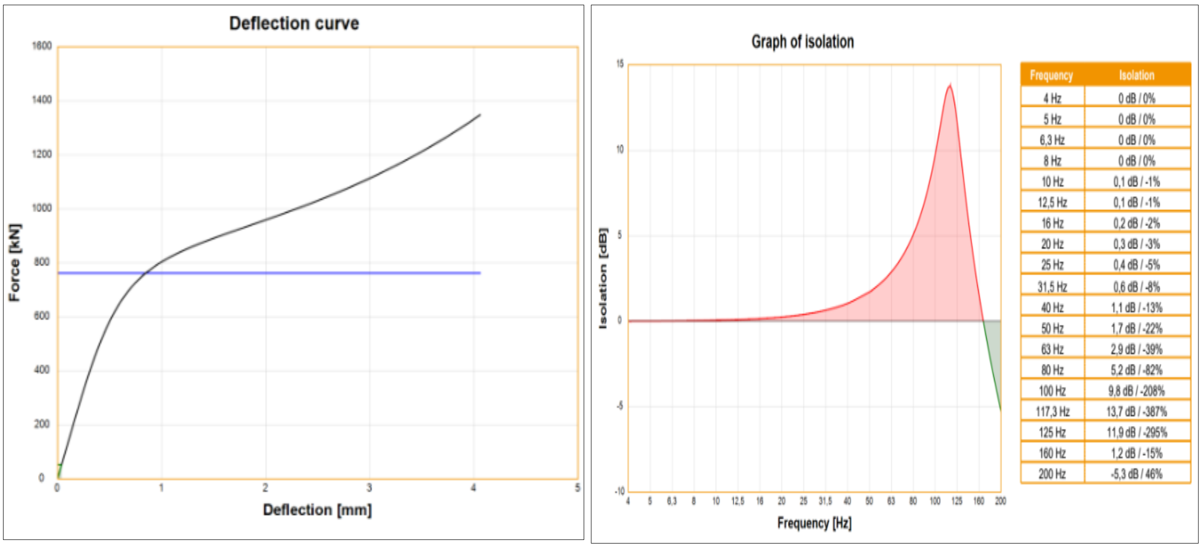

Fig. 6. Force-Deflection and Damping Curves of Sylomer (Getzner, 2022)

Another situation is when the vibrating equipment is on the first floor of the building. In this case, to the extent that the floor heights allow, the first floor is detached from the main building, and it is ensured to work as a separate platform. The most important problem that will be encountered in this case is the formation of soft story irregularity in the building. The way to prevent this is to connect all the frame columns of the building to each other with steel beams in the same way. Since the platform level will be the first-floor level, the platform level has slightly increased. The level of the steel beams is arranged so that they remain below the platform level. In this way, slender columns and different floor heights are prevented, and the system to which the vibrating equipment is connected is detached from the main structure. In the case of the equipment on the upper floors, it is aimed to provide vertical mode participation in a way that prevents resonance. According to the experience gained from steady state analyses, the points where the vibration is the greatest are the periods/frequencies where the highest participation is seen in vertical modes. Based on this experience, by looking at the vertical mode contributions of the building, it is checked whether they are the same as the equipment dominant modes, and if there are overlapping modes, it is tried to get away from these points by trying beams with different stiffnesses if possible. The connections of the beams on which the equipment sits should be designed to resist torsion. In addition, it is very important to support them laterally from several points if possible. In cases where this is not possible, some isolators are used as shown in Figure 7 below. Similarly, slotted holes are used to absorb equipment vibration. Another solution is to choose fiber bolts for connecting the equipment under the control of mechanical discipline to the beams. The energy absorption capacity of these types of bolts is higher than normal bolts.

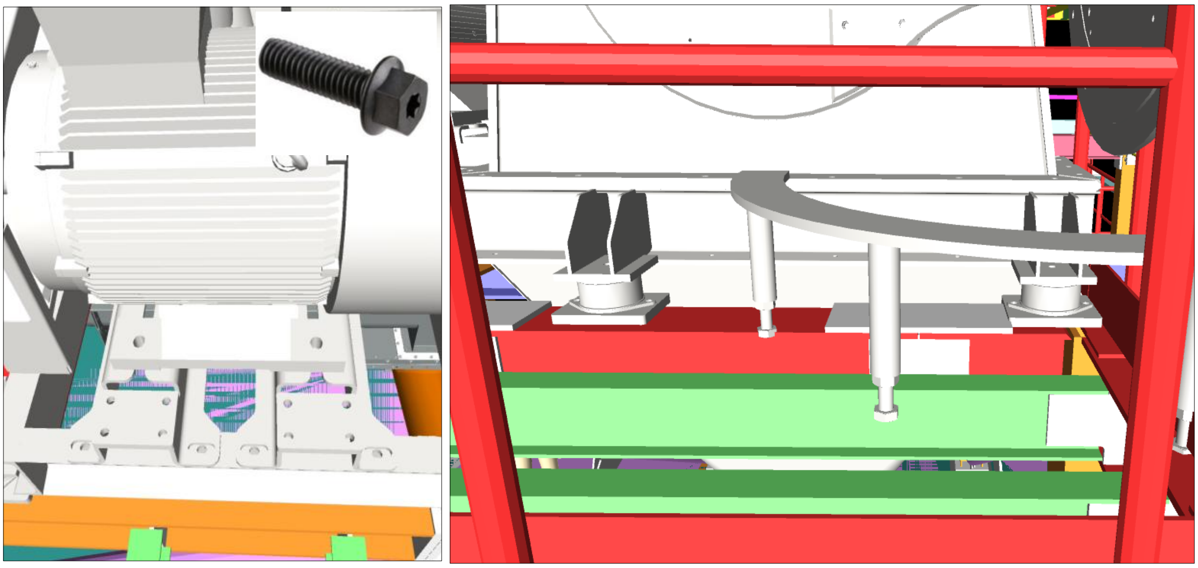

Fig. 7. Fiber Bolts, Slotted Holes and Isolators for Equipment (Navisworks, 2022)

4. Conclusions

According to the results obtained from this study, the conclusions are summarized below:

- Steel structure systems are ideal for high-rise industrial structures. Thanks to its advantages such as lightness, high carrying capacity, fast assembly and large openings, steel is one of the most suitable material options for industrial buildings.
- Heavy and bulky equipment directly affects structural load distribution. Therefore, architectural planning and static calculations should be integrated according to the location and operating principles of the equipment. It is very important to dampen machines that cause high vibration in structures with various methods.
- Engineering methods such as finite element analysis, modal analysis and earthquake calculations, where all possible non-structural elements (tanks, silos, piping, etc.) are integrated, allowing the durability of the structure to be modeled correctly.
- Increasing the fire resistance of steel structures is possible with fire-resistant paint, composite flooring systems and appropriate evacuation plans. At the same time, protection against corrosion is also necessary for long life.
- Solutions such as energy efficiency, natural lighting, grounding, and lightning rod use both reduce operating costs and have an environmental impact. The use of recyclable steel is also an important factor in this context.
- The design process should be carried out with a multidisciplinary approach. Architecture, civil engineering, mechanical-electrical system design and production processes should be considered as a whole, and all stakeholders should be integrated into the project process. The use of BIM in design is of vital importance

Nonlinear static pushover analysis for evaluating steel rack systems' seismically optimal down-aisle configuration

Fuad M. AL-gaadi *[1], Fatih Alemdar[1]

[1] *Yildiz Technical University, Department of Civil Engineering, 34220 Istanbul, Türkiye*

Abstract. Bracing in the down-aisle direction of rack systems is restricted due to operating requirements. Additionally. Single-symmetry-axis thin-walled members are generally used in rack systems. As a result, the structure may experience eccentric situations that might negatively impact system stability. As well as these members are particularly subjected to local and torsional buckling due to lateral loadings and gravitational forces. The most widely used methods for assessing the seismic response of any structural system are nonlinear time history analysis (NTHA) and nonlinear static pushover analysis (NSPA). Despite being the most accurate method for predicting seismic demand and assessing performance, NTHA is computationally demanding and requires selecting and using a relevant set of ground excitations. This paper presents a straightforward method for conducting nonlinear static pushover analyses of standard pallet racking structures under progressively increasing lateral forces. It aims to identify the most effective configuration in the down-aisle direction based on their seismic behavior and energy dissipation capacity. Using Ansys Workbench software, finite element models of four three-story full-scale rack systems with different bracing conditions in the down-aisle direction are developed and evaluated under monotonic lateral loading. In this context, it was found that the system's bracings offer it stiffness; nevertheless, in single-modular racking systems, such as the one we investigated, the external bracings result in torsional effects. As a result, the bracing's positive benefits cannot be utilized fully. Results show that bracing members may be employed to improve the rack systems' behavior in the down-aisle direction.

1. Introduction:

Steel storage rack systems are important for the business since they store industrial goods. Rack structures are in high demand because they can store a lot of merchandise with minimal space over multiple levels in a small area. Typically, cold-formed thin-walled members are utilized in the design of standard storage rack systems. Beams have boxed cross sections, whereas uprights have open, thin-walled sections perforated for attaching beam end connector hooks that connect the upright and beam components without bolts or welds (Fig.1). Because most storage racking sections have a single symmetrical axis, different buckling conditions may occur across connections, sections, or the rack system.

Perforated uprights are affected by local deformation events, including multiple buckling modes (local, distortional, and global) and their interactions, which cause various failure modes in storage rack systems due to differences in the directional stiffness and section characteristics of thin-walled structural (Castiglioni, 2016). Storage racking system design becomes difficult. Inadequate storage rack system design, installation, loading, or maintenance can cause them to overturn or collapse during earthquakes, causing economic losses in damaged goods and worker safety risks.

Standard rack systems can be classified into braced and unbraced frames. In rack systems, the longitudinal direction is referred to as the down-aisle direction, and the transverse direction is the cross-aisle direction. The braced system includes bracings in both the cross-aisle and down-aisle directions. Unbraced rack frames contain bracing only in the cross-aisle direction, keeping the down-aisle unbraced. In general, diagonal bracing distributes lateral forces over the cross-aisle direction. However, due to operating considerations, the system's utilization of bracing is restricted in the down-aisle direction, and the bending stiffness of the adjustable beam-upright column connectors and base connections provides rack stability in this direction.

The Rack Manufacturers Institute's specification (RMI, 2012) works as a design guideline in the United States and certain other countries. As a result, pallet rack analysis and design are extremely complicated. Nonlinear

history analysis (NTHA) is the most effective technique for evaluating seismic structural performance. Nevertheless, this method necessitates the application of an acceptable set of ground motions, as well as an adequate computational tool that conducts the analysis, to provide ready-to-use results within the time restrictions of design companies. Experienced practicing designers prefer the nonlinear static pushover analysis (NSPA), which requires less computational time as an alternative method to time history analysis (NTHA).

Recently, damage and collapse of storage racks caused by earthquakes in regions subject to earthquakes have been investigated by (Bernuzzi & Castiglioni, 2001; Connor, 2012.; Firouzianhaij et al., 2021; Krawinkler et al., 1979). On the other hand, storage racks were excluded from regular design specifications because they were classified as movable equipment. However, in response to earthquake damage, a few countries have offered specifications for storage racks, which include structural component testing by user needs (Fema460, 2005.; Steel Storage Racking, 2012).

Regarding rack system rigidity in the down-aisle direction, beam-to-upright connections and upright thickness are extremely effective (Dai et al., 2018; Galeotti et al., 2021; Gilbert & Rasmussen, 2010). Many studies in the literature evaluate the semi-rigid behavior of the upright-beam connector within the system (Bajoria & Talikoti, 2006). Yin et al. (2016) investigated five distinct beam connectors, including lock fasteners and bolted connections, under both monotonic and cyclical loads. The test findings indicated that bolted connections demonstrate nearly double the load-carrying and energy dissipation capacities compared to locking fastener connections. Prabha et al. (2010) conducted cantilever experiments on 18 samples to figure out the ultimate capacity of hooking connectors, considering upright thickness, number of hooks, and beam height as parameters. Researchers have developed many testing methods to achieve results that more accurately represent actual rack system implementations. Nevertheless, due to the high expenses associated with testing, optimization may be implemented in rack systems through verified numerical studies (Bové et al., 2021; Chulin Chen et al., 2019; Vujanac et al., 2020).

Huang et al. (2021) investigated experimentally how base plate connection thickness, upright thickness, and eccentric anchor bolt conditions affected the flexural behavior of base plate upright connections. The initial stiffness, which was significantly affected by the base plate-upright connection, was found to predict the whole system's behaviour.

Gilbert & Rasmussen (2011) investigated base plate stiffness under various axial loads utilizing a dual-actuator test setup. They figured out that base plate configurations have a significant influence on the total buckling strength and the down-aisle direction lateral resistance of the storage racks.

Avgerinou et al. (2019) conducted pushover testing on rack systems. The test results recommended the use of plane bracings to ensure diaphragm behavior. Furthermore, based on their analytical results, using higher rotational stiffness base plates has been suggested as one of the best techniques for improving rack system capacity. The test results additionally showed distortional buckling developments in the uprights.

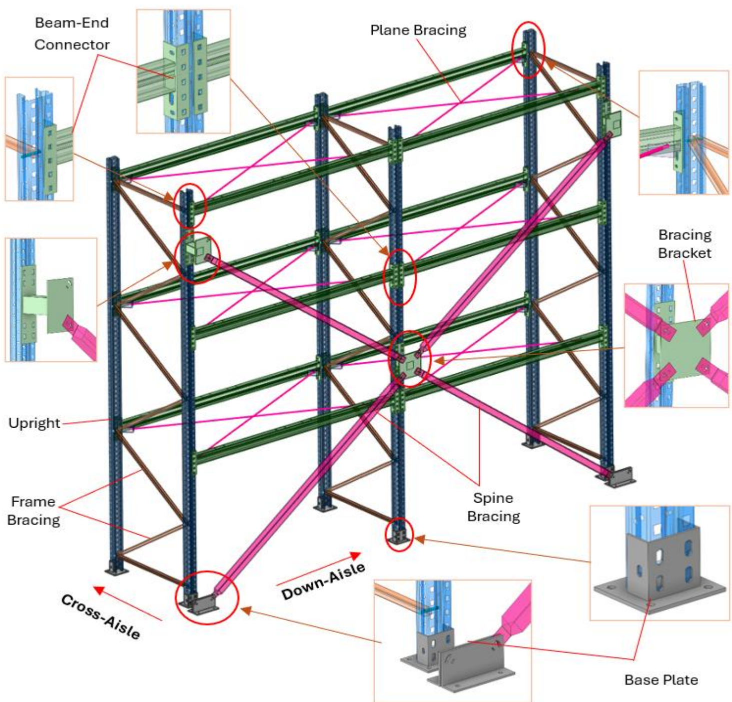

Fig. 1. Components of typical storage rack systems

Kanyilmaz et al. (2016) performed pushover tests on full-scale storage racks to evaluate the key factors affecting the responses and failure modes of different configurations of storage rack systems. In the case of a single bolt that was utilized under different baseplate connection applications, the plasticity variation was extremely limited, with more than half of the drift concentrated on the first level.

Gusella et al. (2022) investigated the failure mode and stiffness of the brace-column connection using joint models. They recommend that experiments using dynamic external forces need to be performed to comprehend the dynamic responses of storage racks. They will also be expected to upgrade the design by considering dynamic external forces, including seismic events.

Petrone et al. (2016) conducted quasi-static tests on the cross-aisle for multiple rack systems to evaluate the seismic performance of these structures after anchoring one side of the storage rack baseplate to the ground using two bolts. The results indicated that the cross-aisle direction is more vulnerable to overturning than the down-aisle direction, and lateral displacement could cause a collapse. The tests showed that the inelastic deformation of the baseplate resulted in stable hysteresis responses due to substantial ductility and energy dissipation.

Andrea et al. (2016) conducted pushover tests on full-scale rack systems, employing different external bracing components that improved system stiffness in the down-aisle direction. The collapse mechanisms for the tension rod prototypes were identified. In their study, they utilized system behavior parameters for estimating the efficiency of the various stability braces and the connection specifications associated with these braces to improve the system's stiffness.

Heo et al. (2023) conducted full-scale shaking table tests to investigate how the base plate-to-ground fixing situations affected the seismic behavior of the rack systems. The experiments were carried out under four different base-to-ground fixing configurations: one bolt, two bolts, four bolts, and fixed conditions. The results demonstrate that a pallet rack with moderate resistance to external forces may resist displacement if it is tightly connected to the ground. According to the results, the damage was severe under the 1-bolt condition, repairable under the 2-bolt and fixing conditions, and fatal under the 4-bolt condition due to cumulative displacement due by permanent external force.

Çelik et al. (2022) evaluated the influence of base-plate types on the down-aisle direction seismic behavior of storage rack systems using pushover testing. The findings indicated that an increase in the rotational stiffness of the base support decreases torsional impacts. Consequently, it can be suggested that in low-rise rack systems, employing high-value stiffness base plates could improve system stability and offer more economical solutions.

Racking designers typically eliminate bracing in the down-aisle direction so that during service, the racks can be accessible from each side of two aisles and goods can be loaded and unloaded easily. However, in active seismic areas, this design can sometimes not be enough for carrying large horizontal loads due to the insufficient lateral stiffness and strength, which is related to the significant second-order effects (Orlando et al., 2017) and the weak rigidity and gaps of the base and beam-to-upright connections (Bonada et al., 2021). As a result, vertical spine braces are commonly used to mitigate the down-aisle's instinctively weak lateral stability; nevertheless, this bracing system is required to be located just at the back, resulting in undesirable global torsional conditions. The literature shows that diagonal bracings in the cross-aisle direction can increase displacement stiffness in rack systems. Down-aisle stability improvement is limited because the system is meant to meet operational goals. This led to applications using tension rods and vertical spine braces. Even while vertical spine bracings provide effective rigidity in back-to-back rack systems, they result in torsional effects. These torsional effects impact the system's collapse mechanism and energy dissipation capacity. Therefore, the safety design of these systems requires investigating methodologies to avoid connection and section torsional behavior.

In this research study, nonlinear static pushover analysis was performed on different configurations of the rack systems to investigate the behaviour of the rack systems in the down-aisle direction under lateral loads. Stability components, such as tension rods and spine vertical bracing systems, were used in the down-aisle direction to increase the stability of such systems in this direction. The FE numerical models were simulated and analyzed using the finite element analysis software ANSYS Workbench. In the finite element analysis, the effect of using the stability components and the base plate to ground fixing conditions on the rack systems' failure mechanisms, energy dissipation, and torsional capacity has been investigated. In addition, in the literature, the perforations on assembling parts of the rack systems are typically neglected in most numerical evaluations. Nevertheless, perforations in the members compound the rack systems and might considerably decrease the critical buckling load of the uprights, based on the local deformations. In this study, the numerical analysis has sufficiently captured all details of the system, including perforations and tabs, to investigate the seismic behavior of the system.

2. Materials and methods:

2.1. Details of the storage rack frame:

This study aims to investigate the global seismic response behavior of down-aisle pallet rack systems. For this purpose, three full-scale rack model systems were designed with different configurations in the down-aisle direction: RK1, RK2, and RK3. RK1 is the configuration that has no vertical or plane bracings, as shown in Fig.4.

To figure out the effects of the bracings that were designed and used in the down-aisle direction on the lateral structural behaviour of the rack system, this model has been selected as the basis for the reference system. The RK2 rack configuration is an upgraded model of the RK1 rack system that is enhanced with plane bracings and a tension rod system, which are commonly used in the down-aisle direction of the rack systems. Console brackets are used in this system as connections for tension rod braces to the rack system. The RK3 rack configuration is a strengthened model of the RK1 rack model in the down-aisle direction that has plane bracings on each level and vertical spine bracings. The RK3 rack system's spine brace sections are much larger than the RK2 rack system's tension rods. In contrast to the tension rod bracing system in RK2, the spine bracing system in RK3 is connected to the rack system and the ground by brace connection plates so that it works as a rigid structure in the down-aisle direction.

In the configurations of braced rack systems, braces are employed just on one side in the down-aisle direction to meet the operational requirements of the rack systems. Consequently, horizontal bracings are employed for connecting upright columns, increasing the distribution of seismic forces from the unbraced vertical plane of the column to the braced vertical plane. Torsional phenomena resulting from global irregularity are effectively minimized. The rack models' geometrical details were chosen based on popular market rack configurations. They match practical applications of conditions concerning weight, unit load specifications, and beam levels. Therefore, all the designed rack models consist of three levels with two spans. The rack's total height is 4300 mm, and the beam length is 2400 mm. The upright section, D-type diagonal braces, and horizontal braces remain constant in all rack models in the cross-aisle direction (Fig. 2).

This study analyzed three different fixing conditions (Table 1) to investigate the impact of base plate-to-ground fixing conditions on the behavior of rack systems in the down-aisle direction: Case 1 (2 bolts), Case 2 (4 bolts), and Case 3 (fixed), as shown in Fig. 5. A nonlinear static pushover FE analysis was performed and evaluated for the three different configurations under lateral loads. The base plate has been connected to the ground using M8.8 bolts.

Fig.3 illustrates details of the upright, beam and brace sections. The beam sections consist of two interconnecting C-lipped channel profiles with dimensions of 100x50x1.5 mm. They have been continuously spot-welded across the beam direction. The uprights are open U-sections with dimensions of 100x70x2 mm. For the diagonal brace in the cross-aisle direction and the spine braces in the down-aisle directions, C 28x28x1.5 mm and SHS 60X60X3 mm profiles were used, respectively.

2.2. Materials:

To take into account the nonlinear effects of the materials in numerical analysis, the material mechanical properties of the rack sections are presented by (Çelik et al., 2022) were considered as input in the FE analysis. The material properties were determined through three coupon tests conducted on plates used in all the profiles of the rack system. The stress-strain graph for the numerical models is obtained using the average values of the tested coupons. The stress-strain relationship of the materials is shown in Fig. 6.

2.3. FE modeling and mesh

Finite element analyses should take geometrical nonlinearities into account for reliable results. The utilization of shell and solid parts additionally contributed to the study to more accurately capture the buckling conditions. Because of their thin wall thickness, the members that comprise diagonal bracing, the beam, upright, X bracing,

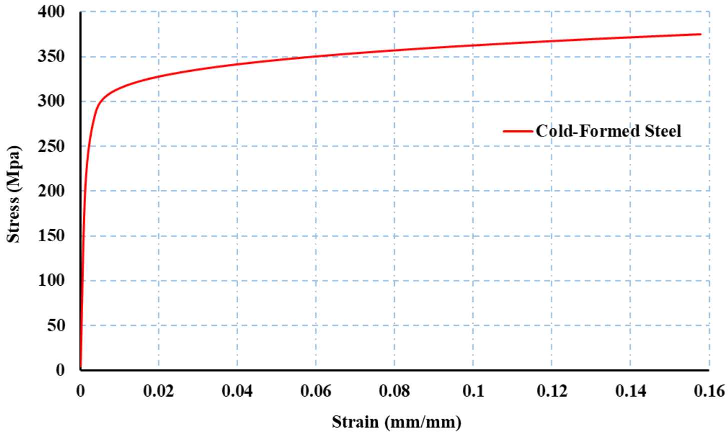

Fig. 6. Stress-strain relationship of the cold-formed steel used in FE analysis (Çelik et al., 2022)

tension rod, upright frame, plane bracing, and connection elements were represented in the numerical models using the Shell 181 element. Shell 181 is the appropriate shell element type for analyzing thin and medium-thick shells structures. It consists of four nodes, each with six degrees of freedom; movements and rotational motions along the X, Y, and Z axes may be taken into account. Pins are employed to connect the uprights to the diagonal bracing and horizontal brace members. A solid 187 elements were utilized to simulate them in the numerical models. The solid 187 elements have the potential for strain hardening, plasticity, and large deflections.

In reality, x-bracing, base plates, tension rods, bracket members, and plane bracing are all bolted together in rack systems. Since the model is very big, the bolts were not simulated in the mathematical models of the rack systems. The beam188 element was utilized to represent the bolts in the numerical models. Linear solutions with large rotations or nonlinear solutions with large strains are appropriate matches for this element. Table 2 shows the details of the elements used for finite element analysis

The elements that compose the upright frames of rack systems are connected by pins. Therefore, the upright frame's vertical, horizontal, and diagonal bracing elements were represented as edge-to-face bonded to a pin. In rack systems, the ends of the beams are joined by welding to the beam-connecting elements. Edge-to-face contact was employed as a bonded interaction between the beam and the beam connection in the numerical models to reflect this condition. The bottom edges of the upright and the base plate surface are connected by edge-to-face contact as a no-separation interaction to represent accurately the upright-base plate connection in the numerical models. Additionally, the uprights are connected to the base plate at their backs using bolts. In the numerical models, the edges of the base plate holes were defined as Ux = Uy = Uz = 0, and the surfaces of the base plates in contact with the ground were defined as Uz = 0.

In the finite element analysis of large rack systems, upright perforations are typically neglected when utilizing shell elements. This study utilizes local meshing at areas of geometric changes, bolt holes, and perforation holes. Furthermore, a convergence evaluation was conducted in all finite element models, finding the appropriate global mesh size of 35 mm. For the RK1, RK2, and RK3 models, the element counts/node counts are 660759/616227, 654013/706529, and 800811/857929, respectively.

Table 2. Details of the elements used for finite element analysis

Part	Element	Description
Upright section, Beam section, Down-aisle bracing	Shell 181	4-noded shell element with six degrees of freedom at each node: translations and rotations in the x, y, and z directions.
Bolts	Beam188	Linear, quadratic, or cubic two-noded solid element with six or seven degrees of freedom at each node: translations and rotations in the x, y, and z directions.
Base plate and Pin	SOLID187	10-noded quadratic solid element with three degrees of freedom at each node: translations in the nodal x, y, and z directions.

2.4. Loading and boundary conditions

A two-step analysis has been developed for the loading conditions in the ANSYS Workbench application. At first, point masses representing the pallets were applied to the beam, as shown in Fig. 4. Point masses were applied as a single point mass on each of the four surfaces on the beam. The finite element analysis neglected the movement of pallets on the beams. At first, considering gravitational force, rack systems were exposed to a vertical load of 72 kN. After that, in the second step of the analysis, lateral loading of the system was applied as shown in Fig. 4 (F force for the first floor level, 2F force for the second floor level, and 3F force for the third floor level). The system has been pushed to its maximum displacement limit, approaching the failure condition. To evaluate their characteristics, such as stiffness, Q-factor, and ductility, the investigated systems were subjected to displacement values exceeding code limitations.

3. Results and discussion:

Thin-walled, cold-formed steel profiles were utilized to design all the considered storage rack systems. The results of the finite element analysis revealed that local deformations in the system's structural components had a significant impact on its performance and capacity. The failure mechanism of the carrier system and its ability to absorb energy are significantly impacted by plastic deformations, particularly at the upright-beam connections, uprights and base plates, and stability and bracket members. In this research, the load-displacement graph was employed to figure out the system's energy dissipation capacity.

Due to the absence of vertical stabilization components in the down-aisle direction within the first specimen, RK1, no torsional impacts have been observed in the pushing direction (Fig.7). Nevertheless, the RK2 and RK3 rack specimens have been enhanced with vertical stability bracings throughout one axis. This situation has induced torsional effects in the whole system and, subsequently, in the uprights as well. Furthermore, the bracket-type assembly of the stability elements led to torsional elastic and post-elastic deformations in these bracket elements. Many researchers used analytical tools to investigate behavioral characteristics. However, the pallet rack has model arrangement challenges, such as the column-beam connection gap, the member connection system utilizing bolts, and the distance between bolts and holes. As a result, it is difficult to determine the specific behavioral characteristics of storage racks using analytical investigations. In this study, to investigate the actual behavioral characteristics of the pallet rack under different baseplate connection conditions, an FE analysis was carried out under the same parameters mentioned in Table 1. The perforations in the uprights and tabs in the traverse-upright connection, material definition, stability bracing system connections, bolts, and pins utilized in base plates, and the diagonals have been simulated to reflect their actual behavior in the created FE numerical models.

The results of Von Misess stress distributions from the finite element model investigation are illustrated in Fig. 7 to 9. In the RK1 model without any bracing in the down-aisle direction, significant stresses are observed at the connections between the beam and the upright, the base plate, and the pushing region in the upright. the base plate and the ground significantly affected the results in comparison to case 1, which used a two-bolt arrangement. The upright sections cannot rotate freely, resulting in increased stress at the base support and the midpoint of the first floor in the RK2 and RK3 configurations.

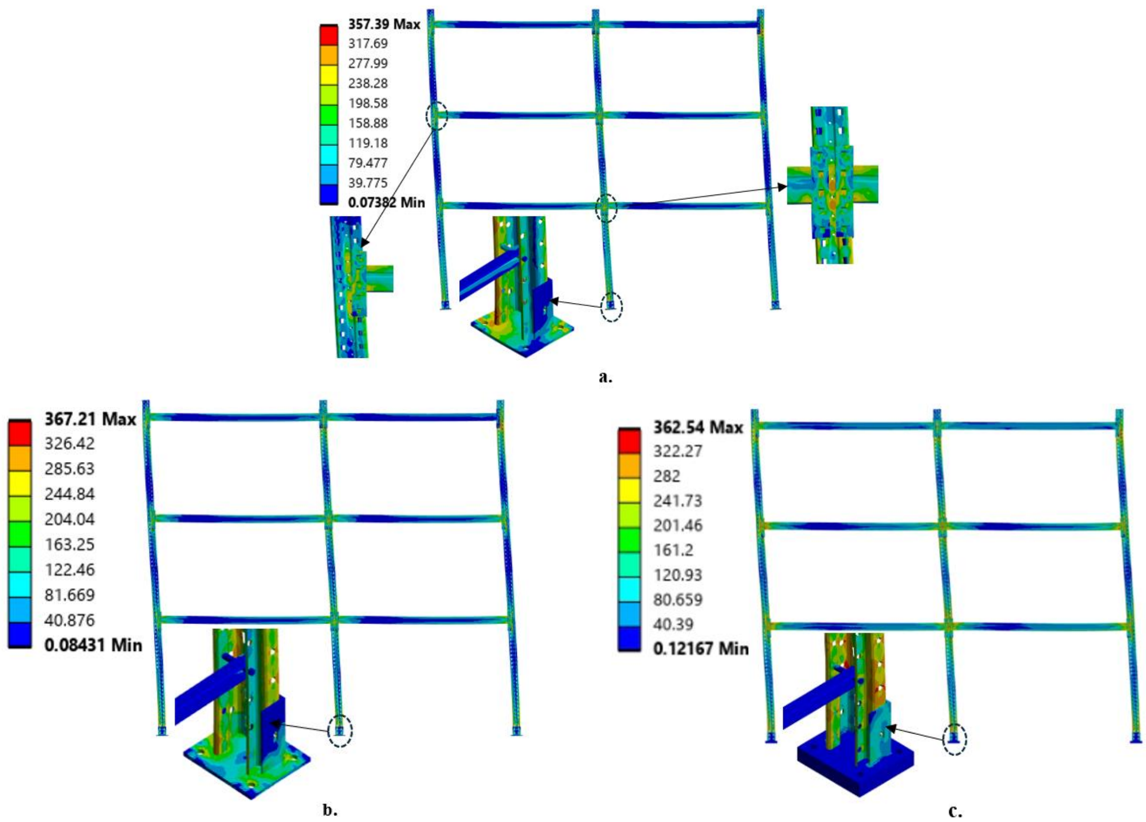

Fig.7. Stress distributions of the numerical models created for: a. RK1.1, b. RK1.2 c. RK1.3

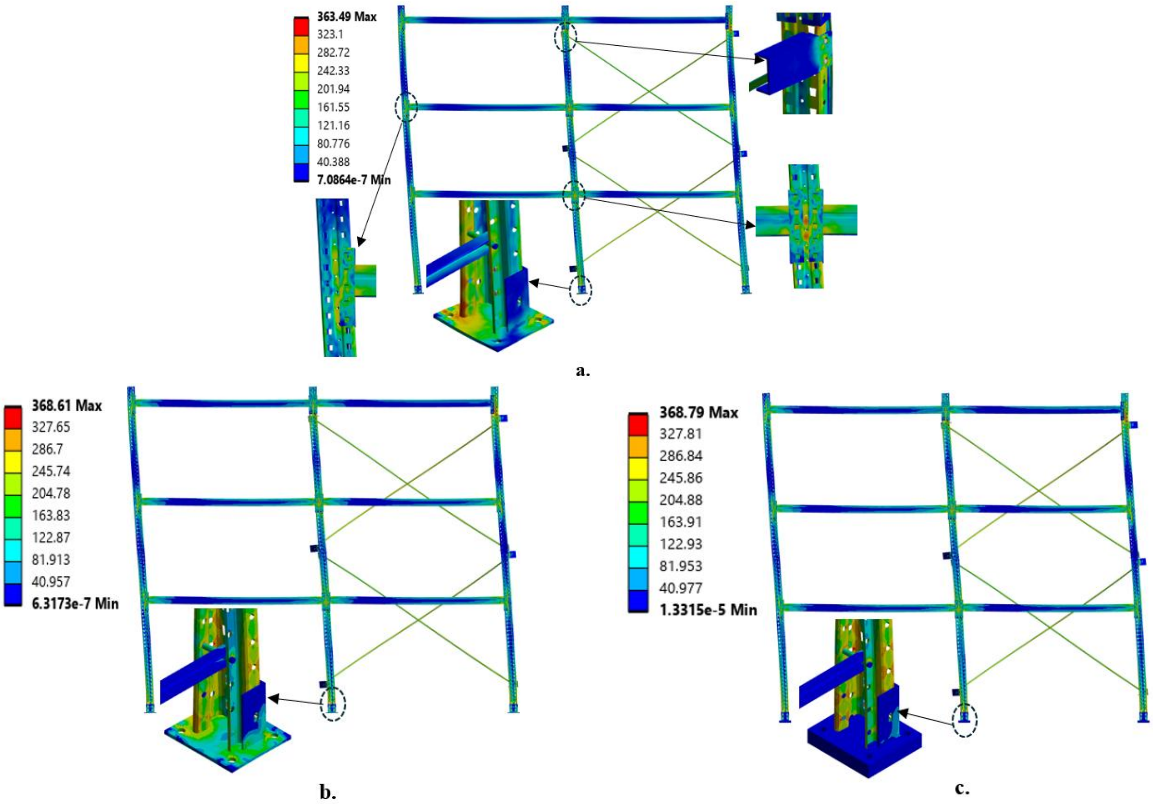

Fig.8. Stress distributions of the numerical models created for: a. RK2.1 b. RK2.2 and c. RK2.3

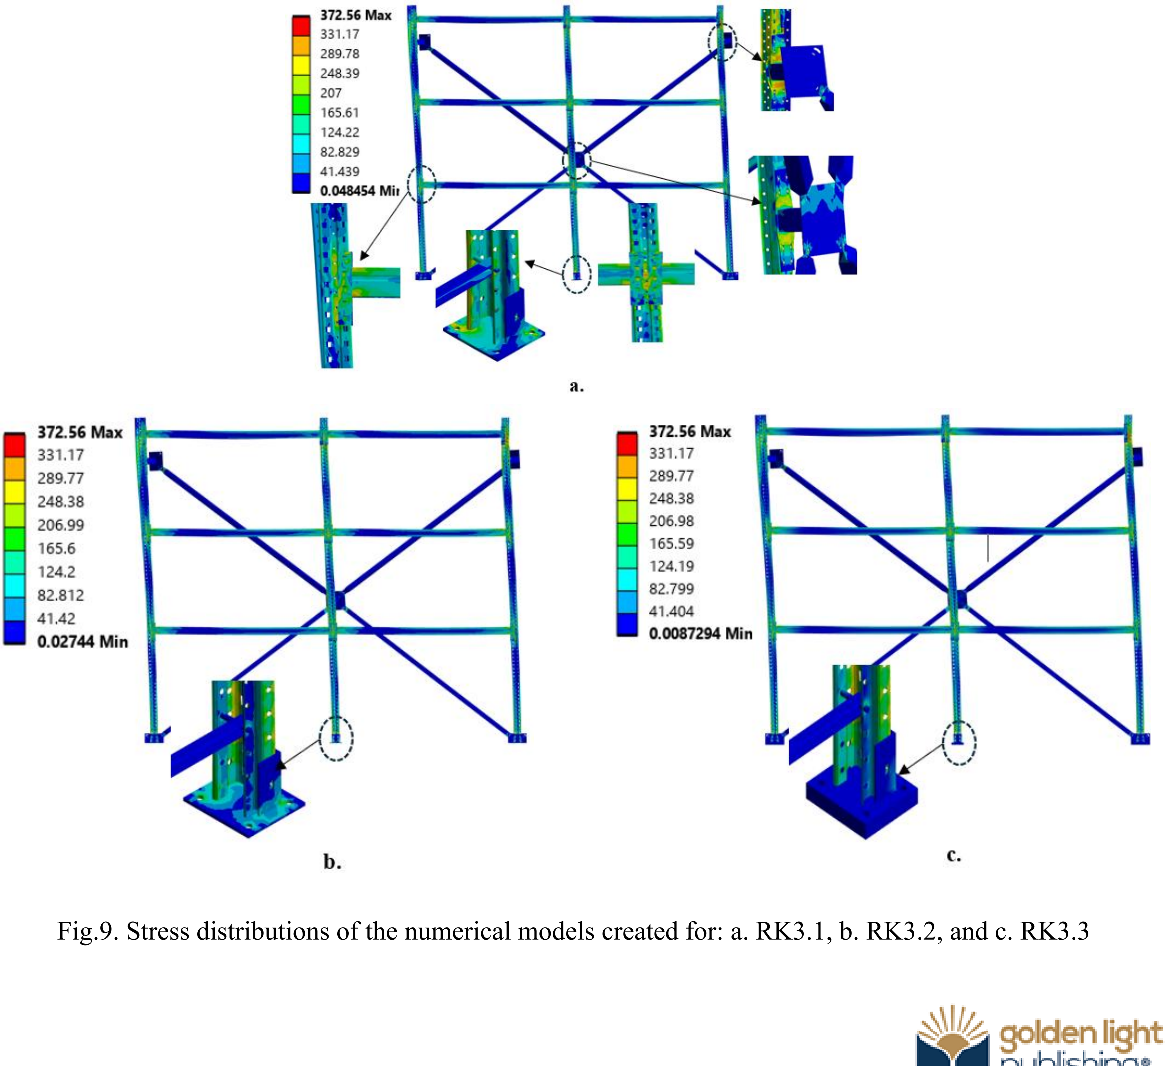

Fig.9. Stress distributions of the numerical models created for: a. RK3.1, b. RK3.2, and c. RK3.3

The RK1 model demonstrates that the beam connector at the first-floor upright-beam connection has exhibited plastic deformation. The evaluation of Von Mises stresses revealed that modifying the fixing conditions between the base plate and the ground significantly affected the results in comparison to case 1, which used a two-bolt arrangement. The upright sections cannot rotate freely, resulting in increased stress at the base support and the midpoint of the first floor in the RK2 and RK3 configurations. Fig. 9 illustrates the deformation of the exterior and planar bracings. The deformation results of the plane bracings' connection components indicate that they effectively mitigate torsional effects.

The analysis of the RK2 model demonstrated plastic deformations in the mid-axis beam-upright connector, the tension rod-to-upright component connection, and the upright component. Other numerical models that have different base plate fixation conditions exhibit stress situations similar to the RK2 model, except in the support regions (Fig. 8). The upright connecting element experienced considerable deformation due to the tension rod component, whose stress type depends on the direction of the push. Furthermore, the upright element developed distortional buckling. The RK2 model exhibited lower displacement stiffness compared to the RK3 model as a result of the tension rod stabilizing bracing. The stability bracing is additionally connected to the side of the upright. This situation resulted mainly in the rotation and buckling of the upright side surface.

Fig. 9 illustrates the deformation of the console members that connect the stability components and the system during the application of load from the RK3 models. As shown in the figure, local buckling was observed at the ends of the X bracing and the upright connecting brackets. This connection works effectively in back-to-back systems due to its central position. In the rack systems investigated in this paper, torsional effects from the upright to the bracing result in torsion-induced buckling and plastic deformations in the connecting plate. RK1 and RK2 were displaced by 200 mm in the displacement-controlled analysis. Nonetheless, local buckling at the X-brace endpoints and upright connection components of the RK3 model affected the results from the finite element study. The connected uprights experience flexural-torsional buckling in specific regions. This situation resulted in the RK3 sample's early failure compared to other models. Consequently, the finite element analysis pushed the RK3 sample to 160 mm. This situation is also reflected in the RK3 model analysis (Fig. 9).

The capacity curves were drawn using the lateral displacement and the base shear force values. Fig.10 presents the capacity curves calculated from the static pushover analysis of all numerical models in a comparative form. The system's stiffness and load-carrying capability are significantly improved when employing a fixed base plate in the ground condition (case 3) compared to the two-bolted or four-bolted arrangements (cases 1 and 2), as shown in Fig.10. This increase was noted in the RK1 system. The capacity curves in Fig. 10 are used for calculating the base shear force values and energy dissipation capacities for the numerical models illustrated in Fig. 12. Consequently, the system's response to the fixing conditions between the base plate and the ground can potentially be evaluated. Fig. 10 illustrates the maximum base shear force and the increase in base shear force of the numerical models.

The RK1 non-braced model exhibits the greatest increases in carrying capacity as a result of the base plate change, as illustrated in Fig. 12a. The condition of a four-bolted base plate with a thickness of 7 mm (case 2) resulted in a 21% increase in carrying capacity in the RK1 model. The fixed 30 mm base plate thickness condition (case 3) resulted in a 79% increase in carrying capacity.

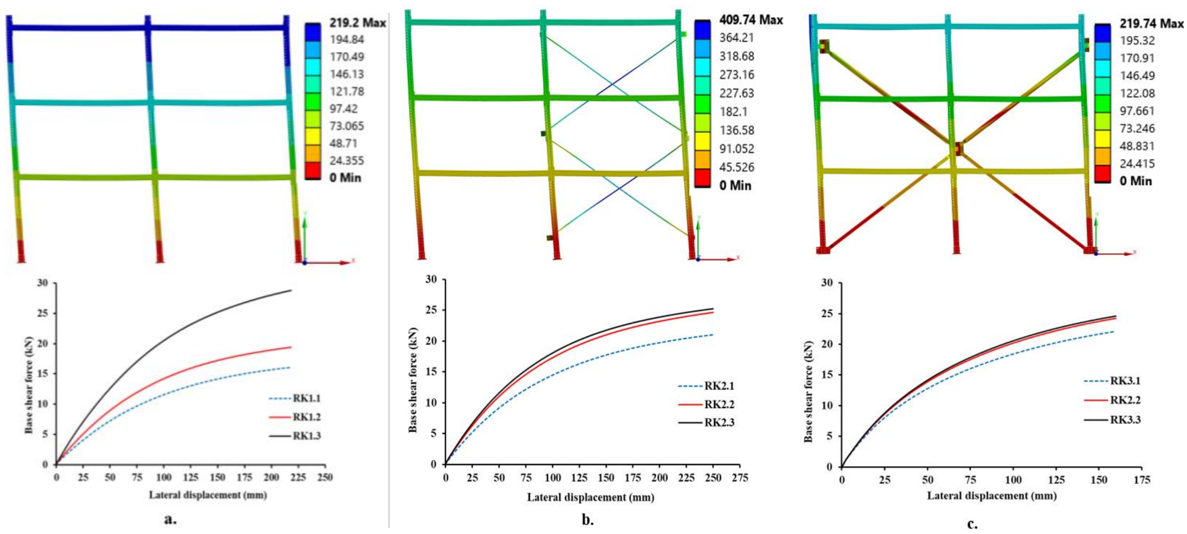

Fig. 10. Comparison of capacity curves of numerical models for: a. RK1, b. RK2, c. RK3

The carrying capacity of the RK2 tension rod model increased by 17.42% when the four-bolted base plate with a thickness of 7 mm (case 2) was used. The fixed 30 mm base plate thickness condition (case 3) resulted in a 20.3% increase in carrying capacity. The condition of a four-bolted base plate with a thickness of 7 mm (case 2) achieved a 9.5% increase in carrying capacity in the RK3 X-bracing model. The carrying capacity increased by 11.2% under the fixed condition of a 30 mm base plate thickness (case 3). Using the two-bolted base plate (case 1) increased the carrying capacity of RK2 and RK3 by 31% and 38%, respectively, in comparison to RK1. On the other hand, when compared to the nonbraced model (RK1), it is demonstrated that the base plate-related changes can be less effective in the models that are employed for the extra stability components (RK2 and RK3). In comparison to the base support fixing conditions, the stability component's response to the displacement develops quicker and is more efficient, which is the primary cause of this issue.

It was found from the research that had been published in the academic literature that capacity curves may be plotted by making use of the global yield shear force and the displacement values that are associated with it. As a result, it is possible to obtain essential information describing the behavior of the rack system, examples of which include system stiffness and ductility. An investigation into the benefits that are associated with base support conditions was carried out in the present study, which focused on brittle failure mechanisms that are generated by torsional effects under different stability conditions.

In this particular development, (Kanyilmaz et al., 2016) implemented the procedure that is described as follows: after obtaining the origin of the F-d curve, the equation E = tgαy is determined.

- Following this, the tangent, which corresponds to one-tenth of the E value, is adjusted so that it intersects both the Fu and du values.
- Both the vertical value, denoted by Vy, and the horizontal value, denoted by dy, are associated with the intersection of these two tangents. System stiffness was obtained using Eq. (1)

$$k = \frac{V_y}{d_y} \tag{1}$$

Where: Vy is the global yield shear force, dy is the yield displacement, E is the elasticity modulus, and dy is the displacement value corresponding to the global yield shear force (Fig. 11).

In terms of operation, the values of the behavior factor q essentially describe the equilibrium that occurs between resistance and the capacity to dissipate energy. The over-strength and the ductility ratio are the two factors that are used to calculate the q-factor. The following equations explain how this value is calculated:

$$\Omega = \frac{V_u}{V_y} \tag{2}$$

$$\mu = \frac{d_u}{d^{'}} \tag{3}$$

$$q = \mu.\Omega \tag{4}$$

Where μ is the ductility ratio,Ω is the over-strength factor, Vy is the global yield base shear, Vu is the ultimate load before collapse, du is the displacement associated with Vu, and d' is the displacement associated with the intersection between the tangent slope and Vu. Table 3 displays the values of the results obtained from the models that were investigated in this study.

Table 3 displays a significant impact of the base plates on the ground fixing conditions used in this study concerning system displacement stiffness and the energy dissipation capacity. The effect for the RK1, RK2, and RK3 models varies between 123–174%, 119–131%, and 102–104%, respectively. The number of bolts and the configuration of the base fixing plate substantially affect the displacement stiffness of the system. This effect is noticeable in models without bracing in the down-aisle direction compared to those that include bracing.

4. Conclusions

This study investigated the seismic response characteristics of a pallet rack subjected to an external force based on different baseplate fixing conditions via nonlinear static pushover analysis. To determine and evaluate the displacement response resulting from external forces, three different configurations in the down-aisle direction of popular pallet rack systems were analyzed using ANSYS Workbench software under varying baseplate connection fixing conditions. The following are the results and conclusions of this study:

- In the numerical analysis, it was found that the system stiffness increased in case 2 and case 3 base plates in comparison to the base plate used in case 1. The percentage increases were as follows: 123% and 174% for RK1, 119% and 131% for RK2, and 102% and 104% for RK3 (Fig. 12.a).
- The stress concentrations on the uprights have been transferred from the base support region to the level of the floor as a result of the base plate fixing situation that has enhanced rotational stiffness. This has occurred in all three configurations. The fact that this situation occurs demonstrates that the base plates to the ground fixing conditions that were used have had a favorable effect on the upright rotational degrees.
- The results demonstrated that the base plate-fixing changes can be less effective in the models that are employed for braced models (RK2 and RK3) rather than the non-braced model (RK1).
- The FE results proved that the load-carrying capacity was significantly improved when employing a fixed base plate to the ground condition (case 3) compared to the two-bolted or four-bolted fixing conditions (cases 1 and 2) as shown in Fig.12b.
- The results indicated that the pallet rack, which lightly resists external force, is capable of withstanding displacement if it is securely fixed to the ground. Nevertheless, the significant displacement at the top may result in cargo falling. The collapse may occur as a result of the displacement caused by a significant external force due to the baseplate's insufficient resistance if it is bolted to the ground with two bolts for simplicity of installation.
- The results indicated that significant global torsional distortions occurred in the braced rack configurations, wherein the spine braces are only connected to the uprights on one side. These kinds of situations can be avoided by employing plane bracing systems that connect both the uprights and the spine bracing planes, thereby assuring effective load transmission between both of them.

Influence of infilled walls on the seismic vibration period of reinforced concrete structures with shear walls

Ali Koçak*[1], Houssein Aleit[2]

[1] Yıldız Technical University, Department of Civil Engineering, 34220 Istanbul, Türkiye
[2] Yıldız Technical University, Graduate School of Science and Engineering, 34220 Istanbul, Türkiye

Abstract. The fundamental vibration period of reinforced concrete structures is critical for assessing seismic performance. Infilled walls interact with structural frames and significantly influence this period by enhancing rigidity. However, traditional design approaches often simplify their contributions, leading to discrepancies in period estimations. This study investigates the effects of infilled walls on the vibration period of reinforced concrete structures with shear walls. The research evaluates their influence on structural dynamics by systematically varying wall parameters, such as thickness, material elasticity, and wall-to-floor ratios. Shear wall configurations are also analyzed to understand their interaction with infilled walls and their combined impact on rigidity. The study develops an original equation for estimating the vibration period, incorporating infill wall characteristics and shear wall configurations. Results demonstrate that wall elasticity, placement, and thickness are pivotal in determining the vibration period. The proposed equation offers a refined approach, improving the accuracy of seismic design and performance assessments for reinforced concrete systems. This research bridges the gap between empirical simplifications and real-world structural behavior, providing valuable insights for engineers aiming to optimize designs for enhanced seismic resilience.

Keywords: Natural period; Infilled walls; Reinforced concrete; Shear walls; Structural optimization

1. Introduction

The fundamental vibration period of a structure is one of the most influential parameters in seismic design, as it directly governs the magnitude and distribution of lateral forces during an earthquake. Accurate estimating this period is essential for ensuring compliance with seismic codes and evaluating new and existing buildings' structural performance and safety (Goel & Chopra, 1997).

Reinforced concrete (RC) buildings, particularly those with frame systems, often include non-structural Masonry-infilled walls that are primarily intended for the architectural enclosure. However, numerous experimental and analytical studies have demonstrated that these infill panels actively contribute to the lateral stiffness and strength of the structure, especially under seismic loading. Infilled walls reduce lateral deformations and can significantly alter the system's dynamic characteristics, notably by decreasing the fundamental vibration period.

Despite their structural influence, infill walls are often simplified or neglected in many seismic designs (Crowley& Pinho, 2004) codes. Most national and international building regulations estimate the fundamental period using empirical equations that rely on building height and structural type without explicitly accounting for the presence of infilled walls or their mechanical properties. Depending on the case, this simplification may lead to unsafe underestimations of seismic demands or over-conservatism in design.

Researchers have proposed refined methodologies and alternative empirical formulations to address this gap. For example, Goel and Chopra (1997) derived period-height relationships based on extensive observations of moment-resisting frames and shear wall-dominated buildings. Similar efforts by Hong and Hwang (2000) and Zarnic and Tomazevic (1998) emphasized the critical role of infill walls in modifying the natural period. Later studies by Panagiotakos and Fardis (1999) confirmed that variations in stiffness caused by infill placement and distribution could dramatically impact modal behavior.

Further investigations have explored the influence of infill material properties, thickness, and opening ratios. These parameters have been shown to affect stiffness, damping, and overall seismic performance (Koçak et al., 2018) demonstrated, through post-earthquake assessments, that neglecting the contribution of infill walls leads to substantial errors in dynamic analysis. More recent studies have also incorporated soil-structure interaction and

* Corresponding author, E-mail: akocak@yildiz.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_580

foundation flexibility to capture better the actual behavior of RC buildings under seismic excitation (Oliveira & Navarro, 2010).

The interaction becomes even more complex in buildings that combine RC frames with structural shear walls. While shear walls are intentionally designed to carry lateral loads, infill walls act as unintended yet influential stiffening elements. The interplay between these two components can either amplify or dampen dynamic responses, depending on their relative stiffness, distribution, and continuity stated by Koçak (2020).

This study aims to systematically investigate the impact of infilled walls on the fundamental vibration period of RC buildings with shear walls. Through comprehensive numerical modeling using SAP2000, various configurations of frame, infill, and shear wall systems are analyzed. Key parameters such as wall thickness, elastic modulus, and shear wall-to-floor area ratio are varied to quantify their individual and combined effects. The ultimate goal is to develop an enhanced empirical expression that accounts for the real stiffness contribution of infill walls in seismic design, thereby narrowing the gap between code-based estimates and actual dynamic behavior (SAP2000, 2024).

2. Methodology and building model

Four representative building models were developed to evaluate the influence of infilled walls on the dynamic behavior of reinforced concrete structures, comprising three, six, nine, and eleven storeys, respectively. All models were designed with uniform storey heights to maintain consistency in vertical geometry. However, the shear wall ratio—the total wall area relative to the floor area—was varied across the different models to capture its effect on lateral stiffness and vibration characteristics.

Fig. 1 illustrates the buildings' architectural layout and structural configuration. It presents a plan view of the sample structure. Table 1 summarizes the detailed geometrical properties of the beams, columns, and shear walls used in the models.

All simulations were conducted using C30-grade reinforced concrete, a commonly adopted material class in modern structural design. The underlying soil condition was modeled as Type Z2, following the classification the Turkish Seismic Code provided, representing medium-stiff soil typically encountered in urban development zones.

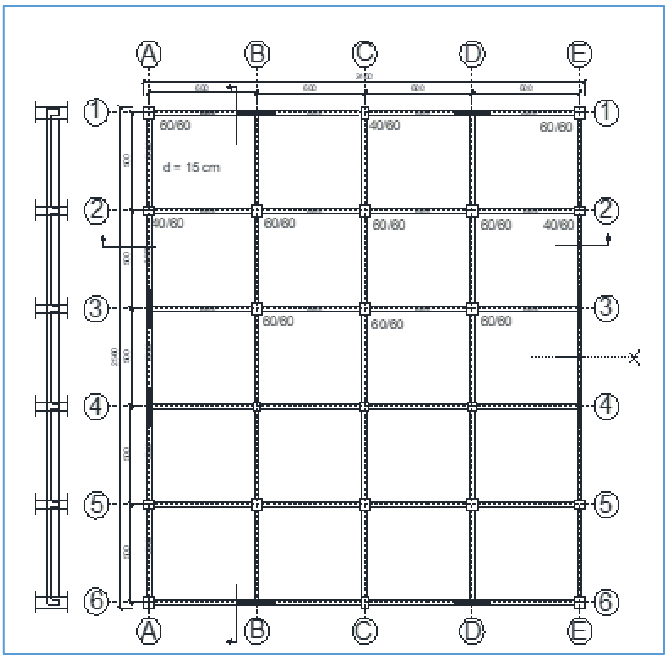

Fig. 1. Plan layout of the representative RC building model used in the analysis

Table 1. Geometrical characteristics of the structural components used in the model

Number of Storeys	Floors	Rectangular Columns (cm x cm)	Square Columns (cm x cm)	Beams
11 STOREY	1. 2. 3.	60 x 60	40 x 60	35 x 60
	4. 5. 6	55 x 55	40 x 55	35 x 55
	7. 8. 9.	50 x 50	40 x 50	35 x 50
	10. 11.	45 x 45	40 x 45	35 x 45
9 STOREY	1. 2. 3.	55 x 55	40 x 55	35 x 55
	4. 5. 6.	55 x 50	40 x 50	35 x 50
	7. 8. 9.	55 x 45	40 x 45	35 x 45
6 STOREY	1. 2.	55 x 55	40 x 55	35 x 55
	3. 4.	55 x 50	40 x 50	35 x 50
	5. 6.	55 x 45	40 x 45	35 x 45
3 STOREY	1. 2.	45 x 45	40 x 45	35 x 40
	3.	40 x 40	40 x 40	35 x 40

The analyses are conducted for the following three conditions: buildings without infill walls, those that contain infill walls for each frame, and buildings with various ratios of infill walls, i.e., percentage of frames with infill walls. For the condition that the infill walls are modeled as diagonal rods (Ersin et al., 1998; Güler et al., 2008), the values suggested by Koçak (2017) are used for the non-axial pressures of the walls manufactured from low endurance bricks. Modulus of elasticity parallel (E_{par}) and perpendicular to the hollow direction (E_{per}) along with their average value (E_{ave}) are listed in Table 2.

Equivalent elastic axial rigidity of the diagonals representing the walls can be represented by Eqn 1:

$$\frac{EA}{L_d} = Et\alpha\beta \tag{1}$$

where:
E: modulus of elasticity (MPa)
t: thickness (mm)
L_d: diagonal length of the wall (mm)
α: coefficient taking the rigidity ratio between the wall and reinforced concrete frame into account
β: coefficient taking the effect of the walls into account

Values provided by Koçak (2017) were used for the coefficients of α and β.

Table 2. Modulus of elasticity of infill walls

Modulus of elasticity (MPa)	E_{per}	E_{par}	E_{ave}
Non-Plastered	2500	4600	3550
Plastered	4200	7800	6000

2.1. Model configuration

Eight structural configurations were analyzed to assess the impact of infilled walls and varying shear wall dimensions on the fundamental vibration period. The first four models (Conditions #1 to #4) represent bare frame structures without infilled walls. In these models, shear walls were incrementally introduced and scaled in size—specifically, 25 cm × 175 cm, 25 cm × 200 cm, 25 cm × 250 cm, and 25 cm × 300 cm, respectively. These variations allowed for systematically examining how increasing shear wall dimensions influence structural stiffness without infill (Kocak et al., 2018).

The second set of configurations (Conditions #5 to #8) mirrored the same shear wall dimensions as the first group but incorporated infilled walls throughout the structural frames. This set, referred to as the "fully infilled" condition, enabled a comparative analysis to isolate and quantify the effect of infilled walls on the overall dynamic behavior of the system. Table 3 summarizes the shear wall dimensions and corresponding area ratios for each building height and configuration.

Table 3. Shear wall area-to-floor area ratios for different building heights

Shear Wall Dimensions (cm x cm)	11 Storey	9 Storey	6 Storey	3 Storey
25 x 175	0.20	0.22	0.22	0.29
25 x 200	0.22	0.25	0.25	0.32
25 x 250	0.26	0.29	0.29	0.37
25 x 300	0.29	0.33	0.33	0.41

3. Numerical evaluation and outcomes

In this study, a series of reinforced concrete frame models were developed to investigate the impact of shear wall dimensions and the presence of infill walls on the fundamental period of multi-story buildings (Koçak, 2013). The analyses were conducted using SAP2000 Version 26, and each building configuration was assessed under fully infilled and bare frame conditions (SAP2000, 2024).

For the first case, Conditions #1 through #4, infill walls were included beneath all frames.

In these configurations, the dimensions of the shear walls were varied incrementally across four levels:

- Condition #1: 25 cm × 175 cm
- Condition #2: 25 cm × 200 cm
- Condition #3: 25 cm × 250 cm
- Condition #4: 25 cm × 300 cm

The second case, represented by Conditions #5 through #8, involved identical structural configurations regarding shear wall dimensions but excluded all infill walls, modeling the buildings as bare frames. These cases ranged from 25 cm × 175 cm to 25 cm × 300 cm shear wall dimensions.

Each structural variant was analyzed at four building heights—3, 6, 9, and 11 stories—to assess how the interaction between shear wall ratio and vertical dimension influences the structure's dynamic behavior (Balkaya et al., 2002). The effect of increasing infill wall ratio on structural stiffness was captured by tracking the reduction in the fundamental period, and the results are presented in Table 3 and visualized in Figs. 2 to 5.

Following Koçak et al. (2013), window openings on external walls and door openings on internal walls were incorporated into the models to reflect realistic boundary and stiffness conditions. The observed reductions in fundamental periods ranged between 10% and 50% for fully infilled models compared to their bare frame counterparts.

An empirical relationship was developed based on the ratio of infill wall area to the total structural system area (sum of column and wall areas). This approach (Hong & Hwang, 2000) provides a rational correlation between infill wall density and structural dynamic response, highlighting the critical contribution of masonry infill in lateral stiffness and seismic performance.

3.1. Estimation of the fundamental period of buildings

The fundamental period of vibration is one of the most critical parameters in structural seismic design and dynamic analysis. Accurate estimating this parameter ensures a realistic prediction of seismic forces and dynamic response (Ozkul et al., 2019). Consequently, various international codes propose empirical formulas based on building height and structural system characteristics.

The Uniform Building Code (UBC, 1997) provides an empirical expression for estimating the fundamental (Goel & Chopra, 1997) period T_d of a building:

$$T_d = C_t (h_N)^{3/4} \tag{2}$$

where:
T_d is the fundamental period (seconds),
h_N is the height of the building measured from the base to the roof level (meters),
C_t is a coefficient that depends on the structural system, with typical values of:

- C_t= 0.0731 for reinforced concrete moment-resisting frames,
- C_t= 0.0488 for all other building types.

The Turkish Seismic Code (1998**)** also adopts a similar empirical form (TSC 1998):

$$T_d = C_t H^{3/4} \tag{3}$$

where:
H denotes the total building height (meters),
C_t values are assigned based on structural typology:

- C_t= 0.07 for reinforced concrete moment-resisting frames and steel eccentrically braced frames,
- C_t= 0.08 for steel frames,
- C_t= 0.05 for other building categories.

Despite the similarity in functional form (both using an exponent of 0.75), the different C_t coefficients lead to variations in the predicted periods between the UBC and Turkish seismic regulations.

Furthermore, Eurocode 8 (EN 1998-1) introduces an analogous formulation for the fundamental period (CEN, 2004):

$$T = C_t H^{3/4} \tag{4}$$

where:
T is the estimated fundamental period (seconds),
C_t is selected according to structural characteristics:

- C_t= 0.05 for reinforced concrete moment-resisting frames,
- C_t= 0.075 for wall-dominated reinforced concrete structures,
- C_t= 0.085 for steel moment-resisting frames.

Unlike UBC 1997 and the Turkish Code, Eurocode 8 explicitly differentiates between frame-dominated and wall-dominated buildings by modifying the coefficient C_t accordingly. This allows a more refined estimation depending on the degree of lateral stiffness contribution from infill walls or shear walls.

This study compares the fundamental periods obtained through detailed numerical modal analyses against the empirical estimations from UBC 1997, the Turkish Seismic Code (1998), and Eurocode 8. The comparison aims to evaluate the conservatism and accuracy of code-based estimations relative to realistic structural behavior.

Table 4 presents a detailed summary of the computed periods for different structural configurations, followed by a discussion of the observed differences. As illustrated in Fig. 6, the estimated periods from this study are consistently lower than those suggested by the seismic codes, particularly for buildings with higher infill wall ratios.

4. Conclusions

In this study, the influence of infill walls on the dynamic behavior of reinforced concrete buildings was systematically investigated through detailed modal analyses. Four building models with varying heights (three, six, nine, and eleven stories) and eleven different infill wall configurations were evaluated to capture a wide range of practical design scenarios.

The results demonstrate that the presence of infill walls considerably enhances the lateral stiffness of buildings, leading to a significant reduction in the fundamental vibration periods (Hatzigeorgiou & Kanapitsas, 2013). It was observed that:

- For nine- to eleven-storey buildings, infill walls reduced the period by approximately 10% to 40% compared to bare frame configurations.
- For low- and mid-rise buildings (three to six stories), the reduction was even greater, ranging between 15% and 45%, emphasizing the proportionally larger contribution of infill walls to the overall stiffness of shorter structures.

The sensitivity of the period to the infill wall area ratio was also analyzed. It was found that:

- For an infill ratio between 0.20 and 0.40, the period reduction ranged from 10% to 25% for taller structures and 14% to 30% for lower ones.
- For higher infill ratios (0.40–0.60), the reduction became more pronounced, reaching 25%–40% in tall buildings and 28%–45% in low- to mid-rise structures.

Notably, an empirical formula was proposed to relate the infill wall area to the expected reduction in the fundamental period. This formula was validated against the results obtained by Yıldırım (2009) and found to closely align with both experimental data and the empirical formulations suggested by Güler et al. (2008).

A comparative evaluation against code-based period estimations revealed notable insights. While the Turkish Seismic Code (1998) and UBC 1997 provide useful baseline estimations, they tend to overpredict the periods for buildings with significant infill wall contribution, especially in the mid-rise range. Eurocode 8, with its more differentiated approach to frame-dominated versus wall-dominated systems, produced period estimates that were closer to the numerical analysis for frame-dominated cases. However, no standard code formula fully captured the reduction trends observed due to varying infill wall ratios (Namata Saidou & Koçak, 2018).

These findings highlight the need for refined empirical formulations that explicitly account for the infill wall contribution in seismic period estimations (Hatzigeorgiou & Kanapitsas,2013). Neglecting the infill effect may lead to conservative period predictions, resulting in misjudgment of seismic forces and inappropriate design decisions. Incorporating realistic stiffness contributions from infill walls can improve the accuracy of seismic demand assessments and the efficiency of structural designs.

Thus, the proposed empirical formula developed in this study offers a practical and more accurate tool for engineers aiming to account for the effects of infill walls during seismic design of reinforced concrete structures.

Seismic evaluation of soil-structure interaction for Bursa Uludağ University Hospital using ambient noise and site response analyses

Seda Özgençli[1], Mustafa Şenkaya*[1,2]

[1]Bursa Uludağ University, Department of Civil Engineering, 16240 Bursa, Türkiye
[2] Earthquake Research and Structural Health Monitoring Laboratory, Bursa Uludağ University, 16240 Bursa, Türkiye

Abstract. This study aims to investigate the soil-structure interaction of the A and B Block building, which includes the Polyclinics section of Bursa Uludağ University Hospital, through seismic parameters. As part of the study, ambient noise recordings were simultaneously conducted on both the hospital building and the underlying soil. Measurements within the hospital were taken near structural elements and around the center of mass on each floor, while ground recordings were collected from four surrounding locations around the building. The findings clearly show that Block A experiences variations in predominant frequencies across its different sides, which may lead to uneven oscillations during an earthquake and potentially generate additional forces, such as torsional effects, within the structure. Conversely, Block B demonstrates relatively consistent predominant frequencies across its corners; however, these frequencies differ significantly from those observed at the ground level. Moreover, the measured frequencies are slightly higher than the values anticipated based on theoretical estimations.

1. Introduction

A significant portion of Türkye is situated within an active seismic zone and faces considerable earthquake hazards. the Bursa Plain representing the city center of Bursa is particularly vulnerable due to its proximity to active faults located both within the region and in the northern and southern parts of the Marmara region. Historical and instrumental earthquake records indicate that Bursa has experienced moderate to severe earthquake impacts at least three times per century. The most imminent threat arises from a potential major earthquake expected to occur along the segment of the North Anatolian Fault beneath the Sea of Marmara.

The Quaternary and Miocene–Pliocene-aged geological formations in the Bursa Plain—where Bursa Uludağ University is situated—are known to amplify the surface effects of potentially destructive earthquakes. The Görükle Campus of Bursa Uludağ University serves as a critical hub for regional services and research and development activities, hosting key institutions such as the Faculties of Medicine and Engineering, a technopark, and various research laboratories (Fig. 1). The campus comprises 52 buildings, many of which have high building importance coefficients and are designated for immediate post-earthquake use. Additionally, a significant number of these buildings contain hazardous materials, posing a risk of secondary disasters in the aftermath of a major seismic event.

One of the most critical structures within the campus is the Bursa Uludağ University Faculty of Medicine Hospital. The Faculty of Medicine (BUU-TF) was established in 1970 as an affiliate of Istanbul University and has since expanded through the construction of various buildings over the years. The hospital encompasses a total enclosed area of 165,543.00 m² and comprises five main blocks: A, B, C, D, and E. This study focuses on Block A, the oldest building within the faculty, which houses outpatient clinics, imaging units, and the radiation oncology department. Block B accommodates inpatient clinics, while Block D is dedicated to ophthalmology services. Block E provides care for pediatric hematology and oncology patients.

The aim of this study is to investigate the ground–structure interaction of Block A and B of BUU-TF by analyzing the dominant vibration periods of both the building and the underlying soil. To achieve this, ambient-noise measurements were conducted using a broadband accelerometer at various locations, including different

*Corresponding author, E-mail: mustafasenkaya@uludag.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_596

floors of the building, around the center of mass, the corners, and the ground beneath the structure. The collected data were then evaluated using the Horizontal-to-Vertical Spectral Ratio (HVSR) method.

The HVSR method, also referred to as the Nakamura method (Nakamura, 1989), relies on the ratio of horizontal to vertical components of ambient seismic noise. This approach is particularly useful for detecting the natural resonance frequency of soft sediment layers above bedrock, which is closely linked to the stiffness and layering of subsurface materials. Besides offering valuable geotechnical insights, the HVSR method is popular due to its straightforward, cost-effective, and non-invasive nature. Bhandary (2021) investigated the resonance effects on the shaking of tall buildings in the Kathmandu Valley during the 2015 Gorkha earthquake using HVSR analysis. Similarly, Mukai (2022) employed the method to evaluate the seismic behavior of historic masonry buildings following the Nepal earthquake. Gosar and Martínec (2008) conducted HVSR-based studies both within buildings and on the underlying soil to determine site effects. Parolai et al. (2005) utilized ambient noise and HVSR analysis to assess the vibrational characteristics of Holweide Hospital in Cologne, Germany. Galipol et al. (2004)examined the structure, soil–structure interaction, and damage effects using the HVSR method. Additionally, Barani et al. (2014) analyzed the structural response of masonry buildings in the historic center of Genoa, Italy, through HVSR measurements.

2. The study area

The majority of the Görükle district and the Görükle Campus, where the BUU-TF is located, is situated on the Miocene–Pliocene-aged Mudanya Formation and partly on younger Quaternary alluvial deposits (Fig. 2). The Mudanya Formation is extensively distributed across the north–northwestern part of Bursa Province and has an estimated thickness ranging from 50 to 300 meters. It is composed of conglomerate, sandstone, siltstone, claystone, marl, and limestone. These lithologies transition laterally and vertically, typically forming various combinations. While most of the rocks in the formation are considered very weak or weak in terms of strength, the limestone in Mudanya formation could represent strongly cemented character in some areas. The alluvium, on the other hand, covers much of the Bursa Plain. According to DSI (1973), its thickness varies between approximately 140–200 meters in the central and eastern parts, around 100 meters in the north, and up to 150–200 meters in the west and northwest. It consists of unconsolidated gravel- to clay-sized materials. The general geotechnical properties of both soil types are considered prone to amplifying seismic loads and effectively transmitting these loads to overlying structures during a potential earthquake.

The Bursa Plain, where the Görükle Campus is situated, is an east–west-oriented basin enriched by river systems, bounded by the Katırlı Mountains to the north and the Uludağ Mountains to the south. The plain generally lies at an elevation below 200 meters, and its slope ranges between 0° and 2° across most of its extent, excluding the steeper mountain flanks (Öncü, 2021). The region is tectonically active and bordered by several significant fault zones. To the south, the Bursa, Uludağ, Uluabat, Mustafa Kemalpaşa, and Manyas faults are prominent, while the northern boundary is defined by the İznik, Gemlik, Zeytinbağı, and Bandırma faults (Özalp, Emre ve Doğan, 2013). Additionally, the North Anatolian Fault Zone (NAFZ) constitutes a major seismic source for the area, particularly for settlements located on the plain. Both historical and instrumental records indicate that Bursa and its surroundings have been exposed to destructive earthquakes. Notable events include the 1419 Gemlik, 1855 Bursa (two successive events in March and April), 1894 Marmara, 1953 Yenice-Gönen, 1964 Bursa–Karacabey, 1970 Gediz, and 1999 Gölcük earthquakes.

3. Methods and data

The HVSR method requires three-component microtremor recordings, which consist of vibrations of either natural or anthropogenic origin. These microtremors are typically associated with displacements ranging from 10^{-6} to 10^{-2} mm and are predominantly characterized by periods shorter than 1 second (Okada ve Suto, 2003). In recent years, such signals have increasingly been referred to as “ambient noise” in the scientific literature (Maggio, Subašić ve Bean, 2022; Panzera ve diğerleri, 2016), and can be collected using mobile single-station seismometers or through various types of sensors installed at permanent seismic monitoring stations.

In the HVSR method, the horizontal-to-vertical spectral ratio of microtremor recordings obtained at the surface is calculated using Equation (1), which represents the ratio of the horizontal to vertical components of the ground motion spectra. This ratio provides insights into the impedance contrast between the overlying soil layers and the underlying bedrock.

$$A(w)_{H/V} = \frac{\left(H_s(w) / H_b(w) \right)}{\left(V_s(w) / V_b(w) \right)} \tag{1}$$

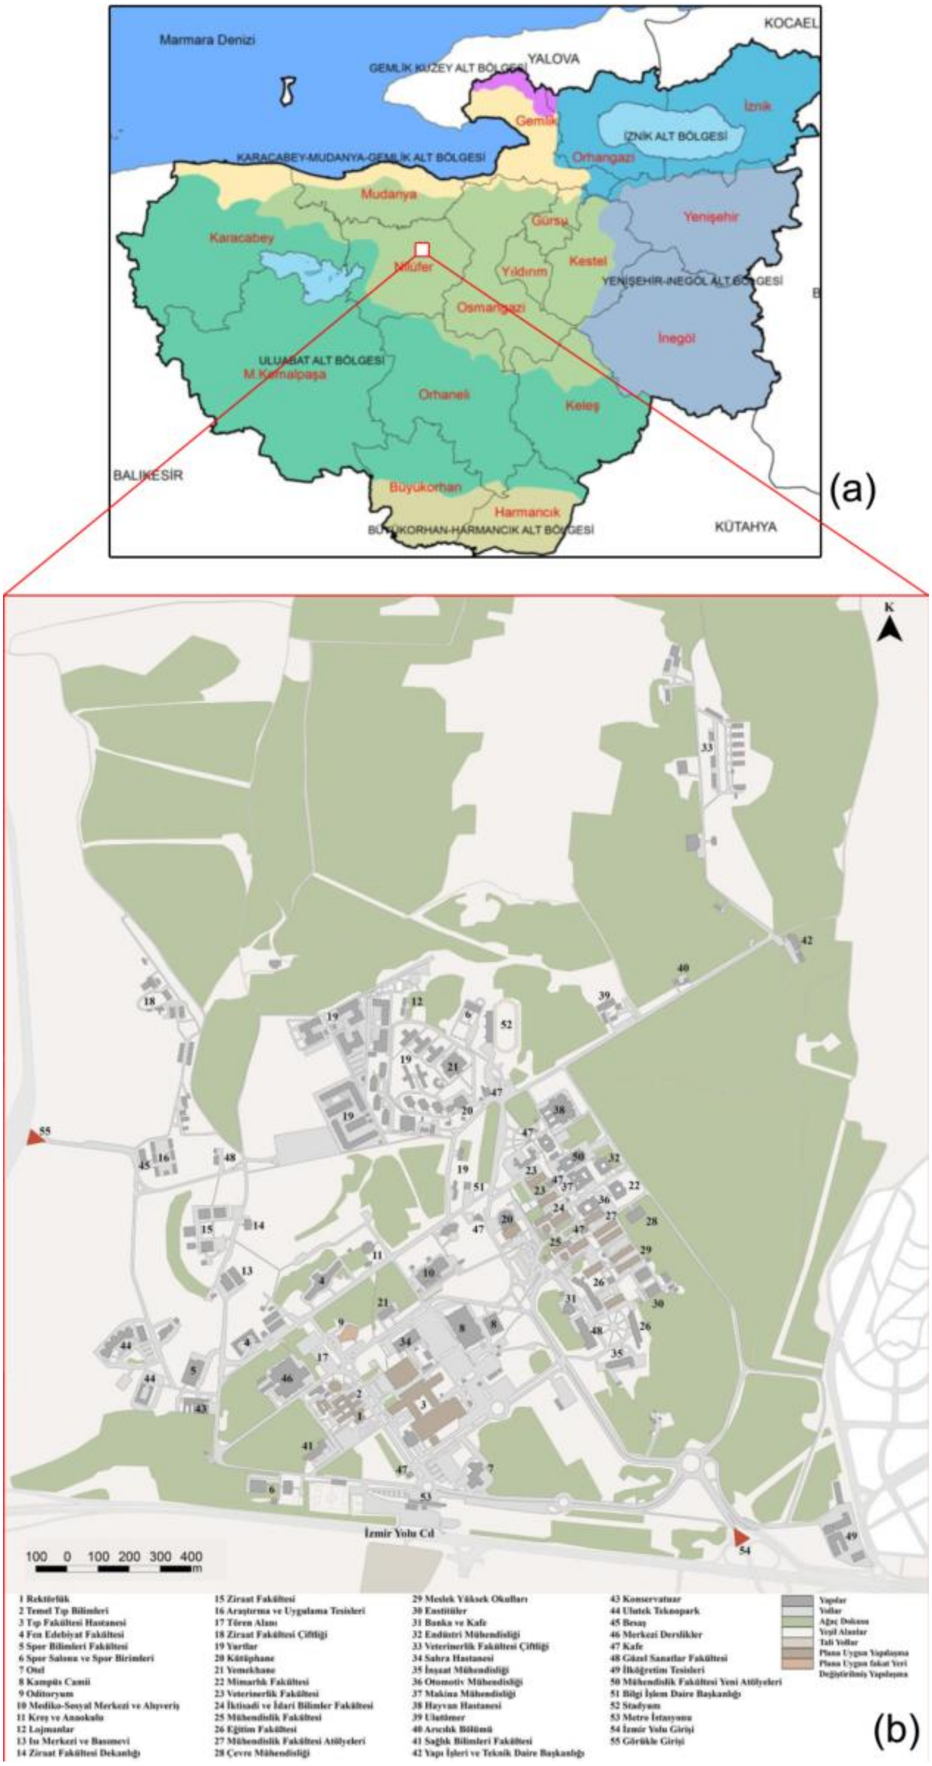

Fig. 1. Location of BUU and distribution of buildings

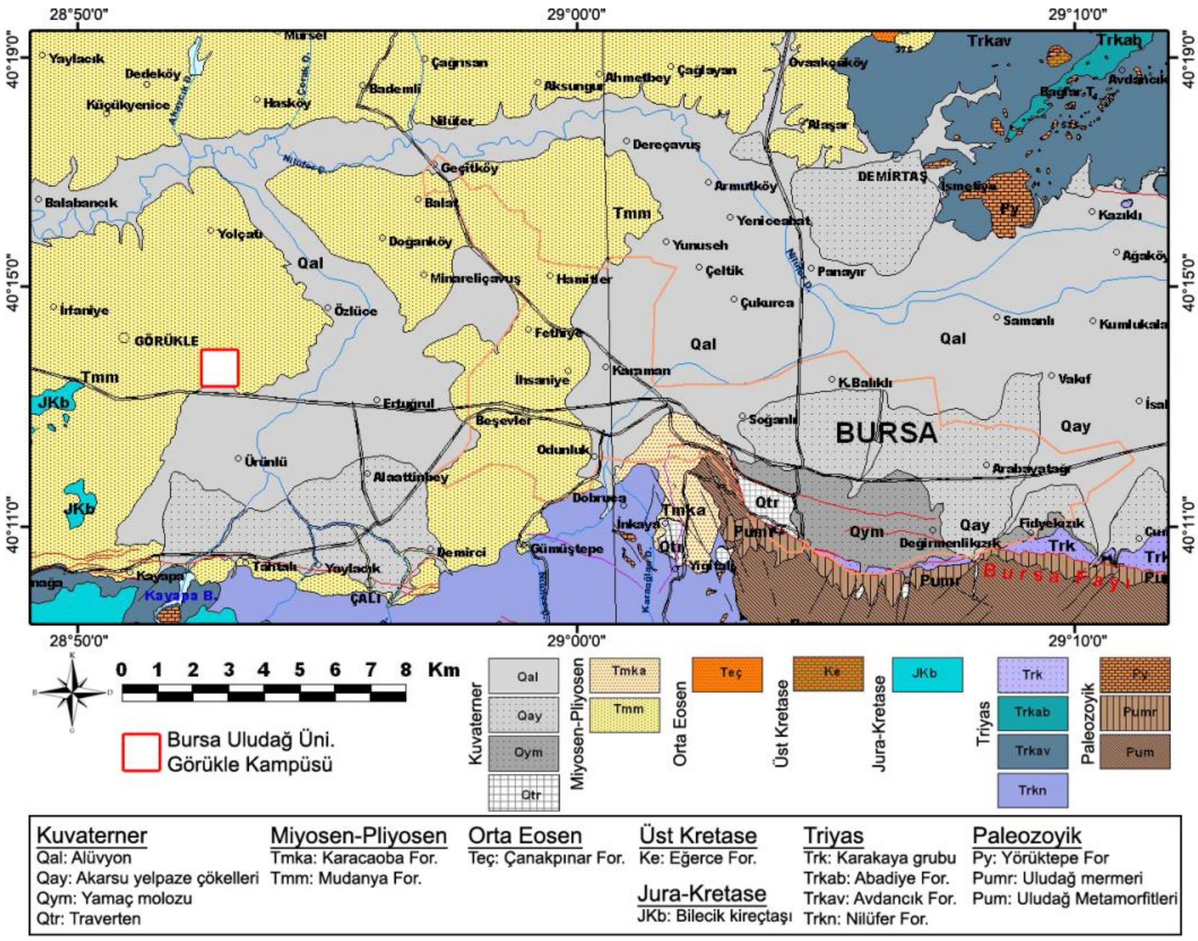

Fig. 2. Geology of Bursa plain. The study are is indicated by red frame.

In this context, Hs and Hb denote the horizontal components of the ground motion spectra at the surface and bedrock, respectively, while Vs and Vb represent the corresponding vertical components. The HVSR method relies on two key assumptions: (i) the spectral ratio of horizontal to vertical motion at the bedrock level is equal to 1 (Hb/Vb = 1), and (ii) the vertical component of microtremor signals is not significantly amplified by the soil layers.

Therefore, the horizontal/vertical spectrum ratio for a microtremor signal recorded at the surface becomes,

$$A(w)_{H/V} = \frac{\left(H_s(w) / H_b(w) \right)}{\left(V_s(w) / V_b(w) \right)} = \frac{H_s(w)}{V_s(w)} \frac{V_b(w)}{H_b(w)} = \frac{H_s(w)}{V_s(w)} \qquad (2)$$

and this ratio is called the HVSR spectral ratio. The HVSR curve is obtained by computing the horizontal-to-vertical spectral ratio across a range of frequencies or periods. The peak of this curve defines the HVSR amplitude, while the corresponding frequency (f_0) or period (T_0) at which the peak occurs indicates the site's fundamental (or dominant) resonance frequency or period.

In recent years, one of the applications of the HVSR method has been the determination of buildings' natural resonance periods under ambient loading conditions (Molnar ve diğerleri, 2022). In these applications, to measure the building's resonance periods in both horizontal directions (transverse and longitudinal), the horizontal components (N-S and E-W) of the broadband seismometer are aligned parallel to the transverse and longitudinal axes of the structure (Gosar ve Martinec, 2008; Parolai ve diğerleri, 2005). Since the target frequency range in these measurements is higher compared to ground-based surveys, the required recording durations can be relatively shorter. When such measurements are carried out simultaneously at each floor of the building as well as at the ground level on which the building stands, the resonance periods and, in particular, the ratios of HVSR amplitudes between floors can reveal the differences in dynamic behavior of the floors and their compatibility or incompatibility with the ground during an earthquake (Bhandary ve diğerleri, 2021; Mukai ve diğerleri, 2022).

Data were collected at nine locations using three-component broadband velocimeters (Fig. 3). One dataset, comprising 30 minutes of recordings, was obtained from a ground-based station to characterize site properties. The remaining eight datasets were acquired from the top floors of Blocks A and B, particularly the 2nd and 6th floors respectively, with each recording lasting a minimum of 15 minutes. Data evaluation was conducted according to SESAME (2004) guidelines, and all results were also assessed against the criteria outlined by SESAME (2024).

4. Results

While the ground measurements indicated a predominant frequency at 0.37 Hz (Fig. 4a), the southwest side of Block A, represented by points 2 and 5 (Fig. 4b and 4c), exhibited a twin-peak response at approximately 0.38 Hz and 4.40 Hz. This condition may give rise to a resonance effect at the site. In contrast, the northeast side, represented by points 4 and 3, showed a predominant frequency at 4.20 Hz, which corresponds well with the building's floor length (Fig. 4d and 4e). This difference in predominant frequencies may cause the northeast and southwest sides of the structure to oscillate differently during an earthquake, potentially inducing additional forces such as torsion within the structure. On the other hand, all corners of Block B exhibited predominant frequencies ranging between 2.20 Hz and 2.61 Hz, which are notably different from the ground's predominant frequency (Fig. 4f to i). However, these frequencies are approximately 1 Hz higher than the expected value estimated by the expression (floor count × 0.1)$^{-1}$.

Fig. 3. Distribution of measurement locations

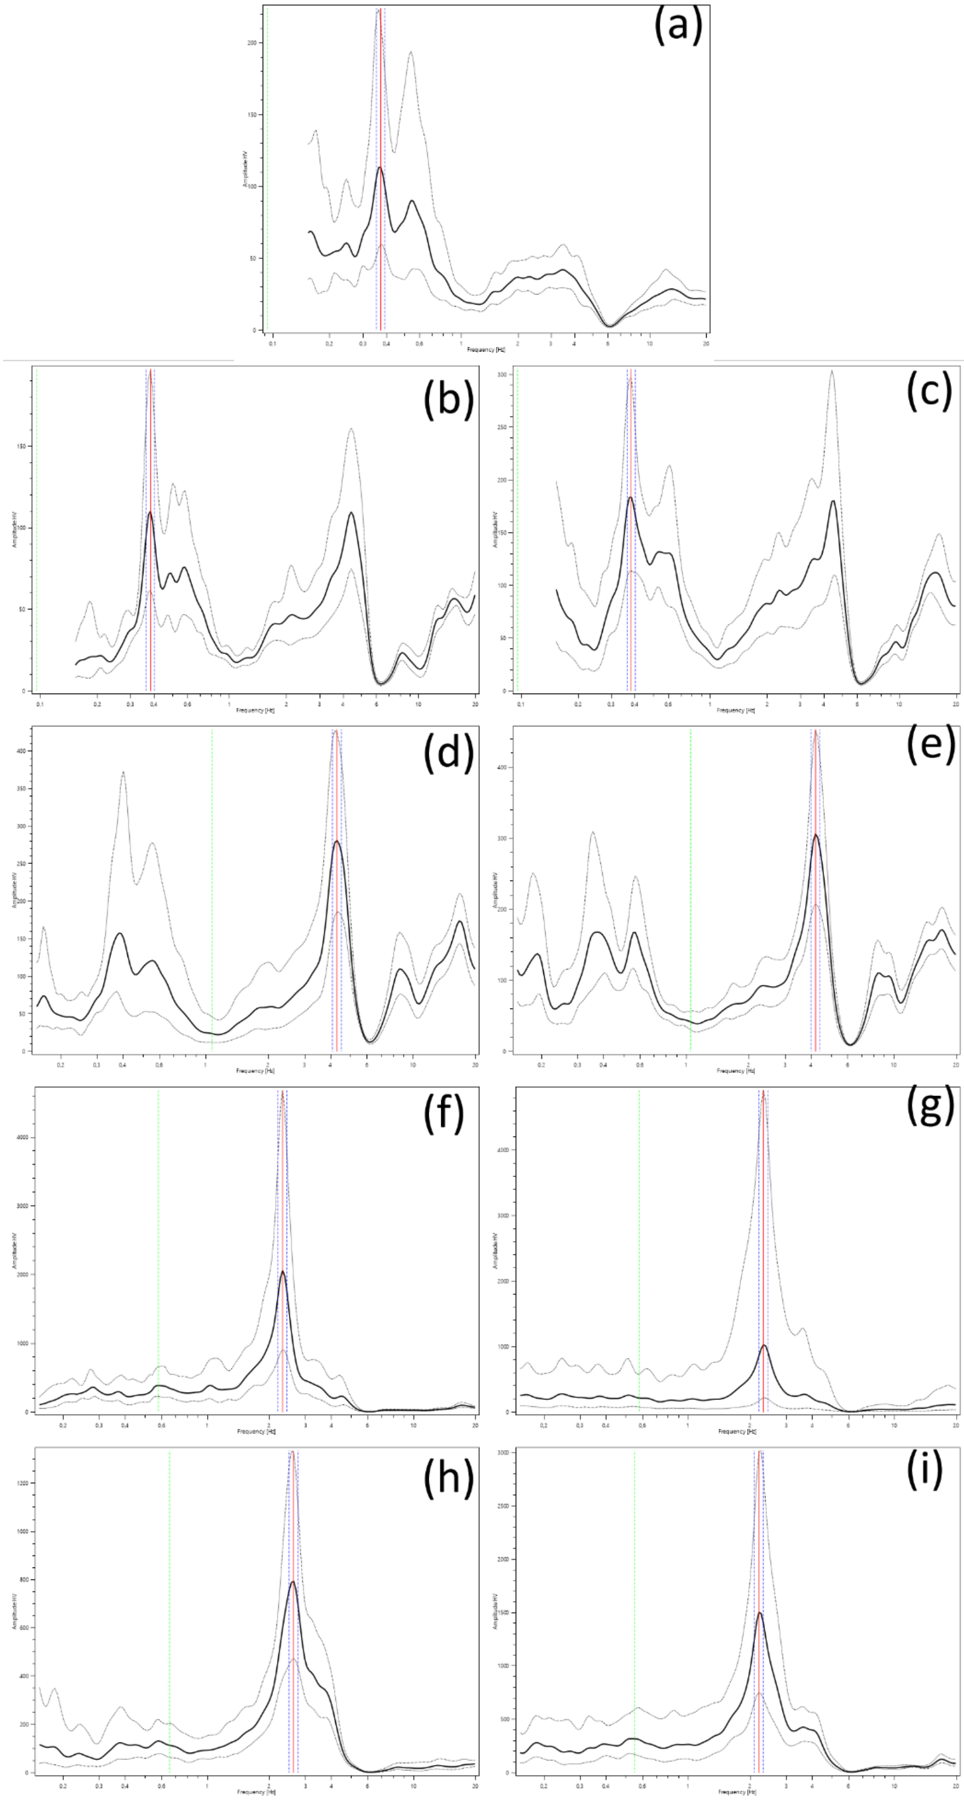

Fig. 4. HVSR result for a) ground, b) 2, c) 5, d) 3, e) 4, f) 6, g) 9, h) 7, i) 8

5. Conclusions

The aim of this study is to investigate the ground–structure interaction of Blocks A (2 floors) and B (7 floors) of BUU-TF by analyzing the dominant vibration periods of both the buildings and the underlying soil. Ambient noise measurements were conducted at eight indoor locations and one location on the ground. The collected data were evaluated using the Horizontal-to-Vertical Spectral Ratio (HVSR) method. The results clearly indicate that Block A exhibits variations in predominant frequencies between different sides, which could cause differential oscillations during an earthquake and potentially induce additional forces such as torsion within the structure. In contrast, Block B displays relatively stable predominant frequencies, although these frequencies are notably different from those of the ground. Nevertheless, the observed values are slightly higher than the expected frequencies.

An examination of the impact of infill walls on the seismic performance of RC prefabricated structures

Joltai Khonaiv*[1], Mehmet Ö. Timurağaoğlu[1], Özkan Hakan[2], Ramazan Livaoğlu[1,2]

[1] *Bursa Uludağ University, Department of Civil Engineering, 16059 Bursa, Türkiye*
[2] *RL ProjeDestek Consulting Company, Bursa, Türkiye*

Abstract. In conventional design practice, infill walls are typically considered as non-structural elements contributing only to mass and gravity loads. However, it is well established that infill walls can significantly enhance the stiffness, reduce vibration periods, and alter internal force distributions of structures during earthquakes. This study investigates the impact of infill walls on the seismic performance of reinforced concrete (RC) prefabricated structures, commonly used for industrial buildings due to their construction efficiency and cost-effectiveness. A representative prefabricated building model was developed, incorporating realistic connection details and nonlinear material behavior. Infill walls were modeled using an equivalent strut approach with appropriate hysteretic behavior. Nonlinear dynamic analyses were performed based on the Turkish Building Seismic Code (TBSC, 2018) for both the pinned RC prefabricated structure with and without infill walls. A total of 44 analyses were conducted using matched earthquake records derived from site-specific seismic hazard analyses. The seismic performance was evaluated by examining demand-to-capacity (D/C) ratios for critical components, including corbel-to-roof beam connections, purlin-to-roof beam connections, and column bending and shear capacities. The results reveal that infill walls significantly increase lateral stiffness, shorten natural periods, and improve modal energy distribution. Strain- and drift-based D/C ratios confirmed that structures with infill walls exhibit lower seismic demands, reduced deformation, and better overall resilience, whereas structures without infill walls showed higher vulnerability under seismic loads. Additionally, secondary elements such as purlin-to-roof beam and corbel connections remained within acceptable performance limits when infill walls were present.

Keywords: RC prefabricated structures; Infill wall; Nonlinear time history analysis; Performance evaluation

1. Introduction

Reinforced concrete (RC) prefabricated structures are widely adopted in industrial-type buildings due to their numerous advantages, including streamlined manufacturing processes, reduced construction time, minimization of workmanship-related errors, and overall cost efficiency. In these systems, structural elements are prefabricated under controlled factory conditions and rapidly assembled on-site, resulting in significant reductions in labor demand and associated costs (Ersoy, 1997).

The 2023 Kahramanmaraş earthquakes revealed significant vulnerabilities in prefabricated reinforced concrete (RC) industrial buildings. Post-earthquake assessments indicated that the poor detailing at the connections in the affected region contributed to the prevailing damage in prefabricated structures. Furthermore, critical deficiencies were identified in beam-column connection details and anchorage systems. The primary contribution of weak connections between prefabricated components, particularly at joint regions, to structural damage was also emphasized worldwide (Muguruma et al., 1995; Savoia et al., 2017; Sezen & Whittaker, 2006). Notably, damage in these structures was attributed more to displacement demands than to seismic forces. These findings underscore the need to enhance the lateral stiffness of prefabricated industrial systems and to limit the use of hinged connections in order to improve their seismic resilience (Arslan et al., 2024; Kırtel et al., 2024). In typical single-story industrial buildings in Turkey, inadequate roof diaphragms and diaphragm connections allowed large relative lateral displacements of frames, leading to complete structural collapse due to insufficient lateral stiffness.

Additionally, full-height and partial-height unreinforced masonry infills imposed excessive seismic demands on prefabricated concrete columns (Arslan et al., 2006; Saatçioğlu et al., 2001). In most structural designs, infill walls are not considered as load-bearing elements but only as additional mass and load. However, under seismic

*Corresponding author, E-mail: 502226023@ogr.uludag.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_597

effects, infill walls contribute significantly to the rigidity of the structure, shorten vibration periods, and significantly affect the distribution of internal forces. Moreover, infill walls make a substantial contribution to damping earthquake energy with their permanent deformations. When infill walls reach their load-bearing capacity, they crack, and their contribution to the rigidity and strength of the structure suddenly ended. The friction that grows at the crack interfaces, due to the structural vibration, increases the damping of the structure. The increase in structural damping reduces the seismic demand on the structure, which means a decrease in the horizontal seismic forces acting on the structure.

The most common approach in considering infill walls in structural analyses is to represent these elements using the compression-only equivalent diagonal strut model. In this method, the structural contribution of the wall is idealized as a uniaxial compression element, taking into account the interaction between the infill wall and the horizontal and vertical elements that make up the frame. In determining the effective width of the equivalent compression strut, the relationship between the diagonal length of the wall (dm) and the effective width (w) is typically utilized. This approach plays a crucial role in defining the effects of infill walls on rigidity and strength, particularly in nonlinear structural analyses. Pioneering studies on this subject have been presented in literature by (Mainstone, 1971; Polyakov, 1960; Smith, 1962).. In prefabricated industrial buildings, it has been observed that infill walls not only increase the lateral rigidity of the structure but also have an effect on displacement demands and base shear forces (Korkmaz & Karahan, 2011).

In this study, the influence of infill wall on the seismic performance of RC prefabricated strutcures are thoroughly scrutinized numerically by modeling connection behavior in details. In accordance with the Turkish Building Seismic Code (TBSC, 2018), nonlinear time history analyses were conducted on a pin-connected RC prefabricated industrial building, both with and without infill walls, using ETABS software (ETABS, 2024). The results were evaluated based on demand-to-capacity (D/C) ratios, considering factors such as the connections between the corbel and roof beam, purlin and roof beam, as well as the bending and shear capacities of the columns.

2. Numerical modeling

In this study, a single-story, single-bay RC prefabricated industrial structure, representative of existing building typologies in Turkey, is analyzed. The structure features columns with a height of 6 meters. It spans 15 meters in the X-direction and 6 meters in the Y-direction, with a total modeled length of 48 meters in the Y-direction, corresponding to eight bays (6 m × 8 = 48 m). The structural layout consists of a single primary axis (A-B) in the X-direction and nine grid lines (1–9) in the Y-direction (Fig. 1).

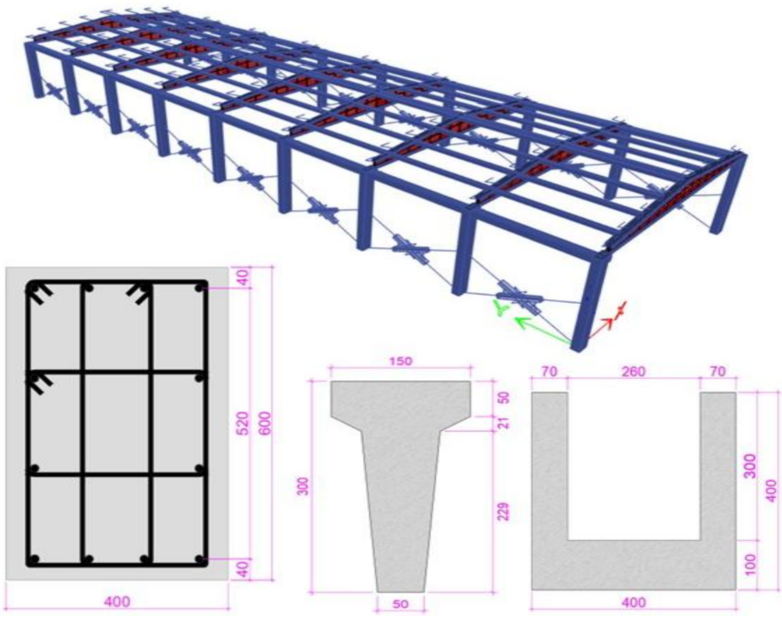

Fig. 1. Generated 3D model view of the single-story structure and cross-sectional details

The vertical load-bearing elements are RC columns with cross-sectional dimensions of 600 × 400 mm. Each column is reinforced with 12 longitudinal bars of 16 mm diameter and transverse reinforcement consisting of 8mm diameter stirrups spaced at 100 mm intervals. Roof trusses are modeled as thin shell elements, with upper chord width of 350 mm, web width of 100 mm, and lower chord width of 250 mm. The prefabricated gutters are represented by U-shaped beam elements with cross-sectional dimensions of 400 × 400 mm. Purlins, which support the roof cladding and act within the truss plane, are modeled with a T-shaped cross-section. Additionally, cantilever (corbel) elements are modeled with a width of 400 mm and a depth of 450 mm.

Figure 1 presents the three-dimensional model of the single-story prefabricated structure, detailing its geometric configuration and principal structural components. The concrete strength class employed is C30 (fck = 30 MPa), while the reinforcement class is S420 (fyk = 420 MPa). The roof cladding is assumed to consist of aluminum sandwich panels. Applied loads include a roof cladding load of 0.12 kN/m², a snow load of 0.75 kN/m², and a façade cladding load of 4.5 kN/m². In accordance with the Turkish Building Seismic Code (TBSC, 2018), mass multiplier factors are taken as 1.0 for gravity loads and 0.3 for snow loads.

2.1. Modeling of connections

The corbel-roof girder connection were modeled to represent nonlinear behavior at the joints. One of the most critical challenges in the seismic design of prefabricated reinforced concrete structures is the proper design of connections, particularly at beam-to-column joints. Prefabricated beam and column elements connected by dowels have been tested under both monotonic and cyclic pure shear loading to understand its seismic behavior. In a study conducted by Psycharis & Mouzakis (2012a), the shear ductility capacity of the connections and the influence of various design parameters on strength were investigated. A formula is proposed for calculating the shear strength of dowel connections that can be used in seismic design.

$$R_u = 1.10 * n * D^2 * \sqrt{f_{ck} * f_{yk}} \qquad \mathrm{d/D} > 6 \tag{1}$$

$$R_u = 1.10 * \left(\frac{0.25d}{D} - 0.50\right) * n * D^2 * \sqrt{f_{ck} * f_{yk}} \qquad 4 \leq \mathrm{d/D} \leq 6 \tag{2}$$

Table 1. Dowel element specifications and material properties for corbel and purlin components

Component	n	D (mm)	d_n (mm)	f_{ck} (MPa)	f_{yk} (MPa)	f_{cd} (MPa)	f_{yd} (MPa)	d/D	C_0	γ_R	R_u (kN)	R_d (kN)
Corbel	2	16	100	30	420	20	365.2	6.25	0.95	1.3	63.2	32.0
Purlin	1	14	60	30	420	20	365.2	4.29	0.95	1.3	13.8	7.0

For the safe design of connections, calculations should be performed considering material safety factors and relevant design parameters. In this context, the coefficient C_0, which depends on the magnitude of rotation at the connection, varies between 0.90 and 1.10. Particularly in systems with flexible columns where large joint rotations may occur, a C_0 value in the range of 0.90–0.95 is recommended. Additionally, a safety factor of γ_R=1.30 is proposed (Psycharis & Mouzakis, 2012b). The maximum shear resistance at the corbel-roof girder connection was calculated as R_u=63.2kN, while the design shear resistance was determined as R_d=32.0kN. Similarly, the maximum and design shear resistances of the purlin-roof girder connection were found to be R_u=13.8kN and R_d=7.0kN, respectively, as given in Table 1.

Based on the calculated shear resistances, nonlinear models were developed to represent the corbel and purlin connections. In these models, dowel connections were represented as link elements. The corbel element was modeled using the degrading hysteresis model by incorporating both force-displacement and moment-rotation relationships, while the purlin element was modeled based solely on its force-displacement behavior. The roof beam–corbel connection was modeled as connection elements based on the commonly used moment-rotation and force-displacement relationships found in the literature based on the experimental studies. On the other hand, the roof beam–purlin connection was defined according to the force-displacement relationship. To accurately represent their dynamic behavior, the roof beams were modeled using shell elements. The calculated moment-rotation and shear force-dispalcement curves are given in Fig. 3. The calculated shear force-displacement relationships at the purlin connections is shown in Fig. 4.

2.1. Infill wall modeling

The initial approach for determining the effective width (w) of the equivalent compression strut is calculated using Equation (2), which represents the diagonal length (d_m) of the infill wall, and various formulas have been proposed in the literature (Abdul-kadir, 1974; Bazan & Meli, 1980; Bertoldi et al., 1993; Cavaleri et al., 2005; Durrani & Luo, 1994; Hendry, 1981; Holmes, 1961; Mainstone, 1971; Paulay & Priestley, 1992; Smith, 1967; Tassios, 1984; TBSC, 2018) on this subject.

$$w = \frac{d_m}{3} \tag{3}$$

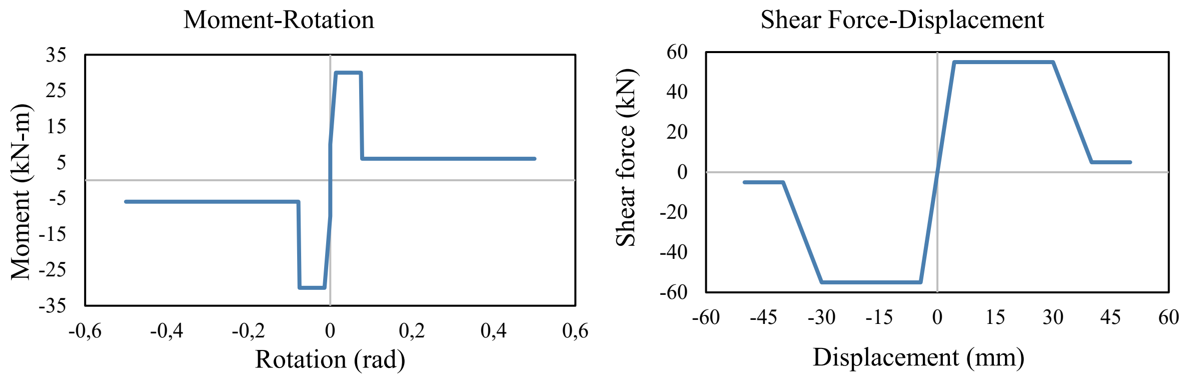

Fig. 3. Nonlinear behavior at the corbel-roof girder connection

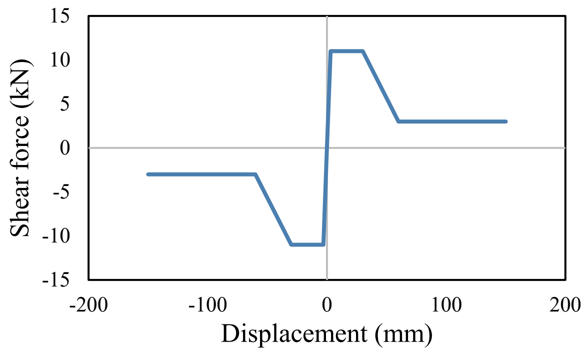

Fig. 4. Nonlinear behavior at the purlin-roof girder connection

Taking all the proposed formulas into account, the effective width (w) of the equivalent compression strut was calculated, and the results are presented in the Fig. 5. The equivalent strut width of the infill wall was calculated based on the proposed formulas, and as a result, the width of the equivalent compression strut was determined to be 1 m. In the model, infill walls were modeled as multilinear plastic link elements using the widely accepted equivalent diagonal strut approach in literature. Based on this representation, the Concrete hysteresis type that is given in ETABS is selected to simulate the cyclic behavior of infill walls under lateral loading. The axial stiffness and force-displacement relationship of the infill wall were calculated, and the resulting nonlinear behavior model is presented in Fig. 6.

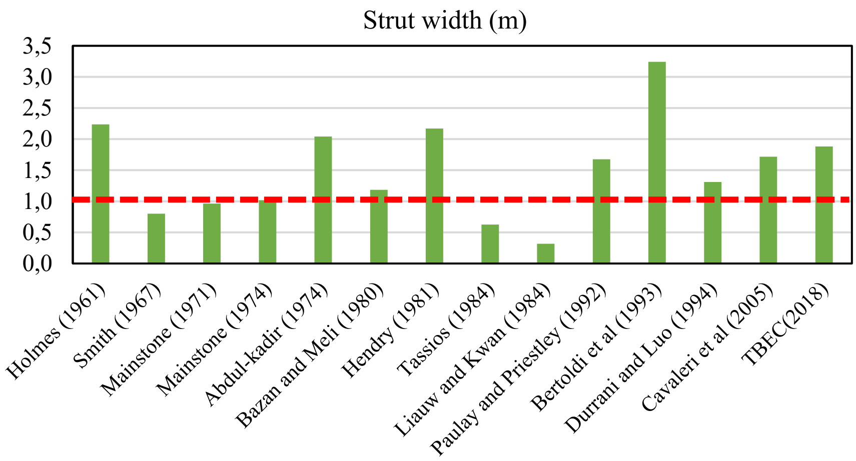

Fig. 5. Calculated effective width of the diagonal strut

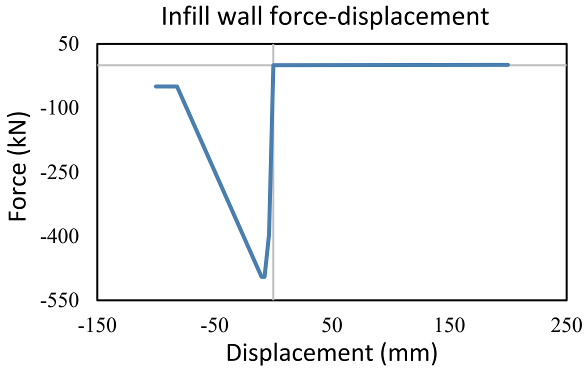

Fig. 6. Nonlinear behavior for infill wall

3. Selection and scaling of earthquakes

According to TBSC (2018), the amplitude of the horizontal component spectra of earthquake records to be used in dynamic analyses must be scaled based on the design spectrum ordinates within the period range between $0.2T_P$ and $1.5T_P$, where T_P represents the fundamental natural vibration period of the structure. This value has been calculated as $T_P = 0.57$ s (1st mode). The design spectra used in the model correspond to the exceedance probabilities for earthquake level DD-1, which is associated with return periods 2475 years.

3.1.1. Scaling of ground motion records

In this study, both horizontal components were multiplied by the same scaling factor during the scaling process. As a result, the original relationship between the horizontal components was preserved after scaling. The number of earthquake records must be at least 11, and the number of record sets from the same earthquake must not exceed three. In the initial stage of scaling the selected records for three-dimensional design, the combined horizontal spectrum should be obtained by taking the square root of the sum of the squares of the spectral ordinates of the two horizontal components of each record set (TBSC, 2018).

3.2 Selection of ground motion records

For each selected horizontal ground motion component, the accepted maximum scaling factor was primarily set in the range of 0.25 to 4.0, and in exceptional cases where this range could not be satisfied, it was allowed up to 5.0. Additionally, the number of records selected from the same earthquake was limited to a maximum of three within the total of eleven records. The spectra of the scaled candidate records were compared with 1.3 times the target spectrum, and 11 suitable records along with their two horizontal components were selected. In light of these criteria, Fig. 7 presents, in terms of acceleration spectrum, the 1.3 times target spectrum for 2475 years according to TBSC (2018), the selected records, and their average. Table 2 lists the selected records along with their corresponding values for Magnitude (M_w), Joyner-Boore distance (R_{JB}), Shear wave velocity (V_{S30}), fault mechanism (FM), and scaling factor (SF). In the FM column, SS denotes strike-slip fault, and RV refers to reverse fault types.

4. Analysis and results (discussion)

To investigate the effects of infill walls on seismic performance of RC prefabricated structures, two structural models—one with infill walls and one without—were subjected to nonlinear time-history analyses using 11 ground motion records, yielding a total of 44 (22x2) analyses. Modal analysis results for the first three modes of both structural models are presented in Table 3. The findings clearly demonstrate the influence of infill walls on the structural stiffness and dynamic behavior of the system. For the system with infill walls, the period of the first mode was determined to be $T_1 = 0.574$s, with 39% modal mass participation in the transverse (UY) direction and 64% in the torsional (RX) direction. In contrast, the system without infill walls exhibited a first mode period of $T_1 = 0.765$s, indicating a more flexible structural behavior. In this mode, the modal mass participation ratios were 87% in the UY direction and 96% in the RX direction, suggesting that a significant portion of the system's vibrational energy is concentrated in the first mode along the horizontal axis (UY).

Overall, it can be stated that the additional stiffness provided by the infill walls results in shorter natural periods, thereby reducing displacements and achieving a more balanced distribution of modal energy. On the other hand, the elongated period observed in the structure without infill wall leads to a notable change in the dynamic response, with higher mode shapes exerting increased influence on the structural behavior.

Table 3. Modal participating Mass Ratio

	Modal Participating Mass Ratio				
	Mode	Period (sec)	UX	UY	RZ
With infill	1	0.574	0	39%	0
	2	0.39	54%	0	0
	3	0.39	0	0	21%
Without infill	1	0.765	0	87%	0%
	2	0.472	0	0	14%
	3	0.428	66%	0	0

As part of this study, the damage levels observed in the columns of a prefabricated industrial structure were evaluated by considering the strain limits of both concrete and reinforcement materials. To accurately capture inelastic deformations, fiber plastic hinges were defined along the columns, and nonlinear time history analyses were performed. In line with material-specific performance criteria, strain limits corresponding to the collapse prevention performance level were adopted, with a threshold of 0.010 for concrete and 0.032 for reinforcement. These limits were based on the strain capacities beyond which damage initiates, potentially affecting the serviceability of the structure.

Following the analyses, strain demands obtained from the plastic hinge regions were used to compute Demand-Capacity (D/C) ratios for both concrete and reinforcement. The given D/C ratios are the average of 22 performed analyses for each model. As illustrated in Fig. 8, significantly lower D/C values were observed in the infilled wall model compared to the model without infill wall, for both materials. This finding highlights the beneficial contribution of infill walls to the overall lateral stiffness of the structure, effectively reducing seismic demands on critical structural elements such as columns. Quantitatively, in the infilled wall system, the average D/C ratio was found to be 0.609 for concrete and 1.1416 for reinforcing steel. In contrast, in the system without infill wall, the corresponding D/C ratios increased to 1.382 for concrete and 2.086 for reinforcing steel. These results underscore the significant role of infill walls in enhancing structural performance by limiting inelastic deformations and mitigating potential damage during seismic events.

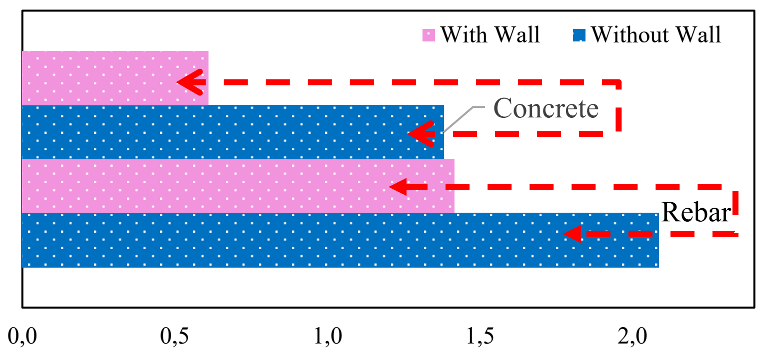

Fig. 8. D/C Ratios in the Column for concrete and Rebar

In addition, D/C ratio based on drift ratios were calculated to assess the lateral displacement capacities of the structures. In these calculations, a drift limit of 3% (0.03) was adopted, in accordance with TBSC (2018). Fig. 9a illustrates the D/C ratios at purlin-roof girder connection for floor drift (calculated as displacement at the top of column divided by column height) and shear force. As presented in the Figure, the systems with and without infill wall, as expected, exhibited similar performance in the UX direction in terms of drift demands (no infill wall available in UX direction). However, in the UY direction, the system without infill wall approached a critical level, with D/C ratio exceeding 1.70. These results clearly demonstrate that the presence of infill walls significantly enhances the lateral stiffness of the structure, thereby reducing drift demands in Y direction under seismic loading.

The nonlinear time history analyses were conducted to evaluate both in-plane and out-of-plane shear demands acting on the purlins. Based on these demands, D/C ratios were calculated, and the results are presented in Fig. 9b. The findings reveal that purlin elements in infilled wall systems experienced notably higher shear demands compared to those without infill for both in plane and out of plane behavior. Nevertheless, these increased demands remained within acceptable limits defined by the CP performance level.

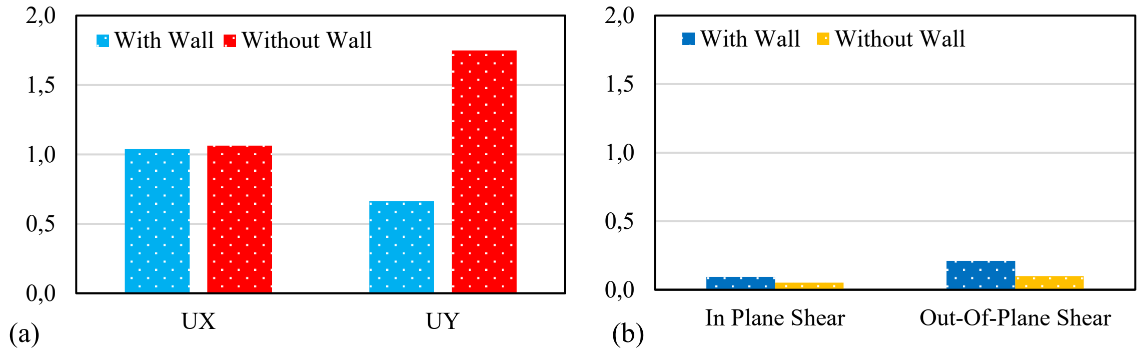

Fig. 9. D/C ratio at purlin-roof girder connection for (a) Floor Drift and (b) Shear Force

Fig. 10 illustrates average D/C ratios for shear force and rotation response at the corbel-roof girder connections. As presented in Fig. 10, several ground motion records (RSN1182XY, RSN1504YX, RSN4847YX, RSN3748YX, RSN802YX) were excluded from the graph due to excessively high out-of-plane rotation demands observed in the infilled wall system. Therefore, the graph was constructed based on the average values of the remaining 17 ground motion records.The analyses revealed that infilled wall systems visibly increases the shear response both in plane and out of plane directions. Additionally, out-of-plane rotation demands on the corbel elements increased significantly although no visible influence of infill wall on in plane rotations is detected.

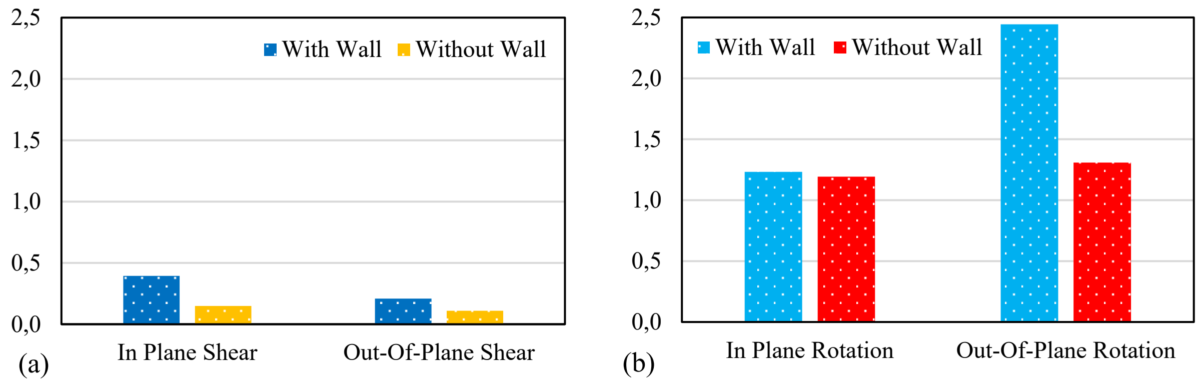

Fig. 10. D/C ratio at Corbel-roof girder connection for (a) Shear force and (b) Rotation

5. Conclusions

This study evaluated the seismic performance of a pin-connected prefabricated industrial building by comparing structures with and without infill walls through nonlinear time-history analyses, in accordance with the Turkish Building Seismic Code (TBSC, 2018). The results showed that infill walls significantly enhance lateral stiffness, shorten natural periods, and improve the distribution of modal energy, particularly influencing the out-of-plane behavior of the system. Strain- and drift-based D/C ratio assessments confirmed that infilled systems experience lower seismic demands and reduced deformation, whereas structures without infill walls are more susceptible to damage. Additionally, secondary elements such as purlin-to-roof beam and corbel connections remained within acceptable performance limits when infill walls were present. Overall, the findings highlight that infill walls substantially improve both the global and local seismic performance of prefabricated structures, supporting their explicit consideration in design and assessment, especially for industrial buildings in high seismic risk regions.

Abstract. Multi-tiered steel eccentrically braced frames (MT-EBFs) can be utilized as lateral load-resisting systems in tall single-story and multi-story buildings due to their high ductility, energy dissipation capacity, and architectural flexibility. However, the stability of link beams and the influence of initial imperfections on the overall performance of MT-EBFs remain critical design considerations. This study evaluates the effects of lateral support on the lateral-torsional buckling behavior of link beams and examines the impact of initial geometric imperfections on the load-carrying capacity of MT-EBFs. The link beams in MT-EBFs are selected to dissipate seismic-input energy through shear yielding. Nonlinear pushover analyses were conducted using SAP2000 and ABAQUS software to evaluate the lateral performance of MT-EBFs under seismic loading. Additionally, the sensitivity of the capacity of the frame to initial imperfections, such as out-of-straightness and residual stresses, is analyzed. The results reveal that adequate lateral support significantly enhances the stability of intermediate beams, reducing the likelihood of lateral-torsional buckling and increasing load capacity. Furthermore, initial imperfections are shown to reduce the load-carrying capacity of the frame by up to 7%, emphasizing the importance of their consideration in design. A comparative evaluation of the results from SAP2000 and ABAQUS highlights the complementary strengths of different modeling approaches for predicting the behavior of MT-EBFs. This study provides valuable insights into the seismic performance of MT-EBFs and offers recommendations for improving their design to ensure enhanced stability under seismic loading.

1. Introduction

Steel structures are fundamental components of modern infrastructure, particularly in regions prone to seismic activity. Designing these structures to withstand earthquake-induced forces requires systems that possess not only adequate strength and stiffness but also significant ductility and energy dissipation capacity. Among various lateral load-resisting systems, Eccentrically Braced Frames (EBFs) have gained prominence due to their ability to combine the stiffness characteristics of concentrically braced frames with the ductility and energy dissipation potential of moment-resisting frames (Popov & Engelhardt, 1988). This is achieved by intentionally designing specific segments, known as links, to yield and absorb seismic energy, thereby protecting other frame members like columns and braces from significant damage.

In applications involving tall single-story buildings (such as convention centers, sports facilities, warehouses, or industrial structures) or certain multi-story configurations, the height necessitates dividing the bracing system into multiple panels along the vertical axis. This leads to the concept of Multi-Tiered Braced Frames (MT-BFs) (Fig. 1). Using a single, long bracing panel in such structures is often impractical and uneconomical due to the required size and slenderness of the bracing members. Multi-tiered configurations allow for shorter, more efficient braces and provide intermediate lateral support points for the columns within the plane of the frame, reducing their effective buckling length (Ashrafi & Imanpour, 2021). While multi-tiered concentrically braced frames (MT-CBFs) have been more commonly studied and implemented, Multi-Tiered Eccentrically Braced Frames (MT-EBFs) offer a potentially advantageous alternative, leveraging the high ductility and stable energy dissipation characteristics inherent in EBF link mechanisms. MT-EBFs consist of multiple braced panels with intermediate links stacked along the frame height, providing architectural versatility alongside their seismic performance benefits.

Despite these potential advantages, the seismic behavior of MT-EBFs presents unique challenges that are not fully addressed by design provisions developed for conventional, single-story EBFs. The interaction between multiple tiers, the stability of intermediate links located at strut levels between tiers, and the flexural demands placed on the continuous columns are critical aspects requiring specific investigation. The nonlinear behavior and ultimate capacity of MT-EBFs are significantly influenced by factors such as the provision of lateral support to the intermediate links and the presence of initial geometric imperfections in the frame members.

The primary energy dissipation mechanism in EBFs, including MT-EBFs, relies on the inelastic action of the links, typically designed for shear yielding, flexural yielding, or a combination thereof. However, the performance of the entire system depends critically on the stability of these links and the surrounding members. Research, particularly on MT-CBFs, has shown that uneven yielding or buckling of braces across different tiers can lead to a concentration of inelastic deformation in one tier (the "critical tier"), imposing large in-plane bending moments on the columns (Imanpour et al., 2016). This phenomenon raises concerns about potential column instability due to combined axial load and bending. Similar issues are anticipated in MT-EBFs, where sequential or uneven yielding of links across tiers can induce significant in-plane moments in the columns.

A pivotal study by Ashrafi and Imanpour (2021) specifically investigated the seismic response of a two-tiered EBF using nonlinear static analysis with the OpenSees framework. This research underscored that the stability of MT-EBFs is heavily dependent on adequate lateral bracing for intermediate links and that conventional EBF design provisions might be insufficient, potentially leading to premature failure modes. They concluded that the potential for link and column instability necessitates revisiting design standards for MT-EBFs, which were (and often still are) restricted in major design codes due to lack of supporting research data.

The instability observed by Ashrafi and Imanpour (2021) involved out-of-plane buckling. However, link beams, particularly those subjected to high shear and bending moments during seismic events, are also susceptible to Lateral-Torsional Buckling (LTB). LTB is a complex failure mode involving simultaneous out-of-plane bending and twisting, which can significantly degrade the link's capacity and ductility if not properly restrained. The effectiveness of lateral support in preventing LTB is therefore a crucial design consideration. Furthermore, the detailing of connections between braces and beams can influence the rotational restraint provided to the link ends, potentially affecting LTB behavior. For instance, Rezaee and Asghari (2024) noted that different connection configurations (e.g., gusset plates vs. direct welding) can offer varying levels of stiffness against LTB in intermediate beams. Ensuring sufficient lateral and torsional restraint is paramount for achieving the desired stable, ductile shear-yielding mechanism in MT-EBF links.

Beyond the provision of lateral support, the structural response of steel frames is invariably affected by initial imperfections. These imperfections, stemming from manufacturing tolerances, fabrication processes, and erection procedures, include deviations such as member out-of-straightness, column out-of-plumbness, and residual stresses locked in during rolling or welding. While design codes provide tolerance limits, even imperfections within these limits can significantly influence the nonlinear behavior and ultimate capacity of steel structures. Ma and Xu (2020) emphasized that initial imperfections increase deflections and decrease the load-carrying capacity of steel frames, potentially leading to instability. Jin et al. (2014) found that while the ultimate deformation of steel braced frames is proportional to the size of imperfections, even frames with small imperfections behave differently from theoretically perfect frames.

Fig. 1. Multi-tiered eccentrically braced frame (Dusicka et al., 2006)

The presence of imperfection can reduce the lateral stiffness of frames, making them more prone to instability, a factor particularly noted in studies on partially braced frames (Hou & Li, 2008). Accurately capturing the influence of imperfections often requires advanced analysis techniques. Geometrically and materially nonlinear analyses incorporating imperfections, frequently represented as scaled eigenmodes derived from elastic buckling analysis, are increasingly used (Slack et al., 2024), (Shayan et al., 2014). The selection of appropriate buckling modes and scaling factors is critical for reliable predictions (Jindra et al., 2024). While the specific direction of imperfections might have a limited effect on the ultimate load, considering combinations of buckling modes is often necessary to capture the most critical scenarios (Arrayago & Rasmussen, 2022). Furthermore, imperfections can exacerbate the structural response under other demanding conditions, such as sudden column removal scenarios, by increasing demands on remaining members and reducing overall ductility (Mageirou & Lemonis, 2021). Therefore, understanding the sensitivity of MT-EBFs to these inherent imperfections is crucial for robust seismic design.

While the study by Ashrafi and Imanpour (2019) provided valuable insights into the necessity of lateral support and the potential failure modes in MT-EBFs, and various researchers have investigated the general effects of imperfections on steel frames, a focused investigation into the interplay between lateral support effectiveness (specifically concerning LTB prevention in links) and the sensitivity of the overall MT-EBF response to initial geometric imperfections remains warranted. Furthermore, the choice of analytical software can influence the predicted behavior, particularly when complex phenomena like LTB and post-buckling response are involved. Design engineers commonly use structural softwaresi such as SAP2000, while more detailed finite element analyses are often performed using ABAQUS , which allows for sophisticated modeling of shell elements, material nonlinearity, geometric imperfections, and contact interactions. A comparative assessment of these tools for MT-EBF analysis is lacking.

This study aims to address these challenges by comprehensively evaluating the nonlinear behavior of multi-tiered steel eccentrically braced frames, with a specific focus on the effects of lateral support conditions on the lateral-torsional buckling behavior of intermediate link beams and the impact of initial geometric imperfections on the overall frame capacity and stability. Utilizing nonlinear pushover analyses conducted with both SAP2000 and ABAQUS software, this research will:

1. Investigate the effectiveness of lateral support configurations in enhancing the stability of intermediate link beams against lateral-torsional buckling.
2. Analyze the sensitivity of the load-carrying capacity and deformation behavior of MT-EBFs to initial geometric imperfections, including member out-of-straightness.
3. Compare the predictive capabilities and results obtained from SAP2000 and ABAQUS for modeling the complex nonlinear response of MT-EBFs, including link yielding and buckling phenomena.

By examining these aspects, this study seeks to provide valuable insights into the seismic performance of MT-EBFs, contributing to a better understanding of their failure mechanisms and offering recommendations for improved design practices that explicitly account for lateral support requirements and the unavoidable presence of initial imperfections, ultimately ensuring enhanced stability and reliability under seismic loading.

2. Seismic design of multi-tier eccentrically braced frame based on TSCB 2018

The seismic design of the two-tiered eccentrically braced frame was carried out in compliance with the Turkish Seismic Code for Buildings (TSCB) 2018, whose seismic provisions for structural steel buildings are substantially consistent with those of AISC 341-16, as well as with the Turkish Code for Design and Construction of Steel Structures (TCDCSS) 2016, which closely parallels the requirements of AISC 360-16. The design process follows capacity design principles which have been developed for building-type structures with diaphragms, ensuring that the structural system effectively dissipates seismic energy through controlled plastic deformations in designated elements while maintaining the stability of other structural components.

Brace	HE200B

The geometry of the frame, shown in Fig. 2, is a two-tiered eccentrically braced frame with a floor height of 4m each (total height of 8m) and a total span of 7m. The bracing system adopts a multi-tiered eccentrically braced configuration, with a 1-meter-long link beam at each tier. This configuration was selected to optimize the distribution of seismic forces and enhance the overall stability of the frame. The steel grade of S275 was used as the material of the two-tiered eccentrically braced frame. The basic mechanical properties of the steel material were shown in Table 1, while the cross-sectional properties of the structural members were detailed in Table 2.

The design process began with the link beams, which are the primary energy-dissipating elements in the MT-EBF. The link beams were proportioned to yield in shear, ensuring that seismic energy is dissipated through stable plastic deformations. To achieve this, the link length e was selected such that it does not exceed $1.6M_p/V_p$, where M_p and V_p are the nominal plastic moment and plastic shear strength of the link beam, respectively. This ensures that the yielding mechanism is dominated by shear behavior. Additionally, the link deformations were limited to the values specified by the limits provided in TSCB 2018. The selected I-shaped link section satisfies the seismic compactness requirements, ensuring that the width-to-thickness ratios for both the flange and web comply with the highly ductile member criteria specified by TSCB 2018. Once the link beams were sized, the adjacent members, including the outer beam segments, braces, and columns, were designed to remain elastic under the capacity-induced forces from the link beams. All structural members other than the link beam also meet the high ductility limit values specified in TSCB 2018, ensuring compliance with local buckling prevention criteria.

The axial load on each column was assumed to be 20% of its axial yield strength, reflecting realistic loading conditions. Columns were modeled to be pinned at the base, though torsional restraint was provided. The beams were connected to the columns with pinned connections, while the braces were pinned at the beam-column connections and rigidly connected at the link beam ends. This connection configuration ensures proper force transfer and stability while maintaining the intended energy dissipation mechanism in the link beams.

The potential for lateral-torsional buckling (LTB) in the link beams was a critical consideration in the design. The stability of the link beams against LTB was investigated in this study, focusing on the effects of lateral and torsional restraints on their behavior and energy dissipation capacity. The braces, which are rigidly connected to the link beams, act as lateral restraints, reducing the risk of LTB. However, the absence of lateral bracing at intermediate tiers introduces a potential vulnerability that will be analyzed in detail.

By adhering to these design principles and code provisions, the two-tiered MT-EBF was designed to provide a robust and ductile seismic response. The link beams serve as the primary energy-dissipating elements, while the other members remain elastic under the maximum expected seismic loads. This approach ensures the safety and reliability of the structure during seismic events.

3. Finite element (FE) model

The nonlinear behavior of the MT-EBF has been investigated by conducting the nonlinear pushover analyses of finite element models developed by using ABAQUS/Explicit software and SAP2000. The two-tiered steel frame was modeled in three dimensions using ABAQUS software to investigate the effect of lateral bracing on the behavior of the intermediate link beam in multi-tier eccentrically braced frames. The primary objective of this analysis was to evaluate the influence of lateral-torsional buckling (LTB) on the seismic performance of the frame and to determine the effectiveness of lateral bracing in mitigating instability in the link beam.

Fig. 5. Finite Element (FE) models of the two-tiered EBF

The material model proposed by Baei et al. (2012) was adopted to accurately represent the nonlinear behavior of the steel material Strain-hardening behaviour was incorporated into the finite element model, as illustrated in Fig. 3. The strain corresponding to the onset of strain-hardening was defined as $\varepsilon_s = 11\varepsilon_y$, while the ultimate strain was taken as $\varepsilon_u = 120\varepsilon_y$. An isotropic hardening model was employed in the numerical analysis to effectively capture the expansion of the yield surface under multi-dimensional stress conditions.

Initial geometric imperfection and residual stress were incorporated into the model by scaling the lateral-torsional buckling mode shapes to 1/750 times the element length (L/750), as illustrated in Fig. 4. This approach, commonly used in advanced finite element analysis, ensures that the model captured realistic structural behavior under seismic loading, including second-order effect and imperfection. The magnitude of L/750 was selected to represent typical fabrication and erection tolerances found in steel construction practice.

To simulate realistic loading conditions, concentrated vertical loads of 500.5 kN, corresponding to 20% of the column's axial yield strength, were applied to the top ends of the upper-story columns. These loads were intended to replicate the compressive forces typically experienced by columns in multi-tier frames under seismic and gravity loads. The structural members were modeled using four-node "S4R" shell elements, which are well-suited for capturing the nonlinear behavior of thin or thick shell structures. All elements in the frame were merged into a single part, ensuring continuity and eliminating the need for explicit modeling of welds. This approach also simplified the analysis by treating the frame as a single, unified structure (Vatansever & Cayir, 2024).

Analysis was conducted using two distinct models to evaluate the effect of lateral bracing on the link beam. In the first model (Fig. 5a), the out-of-plane displacement of the lower-story link beam was left unrestrained (Unbraced Model), allowing for potential lateral-torsional buckling under seismic loading. In the second model (Fig. 5b), lateral bracing was introduced to restrain the out-of-plane displacement of the link beam (Braced Model). This comparison enables a direct assessment of the impact of lateral bracing on the stability and overall seismic performance of the MT-EBF.

4. Validation of finite element model

The experimental study conducted by Berman and Bruneau (2007) on eccentrically braced steel frame systems was used as the basis for the finite element model validation. While this experiment did not specifically examine MT-EBFs, it provides valuable data on the behavior of link beams in EBFs, which is directly applicable to the current study. The member sizes used in the experiment are shown in Fig. 6. The three-dimensional finite element model was created to replicate the experimental setup and specimen. The cross-sectional components of the elements, including flanges and webs, were modeled using the "S4R" shell element available in the ABAQUS library. All elements in the frame were defined using shell elements aligned along their centerlines, as shown in Fig. 7.

To simplify the model, welds at the connections were excluded, as no plastic deformation was expected in these regions. Instead, all elements were merged in the model, creating a single continuous part. Rigid body constraints were applied to the rigid plates located at the top and bottom ends of the columns. Reference points were defined at the center of gravity of these plates, and the plates were rigidly connected to these points. This setup allowed boundary conditions and loading to be applied directly to the reference points. Additionally, reaction forces and displacements at these points were used in the analysis results.

Fig. 8. Comparison of link deformations

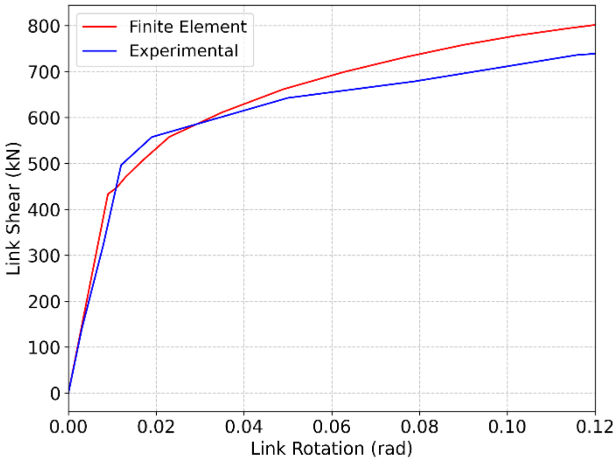

Fig. 9. Comparison of analytical and experimental link shear-rotation curves

To account for second-order effects due to geometric nonlinearity, the "nlgeom" option in ABAQUS was activated. The frame was analyzed using a nonlinear static pushover method. The deformed shape obtained from the analysis was compared with the experimentally observed deformed shape, as shown in Fig. 8. The comparison of the deformed shape of the link beam from the experiment and the finite element analysis (FEA) revealed similar yielding patterns, particularly in the plastic hinge regions. Furthermore, the shear force-rotation curve of the link beam obtained from the experiment was compared with the results from the finite element analysis, as shown in Fig. 9.

The results demonstrated a strong agreement between the experimental and numerical data, with the FEA model accurately capturing both the initial stiffness and post-yield behavior of the link beam. The maximum shear force values from both the experiment and FEA were within 5% of each other, and the rotation capacities showed similar trends. This consistency indicates that the numerical model adequately represents the experimental behavior of the eccentrically braced steel frame system and provides confidence in applying the same modeling approach to the MT-EBF configuration studied in this research.

5. Finite element analysis results

Nonlinear static pushover analyses were performed for both the unbraced and braced models, and the deformed shapes of the frame corresponding to 5% drift ratio were obtained. The deformed shapes for both conditions are shown in Fig. 10. The results revealed that nonlinear deformations in the frame first occurred in the link beam, as expected, confirming the effectiveness of the capacity design approach in concentrating inelastic behavior in the designated energy-dissipating elements.

5.1. Effect of lateral bracing on link beam stability

In the unbraced model, significant out-of-plane deformations were observed in the lower-story link beam due to lateral-torsional buckling. These deformations, shown in Fig. 11a, indicate that the absence of lateral bracing allowed the link beam to become unstable, leading to a reduction in the overall load-carrying capacity of the frame.

The deformation pattern visible in Fig. 11a shows a pronounced twisting of the link beam, with significant out-of-plane displacement. This lateral-torsional buckling mode is particularly concerning as it occurs after the link has already undergone substantial shear yielding, thus compromising the frame's ability to maintain its energy dissipation capacity during continued seismic loading. The buckling pattern indicates that the open-section link beam (I-shaped in this study) does not offer adequate lateral-torsional restraint when the link is subjected to high shear forces.

In contrast, in the braced model (Fig. 11b), the out-of-plane movement of the link beam was effectively restrained, preventing lateral-torsional buckling and maintaining the stability of the frame. The braced model exhibited stable behavior throughout the analysis, with no out-of-plane deformations observed in the link beam even at story drift ratio exceeding 5%. The deformation pattern in this case shows pure in-plane deformation, allowing the link to develop its full shear yielding capacity without premature instability. This highlights the critical role of lateral bracing in enhancing the seismic performance of MT-EBFs.

The capacity curves obtained from the finite element analysis further highlight the critical role of lateral bracing in enhancing the seismic performance of the frame. As shown in Fig. 12, the unbraced model exhibited a significant reduction in lateral load-carrying capacity compared to the braced model. The braced model demonstrated substantially higher capacity that continued to increase throughout the analysis, demonstrating the significant enhancement in structural performance achieved through the provision of lateral bracing.

b) Braced model

Fig. 11. Out-of-plane deformation of the lower-story link beam

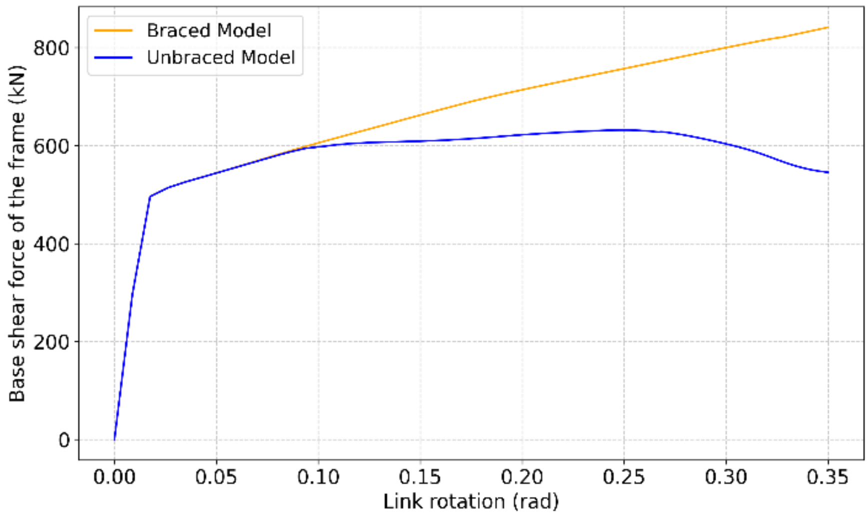

Fig. 12. Pushover curves of the frame to show the lateral bracing

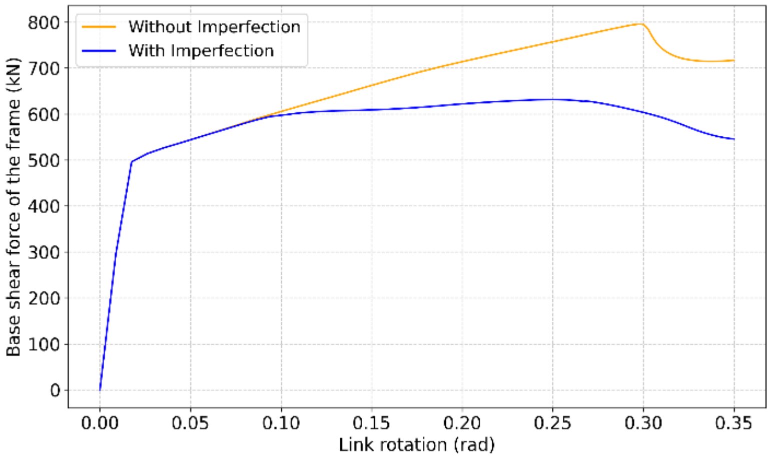

Fig. 13. Pushover curves of the frame to show the effect of the imperfection

The pushover curve in Fig. 12 reveals several important characteristics of the structural behavior. The initial elastic stiffness of both models is identical, as expected, since the lateral bracing does not affect the in-plane stiffness of the frame. The lateral deformations of the frame increase linearly up to 0.25% story drift. At this level, shear yielding of the link beams occurs and nonlinear behavior begins, causing the response curves to diverge. The unbraced model shows limited capacity development and reaches a plateau at higher drift ratios, while the braced model continues to develop increasing resistance. This difference in behavior corresponds with the onset of lateral-torsional buckling observed in the link beam of the unbraced model.

The link rotation measurements indicate that the unbraced model experiences instability at significantly lower rotation demands compared to the braced model. This premature instability in the unbraced model prevents the full development of the link's shear capacity, resulting in reduced overall frame strength and ductility. In contrast, the braced model allows the links to develop their full rotation capacity without instability, leading to superior seismic performance.

5.2. Effect of initial imperfection on link beam stability

The effect of initial imperfection on the behavior of the unbraced model is illustrated in Fig. 13. The pushover curves clearly demonstrate how initial geometric imperfections influence the frame's performance. The model without initial imperfection exhibited a lateral load-carrying capacity approximately 26% higher than the model with initial imperfection. This difference highlights the significant impact of initial imperfection on the overall stability of the frame.

Fig. 13 reveals that both models (with and without imperfections) exhibit identical behavior in the elastic range, with the curves perfectly overlapping until approximately 0.08 radians of link beam rotation. After this point, the curves begin to diverge, indicating that the influence of initial imperfections becomes significant only in the post-yield range. Both models maintain the same stiffness throughout the elastic loading phase, but the model without initial imperfection continues to develop higher capacity in the inelastic range and reaches its peak capacity at a slightly higher story drift ratio. This suggests that initial imperfection primarily affects the post-yield behavior and ultimate capacity rather than the initial elastic response of the frame.

The most significant difference is observed in the post-peak behavior. The model with initial imperfection experiences lateral-torsional buckling at a lower story drift ratio compared to the model without initial imperfection, and the subsequent capacity degradation follows a different pattern. This indicates that initial imperfection serves as triggers for instability, effectively lowering the critical buckling load of the link beam.

The initial imperfection ratio of L/750 used in this study is within typical tolerance limits observed in real structures. Therefore, considering initial imperfection in the design of MT-EBFs is critical for accurately predicting the actual behavior of the frame under seismic loading. The 26% reduction in capacity due to initial imperfections is particularly significant in seismic design, where capacity design principles rely on accurate predictions of member strengths.

5.3. Comparison of SAP2000 and ABAQUS results

The two-tiered eccentrically braced frame was also modeled using SAP2000 software. In this two-dimensional model, a lumped plasticity behavior model was employed for the elements of frame. Plastic hinges were assigned to the midpoints of the link beams and braces, while for the columns and beam outside the link sections, plastic hinges were defined at the ends of the respective members. Since the link beams were designed to yield under shear forces, the plastic hinges in the link beams were modeled as shear hinges. For beam outside the link sections, M3 moment hinges were defined, while for the braces, P axial force hinges were used. In the columns, P-M3 hinges were assigned to account for the combined effects of axial load and strong-axis bending. All plastic hinge properties followed in ASCE 41-13 guidelines.

In the two-dimensional model, the out-of-plane displacements of the link beams were restrained, and a nonlinear static pushover analysis was performed. The deformed shape of the frame at the point of collapse is shown in Fig. 14a. The plastic hinge model used in the analysis is also illustrated in the Fig. 14a, with a strain hardening coefficient of 1.35 taken into account. As the applied lateral load increased, nonlinear deformations were observed primarily in the link beams. Since the shear hinges in the link beams were defined according to ASCE 41-13, collapse occurred when the rotation limit of the link beam was exceeded.

A comparison of the deformed shapes from SAP2000 (Fig. 14a) and ABAQUS (Fig. 14b) reveals interesting differences in how the two software packages represent the collapse mechanism. The SAP2000 model shows concentrated deformations at the predefined hinge locations, with the link beams exhibiting the most significant rotations. The ABAQUS model, on the other hand, shows a more distributed pattern of deformation, with yielding spreading throughout the link beam web and flanges. This difference reflects the fundamental distinction between the lumped plasticity approach in SAP2000 and the distributed plasticity approach in ABAQUS.

Modeling initial geometric imperfection and residual stress in SAP2000 is inherently more challenging compared to ABAQUS. Zhao and Astaneh-Asl (2007) suggested that reducing the elastic modulus can be an effective approach to approximate the effects of initial geometric imperfection and residual stress. In this study, instead of directly modeling these effects in SAP2000, a 5% reduction in the expected yield strength was applied as a calibration method to align the SAP2000 results with those obtained from ABAQUS. This calibration ensured that the SAP2000 pushover curve closely matched the ABAQUS results, effectively accounting for the effects of initial warping, geometric imperfection, and residual stress.

The comparison of base shear versus story drift ratio curves in Fig. 15 shows excellent correlation in the elastic range and good agreement in the post-yield range. Both models predict similar initial stiffness, yield points, and post-yield behavior. The primary difference appears in the ultimate drift capacity, with the SAP2000 model predicting slightly earlier collapse than the ABAQUS model. This difference can be attributed to the distinct methodologies employed in modeling material nonlinearity and failure criteria.

Despite their methodological differences, the close agreement between results validates both approaches for modeling MT-EBF behavior. The ABAQUS model offers more comprehensive capabilities for complex phenomena, such as lateral-torsional buckling and initial imperfections, while the SAP2000 model provides a more accessible approach for routine design work. This comparison suggests that practicing engineers can confidently use either software for MT-EBF analysis with appropriate calibration, selecting based on the specific requirements of their project: SAP2000 for standard design applications and ABAQUS for more detailed investigations of complex instability modes.

6. Conclusions

This study provides valuable insights into the nonlinear behavior of multi-tiered steel eccentrically braced frames (MT-EBFs) under seismic loading. The following conclusions can be drawn from the analysis:

- Lateral bracing significantly enhances the stability of link beams by preventing lateral-torsional buckling. The braced model demonstrated a significant increase in lateral load-carrying capacity compared to the unbraced model, highlighting the critical role of lateral bracing in ensuring the seismic performance of MT-EBFs.
- Initial geometric imperfections, such as member out-of-straightness, reduce the load-carrying capacity of the frame by up to 26%. This emphasizes the importance of considering imperfections in the design process to ensure the reliability of MT-EBFs under seismic loading. The presence of initial imperfections not only reduces the maximum capacity but also affects the post-yield behavior of the frame, leading to earlier onset of lateral-torsional buckling.
- The provision of lateral bracing not only prevents lateral-torsional buckling but also enhances the energy dissipation capacity of the frame, contributing to its overall seismic resilience. By maintaining the stability of the link beams, lateral bracing ensures that they can effectively dissipate seismic energy through the intended shear yielding mechanism. This is particularly important for MT-EBFs, where the link beams are the primary energy-dissipating elements.
- Both SAP2000 and ABAQUS can effectively model the nonlinear behavior of MT-EBFs, with results showing strong agreement despite different modeling approaches. The pushover curves from both software packages show excellent agreement in the elastic range and good agreement in the post-yield range, with the primary difference appearing in the ultimate story drift capacity. This provides confidence in the results and suggests that practicing engineers can use either structural software for the analysis of MT-EBFs, with appropriate calibration.
- For two-tiered eccentrically braced frames, initial geometric imperfection and residual stress can be approximated in SAP2000 by reducing the expected yield strength by 5%. This method, calibrated using ABAQUS results, provides a practical and efficient approach for engineers to account for these effects in their designs.

These findings have important implications for the design and analysis of MT-EBFs in seismic regions. The results emphasize the need for adequate lateral bracing of link beams, particularly at intermediate tiers, to prevent lateral-torsional buckling and ensure stable energy dissipation. Additionally, the consideration of initial imperfections is crucial for accurately predicting the capacity and behavior of MT-EBFs under seismic loading. The comparative analysis of SAP2000 and ABAQUS results provides valuable guidance for practicing engineers on the selection and calibration of analysis tools for MT-EBF design.

Seismic design of high-rise building with differe structural configuration

Sule Yıldırım[1], Mehmet F. Yılmaz[*1]

[1] *Ondokuzmayis University, Engineering Faculty, Department of Civil Engineering, 55105, Samsun, Türkiye*

Abstract. The increasing population of humanity causes the need for all kinds of structures to increase, and the need for high-rise buildings to meet this need is also increasing at a parallel rate. Many studies and research are being carried out on various construction techniques for these high-rise buildings to be economical, sustainable, safe, and continue to be done every passing day. At this point, the diagrid construction technique attracts attention because it is theoretically considered more efficient than traditional construction methods. In addition, its aesthetic appearance attracts attention. However, since a significant part of the diagrid structures built are located in areas with relatively low seismicity, more research is needed to examine the behaviour of diagrid structures under earthquake effects. Within the scope of this research, to better understand the earthquake behaviour of diagrid structures, two different steel structures with traditional braces and diagrid braces will be compared under the effect of various ground motions, and a comparison will be made about the earthquake behaviour of diagrid structures.

Keywords: Steel building; High rise building; Diagrid structures; Concentrically braced system

1. Introduction

The demand for tall buildings is increasing day by day due to the growing population, evolving needs, and limited urban space. Building design and calculation methods have continuously developed from the past to the present, and engineering has started to produce innovative solutions to respond to increasingly complex structural needs. In addition to all these, high-rise buildings are designed to be higher than the previous one in order to respond to changing needs. With the increase in height, the solutions for the safe transportation of both horizontal and vertical loads have become more complex. Although central core or braced systems are generally preferred for tall buildings, diagrid systems, one of the innovative structural systems that have existed in the engineering literature for many years but have recently received renewed attention, offer significant advantages, especially in terms of aesthetics and structural efficiency. This study will focus on the earthquake performance of diagrid structures by comparing the behaviour of diagrid systems under earthquake effects with one of the traditional methods, braced systems.

Diagrid systems are a construction technique that can also be applied in building reinforcement, generally in high-rise buildings. Diagrid systems can be defined as systems consisting of a grid of triangles that encircle the exterior of the building along the structure and thus carry both horizontal loads and vertical loads. "It is a particular form of space truss mixed with tubular system, and the perimeter diagonal grids make the structure stable even without any vertical column in the perimeter of the building. Diagrid is suitable for constructing large buildings with both regular and irregular forms. Compared with conventional framed tubular structures without diagonals, diagrid structures are more effective in minimizing shear deformation because they carry shear by axial action of the diagonal members." (Kim & Lee, 2012a). In this construction technique, the diagrid elements on the exterior of the building significantly eliminate the vertical columns on the exterior face. Diagrid building systems generally consist of a main core, diagonal elements with varying angles, peripheral beams connecting the diagonal elements, other beams connecting the slab and core, and nodes connecting the diagonals and beams. Although theoretically, diagrid structures can safely carry vertical and horizontal loads without additional support, when applied in high-rise buildings, a core is added to the structure, and columns are added at the corner points in order to reduce the dimensions of the diagrid elements and to provide an additional measure.

In this construction method, since there are no vertical columns along the outer line, the horizontal and vertical loads are carried by diagrids along the outer line of the structure. These elements act as both diagonals and columns,

[*] Corresponding author, E-mail: mehmetfatih.yilmaz@omu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_616

and the angles of these diagrids are used differently from the angles of the diagonals used in traditional structures. This angle is related to the load on the structure and the height. Theoretically, the angle for diagrids should take a value between 45-70 degrees. The optimal angle is different for each structure according to the aspect ratio, height, and loads on the structure. “The lateral deflection in a building can be conceived as deriving from two sources. One is produced by the overturning moment, and the other by local shear. The lateral deflection patterns of tall buildings with different aspect ratios are rather different. Generally, in a building with a small aspect ratio less than 3, the shear deflection component predominates, while in a building with a moderate aspect ratio approximately between 3 and 5, the bending deflection component becomes non-negligible and may be on equal terms with shear deflection. For a building with a large aspect ratio from more than 5 to 7, the bending rather than the shear may contribute a lot towards lateral deflection. Furthermore, for a building with a larger aspect ratio beyond 7, the overturning moment deflection predominates instead of the shear deflection.” (Zhang et al., 2012). Since the design of the lower diagrids of the building is based on the bending effect and the upper diagrids on the shear effect, there is not always a single angle for the diagrids, and if necessary, changing the diagrid angle at the upper floors allows for optimal solutions.

In a study conducted by (Kim & Lee, 2012a) for a 36-story diagrid structure, they concluded that the lateral stiffness of the structure decreases as the diagrid angle increases and that both vertical and horizontal loads are optimally carried when the diagrid angle is between 60° and 70° degrees. In addition, when the height of the structure is low, narrower diagonal angles are sufficient since the structure is mostly stressed by shear effect, but as the height of the structure increases, wider diagonal angles become optimal since the structure starts to be stressed by bending effect in addition to shear effect.

In a study conducted by Sun (2015), diagrid models were compared with outrigger and frame models for 60-story and 8-story buildings. The results of the study showed that steel diagrids performed better than all other models in limiting the top displacements; however, their effectiveness in limiting top accelerations was found to be low.

Diagonal elements in diagonal construction are theoretically more efficient than conventional diagonal braced systems since they provide rigidity to the system in carrying loads in horizontal and vertical directions. There are no specific rules and constraints for diagrid structural systems in any of the regulations. However, the design of the elements other than the diagrid elements can be dimensioned as in common construction methods, only additional controls are needed to ensure that the dimensioning and angles of the diagrid elements are optimally designed. However, further studies are needed to better understand the seismic performance of diagrid structures, as “Looking through the entire portfolio of completed diagrid structures, there are very few diagrid tall building structures located in the area where seismic forces govern the lateral design” (Sun, 2015)

2. Finite element modelling of buildings

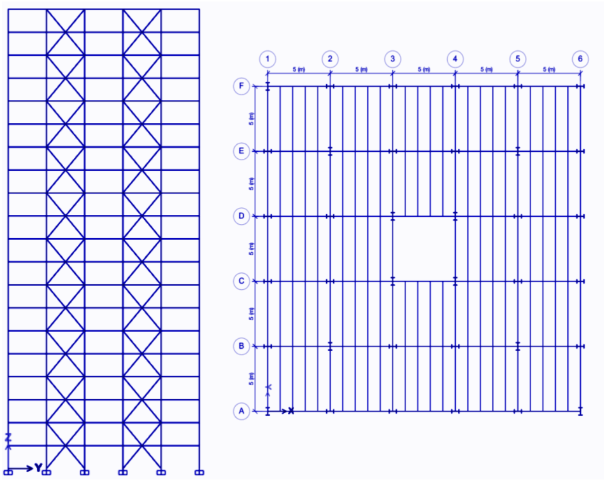
2.1. Description of buildings

Within the scope of this study, in order to better understand the behaviour of diagrid structures under earthquake effects, it will be compared with a steel structure modelled with conventional braces. The ETABS program will be used for the analysis, and the peak displacements, story drifts, and base shear parameters will be evaluated under the influence of the design spectrum taken from the AFAD Earthquake Hazard Map and various selected earthquake records. The location of the buildings in the Istanbul/Ataşehir region is 41.003911° latitude and 29.102972° longitude, and the soil class for this region is ZC.

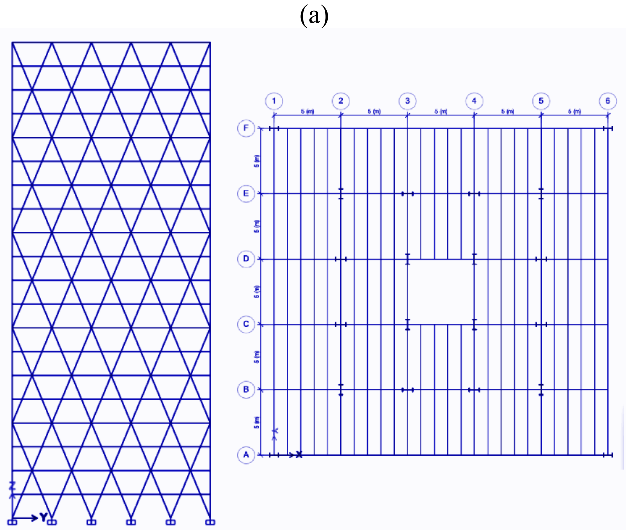
2.2. Modelling of the structures

2.2.1. Creating models

The models of both structures were created and analysed with ETABS program. For ease of calculation, the models are 25 meters by 25 meters, and the approximate floor plans are nearly identical and symmetrical. Also, to avoid large variations in the earthquake effects acting on the structures, the models are arranged so that the building weights are approximately. Each model has 20 stories (see Fig. 1), and the storey heights are chosen to be 3 meters. In both models, the material class was selected as S355 for each element. In the model using the traditional diagonal system, the angle of the diagonals was modelled as 50 degrees to be close to the optimum angle, while in the diagrid system it was modelled as 67.38 degrees. The imposed loads on the building slabs are taken as 2 kN/m² for both typical floors and the roof floor, while the dead loads are taken as 2.5 kN/m² for typical floors and 4 kN/m² for the roof floor.



(a)



(b)

Fig. 1. Model plan and elevation (a) braced model (b) diagrid model

2.2.2. Comparison of dynamic parameters

As a result of the analysis of two models with the same building weight and floor plans, the period of the model with the Diagrid system was determined as 1.37 seconds, and the period of the model with the Braced system was determined as 4.7 seconds. There is almost a 3.5 times difference between the periods of the two models. Accordingly, it can be said that Diagrid systems are more rigid than Braced systems. The mode shapes of both models are the same, and no significant difference can be observed. The first two modes of the models are lateral translation, and the third mode is torsion.

3. Selection of earthquake records

In this study, 20 unscaled real earthquake records were selected to be used. The magnitudes of the earthquake records are between 5.9 and 7.5 (see Fig. 2), the PGA values are between 0.002 and 0.65, and the depths of the earthquakes are between 1 and 19 kilometres. The earthquake records are defined in the U1 and U2 directions, and no earthquake records in the vertical direction were used in the analysis. The mechanisms of the selected earthquakes are mostly strike-slip, but there are also records of blind thrust and oblique-slip earthquakes.

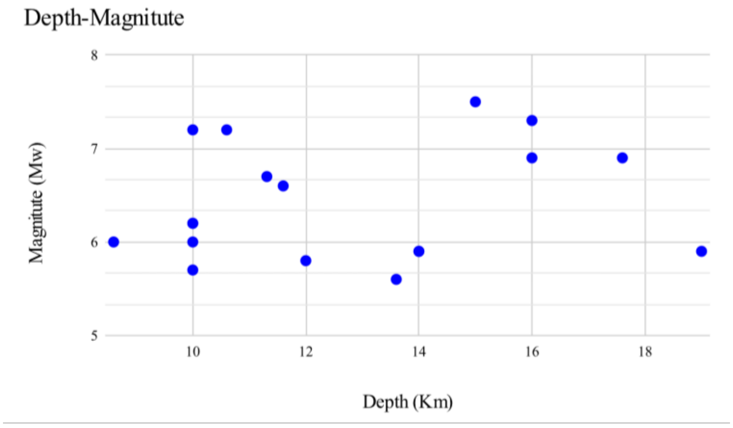


Fig. 2. Earthquake data graph

4. Time history analysis and results

4.1. Comparison of base shear forces
As a result of the analyses conducted using Diagrid and Braced models, it was generally observed that as the peak ground velocity (PGV) increased, the base shear force also increased. Accordingly, a significant relationship was identified between the base shear force and the PGV values of the selected ground motions. When the correlation between PGV and base shear force was examined, the determination coefficients (R^2) were found to be 0.607 for the Braced model and 0.734 for the Diagrid model (see Fig. 3).

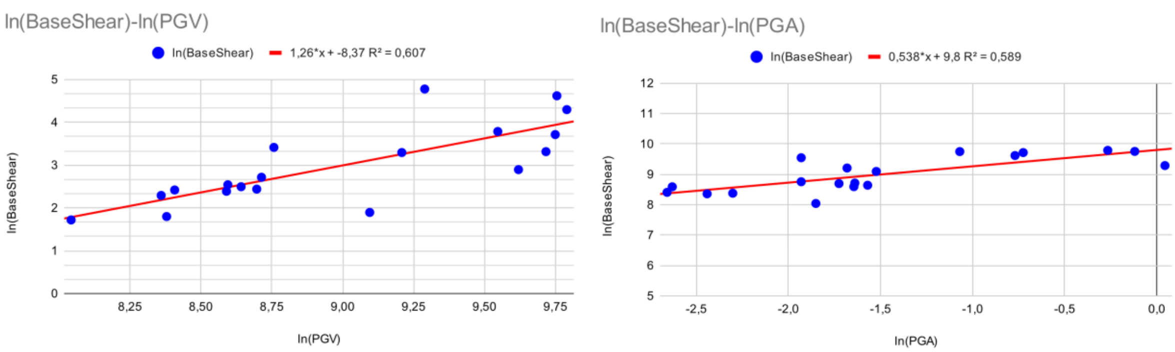

Fig. 3. Braced model base shear-PGV&PGA graph

Similarly, when comparing the peak ground acceleration (PGA) values of the selected ground motions with the base shear forces, it was observed that the base shear force generally increased with increasing PGA values, suggesting a potentially meaningful relationship. The determination coefficients (R^2) between PGA and base shear force were found to be 0.589 for the Braced model and 0.504 for the Diagrid model. Considering all these findings, it was concluded that the correlation between base shear forces and PGV is more pronounced and significant compared to that between base shear forces and PGA (see Fig. 4).

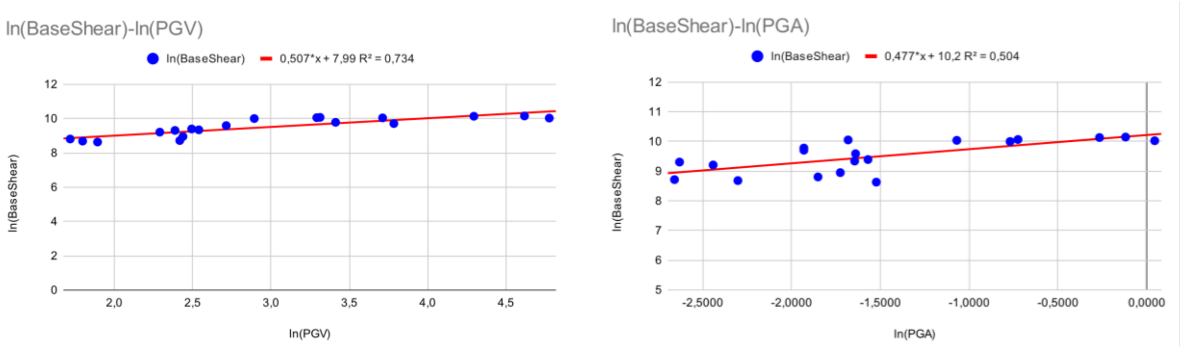

Fig. 4. Diagrid model base shear-PGV&PGA graph

When the maximum base shear forces acting on the Diagrid and Braced models were examined, it was found that in 95% of the analysed ground motions, the base shear values in the Diagrid model were higher compared to those in the Braced model.

4.2. Comparison of top displacements

When the top displacements obtained from the analyses using Diagrid and Braced models were compared with the PGV values of the selected ground motions, no significant correlation was found between these two parameters. The determination coefficients (R^2) for the relationship between PGV and top displacements were found to be 0.224 for the Braced model and 0.17 for the Diagrid model (see Fig. 5). Similarly, when comparing the PGA values of the selected ground motions with the top displacements, no significant relationship was identified between these parameters either, with determination coefficients (R^2) of 0.012 for the Braced model and 0.086 for the Diagrid model.

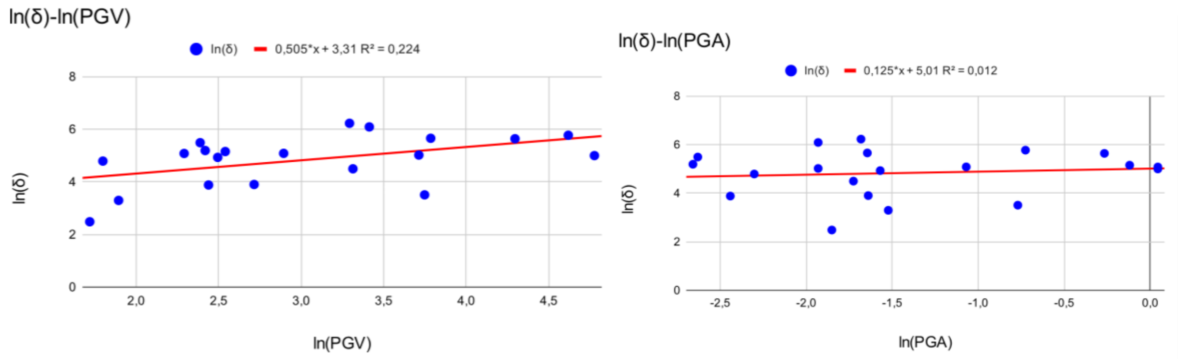

Fig. 5. Brace model top displacement-PGV&PGA graph

As a result, it was observed that both PGA and PGV parameters are not meaningful or sufficient indicators in explaining top displacements (see Fig. 5 and Fig. 6).

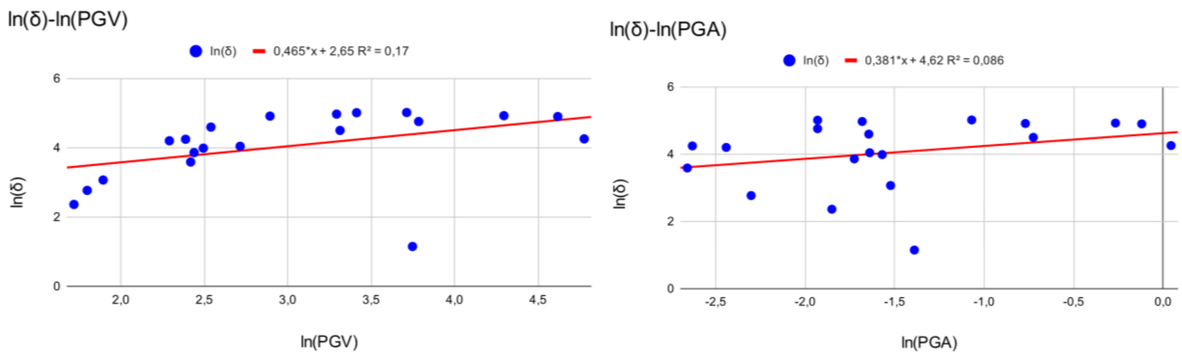

Fig. 6. Diagrid model top displacement-PGV&PGA graph

When the maximum top displacement values of the Diagrid and Braced models were examined, it was found that in 90% of the selected ground motions, the top displacement values of the Diagrid model were significantly lower than those of the Braced model. In cases where the Diagrid model had higher displacement values, the difference did not exceed 13%. Consequently, it was concluded that the Diagrid model performs better than the Braced model in limiting top displacements. This is a result that was anticipated, and similar outcomes have been reported in related studies.

4.3. Comparison of story drift

When the story drift values obtained from the analyses using Diagrid and Braced models were examined, similar to the peak displacements, no significant correlation was found between the story drifts and the PGV and PGA parameters. As a result, both PGV and PGA were determined to be unsuitable parameters for interpreting or predicting story drifts. Analysing the obtained drift values, it was generally observed that the story drift values of the Diagrid model were significantly lower than those of the Braced model (see Figs. 7-10), consistent with the top displacement data.

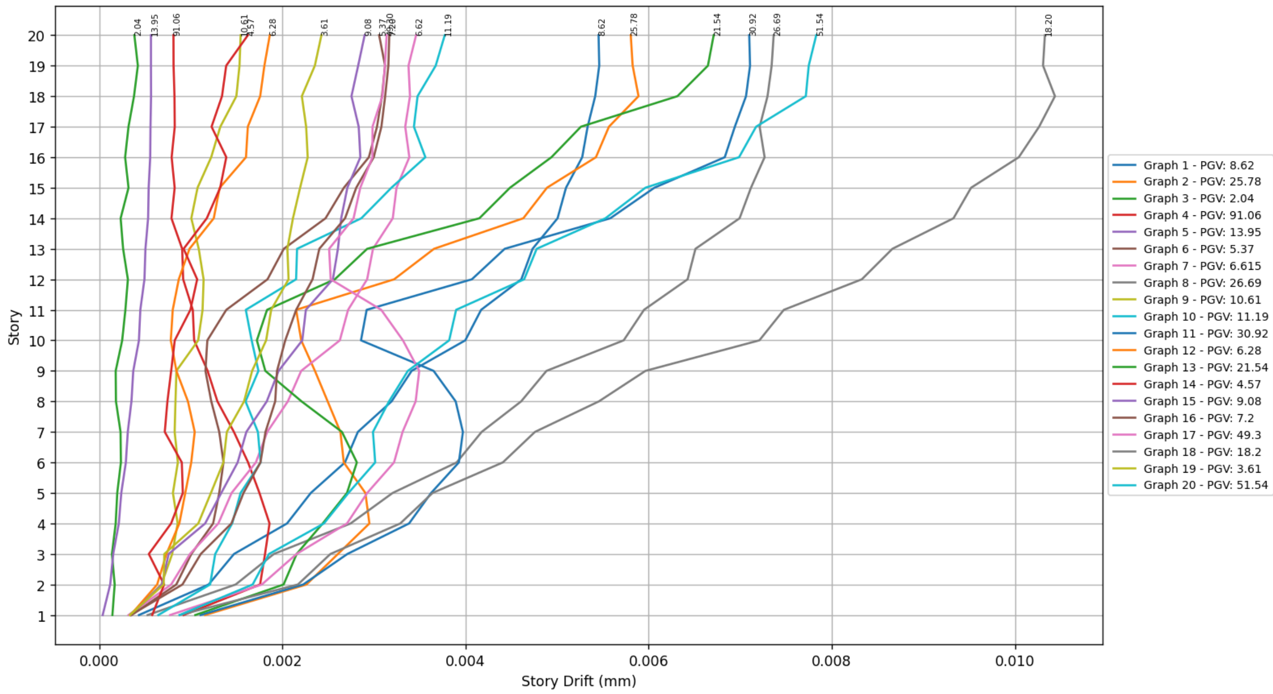

Fig. 7. Braced model story drift X-direction graph

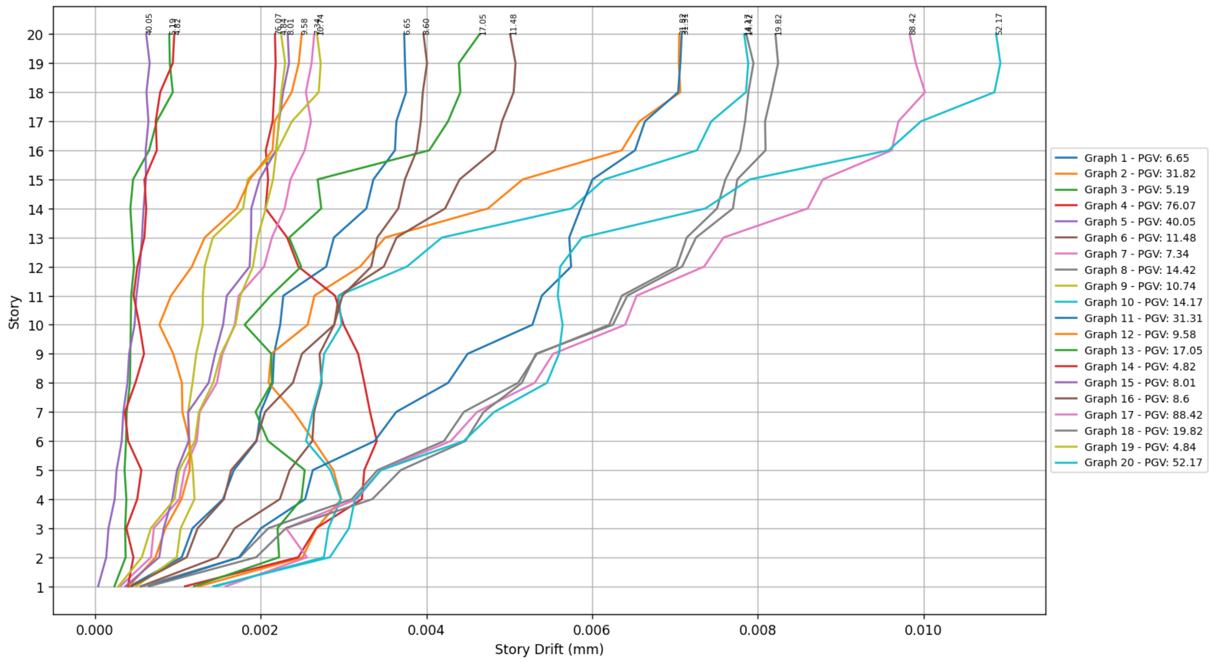

Fig. 8. Braced model story drift Y-direction graph

When the story drifts in the X and Y directions were examined, it was found that the drift values at the first story were quite similar in both models (see Figs. 7-10); however, at the upper stories, the Diagrid model exhibited significantly lower story drifts compared to the Braced model. Additionally, the maximum story drift observed in the Braced model was approximately 3.5 times greater than the maximum drift in the Diagrid model.

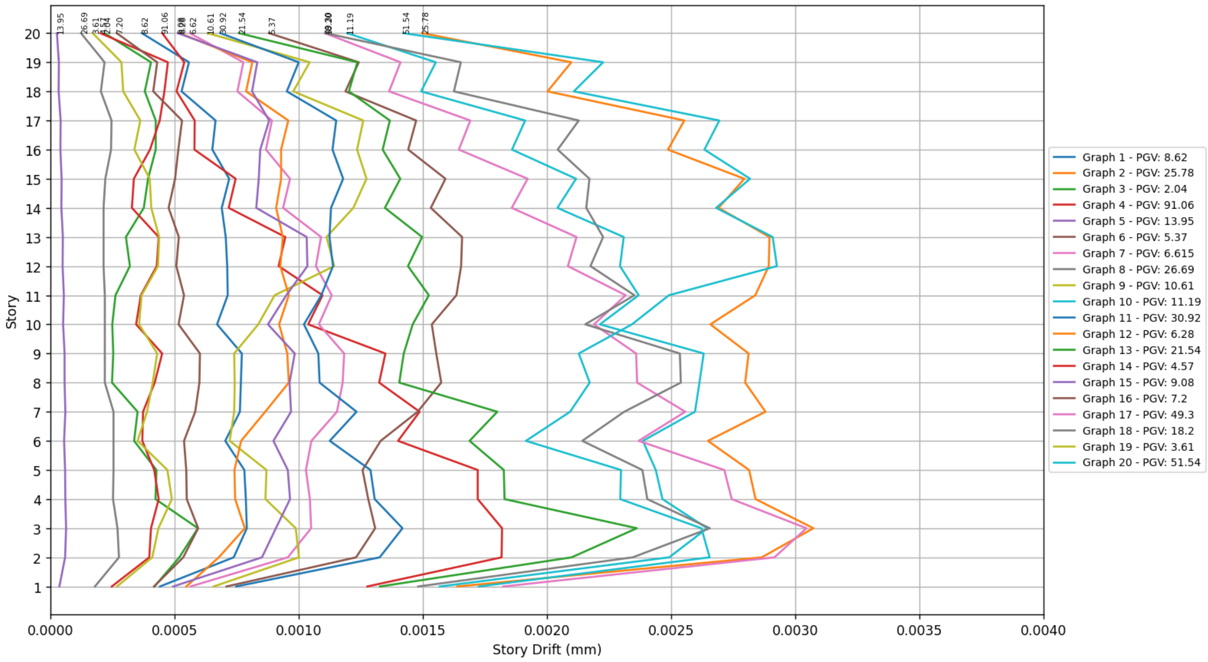

Fig. 9. Diagrid model story drift X-direction graph

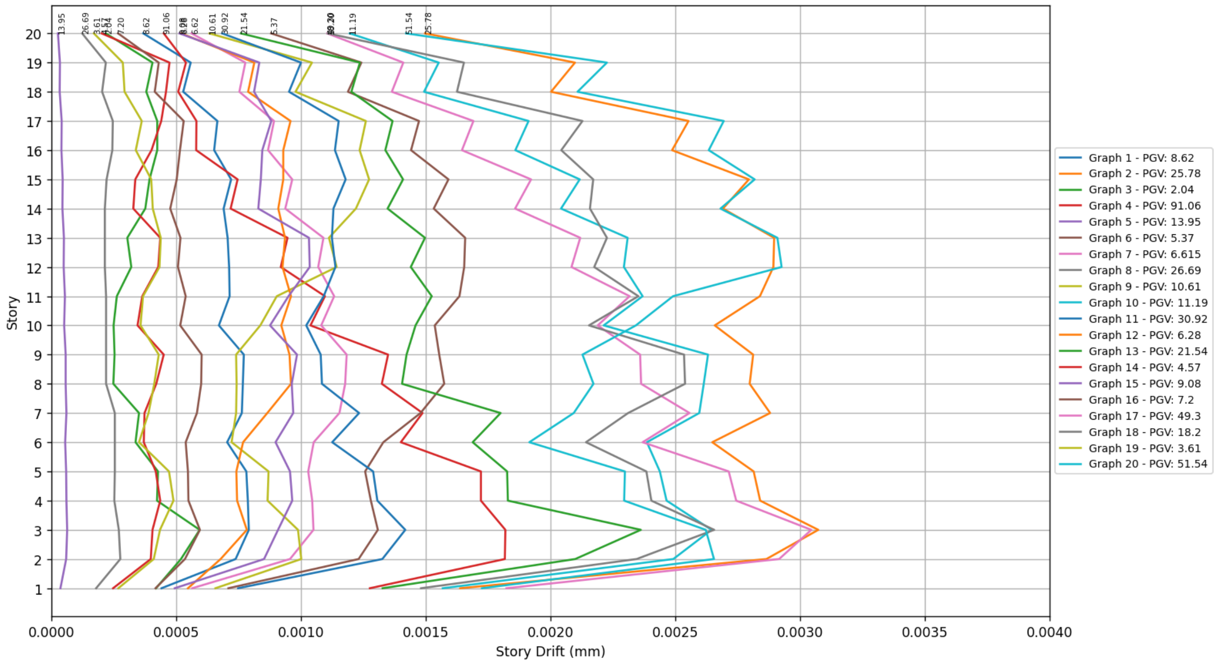

Fig. 10. Diagrid model story drift Y-direction graph

In conclusion, as expected, in addition to its strong performance in limiting top displacements, the Diagrid model also demonstrated generally better performance than the Braced system in limiting story drifts.

5. Conclusions

The growing demand for high-rise buildings in response to modern needs has increased interest in more efficient structural systems. In this study, although not a new system, Diagrid systems, which are gaining popularity but are still relatively uncommon in highly seismic regions, were compared with Braced systems, which can be found almost everywhere, in terms of their seismic performance based on top displacements, base shear forces, and story drifts.

- As a result of the modal analyses, no difference was observed between the mode shapes of the Braced and Diagrid models, which share the same and symmetric floor plans. However, when considering the fundamental periods, the period of the Diagrid model was found to be shorter.
- In the non-linear time history analyses, it was observed that the base shear forces of the Diagrid model were generally higher than those of the Braced model.
- The top displacements obtained from the non-linear time history analyses showed, as expected, that the Diagrid model had significantly lower top displacements compared to the Braced model.
- Similarly, the story drifts obtained from the non-linear time history analyses indicated that the Diagrid model exhibited significantly lower story drifts than the Braced model.

In conclusion, Diagrid systems generally demonstrate stiffer behaviour compared to Braced systems. Moreover, they are considerably more effective than Braced systems in limiting both story drifts and top displacements. However, while these parameters and results provide insight into the seismic performance of the two models, they are not sufficient on their own, and further research and studies are needed.

Retrofitting of single-story RC prefabricated structures with FVD

Özkan Hakan[1,2*], Mehmet Ö. Timurağaoğlu[1], Ramazan Livaoğlu[1,2]

[1] Bursa Uludağ University, Department of Civil Engineering, 16059 Bursa, Türkiye
[2] RL ProjeDestek Consulting Company, Bursa, Türkiye

Abstract. The present study investigates the seismic performance enhancement of single-story reinforced concrete prefabricated (RCP) structures, which are widely used as industrial buildings in Türkiye. Whilst these structures offer certain advantages, such as rapid construction and cost efficiency, they often exhibit vulnerabilities at critical connection points, necessitating additional measures to ensure seismic safety. Given the high seismicity of Türkiye, due to its location on major fault lines, the enhancement of the resilience of such structures is of paramount importance. In this research, viscous dampers were employed to enhance the energy dissipation capacity of a prefabricated structure. The dampers were installed in a symmetrical manner between the upper ends of the columns and the girder beams, aligned parallel to the direction of the beams. Nonlinear dynamic analyses were conducted for high seismicity regions with relatively good soil conditions, utilizing 11 pairs of ground motion records that were compatible with the regional target spectra. The comparative analyses, performed with and without viscous dampers, demonstrated that the inclusion of viscous dampers significantly reduced interstory drifts, improved overall structural stability, and enhanced the nonlinear behavior of prefabricated columns. The findings of this study demonstrate the efficacy of damping-based retrofitting strategies in enhancing the seismic performance of prefabricated industrial structures. The results of this study will contribute to ongoing efforts to increase seismic resilience in earthquake-prone regions, offering practical insights for both design and retrofit applications.

Keywords: Seismic Performance; Fluid viscous dampers (FVD); Prefabricated reinforced concrete, Structures, Structural retrofitting, Nonlinear seismic analysis.

1. Introduction

Single-story reinforced concrete prefabricated (RCP) structures constitute a significant portion of industrial and commercial building stock, particularly in regions with rapidly growing construction demands (Magliulo et al., 2023). While these structures offer notable advantages such as accelerated construction timelines, cost efficiency, and quality control under factory conditions, their seismic performance has raised concerns in past earthquake events. Key vulnerabilities are often associated with insufficient connection detailing, limited lateral stiffness, and inadequate energy dissipation capacity, which can lead to significant damage under strong ground motions (Belleri et al., 2015).

In response to these challenges, retrofitting strategies that enhance energy dissipation without substantially altering the structural configuration have gained increasing attention. Minimizing interventions to the existing structural system is crucial, as excessive alterations can increase project costs, construction time, and operational disruptions, which are often unacceptable for existing facilities. Among the available retrofitting techniques, the application of Fluid Viscous Dampers (FVDs) presents a promising solution by providing effective energy dissipation without introducing undesirable stiffness, while allowing for fast installation and contributing negligible additional mass (Guo et al., 2015). FVDs are capable of absorbing seismic energy efficiently, thereby reducing demand on critical structural components and improving overall seismic resilience. Moreover, their installation can often be accomplished with minimal disruption to existing functionality, making them particularly suitable for retrofitting purposes.

This study aims to improve the seismic performance of single-story RCP structures through retrofitting with Fluid Viscous Dampers (FVDs). Nonlinear dynamic analyses are conducted on representative structural models subjected to selected ground motion records, enabling a comparative assessment between the original and retrofitted configurations. The effectiveness of the proposed retrofitting strategy is evaluated based on reductions in interstory drift demands, connection demands, and ductility demands on prefabricated RC columns. The

*Corresponding author, E-mail: ozkan@rlprojedestek.com

https://doi.org/10.31462/icearc2025_ce_eqe_631

findings are intended to contribute to the development of practical and efficient retrofitting methodologies for enhancing the seismic resilience of existing RCP structures.

2. Viscos dampers and numerical modeling

Fluid Viscous Dampers (FVDs) are passive supplemental energy dissipation devices that generate a resisting force as a function of the relative velocity between their ends, following a nonlinear constitutive relationship. The force-velocity behavior of a typical FVD can be described by the equation:

$$f = c\,|\,\dot{u}\,|\,\mathrm{sgn}(\dot{u}) \tag{1}$$

where f is the damping force, c is the damping coefficient, $\dot{u}$ is the relative velocity across the damper, and α is the velocity exponent, typically ranging from 0.2 to 1.0. Linear damper behavior is obtained when $\alpha = 1$, while most practical FVDs exhibit nonlinear behavior with $\alpha < 1$ (Guo et al., 2015) as illustrated in Figure 1 by the force-velocity and force-displacement relationships for different velocity exponents. In addition to the force-velocity behavior, the internal mechanical configurations of commonly used FVDs are illustrated in Fig. 2a and Fig. 2b to provide a general understanding of their practical application.

The effectiveness of FVDs depends significantly on their placement strategy within the structure. Among the commonly adopted layouts, diagonal and chevron configurations are widely used, wherein damper displacements are directly aligned with interstory drifts, as illustrated in Fig.2c and Fig.2d (Guo et al., 2015). More advanced configurations, such as the toggle and scissor systems, employ linkage mechanisms to amplify damper displacements, thereby increasing the energy dissipation capacity for a given level of story drift, as shown in Fig.2e. and Fig.2f. (Constantinou et al., 2001; Şigaher & Constantinou, 2003).

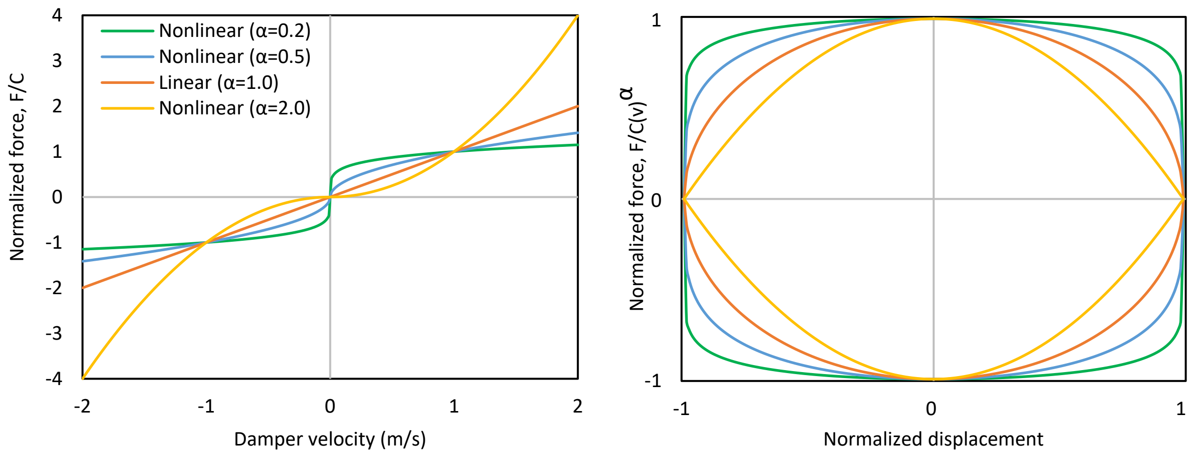

Fig. 1. Force-velocity and force-displacement relationship for FVD under harmonic motion

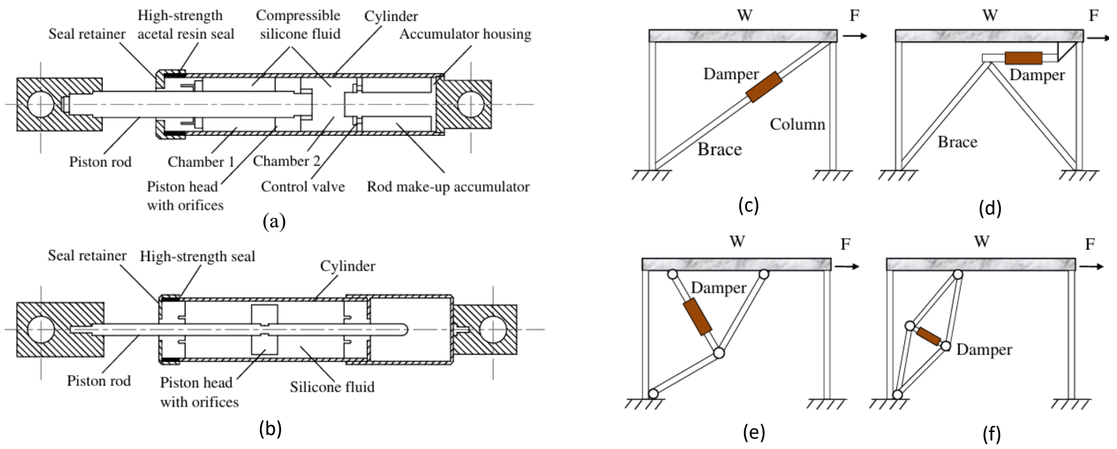

Fig. 2. Configuration of Two Commonly Used FV Dampers and Illustration of a Single-Story Structure with Fluid Viscous Dampers: (a) damper with an accumulator, (b) run-through piston rod, (c) diagonal, (d) chevron, (e) toggle, (f) scissor (Guo et al., 2015)

Inspired by the reverse toggle configuration, this study proposes a novel damper arrangement aimed at further enhancing energy dissipation efficiency while maintaining practical constructability. As illustrated in Fig. 3, the proposed configuration employs an optimized bracing system that magnifies damper deformations under seismic excitation, thereby improving the overall supplemental damping effect.

Two nonlinear time history analysis models were developed for a single-story RCP structure: one without any supplemental damping devices and another retrofitted with two parallelly placed Fluid Viscous Dampers (FVDs). Both models were constructed using Perform-3D. The overall structural configuration is shown in Fig. 4.

In the modeling approach, columns were represented using fiber elements over a length corresponding to the expected plastic hinge regions, allowing for accurate simulation of nonlinear flexural behavior. Beam-to-column and purlin-to-column connections, on the other hand, were modeled based on nonlinear force-displacement relationships derived from the experimental study conducted by Psycharis and Mouzakis (2012), enabling realistic representation of connection nonlinearity observed in prefabricated structures (Psycharis & Mouzakis, 2012).

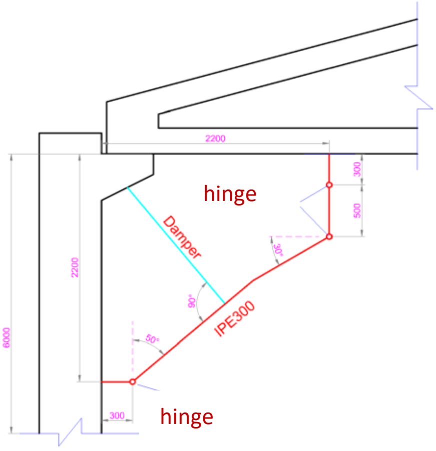

Fig. 3. Schematic diagram of the proposed damper configurations

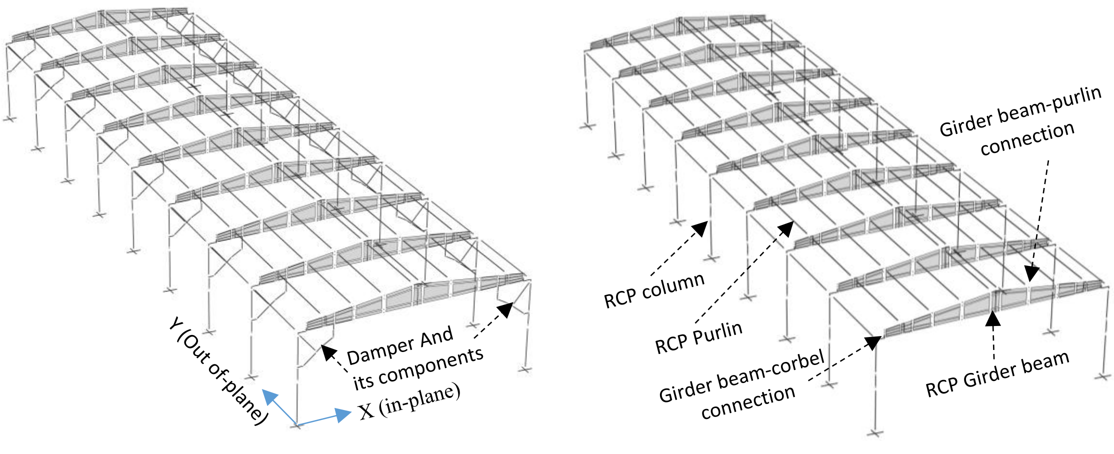

Fig. 4. Generated three-dimensional models of the single-story RCP structure in Perform-3D software

Table 1. Limit values corresponding to the Collapse Prevention (CP) performance level used in the analysis

Limit State	Short Name	CP Limit	unit
Column Rebar Fiber Tension	C-Fbr-T	0.032	strain
Column Concrete Fiber Compression	C-Fbr-C	0.01	strain
Girder Beam-Corbel Connection In-plane Shear Displacement	GBC-In-Sh	20	mm
Girder Beam-Corbel Connection Out-of Plane Shear Displacement	GBC-Out-Sh	20	mm
Girder Beam-Corbel Connection In-plane Rotation	GBC-In-Ro	0.025	radian
Girder Beam-Corbel Connection Out-of Plane Rotation	GBC-Out-Ro	0.025	radian
Purlin-Beam Connection Shear Displacement	PB-Sh	20	mm
Top-of-Column Drift	C-D-	0.03	ratio
Column Shear	C-ShF	2.6	MPa

The structural model represents a single-story RCP structure consisting of eight bays of 6m in the Y direction and a single bay of 15m in the X direction, with a story height of 6m. The columns were modeled as rectangular cross sections with dimensions of 40cm × 60cm, oriented with the longer side parallel to the X axis. Concrete was defined with a characteristic compressive strength of 30 MPa (C30), and reinforcing steel was modeled with a yield strength of 420 MPa (S420). Additionally, low-capacity FVDs with a nominal force of 40 kN (C = 64.83 kN·(s/m)^0.3, α = 0.3) were included in the numerical models.

Based on the nonlinear behavior incorporated into the model, internal force and displacement demands were extracted for critical structural components. Demand-to-capacity ratios (DCRs) were then calculated considering predefined limit states corresponding to the Collapse Prevention (CP) performance level. The limit values adopted for evaluating these ratios are summarized in Table 1.

3. Selection of earthquake ground motion

In accordance with TBDY 2018, eleven ground motion records were selected to represent the DD-1 seismic hazard level based on site-specific conditions. The selected records were scaled and matched to the target spectrum defined for the site. Information regarding the selected ground motions is provided in Table 2, while Fig. 5 illustrates the comparison between the target spectrum and the response spectra of the scaled records.

In the analyses, the selected ground motions were simultaneously applied along the two horizontal directions of the structure. Subsequently, the orientations of the input motions were reversed, and the analyses were repeated to account for directional variability.

Table 2. Properties of selected ground motion records for DD-1 seismic hazard level

Location (City)	Soil class	RSN	Earthquake name	Mw	RJB (km)	Vs30 (m/s)	Fault Mechanism	Scale Factor

3. Comparison of analysis results

Based on the capacity limits defined in Table 1, seismic demands were evaluated across the 11 pairs of nonlinear time history analyses. For each analysis, the maximum structural demands, including internal forces and displacement responses, were extracted and subsequently averaged. Demand-to-capacity ratios (DCRs) were calculated by normalizing the averaged demands with respect to the corresponding capacities. Fig. 6 presents the maximum value among the averaged DCRs obtained from all structural components.

The results clearly demonstrate that the implementation of Fluid Viscous Dampers (FVDs) provides a significant improvement in seismic performance by substantially reducing the maximum demand-to-capacity ratios.

To better quantify the improvements achieved through the use of Fluid Viscous Dampers (FVDs), the percentage reductions in the maximum averaged demand-to-capacity ratios (DCRs) were calculated for critical structural components. The differences between the damped and undamped cases were expressed as percentage changes, as summarized in Table 3. This representation allows for a clearer understanding of the extent of the performance enhancement provided by the dampers.

To further evaluate the behavior of the fluid viscous dampers (FVDs), displacement-force and velocity-force relationships for a representative damper were extracted from all ground motion analyses. These hysteretic responses are presented side-by-side in Fig. 7. It is observed that the dampers operated effectively within a maximum stroke of approximately 2 cm, maintaining stable energy dissipation characteristics throughout the seismic excitations.

4. Conclusions

The present study demonstrates the effectiveness of the proposed small-size, low-capacity viscous damper configuration in enhancing the seismic performance of reinforced concrete prefabricated structures. In contrast to conventional damper systems, such as diagonal, chevron, or toggle configurations, which frequently demonstrate limited efficiency in prefabricated applications, the proposed arrangement attains substantial enhancements in energy dissipation, reduction of inelastic deformations, and enhancement of lateral stability. It is important to note that these benefits are achieved without compromising the structural integrity, architectural considerations, or constructability of the system.

The analysis results confirm that, despite its compact dimensions and reduced force capacity, the proposed damper system effectively mitigates seismic demands. A notable decline in demand-to-capacity (D/C) ratios for columns and roof drift values was observed, thereby demonstrating the system's capacity to regulate critical structural responses and restrict damage incurred during seismic loading. Moreover, the lightweight and space-efficient design of the damper configuration facilitates practical implementation within the dimensional and load constraints commonly associated with prefabricated structures.

The proposed configuration of small-size, low-capacity damper is a promising and practical retrofitting solution for improving the seismic resilience of prefabricated reinforced concrete buildings. It achieves an optimal balance between enhanced performance, cost efficiency, and ease of application.

Risk analysis of buildings with earthquake performance index

Kuban Akkaya [*1], Selin Baş[1], Seda Selçuk[1]

[1] *Cankaya University, Department of Civil Engineering, 06815 Ankara, Türkiye*

Abstract. This research proposal aims to evaluate the most commonly used earthquake performance index by analyzing key structural and geotechnical parameters based on the effects of the 2023 Kahramanmaraş Earthquake. The Rapid Building Type Earthquake Impact Evaluation (RBTEIE) method was evaluated to assess buildings seismic resilience in a specified region. The index is calculated based on several critical parameters, to identify potential damage risks and categorize buildings accordingly. The research methodology consists of data collection, and validation. Data was gathered from various official sources, while validation phase involves testing predictive capacity of the index. We evaluated the effect of two improvements to the RBTEIE index: removing the shear wall parameter in order to improve the applicability of the method and increasing the detail of the visual index to improve the quality of information coming from the visual state of the building. The improved index found was highly accurate when high quality data is collected in predicting building performance in the validation stage. The findings of this study can contribute significantly to regional earthquake risk management and inform urban planning and disaster preparedness strategies.

Keywords: Erthquake performance; Structural analysis; Geotechnical parameters; Damage estimation; Building classification

1. Introduction

In recent years, earthquakes occurring particularly in seismically active regions such as Turkey have clearly revealed the inadequate seismic performance of a significant portion of the existing building stock (Yakut, 2004). This alarming situation has highlighted the necessity for rapid and reliable assessment methods to evaluate the seismic vulnerability of buildings, which constitutes a crucial component of effective disaster management strategies. Assessment techniques such as FEMA 154, the Japanese Seismic Index, and various rapid screening methods widely implemented in Turkey have long been utilized to identify potentially vulnerable structures (Sextos et al., 2008). However, these conventional approaches primarily focus on structural attributes, including building type, number of stories, and material quality, often neglecting critical factors such as soil conditions and regional seismic characteristics.

While most existing rapid assessment methods typically focus on limited structural characteristics like building type, number of stories, and material quality, recent research demonstrates that the inclusion of detailed geotechnical parameters and regional seismic data substantially improves the accuracy of seismic performance evaluations (Erberik, 2008, Halder et al., 2020). To address these shortcomings, the Rapid Building Type Earthquake Impact Evaluation (RBTEIE) method offers a standardized and comprehensive framework by integrating both structural and geotechnical parameters, including soil classification and regional seismic hazard characteristics (RBTEIE, 2023). This approach significantly enhances the accuracy and reliability of seismic vulnerability assessments, especially for mid- and high-rise reinforced concrete buildings, and stands out as a valuable tool for strengthening disaster risk reduction strategies.

There are few studies in the literature that attempts to meause the efficiency and accuracy of RBTEIE method (Yakut, 2004). Our study aims to the validate RBTEIE method through the use of real-world damage data to quantify the accuracy of the index on building assessment. Evaluation of the index with actual data can provide valuable insights for the development of effective risk reduction strategies and for enhancing the safety of the existing building stock.

2. Materials and methods

2.1. Dataset description and parameters

The data utilized in this study were collected from only reinforced concrete (RC) buildings that experienced varying degrees of structural damage during the 2023 Kahramanmaraş earthquakes. Initially, the geographic locations, number of stories, and plan geometries of the buildings were identified through the analysis of Google Earth satellite imagery (Google Earth Pro, 2023). Following this, site-specific seismic hazard parameters, including Peak Ground Acceleration (PGA), Peak Ground Velocity (PGV), and soil classification information, were obtained from the official databases of AFAD (Disaster and Emergency Management Authority of Turkey)

Using these parameters, supplementary seismic hazard indicators such as S_S (Spectral Acceleration at Short Period), S_1 (Spectral Acceleration at 1-second Period), F_1 (Site Coefficient for Short Period), and F_S (Site Coefficient for 1-second Period) were also retrieved from AFAD resources to enhance the accuracy of the seismic hazard characterization (AFAD, 2023). These parameters are essential for estimating the local amplification effects and dynamic characteristics of ground shaking, which vary based on both soil type and seismic input. The compiled dataset comprises a wide range of structural, seismic, and geological parameters, including number of stories, plan geometry, structural irregularities (such as soft stories, short columns, and cantilever extensions), vertical irregularities, regional soil classification, VS30, PGA and PGV values, as well as the distance to the nearest active fault line. In total, 20 parameters were considered in the seismic vulnerability assessment framework, as typically used in the RBTEIE index. All parameters are listed in Table 1.

Table 1. Parameters

Data Source	Collected Parameter(s)
Google Earth	Building conditions Visual assessment Slope Vertical Asymmetry Plan Asymmetry Short Columns Soft Story Cantilever Pounding Effect
AFAD TDTH	PGA and PGV values S_S, S_1, F_1, F_S, S_{DS}, S_{D1}
TKGM	Number of stories Structural type of the building
AFAD TADAS	VS30 Soil class

The Fig. 1. illustrates distribution of buildings according to their number of stories and percent of collapsed buildings for each story group. Notably, while mid-rise buildings (particularly five-story structures) constitute the largest share of the total dataset, the collapse ratio increases significantly for six or more story buildings.

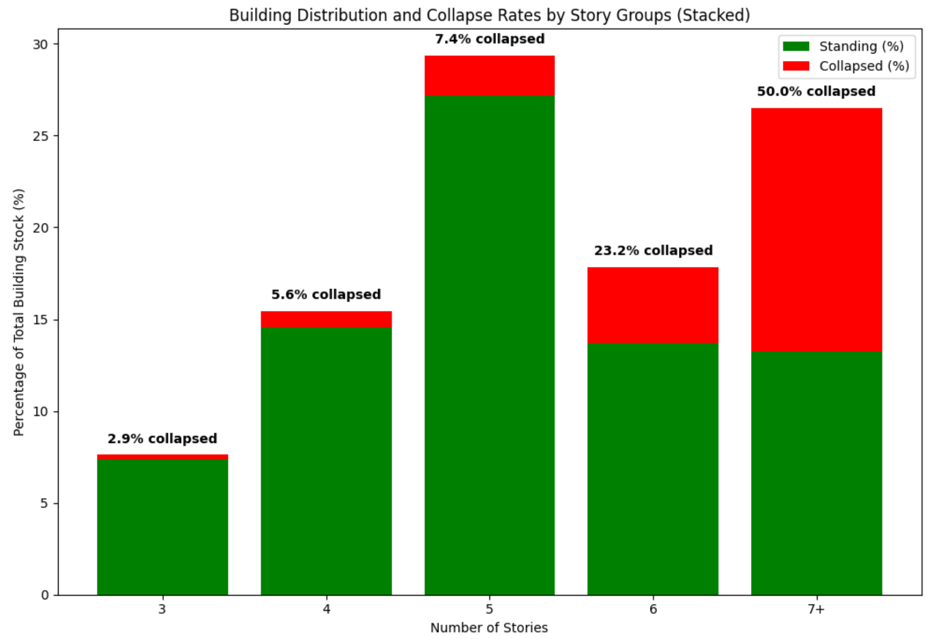

Fig. 1. Distribution of Building Stock and Collapse Rates Across Different Story Groups

The significant increase in collapsed buildings for six or more stories highlights the critical role of story number as a determinant of seismic vulnerability. The collapse rate exceeds 50% in the buildings categorized as seven stories or more, revealing a clear trend of increasing structural vulnerability with greater building height. This pattern suggests the necessity for targeted seismic risk mitigation, especially in taller structures. In Fig. 1., both collapsed buildings and heavily damaged buildings are evaluated together under the category of "failed" structures.

Buildings that were demolished following damage assessment studies conducted after the earthquake were classified as heavily damaged. This approach enables the effective inclusion of not only the buildings that experienced total collapse during the earthquake, but also those that suffered severe structural damage and were subsequently designated for demolition, within the seismic vulnerability assessment framework.

2.2. Seismic vulnerability assessment and performance index (PP) calculation

In this research, the Rapid Building Type Earthquake Impact Evaluation (RBTEIE) methodology was adopted as the core assessment approach to evaluate the seismic vulnerability of buildings (RBTEIE, 2023). The RBTEIE framework allows for the integration of both structural characteristics and geotechnical conditions to provide a holistic risk assessment. The evaluation process involved several key analytical steps, including structural irregularity identification, hazard zone determination, and visual quality assessment. As mentioned earlier, the effect of two improvements to the RBTEIE index, removing the shear wall parameter and increasing the detail of the visual index, was evaluated.

It is important to mention that we assumed all buildings were designed as reinforced concrete frame systems without shear walls. We made this assumption based on our data collection system, which uses Google Street View. It was not possible to detect the presence of shear walls from the street view of the building, so we decided to omit the shear wall parameter used in the RBTEIE method. This assumption can be useful in decreasing data collection duration since it can take a lot of time to evaluate the presence of a shear wall if the structural plans of a building are not available. Removing the shear wall parameter from the RBTEIE method would make the method more practical. Consequently, we also evaluated the effect of the shear wall parameter on the accuracy of the index.

We wanted to increase the detail and quality of data obtained from visual state of the building. Consequently, the visual construction quality of the buildings was classified into four damage levels based on observable indicators: 0 for no visual markings/problems, 1 for slight visual problems, 2 for moderate visual problems, and 3 for severe visual problems. This classification was derived from the presence of white and/or brown stains, surface cracking, concrete spalling, and general deterioration of structural integrity. Brown stains were associated with corrosion-related rust stains, while white stains were interpreted as signs of leaching (efflorescence) due to moisture migration within the concrete.

For each building, individual damage-related parameters were used to determine total score that was used to assign the building to one of the defined quality categories in RBTEIE index. This process provided an objective quantification of visual quality, which was then incorporated into the vulnerability analysis as a numerical parameter.

The Performance Index (PP) (RBTEIE, 2023), representing the seismic vulnerability score of each building, was calculated using the following equation:

$$PP = TP + \sum(Oi \times OPi) + YSP \quad (1)$$

Where, TP (Base Performance Score), reflects the inherent seismic resistance based on the number of stories and the seismic hazard level at the building site.

YSP (Structural System Contribution), accounts for the structural system's effect on overall performance (assuming a bare frame system for all buildings in this study).

$\sum(Oi \times OPi)$, represents the cumulative impact of observed structural irregularities, weighted according to their assigned significance. In this expression, Oi denotes the presence (binary or graded occurrence) of the i-th structural irregularity observed in a building (e.g., soft story, short column, cantilever extension), while OPi corresponds to the predefined penalty score that quantifies the relative importance or severity of that irregularity in terms of its contribution to seismic vulnerability.

3. Results and discussion

The total performance score of each building was determined by summing the base score (TP), the structural system contribution (YSP), and the weighted influence of various structural irregularities. The TP value reflects the inherent seismic resistance based on the number of stories and the seismic hazard level of the building's location, while the YSP component represents the structural system's contribution to overall performance. In the scope of this analysis, all buildings were assumed to have simple reinforced concrete frame system without shear walls.

The effectiveness of this risk classification system was validated through comparative analysis between the computed PP scores and the observed damage states of the buildings. Fig. 2 illustrates the prediction accuracy for identifying safe (undamaged or slightly damaged) and risky (collapsed or heavily damaged) buildings at various PP score thresholds. The horizontal axis represents the applied risk limit, while the vertical axis shows the prediction success rate (%). The results demonstrate that the optimal separation between safe and risky groups occurs within the -20 to 0 score threshold. When this range is applied as the decision boundary, the model achieves an overall prediction accuracy of approximately 80%, indicating a strong classification performance around this threshold interval. Using this information, the calculated PP scores (see Table 2) were categorized into four distinct seismic vulnerability groups based on threshold values derived from empirical data analysis and supported by field observations. The classification thresholds were defined through empirical analyses supported by field observations, allowing for the categorization of buildings into four distinct risk groups: Very High Risk, High Risk, Moderate Risk, and Low Risk.

It is noteworthy that while Yakut (Yakut, 2004), in the context of the 1999 Düzce earthquake, reported a prediction accuracy level of approximately 50% using a rapid seismic performance assessment approach, the method applied in this study achieved an accuracy of around 80% within the defined -20 to 0 PP score threshold. This significant improvement can be attributed to the integration of detailed post-earthquake damage data, particularly the careful consideration of visible structural deficiencies and ground-related parameters, which enhanced the model's capability to differentiate between vulnerable and resilient buildings.

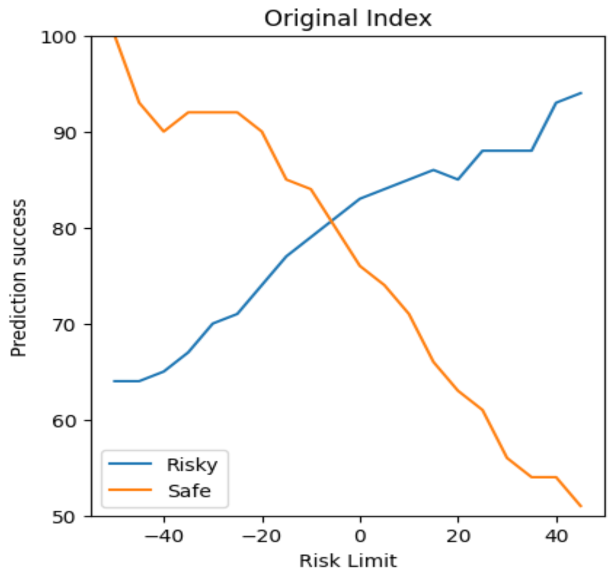

Fig. 2. Prediction Success Rates of Risk Classification Based on Original PP Score Across Various Risk Limits

Table 2. PP score

Risk Category	PP Score Range
Very High Risk	-20 ≤ PP < 0
High Risk	0 ≤ PP < 20
Moderate Risk	PP ≥ 20
Low Risk	-20 ≤ PP < 0

Figure 3 visualizes the distribution of PP scores against the number of stories, with red dots representing collapsed or heavily damaged buildings and green dots representing non-collapsed and non-heavily damaged structures. The plot reveals a general trend where higher-rise buildings exhibit lower PP scores and demonstrate greater damage susceptibility, supporting the validity of the scoring system and the proposed risk classification approach. Moreover, when applying the risk threshold determined through empirical analysis, it is clearly observed that buildings positioned below the PP score of 0 predominantly correspond to the risky group (failed structures), while those above the score of 0 are largely concentrated within the safe group. This distinction reinforces the effectiveness of the selected score interval, where 0 serves as a critical boundary separating high-risk buildings from low-risk or safe structures within the assessment framework. These analytical results indicate that the PP-based classification provides a reliable and effective framework for identifying the seismic vulnerability of buildings. The methodology not only aligns well with observed damage patterns but also reinforces the practical applicability of the RBTEIE method as a rapid assessment tool for earthquake risk mitigation.

Fig. 4 presents the PP-based risk distribution for both collapsed buildings and those that remained standing after the 2023 Kahramanmaraş earthquakes. The left side of the Fig. illustrates the risk categorization of collapsed structures, while the right side depicts the classification of standing buildings. As can be seen from these graphs approximately 75% of the buildings were classified as very high risk and high risk using the improved index. Likewise, approximately 78% of the non-damaged buildings were classified as low risk and moderate risk when we calculated RBTEIE index. These findings confirm that the proposed PP scoring system and its associated risk thresholds are consistent with the actual damage outcomes observed in the field. The dominance of higher-risk scores among collapsed buildings, along with the prevalence of lower-risk scores among standing structures, demonstrates the capability of the RBTEIE index to effectively differentiate between vulnerable and resilient buildings.

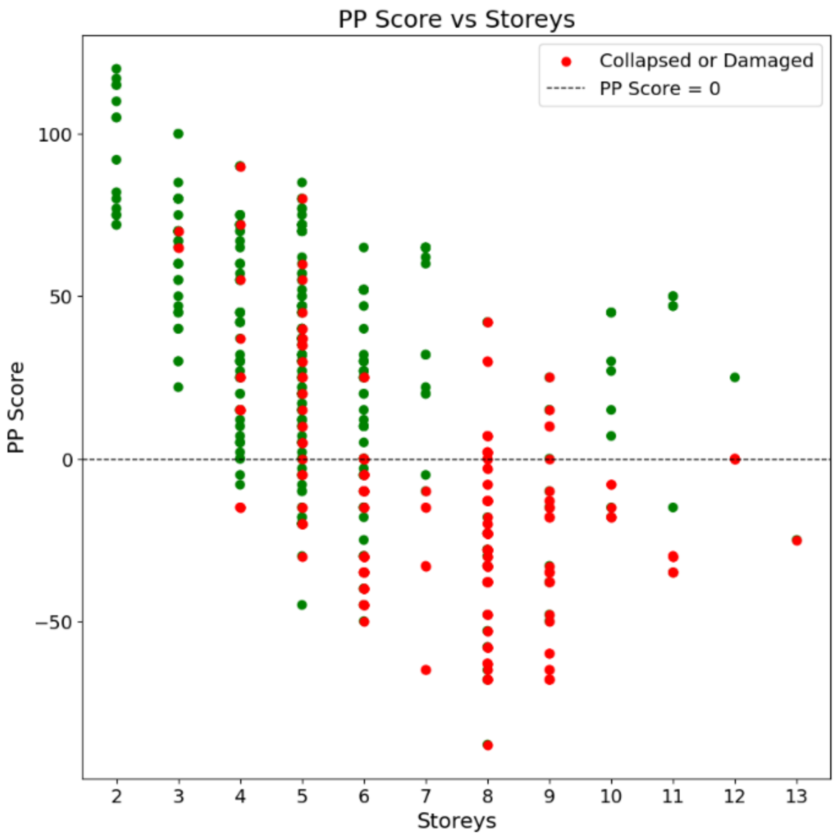

Fig. 3. Distribution of PP Scores by Story Level and Damage Condition

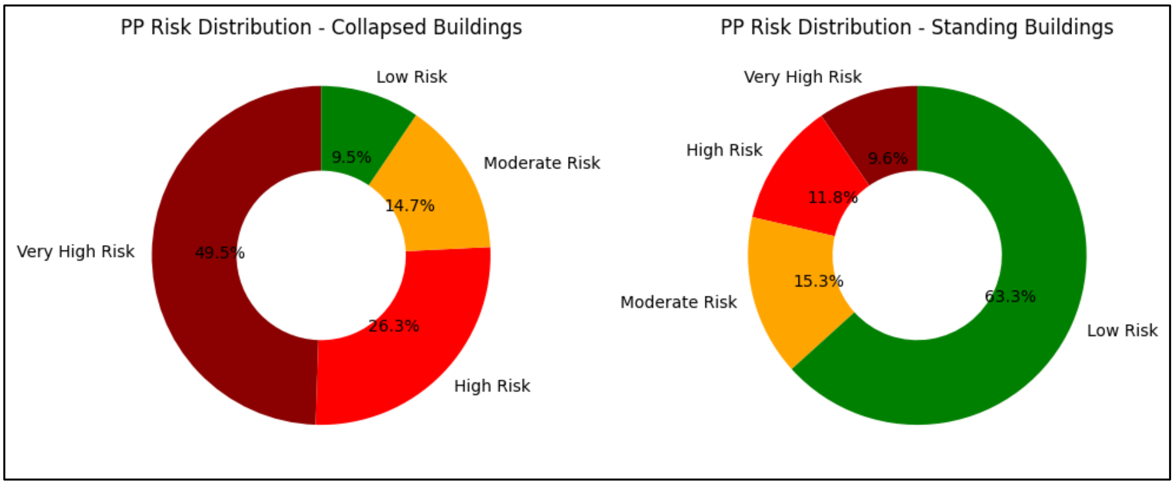

Fig. 4. Distribution of PP categories for all collapsed/non-collapsed buildings

4. Conclusions

This study presented a detailed seismic vulnerability assessment of reinforced concrete buildings affected by the 2023 Kahramanmaraş earthquakes, employing the Rapid Building Type Earthquake Impact Evaluation (RBTEIE) methodology. We proposed two improvements to the RBTEIE method: integrating a more structured and detailed visual assessment parameter and removing the presence of shear wall parameter.

One of the significant outcomes of the study was the achievement of prediction accuracy levels approaching 80%, despite the structural system of all buildings being uniformly assumed as reinforced concrete frame systems due to the lack of specific data on shear wall presence. This high level of accuracy can primarily be attributed to the detailed and systematic evaluation of visible damage parameters, including surface cracking, white markings, concrete spalling, and other observable structural deficiencies. The careful quantification of these visual indicators allowed for a realistic reflection of the actual damage state of the buildings, enhancing the predictive power of the applied vulnerability model. In addition, the risk thresholds were determined by prioritizing the safe region, and the classification boundaries were adjusted accordingly to maintain accuracy within this zone.

The risk classification based on the Performance Index (PP) proved to be effective in distinguishing between damaged and undamaged structures. Collapsed and heavily damaged buildings were predominantly concentrated in the higher-risk categories, while the majority of standing structures were correctly classified within the low-risk group. This consistency between the computed PP scores and the observed damage patterns confirms the validity and reliability of the proposed scoring system. The overall results highlight the effectiveness of the RBTEIE framework as a practical and reliable tool for rapid seismic vulnerability evaluation, especially when supported by real damage data obtained from post-earthquake field observations.

The study also reaffirmed the critical role of number of stories as a dominant vulnerability factor, particularly in conjunction with structural deficiencies such as soft stories, short columns, and plan irregularities. The observed increase in collapse ratios among mid- and high-rise buildings highlights the necessity for targeted mitigation policies focusing on these structural groups.

In summary, this research demonstrates that even without crucial structural system information, when combined with a careful evaluation of visible damage indicators, seismic vulnerability assessments can achieve high levels of predictive accuracy. The results emphasize the value of integrating real life damage data and multi-parameter assessment methodologies, such as RBTEIE, for developing effective disaster risk reduction strategies and improving the resilience of the existing building stock.

Future work is recommended to expand upon these findings by incorporating a wider range of variables and by validating the methodology across different seismic regions and building typologies. Such efforts will contribute to refining vulnerability models and enhancing their applicability in real-world risk management practices.

[2] *RL ProjeDestek Consulting Company, Bursa, Türkiye*

Abstract. Soil-pile interaction is a critical aspect of foundation engineering, particularly for structures built on soft or loose soil. The interaction is governed by the transfer of loads from the pile to the soil and the resulting response of both materials. The interaction depends on various factors, including the pile type, soil properties, depth of the pile, and loading conditions. It is important to consider the soil's resistance to penetration, its shear strength, and the frictional forces between the pile and the soil. Modern techniques, such as numerical modeling and advanced analytical methods, allow engineers to better predict pile behavior and optimize foundation design. The study is focuses on kinematic interaction of a soil-pile system investigating the pile response in upper and lower limits of ZD soil class according to Turkish Building Seismic Code (TBSC, 2018). The pile-soil interface is modeled through contact elements that simulate friction and normal forces between the pile and the soil. Additionally, the nonlinear behavior of the soil is incorporated to improve the accuracy of predictions. The absorbent boundary condition is applied at the boundaries of the model and the response of the system is calibrated against one-dimensional site response analysis. The nonlinear time history analyses are carried out under mentioned boundary conditions and structural loadings. The responses of piles in the soil at the lower and upper limits of the ZD soil class are compared in terms of shear force and moment variation throughout the pile length.

Keywords: Kinematic interaction; Soil structure interaction; Soil pile interaction; Dynamic analysis

1. Introduction

The interaction between structures and the supporting soil has long been a critical consideration in the fields of geotechnical , earthquake and structural engineering. Commonly referred to as soil-structure interaction (SSI), this phenomenon becomes especially significant under dynamic loading conditions such as earthquakes, where the assumption of a fixed-base structure fails to capture the realistic behavior of the system (Kramer, 1996; Wolf, 1985). Traditional design practices often neglect SSI effects by fixing the base of the structure. However, this simplification can lead to unsafe or overly conservative designs, particularly in soft or layered soil profiles (Mylonakis & Gazetas, 2000).

Pile foundations are widely used in regions with weak surface soils to transfer structural loads to deeper, more competent layers. The inclusion of piles introduces additional complexity into the SSI problem, resulting in what is commonly referred to as structure-pile-soil interaction (SPSI). In such systems, load transfer mechanisms are governed by both shaft friction and end-bearing, with the piles acting as intermediaries between the superstructure and the underlying soil. The solution of such systems can be approached either directly or using a substructure approach based on the principle of superposition, where the solution is carried out in two stages: kinematic and inertial interaction.

Recent advancements in computational modeling, particularly through the finite element method (FEM), have enabled more accurate simulation of SPSI effects. These method can account for nonlinear soil behavior, interface friction between pile and soil, group effects in pile foundations, and even the degradation of stiffness under cyclic loading. Such comprehensive modeling is essential for understanding the real dynamic response of the structure-foundation-soil system.

Kinematic bending effects at the pile head in homogeneous and layered soils are widely studied and highlighted in literatüre (Chiou & Wei, 2021; de Sanctis et al., 2010; Di Laora et al., 2012; Di Laora & Rovithis, 2015; Luo et al., 2021). In cases where the pile head is embedded in soft or highly compressible soils, the overall load-transfer mechanism and deformation pattern of the pile can be significantly altered. Soft soils at the pile head may lead to

*Corresponding author, E-mail: omertao@uludag.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_678

reduced lateral stiffness and increased head displacement under lateral or combined loading, which in turn can amplify bending moments along the pile shaft (Reese & Van Impe, 2011). Additionally, the presence of weak soils in the upper layers can contribute to non-uniform settlement and increased differential displacements across pile groups, potentially compromising the structural performance of the superstructure supported by the pile cap. Therefore, proper characterization of near-surface soil conditions is critical for accurately predicting pile performance and ensuring the integrity of pile-supported systems.

This study aims to investigate the kinematic response of soil-pile system under two separate soil profiles being in the upper and lower levels of ZD soil class under three different earthquake ground motion records. Emphasis will be placed on assessing how soil properties influence the pile response, providing insights for more resilient and optimized foundation design. The results are evaluated by comparing the force and moment responses obtained from both profiles.

2. Soil profile and numerical modeling

Based on the data obtained from borehole drilling, field, and laboratory tests, it has been determined that the soil structure in the project area consists of light brown-colored, locally gravelly layers of low plasticity silty clay/sandy clay/clayey silt near the surface, and beige-colored, high plasticity silty clay/sandy clay/clayey silt units at deeper levels (~120m) as shown in Fig. 1. The idealized profiles are selected based on field and laboratory tests. The identification of geological unit variations and the assessment of shear wave velocity (Vs) as a function of depth were determined based on the results obtained from Multi Channel Analysis of Surface Wave (MASW) method conducted in the field as given in Fig. 1.

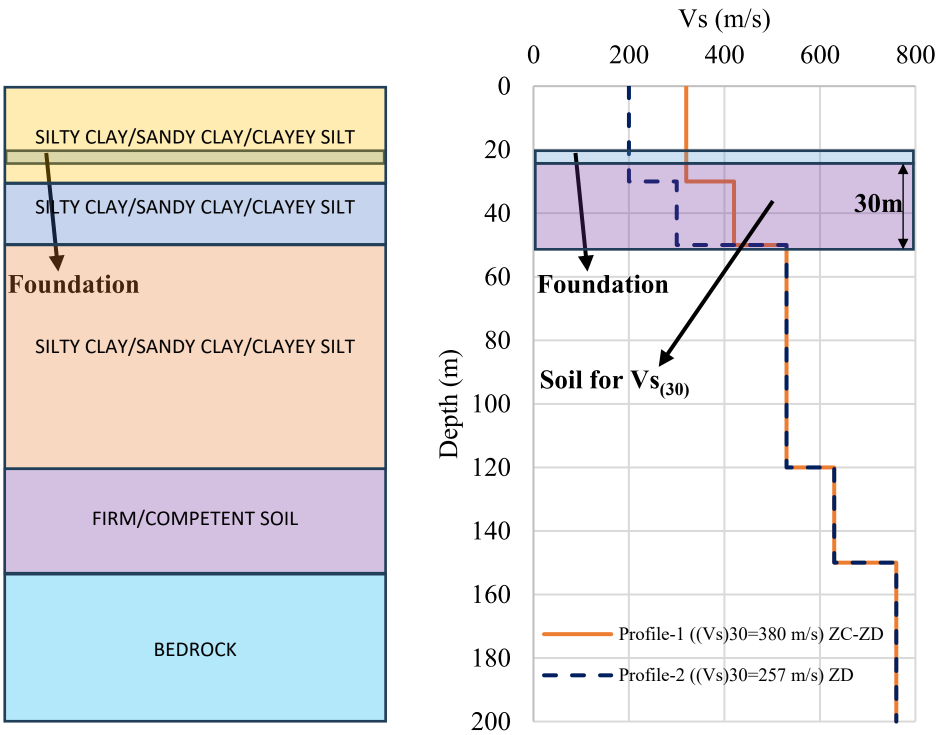

Fig. 1. Soil layers and Vs profiles used in numerical models

The foundation system has a 3m raft thickness with 36 piles with lengths of 32m, 71 piles with lengths of 36m and 66 piles with lengths of 43m. The piles are rectangular shaped barettes with 0.8x2.4m dimensions to resist vertical and horizontal loads. The visual representations associated with the 3D model generated using the Midas GTS NX (2023) finite element program are presented in Fig. 2. It is important to note that smaller element sizes were employed in the region where the building's foundation is to be located, while larger element dimensions were applied towards the model boundaries. To mitigate reflection effects at the lateral boundaries of the model, free-field elements were incorporated to minimize the impact of reflections. These elements utilize the infinite element model proposed by Lysmer and Kuhlemeyer (1969). Within the 3D model, the compliant base feature, available within the software package, was utilized to prevent the reflection of waves reaching the base of the soil domain. In the 3D finite element model, the soil, foundation (raft), and basement walls were modeled using solid elements, while the piles were represented by beam elements. The building foundation, along with the surrounding basement walls up to the ground floor level, was modeled using massless, infinitely rigid elements (Fig. 2) in accordance with TBSC (2018). An appropriate interface has been defined between the pile and the soil. To define these interfaces, it is necessary to determine the ultimate shear force, shear stiffness (K_t), and normal (K_n) stiffness parameters. In this study, the ultimate shear force for the pile-soil interaction was determined using the beta method found available in the literature (Das, 2016). Tip resistance is also defined at the pile bottom to account for the soil resistance at the bottom of piles. The rotation of piles at the Z directions (R_z) is contrained to to prevent torsional behavior. For the 1D analyses, the elastic-half-space option was used in the Deepsoil program (Hashash et al., 2024) at the base to prevent reflections. Three ground motion records were employed for the analysis while one of them (RSN721_X) is used for model dimension calibration in site response analysis. The corresponding record and response spectrum for the earthquakea are shown in Fig. 3.

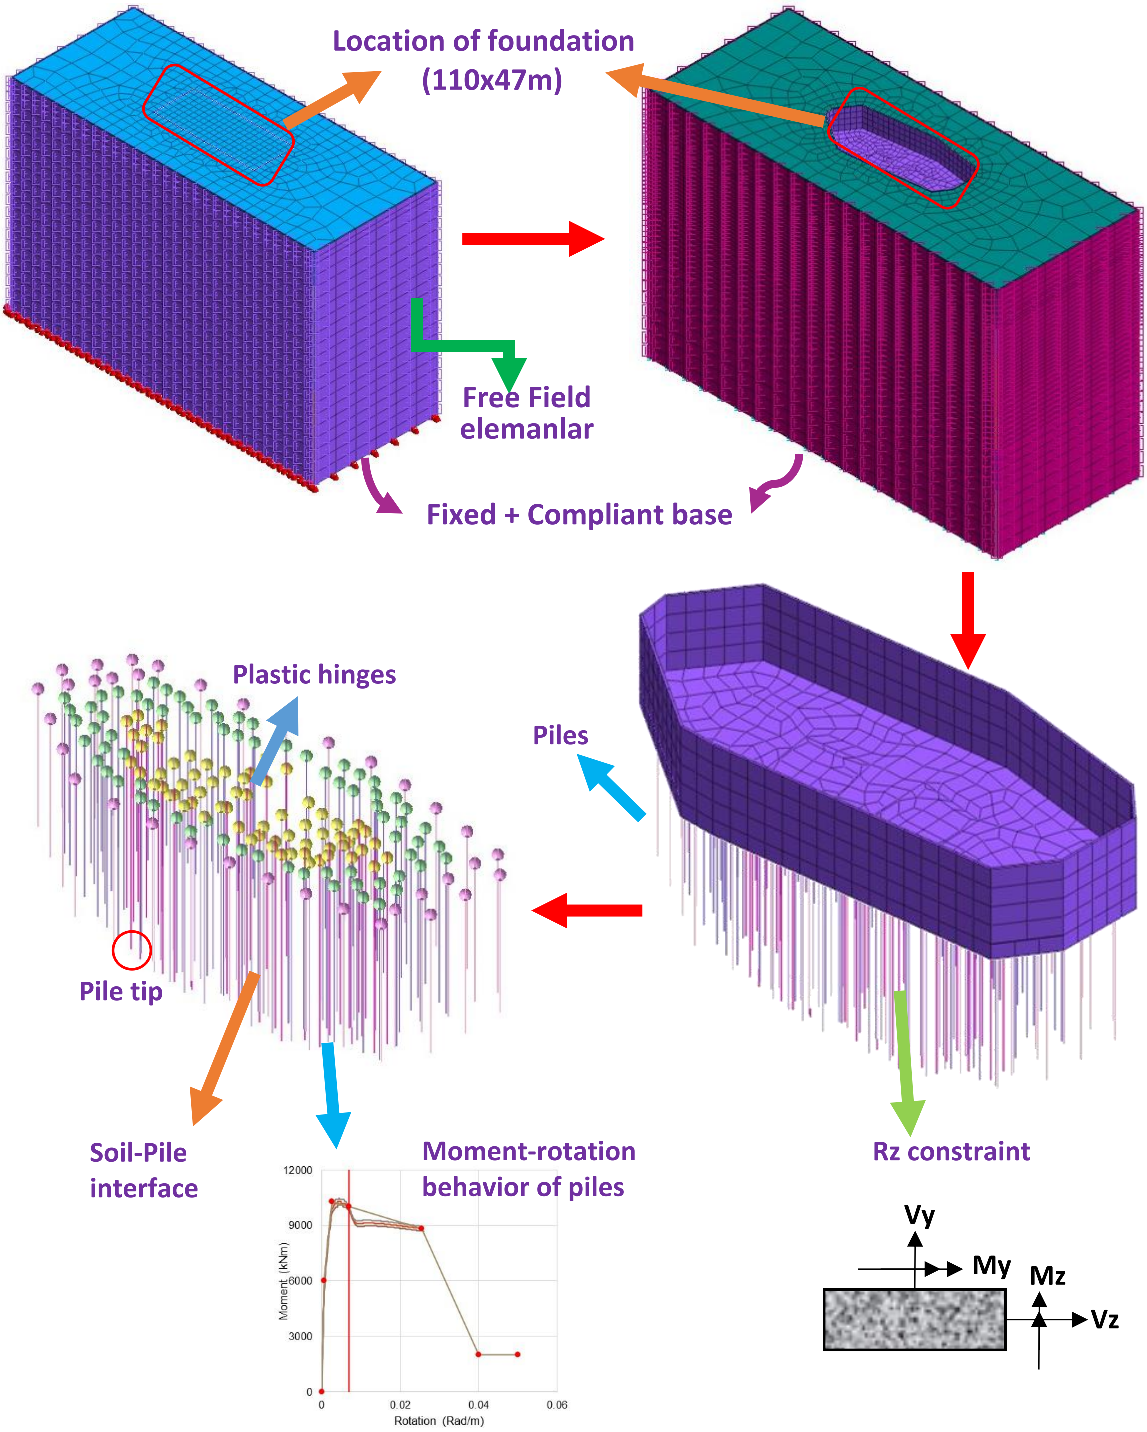

Fig. 2. Generated 3D soil model, foundation and piles

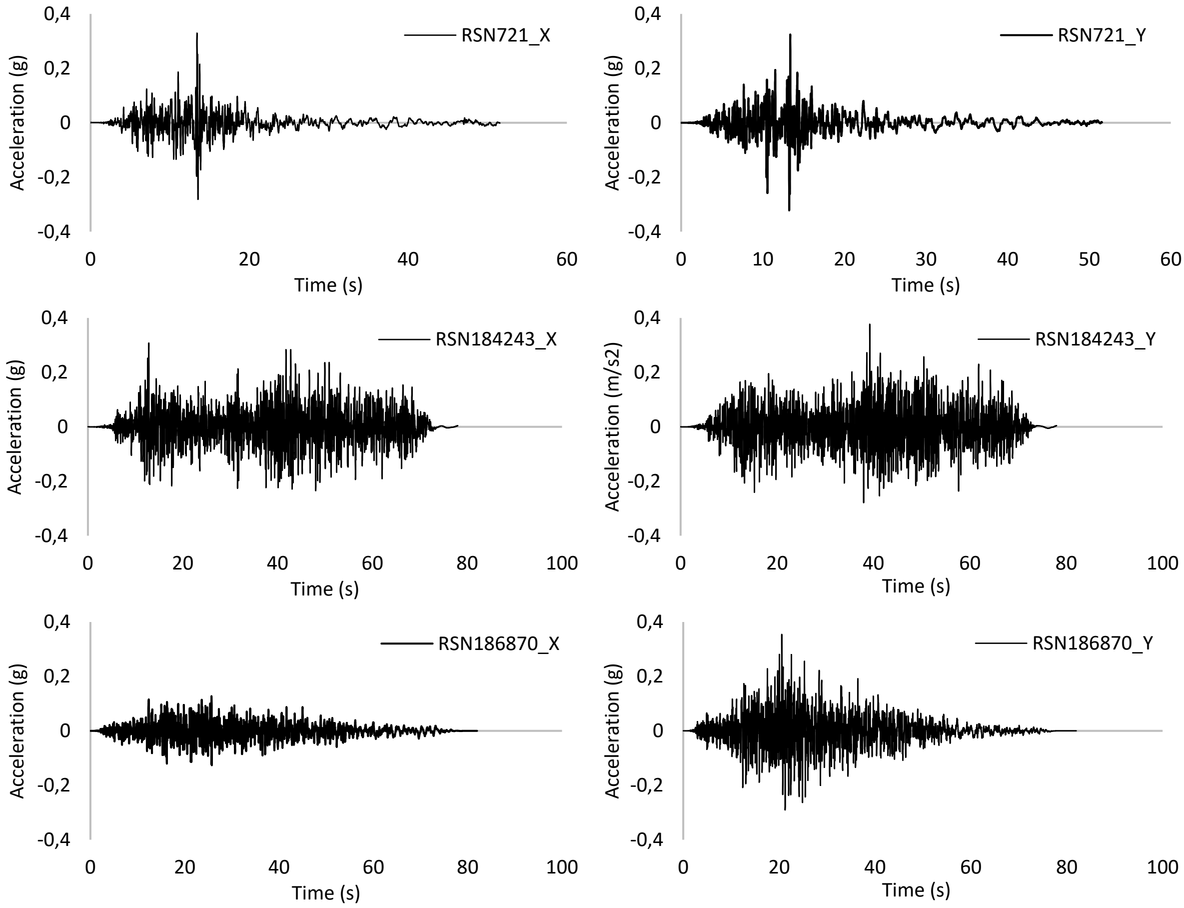

Fig. 3. Time history and response spectrum of the records

3. Soil model parameter calibration

In the present study, the Ramberg & Osgood (1943) material model, which is widely recognized in the literature for representing the nonlinear material properties of soil, has been employed. Initially developed for metals such as aluminum, which exhibit an undefined yield stress, this model was subsequently adapted by Faccioli et al. (1973) to model the shear modulus reduction curves of sands, thus facilitating the representation of soil behavior. The model is implemented in the Midas GTS NX (2023) software package. To characterize soil behavior within the framework of this model, three parameters are required: the initial shear modulus (G_0), the reference strain (γ_r), and the maximum damping value (h_{max}). In light of these parameters, the yield criterion of the model is formulated through simple equations (Midas GTS NX, 2023) in which masing's rule is applied to represent the curves for unloading and reloading behavior. During the calibration process, the reference strain for each layer was determined individually, based on the shear strength (τ_f), cohesion (c), and internal friction angle (ϕ) of each respective layer. The maximum damping value was then established by comparing it with the results presented by Darendeli (2001), as illustrated in Fig. 4, for layer 2. Similar calibration procedure is applied for each layer. In this study, the maximum damping value was set as 20%. Furthormore, an additional 1% Rayleigh damping was introduced into the numerical model to represent damping at small deformations. Additional damping is input in 3D model throuhout Rayleigh damping.

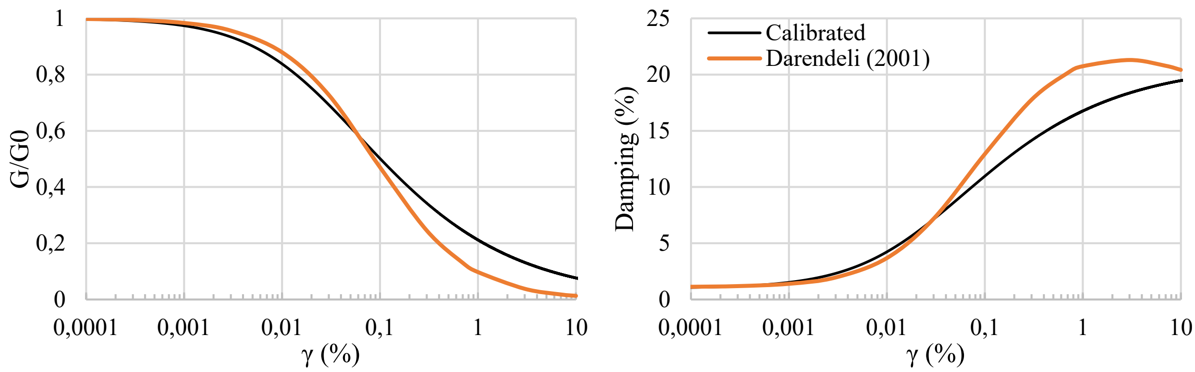

Fig. 4. Shear modulus and damping curves for Layer 2

4. Comparison of analysis results

The analysis are conducted in two phases namely site response analysis and kinematic interaction analysis. In site response analyses, the soil responses occurring at various depths are evaluated in the absence of the superstructure. In contrast, kinematic analyses consider the presence of the pile foundation, allowing for the assessment of responses that develop within both the piles and the foundation. Although the TBSC (2018) suggests dimensions seven times the foundation dimensions (110x47m), a 300x120m soil model has been selected for the 3D model. In this way, a significant analysis burden is mitigated while striving to achieve a behavior that is consistent with the results obtained from the 1D model.

The acceleration response spectrums at the ground surface for both soil profiles under RSN721 earthquake is given in Fig. 5. For both profiles, it is observed that the 1D and 3D analysis results exhibit a high degree of consistency, with comparable response values obtained at both the foundation edges and its center. This indicates that the response in generated 3D model is a reliable model compared with 1D model results. When the results of both profiles are compared, it is observed that in cases where the upper layer consists of weak soil, responses tend to be attenuated at shorter periods (0–0.5 s), whereas relatively larger responses occur at intermediate periods (0.5–2.0 s).

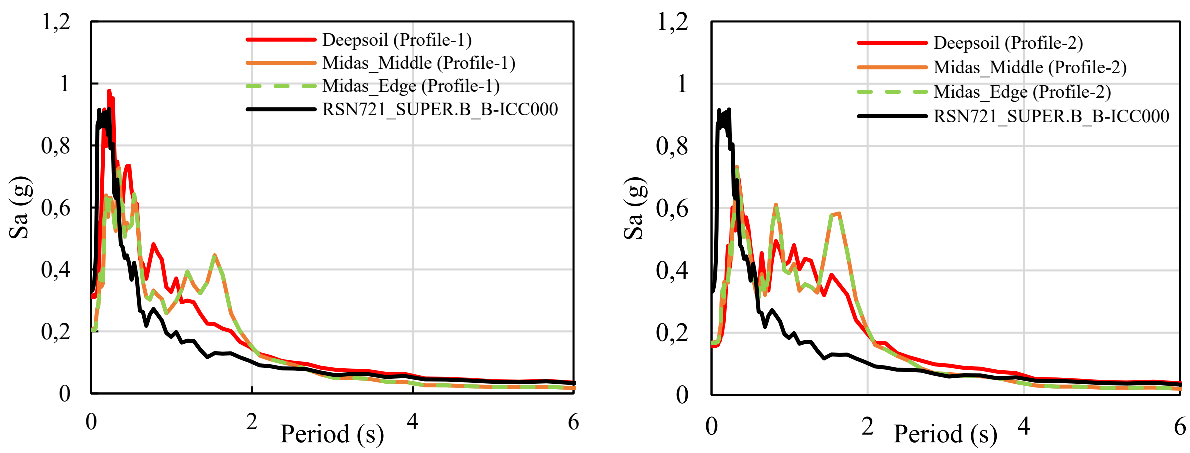

Fig. 5. Comparison of 1D and 3D site response analysis

Evaluations of analysis results were conducted based on the average values of the nonlinear analyses performed in the time domain for three different ground motions. Since the superstructure is positioned at the center of the foundation, longer piles are placed in this area to resist the loads from the superstructure, while the pile lengths decrease towards the edges. The average values of the maximum absolute results obtained from the analyses are presented as the Mz and My versus depth relationships in Fig. 6, and the Vz and Vy versus depth relationships in Fig. 7. In the figures, P1 and P2 defines soil Profile-1 and Profile-2, respectively and explained in Fig.1. The figures show that the moments at the pile head are increased up to 50% in Mz of pile length of 32m for weak soil profile (P2). An examination of both figures in terms of moment and shear force variations indicate that as the pile length increases, the difference between the results for the weak soil condition (Profile-2) and the good soil condition (Profile-1) at the base of the foundation becomes less pronounced. The primary reason for this is that the longer piles are located near the center of the foundation, surrounded by shorter piles, with the shortest piles positioned along the foundation boundaries. AS can be seen from both figures, the observed increases in moment and shear force near the toe regions of the shorter piles located at the foundation edges can also be attributed to this configuration. On the other hand, the largest moment occurs at the pile head of short barrettes (32m) located at the base boundary, while the lowest moments are observed in the longer piles situated in the middle. In the direction where the pile stiffness is relatively low, moments develop along the length of the pile, whereas in the direction of higher stiffness, the moments are high at the pile head and exhibit a decreasing trend towards the pile tip. The opposite responses are observed for shear forces (Fig. 7).

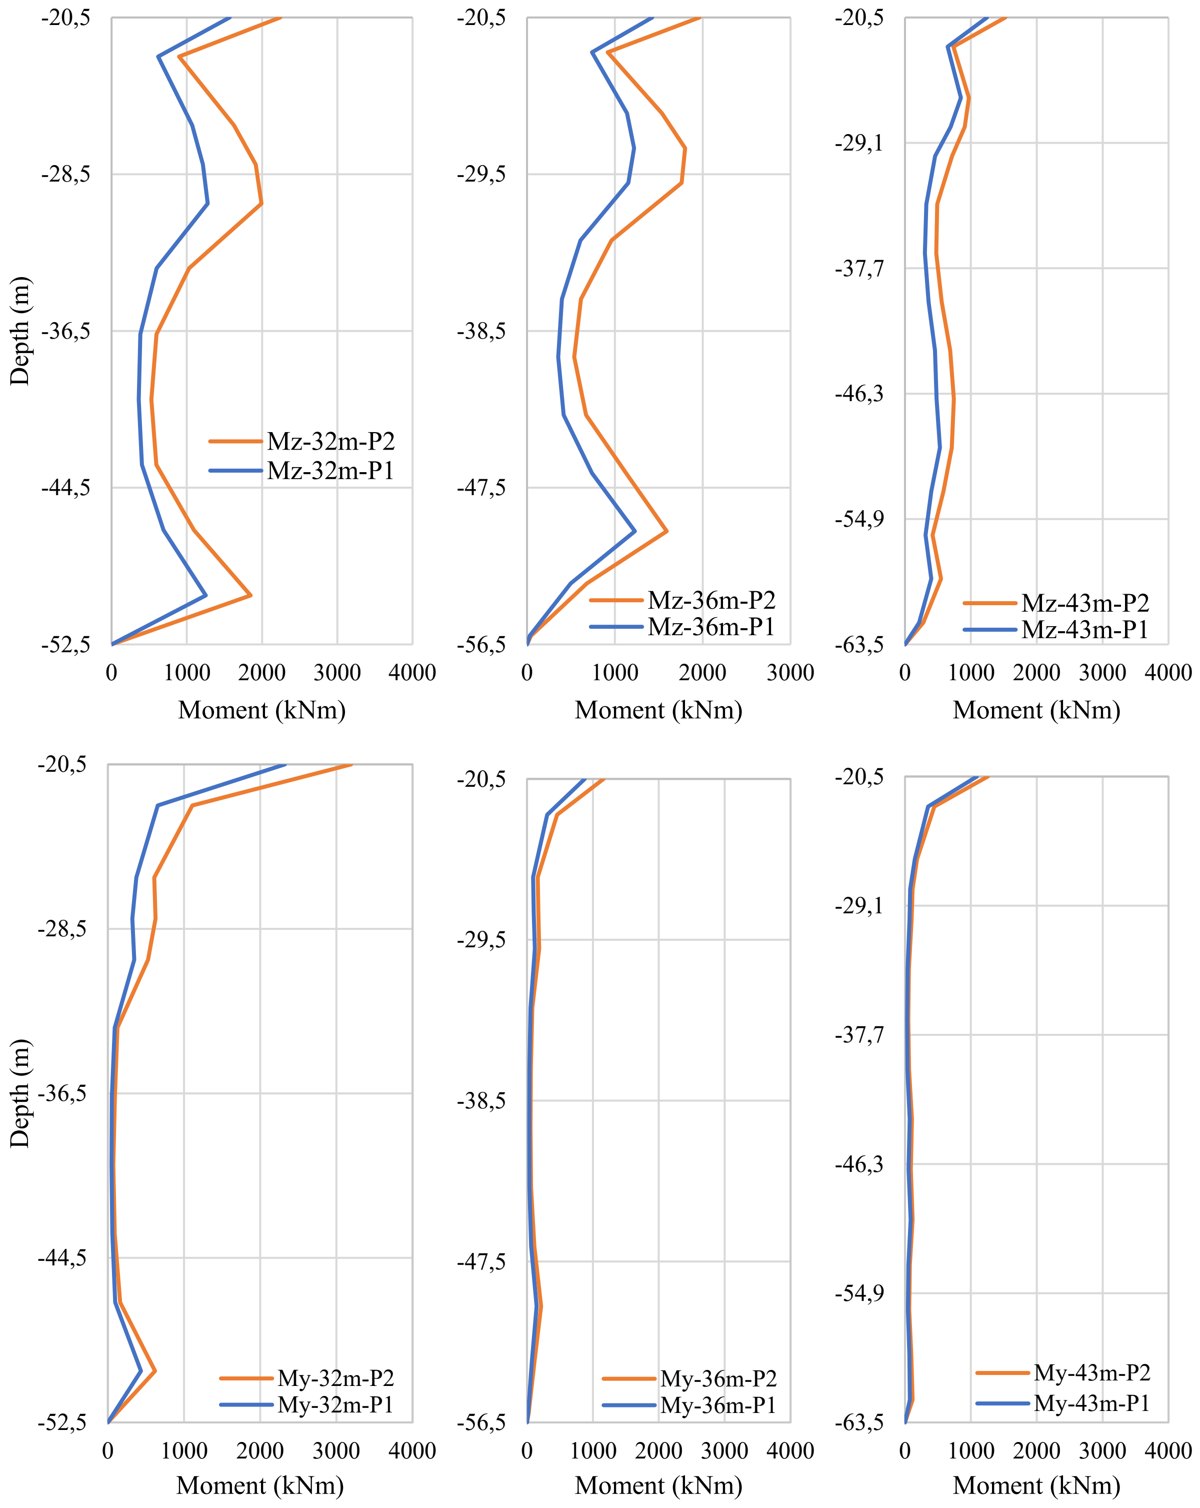

Fig. 6. Comparison of average Mz and My-depth relationship for barette piles

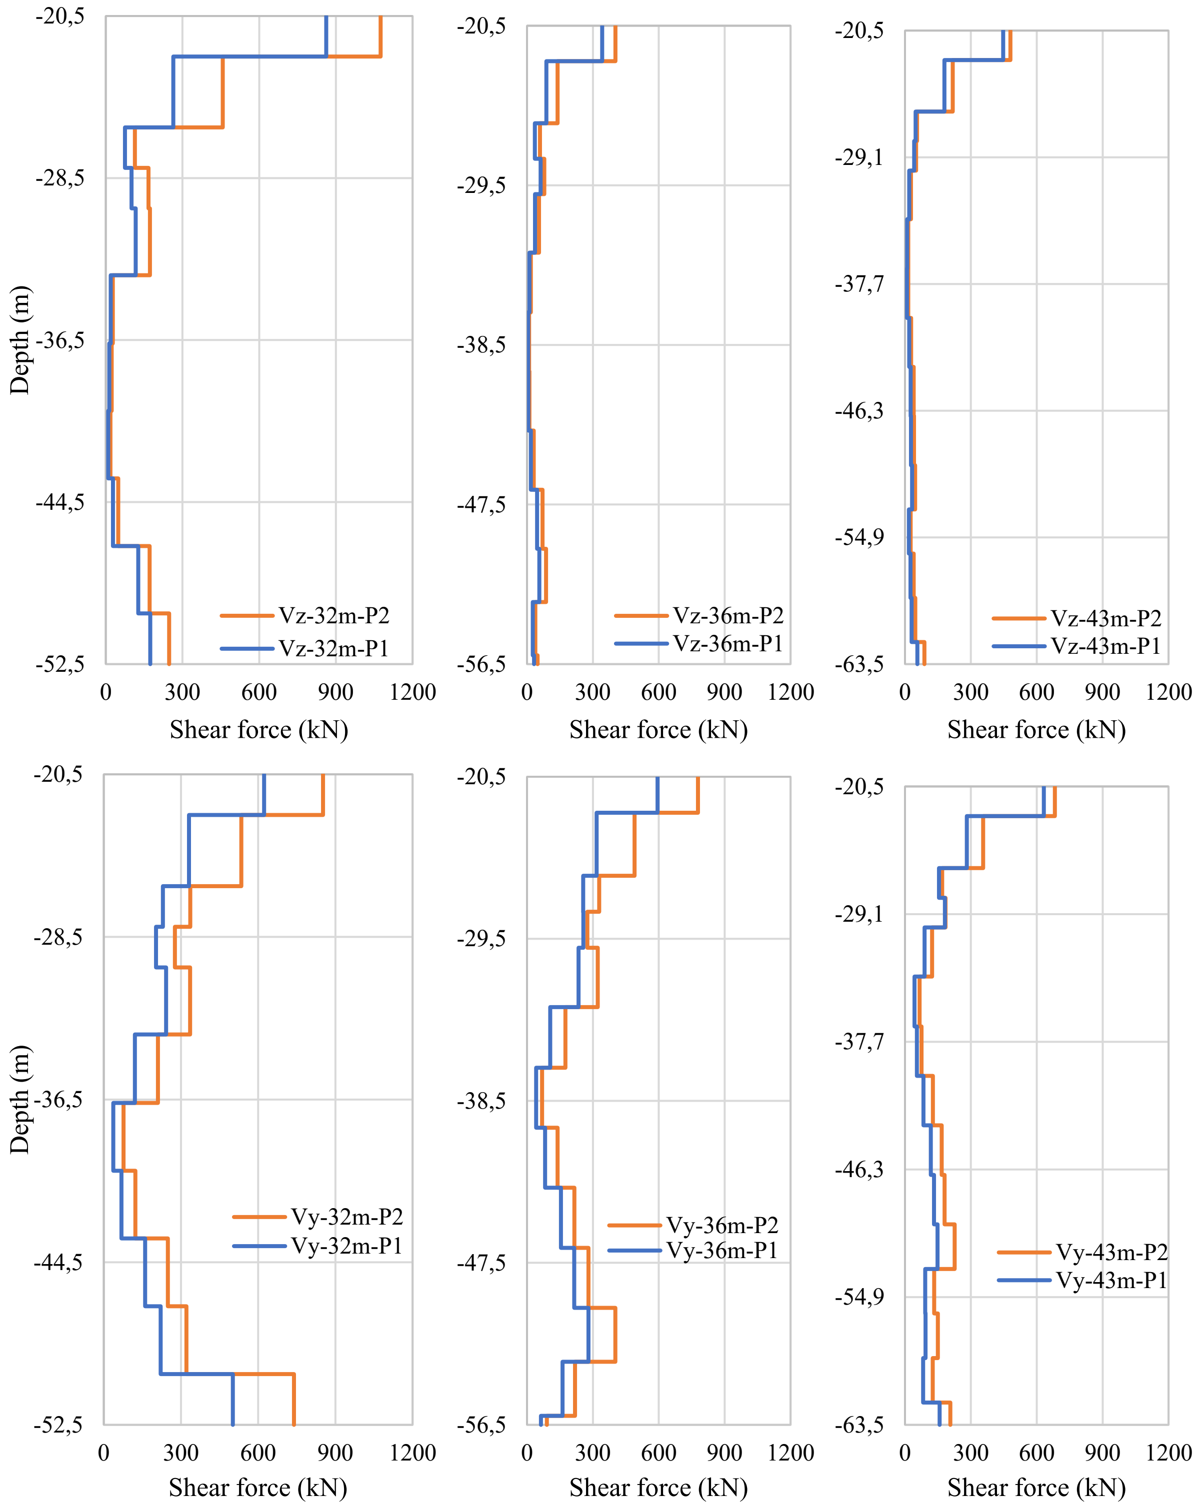

Fig. 7. Comparison of average Vz and Vy-depth relationship for barette piles

One of the key results obtained from the kinematic interaction analyses is the foundation input motions (FIM). Figures 8a and 8b present the response spectra obtained at the foundation level as a result of the conducted analyses, for Profile-1 and Profile-2, respectively. Additionally, the response spectrums for both profiles are compared in Figure 8c, indicates that the response at the foundation having the weak soil profile is slightly higher that the relatively better soil profile. This slight difference in the response spectrum may cause significant alterations in the internal forces generated in piles as indicated above.

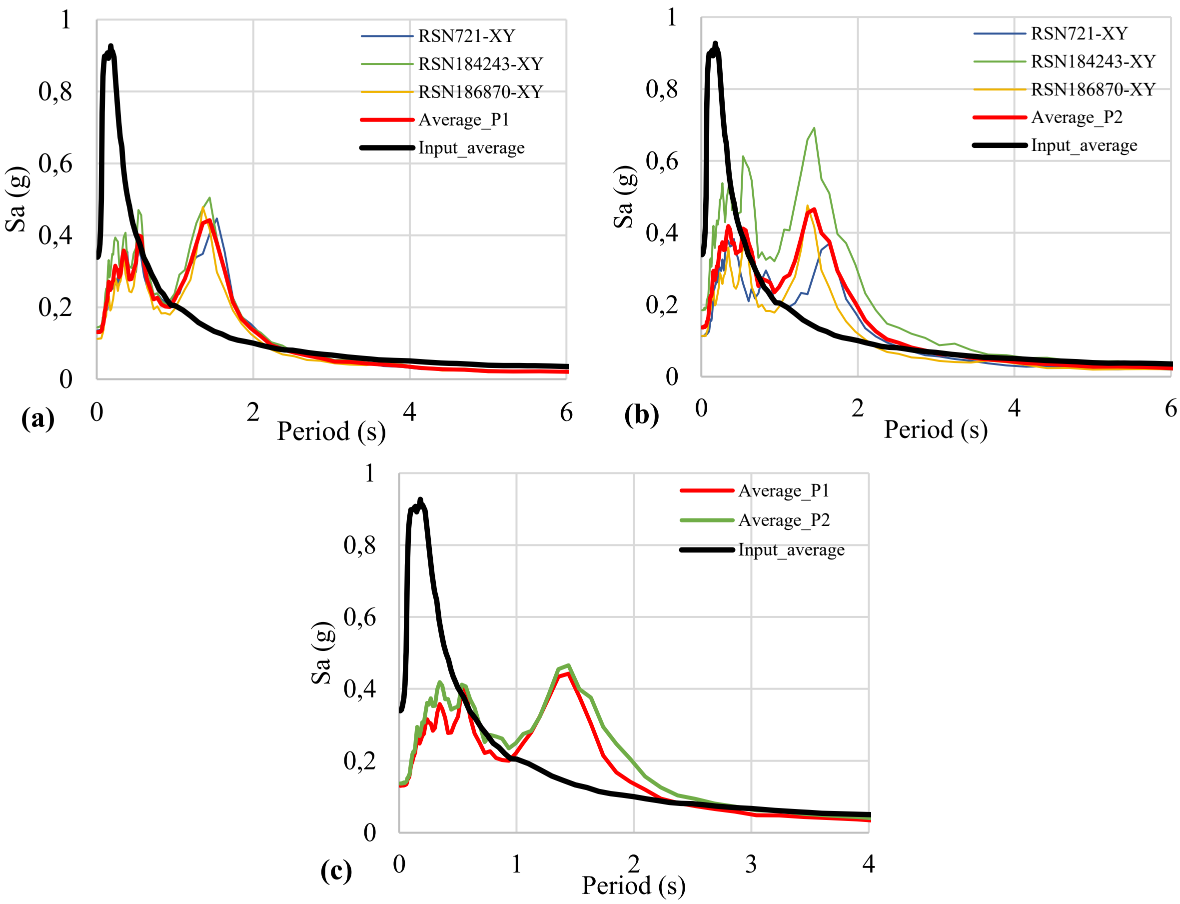

Fig. 8. Comparison of response spectrums at the foundation level for both profiles

5. Conclusions

The study compares the kinematic response of piles in the soils at the lower and upper limits of the ZD soil class in terms of shear force and moment variation throughout the pile length. For this study, a detailed 3D numerical model has been developed to represent the nonlinear behavior of the soil under dynamic loads and the pile-soil interaction.

In conclusion, the conducted site response and kinematic interaction analyses provide valuable insights into the dynamic behavior of pile foundations under seismic loading seated on weak soil profiles. The comparison of the 1D and 3D analysis results demonstrates a high degree of consistency, confirming the reliability of the 3D model in replicating the response behavior observed in the 1D model.

The evaluation of acceleration response spectra reveals that the response characteristics are influenced by the soil profile, with weaker soils leading to more pronounced attenuation at shorter periods and larger responses at intermediate periods.

Furthermore, the results highlight the importance of pile length and distribution in controlling the internal forces within the foundation. Specifically, longer piles, positioned centrally within the foundation, experience reduced variation in internal forces along the pile length, while shorter piles at the foundation edges exhibit higher moments and shear forces. The kinematic interaction analysis results further emphasize the impact of soil conditions on the seismic behavior of the foundation. The comparison of the response spectra for both soil profiles suggests that foundations resting on weaker soils experience slightly higher seismic responses, thereby underscoring the significance of soil-pile-structure interaction in the design and performance of pile foundations.

Abstract. It is important for existing RC buildings to be prepared for possible earthquakes in the future in order to minimize the damages that may occur after earthquakes. Even if the existing building stocks are considered to have been built in accordance with the seismic codes valid at the time of construction, they may have weaknesses that may cause some negativity during earthquakes. For this reason, existing building stock in a region should be evaluated in order to be minimally affected by earthquakes. In the first stage of the evaluation of the existing building stock, rapid visual screening (RVS) methods are used. With these methods, risk prioritization of buildings is carried out based on the characteristics of the buildings that can be determined by looking at them from the outside. Despite being described as fast, fieldwork has negative aspects in terms of labor and time. Within the scope of this study, it is aimed to use artificial intelligence tools in the evaluation of structures. The images of the buildings were used as training data in deep learning models, and the detection of negativity situations was made through conventional neural network(CNN) methods. The obtained visuals of the buildings were transferred to the digital environment and building performance scores were obtained. The images were evaluated in terms of critical parameters affecting the building condition. In order to classify these parameters, four different advanced deep learning models such as VGG16, DenseNet121, InceptionV3 and ResNet101 were used. Looking at the results; Parameters that stand out for their high accuracy and F1-scores in all models include Heavy Overhang (accuracy over 80%), Soft-Weak Story (accuracy over 75%) and Structural System Type (accuracy over 70%).

Keywords: RVS; Earthquake risk assessment; Existing building stock; CNN; Artificial intelligence

1. Introduction

Turkey is located in active seismic zones, which indicates that the country is facing a significant seismic hazard. In particular, large active fault lines such as the North Anatolian Fault (NAF) and the East Anatolian Fault (EAF) have caused many earthquakes in the historical process. In addition, the West Anatolian Fault is considered as one of the active faults in Turkey. The distribution of active fault lines in Turkey is presented in Figure 1 (Akkar et al., 2018).

In recent years, destructive earthquakes have occurred on active fault lines in Turkey. On January 24, 2020, an earthquake with a magnitude of 6.8 (Mw) occurred in the Sivrice district of Elazig, according to Disaster and Emergency Management Affair(DEMA) data, and this earthquake caused serious structural damage in Malatya and Elazig(AFAD, 2020). As a result of the disaster, 41 people lost their lives and 1607 people were injured. Similarly, on October 30, 2020, an earthquake with a magnitude of 6.9 (Mw) occurred on the West Anatolian Fault, off the Aegean Sea, at 14:51 Turkey time, according to the data of the Kandilli Observatory. In this earthquake, 117 people lost their lives and approximately 1100 people were injured. One of the biggest earthquakes that has occurred in recent years is the February 6, 2023 Kahramanmaraş earthquakes, and these tremors took place on the East Anatolian Fault (DAF) (AFAD, 2023). Two destructive earthquakes, which occurred 9 hours apart, affected a wide geographical area. As a result of the earthquakes with a magnitude of 7.7 (Mw) with the epicenter of Pazarcık at 04.17 local time and 7.6 (Mw) with the epicenter of Elbistan at 13.24, more than 250,000 buildings in 11 provinces became unusable and the death toll from the earthquake exceeded 50,000 (Nemutlu et al., 2023a).

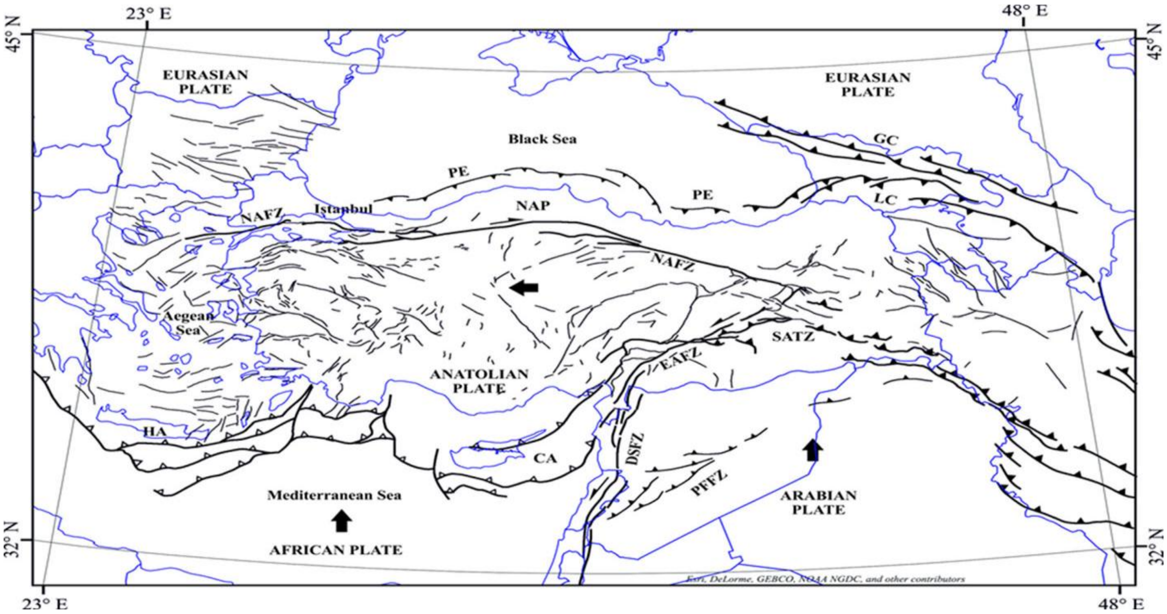

Fig. 1. Active fault of Türkiye

In order to minimize the impact of earthquakes, it is of great importance to evaluate the existing building stock before the earthquake. In this context, studies have been carried out in the literature to evaluate the existing building stock in various regions throughout Turkey(Ay & Erberik, 2008; Çavuş & Akyol, 2015; Işık, 2013a, 2013b; Işık et al., 2016, 2018). In his doctoral study, Işık discussed the probabilistic evaluation of seismic performance for Bitlis province(Işık, 2010). In the study, first of all, seismic hazard analysis was performed, and then first, second and third stage methods were used to determine the existing building inventory. In line with the data obtained, fragility curves were created and the vulnerability of the structures against earthquakes was examined. As a result of the study, an earthquake damage loss model based on different earthquake scenarios was developed and social and economic losses were evaluated in terms of the post-earthquake period. In cooperation with Izmir Metropolitan Municipality, Özçelik et al. carried out building stock inventory studies and earthquake safety assessment in Balçova and Seferihisar districts (Özçelik et al., 2013). In this context, a questionable zoning information system was created, special data of buildings were used and risk assessment was made at the building level. In the study, it was also aimed to identify the buildings that need to be improved, to make cost analysis for reinforcement works and to develop post-disaster response plans. In recent years, street screening methods have come to the fore as an important approach in terms of evaluating the existing building stock. In particular, the February 6, 2023 Kahramanmaraş earthquakes once again revealed the importance of the seismic behavior of structures. Although street scanning methods do not directly identify risky buildings, they help identify risky areas and allow prioritization. In this way, the relevant institutions can prioritize the evaluation of the existing building stock.

In the study carried out by Nemutlu, an analysis was made on the evaluation of the building stock of Bingöl province and a loss model was created based on the post-earthquake vulnerability of the buildings (Nemutlu, 2023). In the study, the prioritization of the buildings was ensured by using the street scanning method and risky areas were identified. Similar street survey studies have been carried out in many cities throughout Turkey, and risk analyzes of the buildings have been carried out in line with the structural performance scores obtained. When we look at the studies in the literature, it is seen that the field survey method is widely used. In the street scans carried out in line with the forms prepared by different regulations and institutions, the structural features are determined by visual inspection of the buildings from the outside. These structural features are scored according to their positive or negative effects, resulting in a total score for each building. Depending on the distribution of the scores obtained, certain levels are established and risk prioritization is made. However, this method requires significant time and labor. In order for the data collection process to be carried out in a healthy way, qualified human resources, sufficient time and technical equipment are needed. In the literature, studies on rapid visual evaluation methods with images obtained using drones are limited. However, there is a variety of research available on the integration of AI tools into rapid visual scanning methods. In the study conducted by Bektaş and Kegyes-Brassai, neural networks were integrated into the traditional street scanning method and the behavior of buildings against earthquakes was estimated with an accuracy rate of 68% using the parameters determined on the basis of the building (building period, spectral acceleration, etc.) (Bektaş & Kegyes-Brassai, 2024). In the research of Yu et al., buildings with soft floor irregularities, which are frequently encountered in earthquake-induced damages, were determined by deep learning-based models. Within the scope of the study, street images were obtained from Google to detect buildings with soft floor irregularities (Yu et al., 2020). In another study, rapid visual scanning methods were carried out with a fuzzy logic-based model. In this study, a fuzzy logic model was created on 40 buildings damaged in the 2019 Albania earthquake. The study reveals that it is possible to integrate artificial intelligence tools into street screening methods (Bektaş & Kegyes-Brassai, 2023). In general, studies in the literature show that artificial intelligence tools can be successfully integrated into street scanning methods. In this direction, it is considered that artificial intelligence-supported approaches can provide a faster and more systematic evaluation opportunity by reducing time and labor costs in field scans.

Within the scope of the project proposal, which forms the main basis of this study, it is aimed to develop original methods for automating the street scanning method. In this direction, problem-specific optimization processes will be carried out using various deep learning models. Although the street scanning method does not directly detect risky buildings, it is a fast and satisfactory method in terms of identifying risky areas and directing. Although it is stated in the literature that the street screening method is a rapid evaluation tool, it is possible to accelerate this process with today's technological possibilities. Images for structural evaluation will be obtained with the street scanning method to be carried out in the study area. Then, the parameters and images obtained by this method will be trained using artificial intelligence architectures and the re-estimation of the parameters will be performed. In this context, the main purpose of the study is to quickly prioritize the earthquake risk of the structures in the determined region with the support of artificial intelligence and to evaluate the applicability of the method. Thus, it is aimed to develop a more efficient and systematic analysis process compared to traditional field scans. The building evaluation process, which is carried out manually by qualified personnel in the field in traditional methods, will be automated with the support of artificial intelligence, thus providing a faster and more systematic analysis

2. Materials and method

It is of great importance to estimate the damages caused by earthquakes before a possible earthquake occurs. If we have detailed information about a possible earthquake in a certain region and up-to-date building inventory data, it may be possible to predict the damages that may occur in line with this data and take the necessary precautions. However, examining the earthquake performance of the buildings in a region in detail on a building basis is a very difficult process in terms of time and cost (Işık, 2013c). For this reason, the street screening method has been developed as a fast and economical method.

When the damages that occurred in past earthquakes are examined, it is known that structural damages vary depending on the building characteristics. Therefore, it is necessary to classify and evaluate the main characteristics of structures. There are many different street screening methods in the literature. Some of these are the street screening method developed by the Federal Emergency Management Agency (FEMA) and the eight-parameter street screening method developed by Haluk Sucuoğlu et al. (2007) (P-155, 2015, s. 155; Sucuoğlu, 2007). In addition, in the regulation of the Ministry of Environment, Urbanization and Climate Change on the Principles for the Detection of Risky Structures, a street screening method that can be applied to buildings between 1 and 7 floors is defined for reinforced concrete and masonry structures (RYTEİY, 2013). It would be an appropriate approach to use this method in order to be compatible with current earthquake regulation data.

The street scanning method to be used within the scope of this study will also be carried out on the basis of the method defined in the relevant regulation. This method calculates building performance scores using specific structural parameters. As stated in the study conducted by Nemutlu et al. (Nemutlu et al., 2023b), the parameters evaluated within the scope of the method in question are; the number of floors of the building, the earthquake hazard of the region where it is located, the characteristics of the structueral system, the soft/weak storey condition, irregularities in the plan and vertical, topographic effects, the visual quality of the building, ground characteristics, short column effect, building order and heavy overhangs. In order to apply the street scanning method, a form containing the parameters given above is prepared digitally and physically and these forms are used in field studies. Afterwards, these forms are transferred to the digital environment and the performance scores are calculated. In the relevant form, in addition to the structural features of the building, information such as visuals, location information, ground features of the building are filled in. According to these forms, the buildings are evaluated and the performance scores of each building are calculated. This score is obtained for each building in the study area. As a result of the performance scores obtained, the score distributions of the buildings in the study area are examined. For the specified threshold level, scores below this score are considered risky, and scores above it are considered risk-free. Thus, the regions where the buildings below the threshold score are concentrated are determined as priority regions and the detailed evaluation of the buildings in these regions is started.

Evaluation of the existing building stock in earthquake-prone areas is of critical importance in terms of earthquake preparedness. Site scans performed by expert engineers are a common method that evaluates the earthquake risk of buildings by analyzing the structural features of these structures with the street scanning method. However, when this process is carried out manually, it is time-consuming and requires high labor. At this point, the integration of artificial intelligence and drone technologies will allow the process to be carried out more quickly and efficiently.

Drone technology offers a number of advantages over traditional methods. Drones have the capacity to scan large areas in a short time and can obtain visual data from higher angles, different perspectives, and more comprehensive than taking photos from the ground. This allows for a more detailed analysis of structural features, especially on the upper floors of buildings. In addition, drones offer the ability to collect data in hard-to-access areas such as narrow streets, increasing both safety and the efficiency of the process.

In addition, artificial intelligence techniques to be used in automation produce numerical data and quantitative results, making the process more objective and accurate. While this automation minimizes human errors, it also allows large amounts of data to be processed quickly. Structural assessments obtained by processing drone images provide an effective and fast method of prioritizing earthquake risks in the region. As a result, a robust and scientifically based evaluation mechanism that can be used in disaster management processes will be established.

The scope of the buildings examined within the scope of the study includes residential type structures. Public institutions, mosques, warehouses, buildings used for commercial purposes, schools, huts will not be considered within the scope of the study. The process of obtaining the images used in the study and evaluating the street scanning method is given in Figure 2.

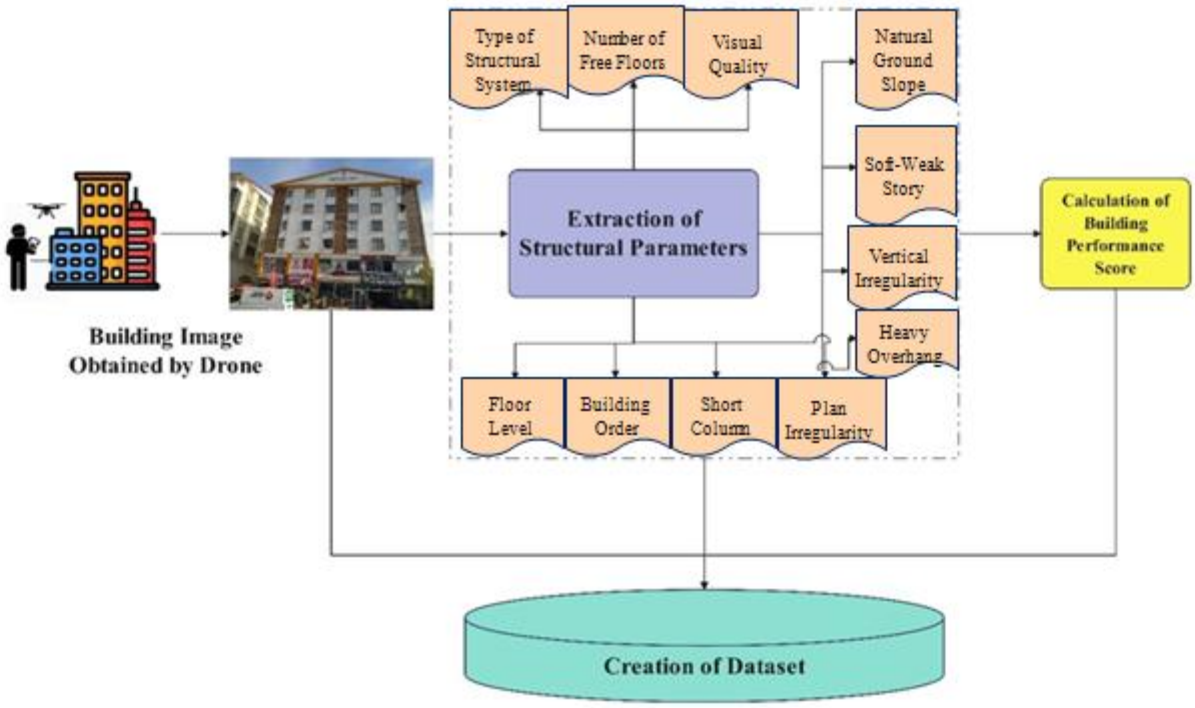

Fig. 2. Preparation of the dataset

Training of the proposed artificial intelligence model is a comprehensive process that aims to automate building performance evaluation and consists of stages such as data collection, labeling, pre-processing, model design and performance evaluation. For the training of the model, first, high-resolution images were obtained from buildings in different regions by means of drones. In order to accurately reflect the structural features of the buildings, images taken from different angles (front and top) were used. Along with the images, labels containing building features will be created based on manual inspections, and the model will be trained with a supervised learning approach. For training the deep learning model, the images will first be resized to match the input size of the model (256x256x3 or 512x512x3 as needed). Deep learning-based Convolutional Neural Networks (CNN) architectures will be used in model design. In particular, special CNNs will be optimized to learn the characteristics of buildings, such as the number of floors, visual quality and structural irregularities. For a faster and more effective learning process, pre-trained models such as DenseNet121(Li et al., 2021), Inceptionv3(Szegedy et al., 2016) and VGG16 will be used with the transfer learning method.

In this regard, in the first step, the images will be classified separately according to the structural parameters given in Figure 2. For example, the case of severe displacement will be trained in two classes as "YES" and "NO". Heavy overhangs will form an important part of the risk analysis, as they can adversely affect the performance of buildings. Similarly, the tile level will be trained in two classes, "SAME" and "DIFFERENT". In addition, a parameter such as the type of structural system is a parameter that specifies the type of load-bearing system of the building, and this parameter will be trained in two classes as "Reinforced Concrete Frame" and "Reinforced Concrete Frame -Shear Wall". In this way, the training of each structural parameter using 11 structural parameters will be carried out separately using the convolutional neural network (CNN) (Alzubaidi et al., 2021; Hüseyin Üzen, 2022; M. Shaha & M. Pawar, 2018; Saida et al., 2023; Xia et al., 2023). The planned framework for the development of the proposed model is given in Figure 3.

During the training of the model, 80% training and 20% test data sets were adjusted by randomly selecting from the images obtained using drone images. This data separation rate aims to increase the generalizability of the model and prevent overfitting. The model will be trained on different building categories and structural features. In order to reduce the error rate in the training process, the cross entropy loss function and the Adam optimization algorithm were used. This method speeds up the model's learning process and improves its accuracy.

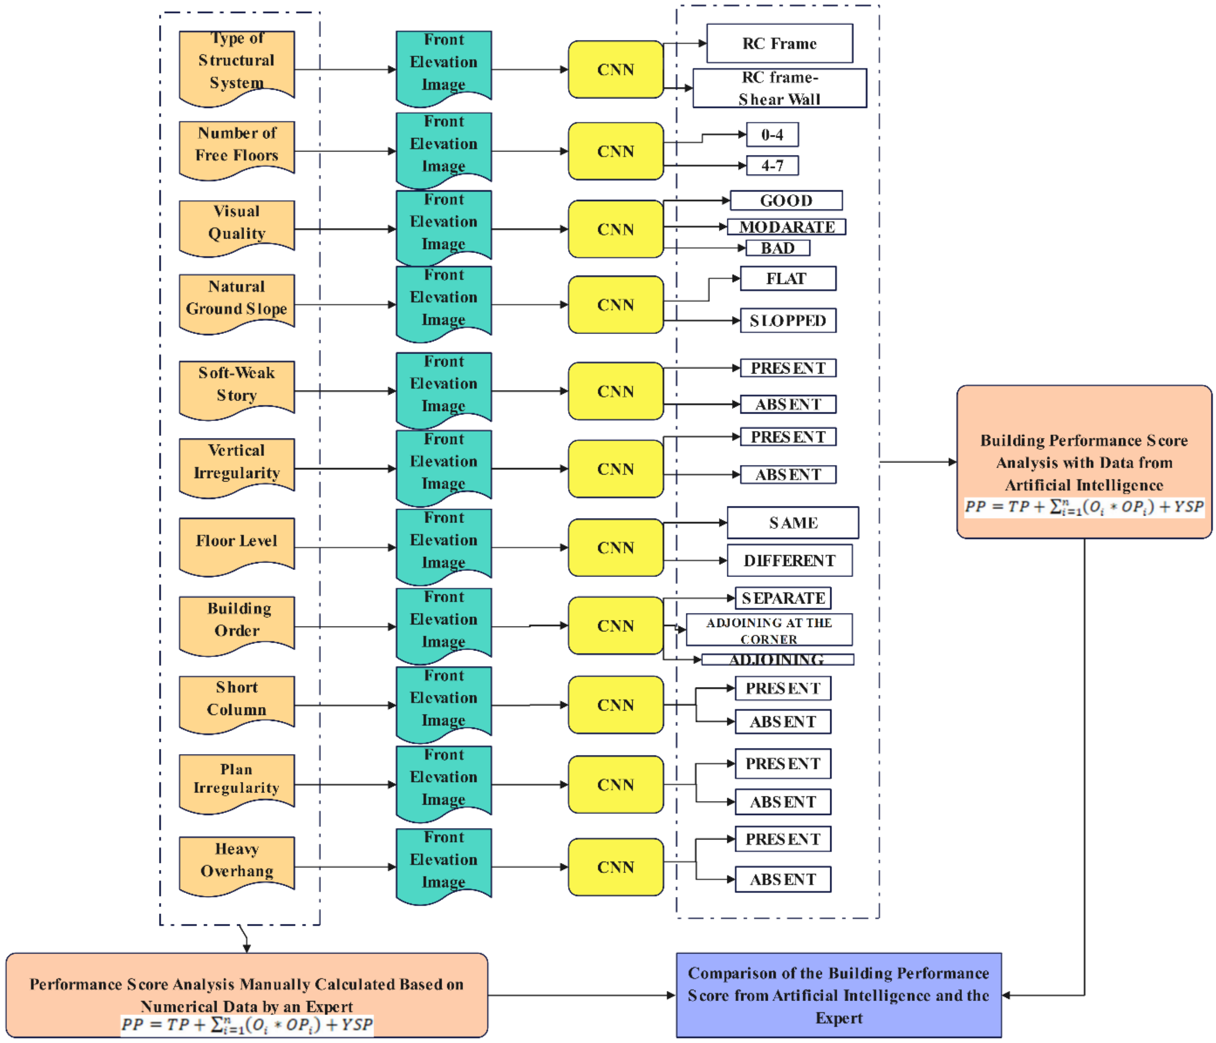

Fig. 3. Implementation of the proposed model

The success of the model will be evaluated with various performance metrics during training. These metrics include accuracy, precision, recall rate, and F1 score. Accuracy is calculated as the ratio of the correct classifications of the model to all predictions; Precision refers to the ratio of the model's correct positive predictions to all positive predictions. The recall rate shows the ratio of true positive predictions to true positive situations, while the F1 score is the harmonic mean of the accuracy and recall rate. These metrics are used to evaluate the overall performance of the model and how it performs, especially on unbalanced data sets (e.g., rare types of damage).

3. Results

In this study, a comprehensive preliminary analysis was carried out to evaluate the feasibility of the planned project. In this analysis, 344 images labeled in detail by expert academics working in the earthquake area(Bingol city center) were used.

The images used consist of buildings in 14 neighborhoods in the city center of Bingöl province. The building images prepared for the preliminary study are the buildings on the main streets of the neighborhoods in the city center. The building stock on the main streets generally reflects the building stock in the neighborhoods. The building visuals obtained for the preliminary study were obtained with the help of street scanning. The obtained visuals and the parameters required for the evaluation of the buildings were transferred to the digital environment after the field work and building performance scores were obtained.

The images were evaluated in terms of critical parameters such as 'Heavy Overhang', 'Floor Level', 'Vertical Irregularity', 'Visual Quality', 'Short Column', 'Irregularity in Plan', 'Number of Free Floors', 'Building Order', 'Structural System Type' and 'Soft-Weak Storey' affecting the building condition. In order to classify these parameters, four different advanced deep learning models such as VGG16, DenseNet121, InceptionV3 and ResNet101 were used. In the experimental study, the dataset was divided into 80% training and 20% testing, and each model was trained to classify the relevant building parameters. After the training process, the models were tested on the test dataset. The results obtained are summarized in Table 1 in order to compare the classification performance of the models. Table 1 contains the macro accuracy (ACC) and macro F1-scores of each model in parameters such as 'Heavy Overhang', 'Floor Level', 'Vertical Irregularity', 'Visual Quality', 'Short Column', 'Irregularity in Plan', 'Number of Free Floors', 'Building Order', 'Structural System Type', 'Soft-Weak Floor' and 'Building Estimated Age' (Alzubaidi et al., 2021; He et al., 2016; Simonyan & Zisserman, 2014; Szegedy et al., 2016).

Table 1. Classification Performance of Deep Learning Models for Building Parameters

Parameter	VGG16 ACC	VGG16 F1-score	DenseNet 121 ACC	DenseNet 121 F1-score	Inception V3 ACC	Inception V3 F1-score	ResNet1 01 ACC	ResNet1 01 F1-score
Heavy Overhang	85.29	82.29	83.82	80.23	85.29	81.11	80.88	74.99
Floor Level	77.94	73.81	75.00	67.30	76.47	67.31	83.82	79.58
Visual Quality	52.94	52.01	57.35	56.20	63.24	63.29	60.29	59.96
Short Column	95.59	48.87	95.59	48.87	95.59	48.87	95.59	48.87
Number of Free Floors	51.47	43.02	47.06	39.15	47.06	35.94	52.94	43.33

Irregularity in Plan	69.12	40.87	88.24	46.87	86.76	46.46	86.76	46.46
Vertical Irregularity	Data Insufficient							

The data presented in Table 1 compares the performance of four different deep learning models (VGG16, DenseNet121, InceptionV3, ResNet101) used in the classification of building condition parameters. The performance of the models was evaluated on macro accuracy (ACC) and macro F1-scores. Based on these values, Table 1 reveals several important points. Among the parameters that attract attention with their high accuracy and F1-scores in all models are "Heavy Overhang", "Soft-Weak Floor" and "Structural System Type". In particular, DenseNet121 and InceptionV3 performed better than other models in the "Structural System Type" parameter. On the other hand, in parameters such as "Visual Quality" and "Number of Free Floors", the performance of all models remained low in general. This suggests that these parameters are more difficult to classify and require more data or model optimization. In particular, the decline in F1-scores indicates that the models are struggling to balance these parameters. The sample distributions in the dataset related to these parameters are presented in Table 2.In the sample distribution given in Table 2, the data distributions of "Heavy Overhang", "Soft-Weak Storey" and "Structural System Type" parameters are partially balanced. However, there is a class imbalance in the "Number of Free Floors" parameter. The balance of the dataset in the parameters of "Heavy Overhang", "Soft-Weak Storey" and "Structural System Type" and the low number of subclasses contributed to the high success of deep learning models. However, although a balanced distribution was achieved among the subclasses in the "Visual Quality" parameter, the success was low. The main reason for this is that the "Visual Quality" parameter is labeled with a personal approach, and structurally, the subclasses are similar. Therefore, the deep learning model is insufficient to separate subclasses. To solve this problem, it is necessary to create a more standard dataset and increase the number of samples. In addition, the low number of 7-storey buildings in the "Number of Free Floors" parameter directly affects the success. In addition, it is difficult for the deep learning model to determine the number of floors in buildings with mezzanines. To solve this problem, it is planned to increase the dataset for future studies and to perform analyzes using 3 classes as 0-2, 3-5, and 5+.

Table 2. Distribution of building parameters based on class labels

Heavy Overhang	Count	Soft-Weak Floor	Count	Structural System Type	Count	Visual Quality	Count	Number of Free Floors	Count
PRESENT	240	PRESENT	185	RC Frame and Shear Wall	232	GOOD	130	1	31
ABSENT	104	ABSENT	159	RC Frame	112	MODERATE	126	2	25

								7	9

As a result, poor performance in the "Visual Quality" and "Number of Free Floors" parameters indicates difficulties in the classification of these parameters. This indicates that these parameters, with the diversity of the data and their quality deficiencies, require more complex structures. In particular, more data and model optimization is required for the correct classification of parameters such as "Number of Free Floors".

The model-by-model comparison evaluates the classification performance of building condition parameters of four different deep learning models (VGG16, DenseNet121, InceptionV3, and ResNet101) based on the F1-score. The F1-score provides a more accurate measure of performance in the event of an imbalance between classes. The results presented in Table 1 show the performance of each model in terms of F1-scores. The VGG16 performed best in the "Heavy Overhang" parameter, achieving the highest F1-score. DenseNet121 and InceptionV3 achieved results close to VGG16, with VGG16's superiority evident. The ResNet101 has shown a lower performance compared to other models. The ResNet101 achieved the highest F1-score in the "Floor Level" parameter, outperforming the other models. ResNet101 gives better results in this parameter, suggesting that the model may be better suited for this specific classification task. InceptionV3 achieved the highest F1-score in the "Structural System Type" parameter, outperforming the other models. DenseNet121 and ResNet101 have also achieved quite good results, but the superior performance of InceptionV3 is remarkable. VGG16 showed the lowest performance in this parameter. ResNet101 and DenseNet121 achieved the highest F1-scores in the "Soft-Weak Storey" parameter. These two models have shown high performance in this parameter. The InceptionV3 was just behind these two models, while the VGG16 achieved a lower F1-score. Based on the F1-scores, it can be said that each model has strengths and weaknesses in certain parameter classifications. In particular, VGG16 excelled in the "Heavy Overhang" parameter, while ResNet101 achieved the highest success in the "Floor Level" parameter. InceptionV3 gave the best results in the "Structural System Type" parameter, while DenseNet121 and ResNet101 achieved strong results in the "Soft-Weak Storey" parameter. The performance of each model varies according to the difficulty levels of the parameters, which emphasizes that different requirements on a parameter basis should be taken into account when choosing a model. Overall, low F1-scores in some parameters indicate that deep learning models face particular challenges. In the "Visual Quality" parameter, the performance of all models was below average; in particular, the VGG16 performed inferiorly to other models with an F1-score of 52.01. This low achievement indicates that the "Visual Quality" parameter is not able to handle the model's data variance well enough in the classification task, or that the parameter presents challenges in terms of labeling and data diversity. In the "Short Column" parameter, all models achieved similarly low F1-scores; Poor performance on this parameter indicates that the model is not able to perform this specific classification task well enough. A similar low success rate was observed in parameters such as "Number of Free Floors" and "Building Estimated Age", indicating that the models could not provide adequate performance on these tasks and required further data or model optimization on these parameters. Overall, these underperformances reveal that the parameters involved require more complex structures or more data, and that the ability of existing models to deal with these challenges is limited. The complexity matrices of the methods in the "Visual Quality" parameter for Model-Based Comparison are given in Table 3.

In the "Visual Quality" complexity matrices given in Table 3, it is seen that the DenseNet121 and InceptionV3 models exhibit the highest performance in the "Good" class. These models correctly predicted most of the true values in the "Good" class and showed lower numbers in the wrong classifications. VGG16 and ResNet101, on the other hand, performed lower in the "Bad" class, indicating that these models had difficulty correctly predicting the "Bad" class. Performance in the "Moderate" and "Bad" classes reflects the difficulties experienced by each model in transitioning between classes. The main reason for these poor performances is the high similarities between the classes. In addition, the limited dataset causes artificial intelligence systems to have difficulty distinguishing between "Moderate" and "Bad" classes. This means that the collection of a more comprehensive and diverse dataset is expected to improve the quality of model training and provide higher performance.

It is seen that the number of parameters used in the studies carried out in the literature is generally limited. In this study, the evaluation of 14 different parameters reflecting the building characteristics stands out as an important factor that distinguishes the study from the existing literature. On the other hand, existing artificial intelligence models are generally limited to traditional machine learning methods and have deficiencies in developing a problem-specific network architecture.

4. Conclusions

Within the scope of the study, it is aimed to integrate artificial intelligence tools into the street scanning method, which is one of the rapid evaluation methods of existing reinforced concrete buildings. In this context, the data obtained with different deep learning models were evaluated and the performance of parameters and deep learning models among each other was evaluated. The results obtained were evaluated with their justifications.

Performance analysis of deep learning models used in the classification of building condition parameters reveals success differences in various parameters. High macro accuracy (ACC) and macro F1-scores were obtained in parameters such as "Heavy Overhang", "Soft-Weak Storey" and "Structural System Type". In particular, DenseNet121 and InceptionV3 showed high performance in the "Structural System Type" parameter, while VGG16 and ResNet101 gave lower results in this parameter. In other parameters, significant differences were observed in the performance of the models. In general, low successes were achieved in the "Visual Quality" and "Number of Free Floors" parameters. The sample distributions presented in Table 7 show that the parameters of "Heavy Overhang", "Soft-Weak Floor" and "Structural System Type" are evenly distributed in the dataset. However, the class imbalance in the "Number of Free Floors" parameter directly affected the classification performance related to this parameter. In addition, although the data distribution is balanced in the "Visual Quality" parameter, it is seen that the model cannot classify this parameter well enough. It can be concluded that this is due to the diversity of the dataset and the deficiencies in the labeling processes. The imbalances and low-performance parameters in the dataset in the study highlight the importance of improving data diversity and labeling processes to increase analysis success. The follow-up studies will not only evaluate existing deep learning approaches, but also aim for higher accuracy and overall performance using hybrid modeling strategies and data enrichment techniques. By strengthening the role of artificial intelligence in building condition assessment processes, it will provide significant innovations and efficiencies to applications in the sector.

Seismic performance assessment of an existing pre-stressed reinforced concrete bridge

Ömer F. Ertaş*[1], Kadir Güler[1]

[1] Istanbul Technical University, Department of Civil Engineering, Ayazaga Campus 34469 İstanbul, Türkiye

Abstract. The seismic performance evaluation of existing reinforced concrete bridges is important in terms of emergency actions and ensuring continuity of services after an earthquake. Depending on the seismic performance level, the existing bridges may require strengthening; if it is not feasible, it may be required rebuilt. In this study, the seismic performance evaluation of an existing reinforced concrete bridge was accomplished, whose deck consists of precast pre-stressed beams and topping concrete. The existing bridge was built in 1989 in the Merzifon district of Amasya Province. The bridge has four spans, total length of bridge is 73.80m. The bridge deck consisting of prestressed RC beams and topping concrete is connected to the bridge cap with elastomeric bearings. The bridge cap is connected to piers (as piles) of the bridge. CSI Bridge software was used to establish the bridge numerical analysis model. In the numerical model, springs are assigned to the piles (piers of the bridge) to consider the soil-structure interaction. According to the Turkish Earthquake Code for Bridges (2020), the earthquake performance assessment of the bridges is proposed to carry out in two stages. In Stage 1, seismic performance evaluation was made by obtaining the strain method. At this stage, it is aimed to show the Limited Damage performance at the DD-2 Earthquake Level (design earthquake) by using pushover analysis of the piers. In Stage 2, it was checked whether the Collapse Prevention performance level was achieved at the DD-1 Earthquake Level (maximum earthquake) by using the non-linear time history analysis method. Based on the results obtained in both stages, it is decided the necessity of strengthening level and technique of the existing bridge. The numerical results on the seismic performance assessment of the considered bridge are given in tables and graphs, comparatively.

Keywords: Seismic performance; Concrete bridge; Pushover analysis, Pre-stressed concrete

1. Introduction

Bridges and viaducts are among the most important components of today's road and railway transportation networks. While these art structures are so important for transportation, it has become a necessity to determine the seismic performance of existing bridges and viaducts in countries with high seismicity. It is necessary to evaluate whether the bridge will be able to continue its operational activities after a possible earthquake and whether emergency aid will not be able to reach the relevant places. There are lot of studies on the performans assessment of existing bridges (Batbayar, 2008; Elmas, 2008; Şengül, 2018). Design and earthquake performance assessment of a bridge with prestressed concrete girder is studied by Salimee (Salimee, 2019).

In this study, the seismic performance of one of the existing bridge, the Kayadüzü overpass bridge on the Suluova-Amasya state highway, is evaluated by using nonlinear analysis method. According to the numerical results obtained. The numerical results are carried out by using CSI Bridges software. The results are given in figures and tables.

2. Materials and methods

2.1. General information

The bridge examined in this study consists of two identical parallel bridges on the main artery on the Suluova-Amasya road. The location and picture of the bridge are shown in Fig. 1 and Fig. 2. According to the information obtained from the project of the bridge, the construction year is 1989. The bridge has 4 spans in total, each span has 18 m long. The total length of the bridge is 73.8 m and the width is 12 m. As can be seen in Fig. 3, the bridge has a skew of 15°. The center piers of the bridge consist of 4 circular columns joined by a cap beam. These circular columns continue on the soil for 25 m and work as pile-columns that also form the foundation of the bridge(Fig. 4). The pile-columns are friction piles. As shown in Fig. 5, the superstructure of the bridge consists of

Fig. 2. General view of Kayadüzü bridge

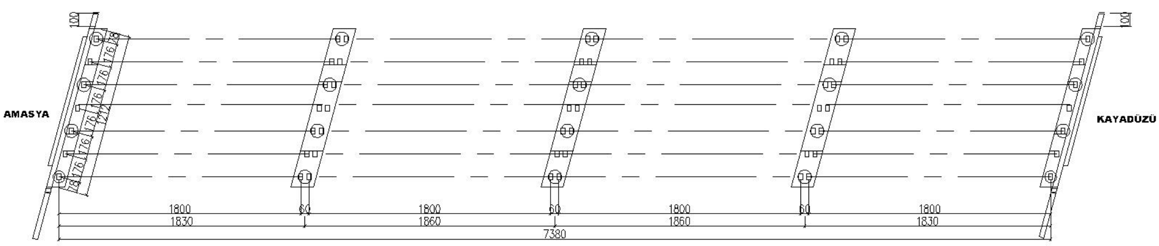

Fig. 3. Bridge plan view

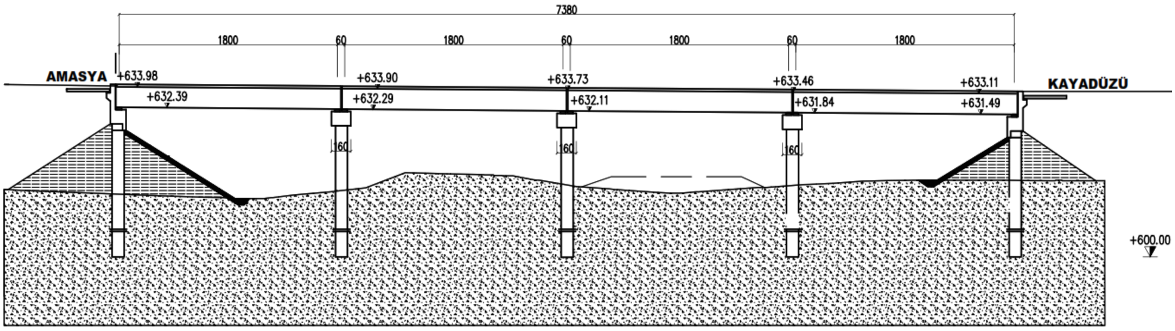

Fig. 4. Bridge longitudinal cross section

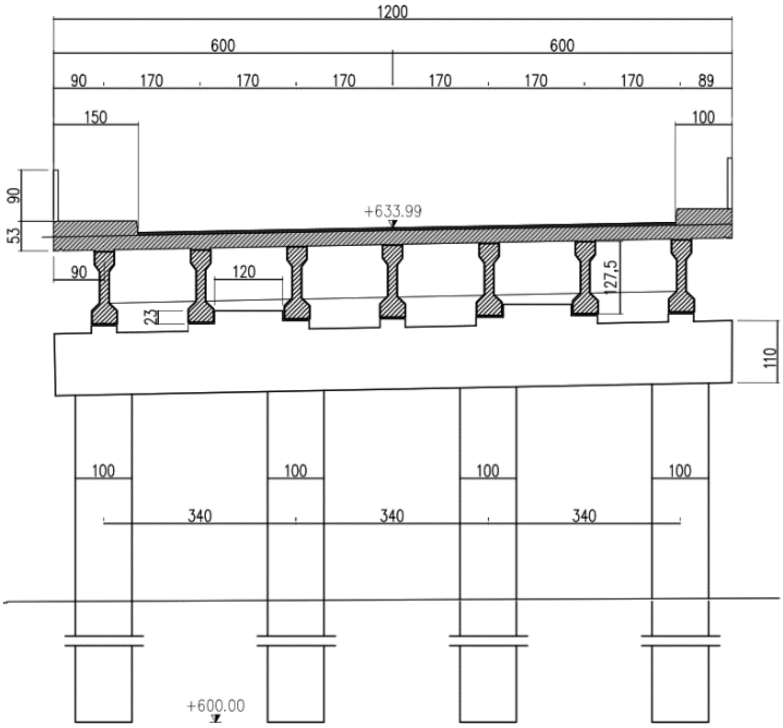

Fig. 5. Bridge cross section

2.2. Calculation principles and modeling of bridge

In the modeling of the bridge, CSIBridge software was used(CSI, 2022). The structural system is modeled with finite frame elements. Damping ratio was assumed to be 5% in the analysis. Elastomeric bearings, between precast prestressed beams and cap beams, are assigned as linear link elements. Fixed elements were used to transfer the loads from the deck and precast beam to the elastomeric bearings. The connections between the elastomer bearings and the cap beam were also modeled with fixed elements. In order to transfer the dead loads such as coating and sidewalk to the system, a load of 27.03 kN/m was applied to the unit length of the bridge deck.

In order to determine the concrete compressive strength of the structural members of the existing bridge, a certain number of core samples were taken from the structural members. based on the compressive test results obtained from the laboratory, the material strengths of the structural elements were found as shown in Table 1.

Table 1. Existing concrete compressive strengths

Structural Element	Core Size	Number of Cores	f_{cm}(N/mm^2)
Pile-Column	h/R=1(100mm)	6	19.01
Cap Beam	h/R=1(100mm)	6	23.08
Pre-Stressed Beam	h/R=1(100mm)	3	53.24
Deck	h/R=1(100mm)	4	37.72

Diameter of pile-columns is 1.00 m. Reinforcement details used in the section are; 12ϕ26 longitudinal rebar and ϕ10/10 spiral ties. The rebar steel in pile-columns is S220 (plain reinforcement) and S420 (deformed reinforcement) in other structural elements. Section details of columns and prestressed beams are given in Fig. 6. Xtract program based on Mander concrete model (Mander et al., 1988) was used to calculate the material properties, cracked section properties and element strengths of the columns (Xtract, 2001). Confined and unconfined concrete models and the material model of the rebar steel are given in Fig. 7. The cracked section stiffnesses for the columns were reduced by the stiffness reduction factors calculated with the data obtained from the moment-curvature relationship according to Eq. 1. Cracked and uncracked section properties of the columns are given in Table 2.

For the interaction of the pile-columns with the soil, springs are defined on the piles. In the part buried in the ground, lateral springs with 2/3 of the vertical spring coefficients are defined. The modulus of subgrade reaction values used in the definition of springs are given in Table 3.

Depth	$Kh(kN/m^3)$
0-13 m	4000
13-25 m	7000

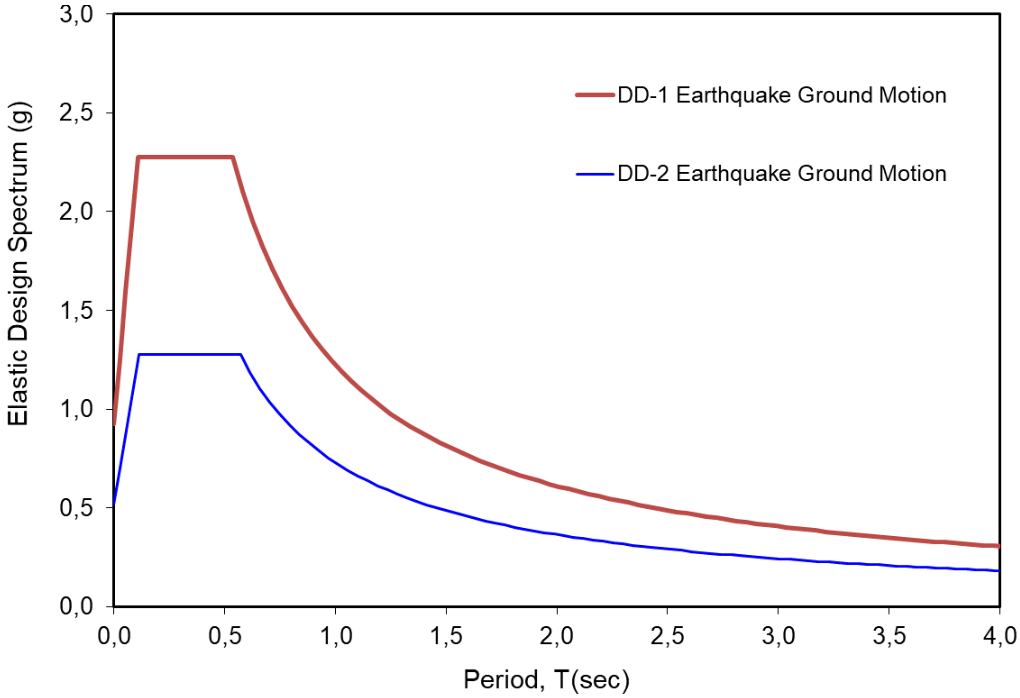

Fig. 8. DD-1 and DD-2 Elastic design spectra

The soil class was assumed as ZD TBSC (2018) with the drilling data included in the bridge project. Along the 25 m length of the pile columns within the ground, it was determined that there were soft clay layers between 0-13 m and solid clay layers between 13-25 m.

Design spectra for DD-1 and DD-2 ground motions to be used in the analysis were obtained from AFAD "Turkish Earthquake Hazard Map" (https://tdth.afad.gov.tr) considering ZD soil class. The spectra obtained are shown in Fig. 8.

2.3. Calculation methods and numerical analyses

Earthquake performance assessment of the bridge will be evaluated in two stages according to the Turkish bridge earthquake code (TKDY, 2020). Stage 1 level evaluation will be based on nonlinear pushover analysis method using DD-2 Earthquake ground motion level. Stage 2 level assesment will be carried out by nonlinear time history analysis method using DD-1 ground motion level. The Stage 1 assesment will aim to provide immediate occupancy performance level and the Stage 2 level earthquake calculation will aim to provide to check the collapse prevention performance level.

3D model of the bridge is shown in Fig. 9. The deck is assigned in the model as a composite section with girders. As it is a reinforced concrete bridge, the damping rate is assumed to be 5%.

The frequency, period and mass participation ratios of the first 12 modes obtained from the modal analysis of the bridge are given in Table 4. The mode shapes of the first 3 modes are shown in Fig. 10. Analyses were performed separately for transverse and longitudinal directions and the results were examined.

Fig. 10. Mod shapes of the four span bridge

2.3.1. Nonlinear pushover analysis

In this part, a nonlinear static pushover analysis of the bridge in the transverse and longitudinal directions is performed. Static pushover analysis was performed separately for each pier. First of all, to provide the nonlinearity, a lumped plastic hinge was defined at a distance of Lp/2 from the connection point of the columns with the cap beams and at the points where the moment is maximum in the piles in the soil. PMM hinge was defined since the columns carry both axial force and moment in both axes. Hinge properties were determined by interaction diagram obtained from the normal force transferred to the columns and the sectional properties. Hinge length (Lp) was calculated by Eq. 2 according to Caltrans (2019). In the equation, f_{ye} symbolizes the expected yield strength of the reinforcing steel and d_{b1} symbolizes the nominal diameter of the longitudinal reinforcement of the column. The locations of the hinges are shown in Fig. 11.

In the first step, the static pushover curve of the bridge in the transverse and longitudinal directions, which gives the relationship between base shear force and peak displacement, was obtained. The pushover curves in transverse and longitudinal directions are shown in Fig. 12 and Fig. 13. As it is seen Fig. 12 and Fig. 13, lateral rigidity is stronger in transverse direction as it is anticipated, the reason frame behavior while its lateral rigidity is low in the longitudinal direction due to cantilever behavior.

$$L_p = 0.08L + 0.22f_{ye}d_{b1} \geq 0.044f_{ye}d_{b1} \quad (2)$$

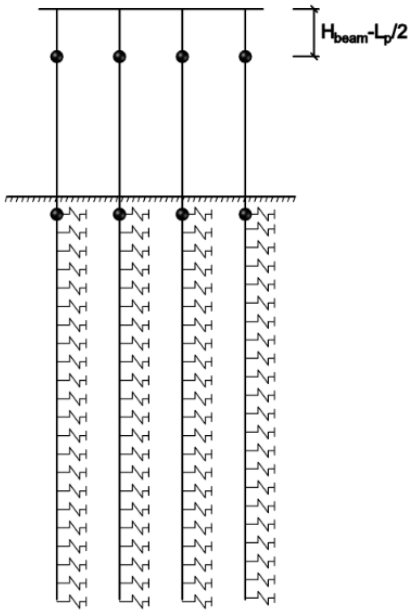

Fig. 11. Plastic hinge layout of pile-columns

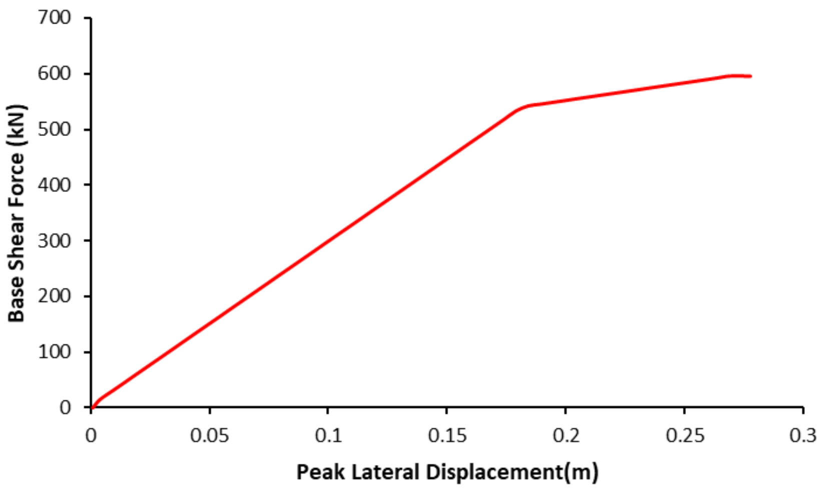

Fig. 12. Pushover curve in longitudinal direction

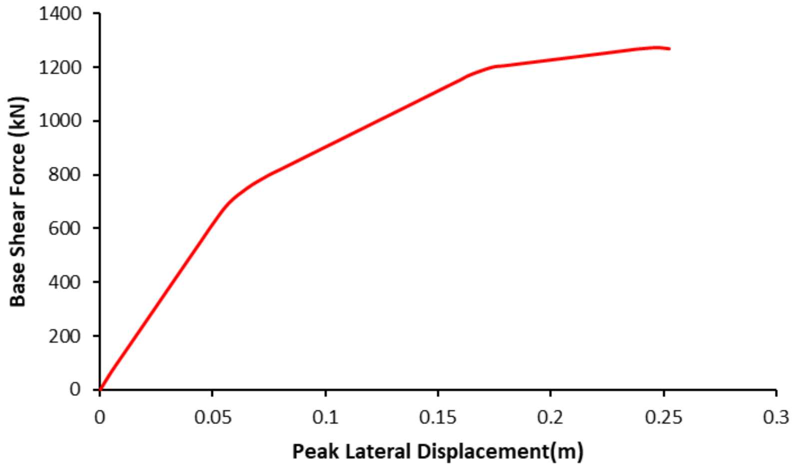

Fig. 13. Pushover curve in transverse direction

At the second step, pushover curves obtained were converted into Sa-Sd capacity curve. In the next step, the horizontal elastic design spectrum obtained for DD-2 Ground Motion level was converted into spectral acceleration-spectral displacement graph. In the last step, the performance points in the transverse and longitudinal directions of the bridge were determined by matching the Sa-Sd spectra obtained from the design spectrum with the demand curve. Accordingly, the performance point of the bridge in the longitudinal direction is 22 cm and the performance point in the transverse direction is 13 cm.

The bridge is pushed transversely and longitudinally to the performance points. The span lengths, pier heights, dimensions and dead loads on each pier are equal to each other. For this reason, the analysis results for only one pier of the bridge were assessed. The performance levels of the other piers will be considered equal to the analyzed pier. As a result of the pushover analysis, the plastic rotations occurring in the plastic hinge joints and the limit values for the performance levels are shown in Table 5. The plastic hinges resulting from the pushing of the bridge in two directions are shown in Figure 14. The hinges in green color represent the plastic deformation and the gray ones represent the hinges that do not show plastic behavior. The life safety and collapse prevention limit values of the plastic hinges are calculated according to Eq. 3 and Eq. 4. Table 5 yields that, the existing bridge structural system both transverse and longitudinal directions satisfies the immediate occupancy performance level under nonlinear pushover analysis.

As a result of the analysis performed at stage 1 level, it is observed that the bridge meets the immadiate occupancy performance level. The target performance level of immadiate occupancy performance level has been satisfied. The bridge structural system is sufficient.

$$\theta_p^{(LS)} = \left(0.5\phi_u - \phi_y\right) L_p \tag{3}$$

$$\theta_p^{(CP)} = \left(0.67\phi_u - \phi_y\right) L_p \tag{4}$$

2.3.2. Nonlinear time history analysis

A total of 10 earthquake records were selected from PEER Strong Motion Database (PEER, 2025) for nonlinear time history analysis. The records were selected based on their distance to the fault and the shear-wave velocity between 180-360 m/s since the soil class of the bridge is ZD. Details of the selected earthquake records are given in Table 6. Direct integration method was selected as the analysis type . This analysis type considers the change of the stiffness matrix with each time interval due to the nonlinear behavior. The coefficients in the Rayleigh proportional damping matrix were determined according to the periods of the first two modes that contribute the most mass participating in the longitudinal and transverse directions of the bridge.

The target spectrum was obtained by scaling the spectra generated by the SRSS method of the selected recordings with the simple scaling method to approximate the DD-1 design spectrum. The scaled spectra, the target spectrum obtained by averaging these spectra and the design spectrum are shown in Fig. 14. For each earthquake, the scaled acceleration records in two perpendicular directions were introduced to the model in transverse and longitudinal directions.

Nonlinear multilinear plastic link elements have been defined in the hinge areas of the piers instead of lumped plastic hinges. These elements are defined to add the energy damped by each element in addition to the energy damped by the bridge as a whole. Takeda model (Takeda et al., 1970) is used as hysteresis type. The translational and rotational stiffnesses used in the definition of multilinear plastic elements were calculated using section properties and plastic hinge length (Table 7 and Table 8). The section properties and force-deformation relationship used in the calculations were obtained from moment curvature graphs under the effect of 4 different axial forces. θp was obtained by Eq. 5, $\theta p1$ by Eq. 6 and $\theta p2$ by Eq. 7 (Priestley et al., 1996). The obtained plastic rotations are shown in Table 9.

$$\theta_{p1} = L_p(\phi_u - \phi_y) \tag{6}$$

$$\theta_{p2} = L_p \phi_{y\,ideal} \tag{7}$$

P-y curves were created with the drilling data in the existing project in order to provide the pile-soil interaction of the bridge. As a result of the investigations, since the soil response does not increase linearly with displacement, the displacement-force relationship corresponding to each displacement was obtained and defined to the piles as multilinear elastic link elements separately for different depths in the model.

Two load combinations were defined to obtain the bridge strain demands in the transverse and longitudinal directions by averaging 10 scaled earthquake records separately for the two directions. In each combination, a total of 20 loading cases were averaged to obtain the strain demands.

When the results are considered, the largest R3 deformation occurred in the link element no. 177 and the largest R2 deformation occurred in the link element no. 175. The largest observed rotational deformations are given in Table 10.

Table 10. Maximum Rotational Deformations of Link Elements

Longitudinal (R2)	0.0038	0.0051	0.00734

Stage 2 evaluation of plastic rotation limits for life safety and collapse prevention performance levels were calculated according to Eq. 3 and Eq. 4. Rotation values obtained from the average of 10 earthquake records in the transverse and longitudinal directions of the bridge were calculated according to Eq. 6.

The calculated performance level limits and the maximum rotations occurring in the link elements are given in Table 11. When the results are compared, it is seen that the bridge achieved the limited damage earthquake performance level in the transverse and longitudinal directions.

As a result of the analysis performed at stage 2 level, it was observed that the performance level of collapse prevention was satisfied. The bridge structural system is sufficient. No strengthening is required.

3. Conclusions

In this study, the earthquake performance of a 4-span reinforced concrete bridge exist on the Suluova-Amasya state highway is examined. The assessment was done in two stages. In the first stage, nonlinear pushover analysis was performed separately for the transverse and longitudinal behavior of the bridge considering DD-2 (design earthquake) ground motion level. Plastic hinges were defined at the piers, the bridge was pushed in two directions up to the performance points and the plastic rotations at the plastic hinges were developed. According to the results obtained from the pushover analysis, the plastic rotational deformations of the 3 piers of the bridge in both directions are between the immediate occupancy and life safety performance level limit values. The performance level of the bridge was determined as immediate occupancy according to the pushover analysis.

In the second stage evaluation, nonlinear earthquake calculation method nonlinear time history analysis was used. 10 earthquake records were selected and scaled according to DD-1 (maximum earthquake) ground motion level and applied to the system in transverse and longitudinal directions. Multilinear link elements were defined at the piers using Takeda model and deformations were observed by averaging 10 records separately in transverse and longitudinal directions. According to the results, plastic rotations in both directions provided immediate occupancy performance level.

The bridge satisfied the first stage evaluation performance target of immediate occupancy and the second stage performance target of collapse prevention according to the code. No retrofitting is required for the bridge pile-columns.

Predicting displacement demands in SDOF systems using seismic input energy: A machine learning approach

Furkan Çalım*[1], Ahmet Güllü[1], Ercan Yüksel[1]

[1] *Istanbul Technical University, Faculty of Civil Engineering, Istanbul, Türkiye*

Abstract. This study investigates the seismic input energy–displacement demand relationships and establishes a robust correlation between them. A suite of ground motion records is utilized to perform linear and nonlinear time history analyses on SDOF systems with varying dynamic properties. The computed seismic input energy and corresponding displacement demands are analyzed to identify trends and patterns, providing insights into the energy-displacement relationship across different seismic scenarios. Based on this comprehensive numerical investigation, the study further investigates the effectiveness of different machine learning models (i.e., linear models, tree-based models, boosting algorithms, neural networks, and kernel methods) in predicting the relationship between seismic input energy and displacement demands. The performance of these models is assessed regarding their accuracy, robustness, and generalization capability. The results provide valuable insights into the optimal machine learning approach for estimating displacement demands, which are among the essential input parameters for structural performance evaluation and design methodologies. This research contributes to the growing body of knowledge in energy-based seismic engineering and highlights the potential of data-driven approaches in earthquake engineering applications.

Keywords: Machine learning; Earthquake engineering; Seismic input energy; Displacement demands; Nonlinear time history analysis

1. Introduction

In recent years, energy-based approaches have gained traction in seismic design and performance assessment. As they consider crucial parameters like the frequency content, duration, and cumulative damage potential of ground motions, they offer a sought-after alternative to conventional force- and displacement-based methods (Benavent-Climent and Mollaioli, 2021; Varum et al., 2023).

Seismic input energy imparted into the structures by a ground excitation has emerged as a promising metric for evaluating structural demands. Several studies in the literature have highlighted its potential in frame-type reinforced concrete and steel buildings (Fujii and Shioda, 2023; Güllü et al., 2023). However, these methods may prove less effective when the building exhibits complex nonlinear dynamic behavior, which is not fully captured in simplified models.

To address this challenge, machine learning algorithms have gained extra popularity because they can model complex relationships without needing explicit mathematical equations. Machine learning applications in earthquake engineering practice (Xie et al., 2020) have included different topic areas, such as seismic hazard analysis (Tang et al., 2022), system identification and damage detection (Salkhordeh et al., 2023), seismic fragility assessment (Kazemi et al., 2023), and structural control for earthquake mitigation (Chen and Chien, 2020). However, studies specifically focusing on predicting displacement demands based on seismic input energy using machine learning algorithms are still limited.

This study aims to fill the gap by evaluating the predictive performance of various machine learning algorithms, including linear models, tree-based models, boosting algorithms, neural networks, and kernel methods, to estimate the displacement demand of SDOF systems using seismic input energy as the primary input feature. A total of 16 models are trained and tested utilizing the ground acceleration records from the 2023 Kahramanmaraş earthquakes. The goal is to discuss the applicability of machine learning models in energy-based seismic engineering applications and to determine the most effective algorithm in predicting the displacement demand of SDOF systems.

2. Materials and methods

A comprehensive machine learning approach was adopted to predict the displacement demands in SDOF systems from the 2023 Kahramanmaraş earthquakes. Several algorithms were evaluated regarding their predictive performance in capturing the relationship between the seismic input energy and structural response. These models were trained and validated on a dataset derived from extensive linear and nonlinear time history analyses. The performance of each algorithm was comparatively assessed based on accuracy metrics, providing insight into their applicability and robustness.

2.1. Ground motion data

The 2023 Kahramanmaraş earthquakes refer to a catastrophic earthquake doublet that struck southeastern Türkiye on February 6, 2023. The first event of the doublet, with a moment magnitude of 7.8, occurred at 04:17 a.m. local time, centered near Pazarcık in Kahramanmaraş province. Around nine hours later, at 01:24 p.m. local time, the second event with a moment magnitude of 7.5 took place near Elbistan county, approximately 90 kilometers north of the first epicenter. The sequence of two large-magnitude earthquakes generated extremely intense and long-duration ground shaking. These characteristics contributed to widespread structural damage across 11 provinces.

In the current study, a seismic demand dataset was generated using the ground motion records from the first event of the doublet. The acceleration records from the 200 nearest stations to the epicenter were utilized in the analyses. The seismic input energy and displacement demands were computed after performing linear and nonlinear time history analyses on a wide range of SDOF systems with varying natural periods (T), damping ratios (ζ), and displacement ductility demands (μ). For the success evaluation of the developed machine learning models, the data for the SDOF systems with a natural period of 1.0 s and a damping ratio of 5% were employed, as displayed in Fig. 1.

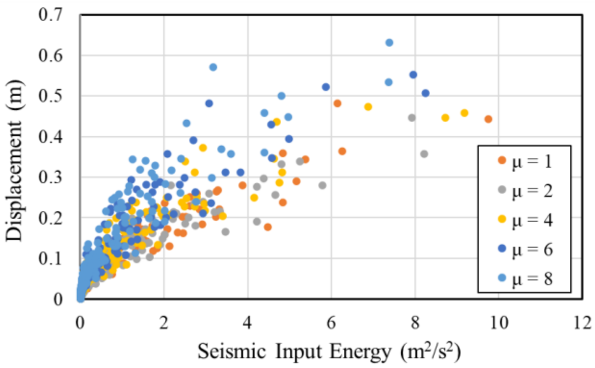

Fig. 1. Seismic input energy and displacement demand dataset

2.2. Machine learning models

Several machine learning models were investigated regarding their effectiveness for predicting the displacement demand of SDOF systems using seismic input energy. This section summarizes the employed machine learning models categorized by their types: linear models, tree-based models, boosting algorithms, neural networks, and kernel methods.

2.2.1. Linear models

Linear models form the foundation of many machine learning approaches. They are commonly used for regression tasks due to their simplicity, efficiency, and interpretability, as they assume a linear relationship between input features and the target variable. In this study, three linear models (i.e., Ridge Regression, ElasticNet, and Bayesian Ridge Regression) were utilized to capture linear trends within the data.

Ridge Regression is a linear model that addresses the multicollinearity issues in linear regression by introducing a penalty term to the loss function. This reduces model complexity and prevents overfitting. However, this method's shortcomings include complicated interpretation and the inability to perform variable selection (Hoerl & Kennard, 1970).

Bayesian Ridge Regression incorporates Bayesian principles into linear regression. In this model, the coefficients are treated as random variables with specified distributions, allowing for the estimation of uncertainties. Even though it is robust to multicollinearity, it is computationally more intensive (MacKay, 1992).

ElasticNet is a hybrid approach that combines the penalty terms of the Ridge and Lasso Regressions. It is effective when working with multiple correlated variables. However, it is a complex and computationally intensive method as it requires tuning two hyperparameters (Zou & Hastie, 2005).

2.2.2. Tree-based models

Tree-based models are popular for regression and classification tasks because of their intuitive structure, interpretability, and capacity to model nonlinear relationships. This study employed three different tree-based models (i.e., Decision Tree, Random Forest, and Extra Trees) to evaluate their displacement demand prediction performance.

Decision Tree is a non-parametric model that splits the feature space into separate regions according to feature values, forming a tree-like decision structure. Each internal node represents a test on a feature, each branch signifies the result of that test, and each leaf depicts a predicted value. While they offer several benefits, such as ease of interpretation and visualization, compatibility with both numerical and categorical data, and minimal data processing requirements, they also have limitations. These include susceptibility to overfitting and sensitivity to minor data fluctuations (Breiman et al., 1984).

Random Forest is an ensemble machine learning method that constructs an assembly of decision trees during the model's training and outputs the mean prediction of individual trees. Its randomness comes from selecting random subsets of features for each tree, enabling the model to reduce overfitting. However, it may be less interpretable and more computationally intensive than individual decision trees (Breiman, 2001).

Extra Trees (i.e., Extremely Randomized Trees) is an ensemble method similar to the Random Forest. However, it introduces more randomness during the splitting process. Later, it chooses the best option among the selected splits for each feature, which further reduces the overfitting. Even though it is faster to train, it may perform worse than Random Forest on certain structured datasets (Geurts et al., 2006).

2.2.3. Boosting algorithms

In the boosting algorithms, the models are sequentially trained to correct the errors, improving their overall predictive performance. They combine weak learners into a strong predictive model, which is effective in capturing nonlinear patterns. This study analyzed four boosting algorithms (i.e., AdaBoost, Gradient Boosting, XGBoost, and LightGBM).

AdaBoost (i.e., Adaptive Boosting) is a boosting algorithm that combines multiple weak learners by reweighting the samples. The purpose is to focus on the misclassified instances in the following iteration. Its advantages include being simple and effective for binary classification tasks, improved model performance, and robustness to overfitting. In contrast, it is sensitive to outliers and might not perform well on high-dimensional datasets (Freund and Schapire, 1997).

Gradient Boosting focuses on improving weak learners step-by-step by correcting the residual errors of the previous one. It provides high predictive accuracy and flexibility through custom loss functions. However, the training task might be relatively slower as it builds models sequentially. In addition, it might be sensitive to outliers and overfitting (Friedman, 2001).

XGBoost is currently one of the most popular machine learning algorithms due to its improved performance in structured datasets. It employs regularization for the penalty terms of the Ridge and Lasso Regressions, which prevents overfitting. In addition to being efficient in terms of training time and scalability, it requires extra care in tuning its hyperparameters (Chen and Guestrin, 2016).

LightGBM uses histogram-based algorithms that require less memory and offer faster training times compared to XGBoost. It can handle large datasets efficiently and supports categorical features natively. However, overfitting may be an issue when working with small datasets (Ke et al., 2017).

2.2.4. Neural networks

Neural networks, which can automatically learn feature representations, are capable of modeling complex and nonlinear relationships. In this study, the Multi-Layer Perceptron (MLP) algorithm was utilized to evaluate its performance in generalizing displacement demands of SDOF systems based on seismic input energy.

MLP is an algorithm capable of modeling complex nonlinear relationships, trained using backpropagation. While it performs well across a wide range of regression tasks, its drawbacks include longer training times, higher computational resource demands, and the necessity for large amounts of data and careful tuning (Rumelhart et al., 1986).

2.2.5. Kernel methods

Kernel-based machine learning models capture nonlinear relationships by projecting input data into higher-dimensional feature spaces, enabling effective learning in complex domains. This study investigated three kernel-based models (i.e., Support Vector Machines (SVM) with a Radial Basis Function (RBF), a linear version of SVM, and Kernel Ridge).

SVM with RBF operates in a higher-dimensional space, adeptly handling complex nonlinear relationships. While it is a powerful algorithm for nonlinear regression, it is also computationally intensive and requires careful tuning (Cortes & Vapnik, 1995).

On the other hand, the linear version of SVM is suitable for datasets with approximately linear relationships between input features and target parameters. Although it is fast and efficient when using linear kernels, its performance declines with complex datasets (Cortes & Vapnik, 1995).

Kernel Ridge operates in a high-dimensional feature space by combining Ridge Regression with the kernel trick to effectively model nonlinear relationships. It is more suitable for small and medium-sized datasets rather than large ones (Saunders et al., 1998).

2.2.6. Other models

This study also evaluated some additional machine learning algorithms that do not strictly fall into the aforementioned categories. These models (i.e., K-Nearest Neighbors and Bagging Regressor) offer ensemble performance capabilities.

K-Nearest Neighbors (KNN) predicts the target variable by averaging the training sample values. Because it does not require a training phase, it is simple to implement and performs well with low-dimensional data. However, when dealing with high-dimensional data, it tends to slow down in making predictions and may encounter performance difficulties (Cover and Hart, 1967).

Bagging Regressor is a collective model that trains multiple decision trees on random subsets of the input data. To reduce the variance and prevent overfitting, the average of their predictions was used as the overall prediction of the model. Even though it is a simple and well-performing algorithm on unstable models, it fails to reduce bias. (Breiman, 1996).

2.3. Training and testing strategy

A Python-based code was utilized to employ the detailedly discussed machine learning models. The dataset, including the features (i.e., seismic input energy and ductility ratio) and the target variable (i.e., displacement demand), was introduced to the model. Later, it was randomly split into training and testing sets with an 80-20 ratio. To improve numerical stability and model performance, data normalization was applied. After initializing each machine learning model with some basic parameters, they are trained and used for the prediction of displacement demands.

3. Results and discussions

Each machine learning model was trained using a randomly selected 80% portion of the original dataset, and its performance was subsequently evaluated for the remaining 20%. The predicted displacement demand values were compared with the corresponding actual ones for each model. Given that the total dataset length was 2000, each comparison was made for 400 data points, each representing an individual ground motion record. An evaluation was made regarding the computed R^2 score, which is a statistical measure indicating the wellness of a regression model. It is computed by subtracting the ratio of the sum of squared residuals to the total sum of squares from one.

Fig. 3 displays the predicted versus actual values for the displacement demands for linear models. ElasticNet had the lowest predictive performance among them, with an R^2 value of only 0.5457, indicating its limited effectiveness in estimating SDOF systems' displacement demands. On the other hand, Ridge Regression and Bayesian Ridge models showed moderate prediction accuracy, with predictions clustering around the 45º-line with some visible scattering.

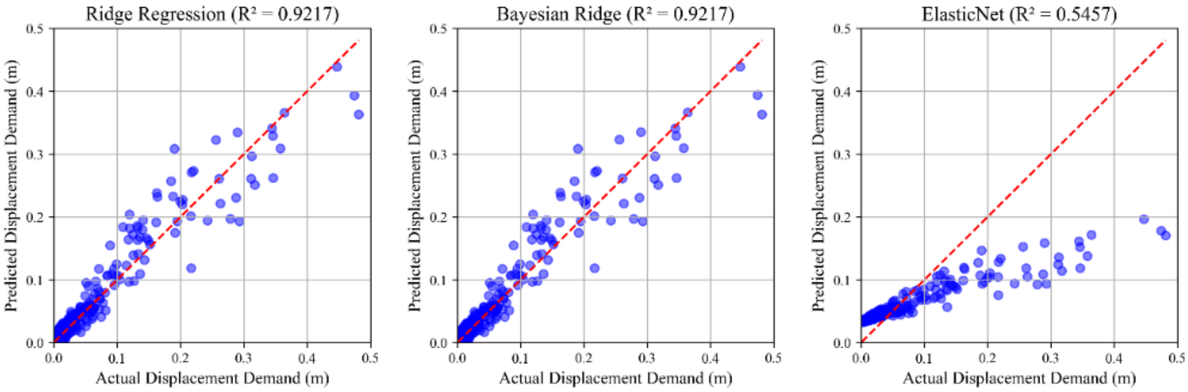

Fig. 3. Predicted versus actual values for the displacement demands using linear models

Fig. 4 presents the predictive success evaluation of tree-based machine learning models. All three models (i.e., Decision Tree, Random Forest, and Extra Trees) displayed improved prediction performance over linear models. In particular, Decision Tree provided the best fit among them with fewer extreme outliers and an R^2 value of 0.9330, suggesting more substantial generalization capabilities.

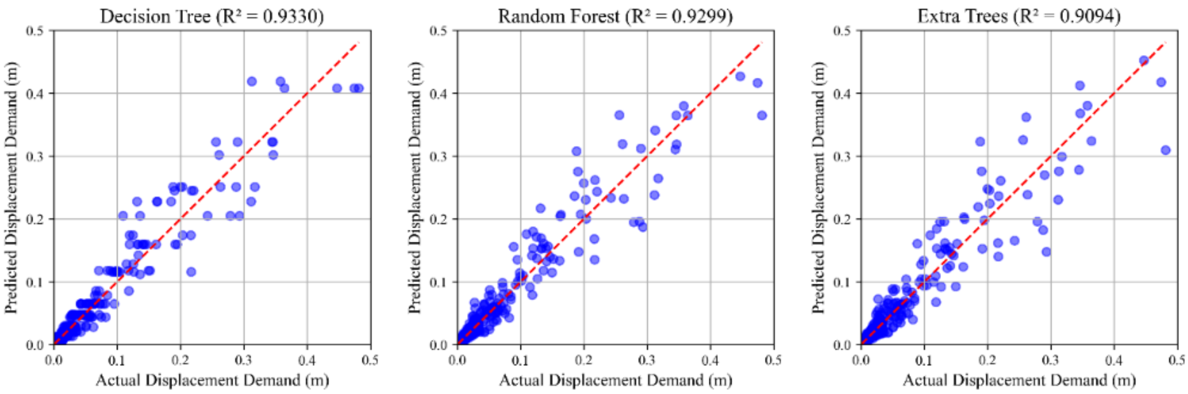

Fig. 4. Predicted versus actual values for the displacement demands using tree-based models

Boosting algorithms (i.e., AdaBoost, Gradient Boosting, XGBoost, and LightGBM) resulted in the most concentrated prediction clusters along the 45º-line and relatively higher R^2 scores, as displayed in Fig. 5. Specifically, Gradient Boosting and LightGBM outperformed the others, with R^2 scores of 0.9413 and 0.9363, respectively.

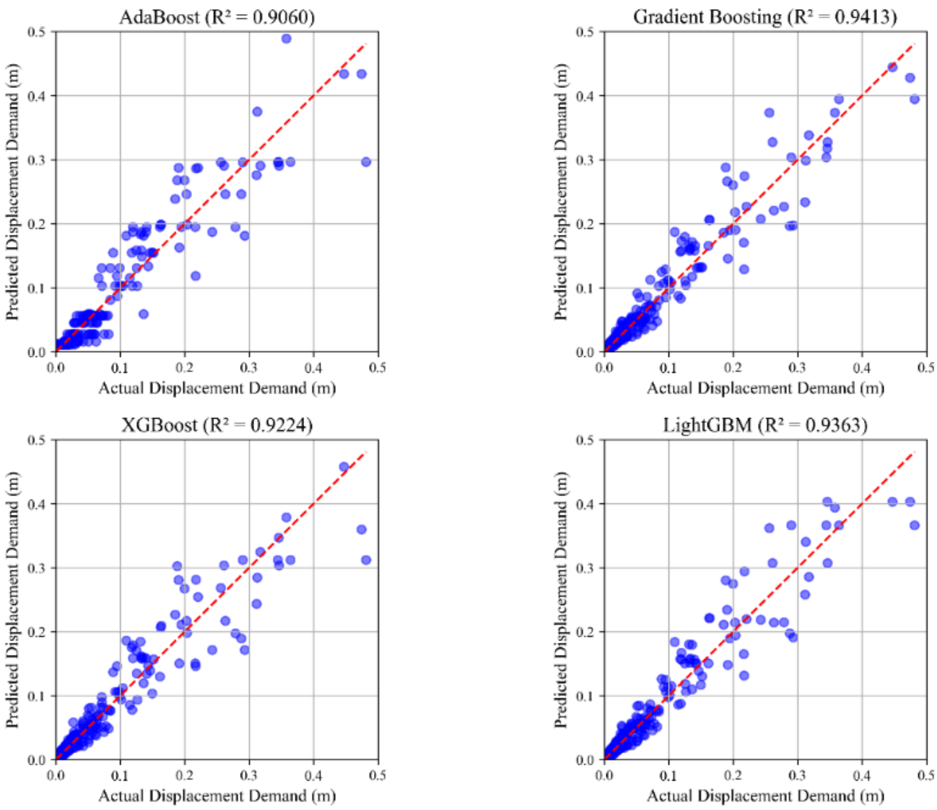

Fig. 5. Predicted versus actual values for the displacement demands using boosting algorithms

The MLP model, which employs a neural network algorithm, showed competitive results by yielding predictions closely matching the actual displacement demand values, as presented in Fig. 6. Its predictions resulted in an R^2 value of 0.9336.

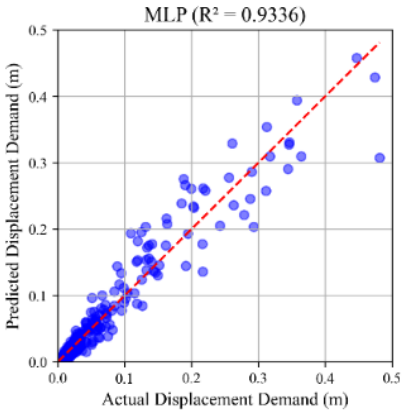

Fig. 6. Predicted versus actual values for the displacement demands using neural networks

Fig. 7 compares the actual displacement demands to those predicted by the kernel methods. The Kernel Ridge model delivered the strongest performance among all the evaluated machine learning models, with an R^2 value of 0.9421. It resulted in smooth and consistent predictions. On the other hand, both linear and RBF-type SVR performed very poorly (i.e., with R^2 values of 0.6500 and 0.1406, respectively), especially for the lower displacement demands.

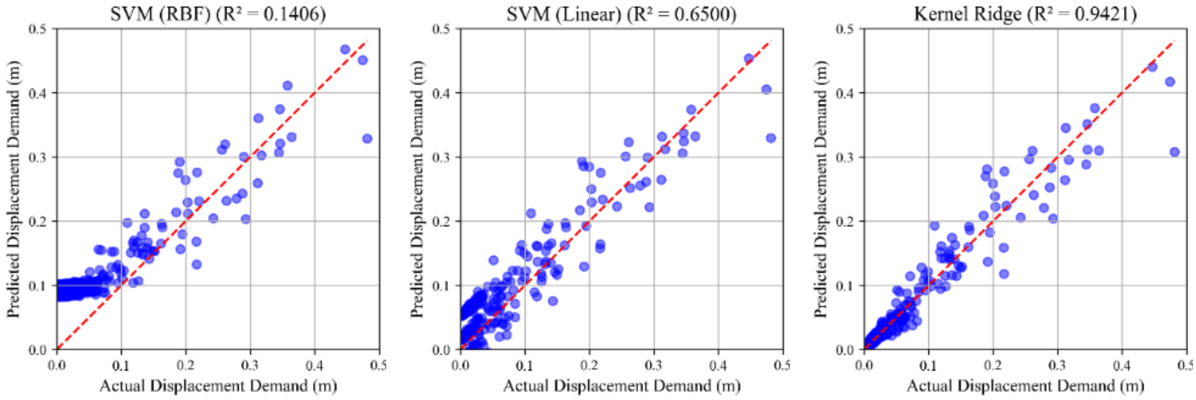

Fig. 7. Predicted versus actual values for the displacement demands using kernel methods

The KNN and Bagging Regressors yielded satisfactory prediction performances, with R^2 values of 0.9339 and 0.9281, respectively, as shown in Fig. 8. While KNN outperformed Bagging Regressor in terms of stability and alignment with actual demand values, a performance degradation was observed in the moderate displacement demand predictions by Bagging Regressor.

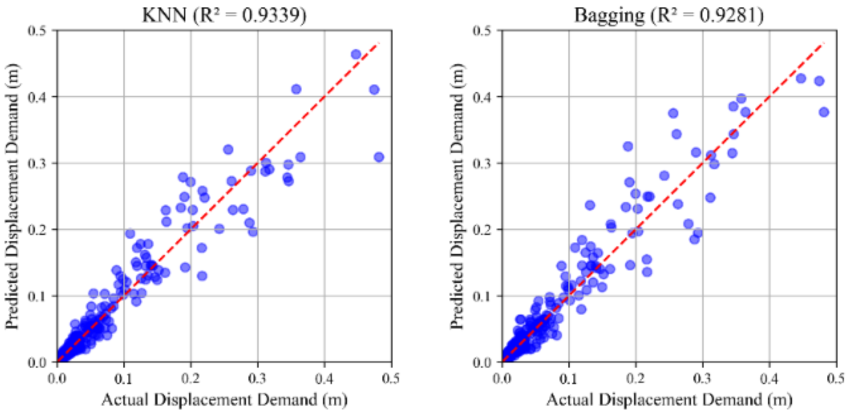

Fig. 8. Predicted versus actual values for the displacement demands using other models

Fig. 9 compares the model performance based on the error metrics. Specifically, root mean squared error (RMSE) and mean absolute error (MAE) values were calculated for each machine learning model to assess their prediction accuracy. RMSE indicates the square root of the average of the squared differences between predicted and actual displacement demand values. In contrast, MAE represents the average of the absolute differences between predicted and actual values. While the SVM (RBF), ElasticNet, and SVM (Linear) models produced the highest error values, the other models resulted in relatively lower and similar RMSE (i.e., approximately 0.02) and MAE (i.e., approximately 0.01) values. In general, the boosting algorithms yielded the best predictive performance. However, particularly, the Kernel Ridge model from the kernel methods became the most successful one among the others, with an RMSE value of 0.0192 and an MAE value of 0.0089.

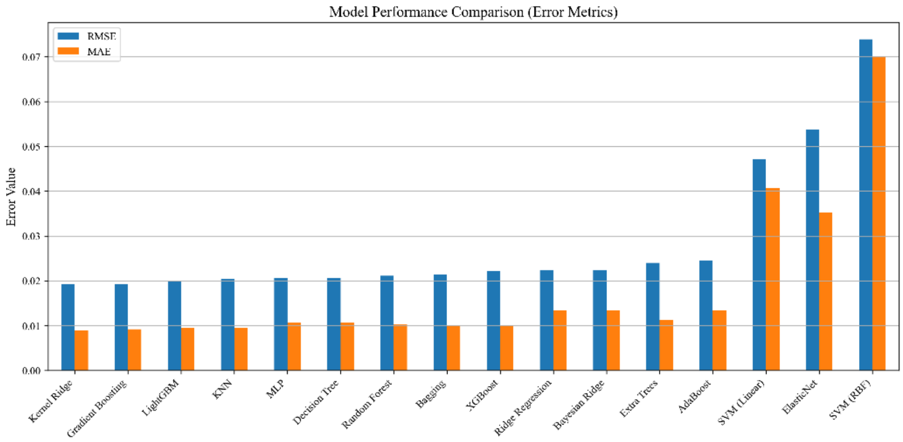

Fig. 9. Model performance comparison

4. Conclusions

This study investigated the use of seismic input energy in predicting displacement demands, utilizing a broad range of machine learning models. The predictive performance of the selected 16 models was compared using data generated from linear and nonlinear time history analyses of the 2023 Kahramanmaraş earthquake's acceleration records. The following conclusions were drawn:

- The boosting algorithms yielded the most reliable displacement demand predictions, whereas the linear models and some kernel methods yielded the least successful ones. Specifically, Support Vector Machines with a Radial Basis Function, ElasticNet, and a linear version of Support Vector Machines achieved the lowest R^2 scores and highest error metrics.
- Among the studied machine learning models, Gradient Boosting, LightGBM, and Kernel Ridge Regression stood out, resulting in R^2 values above 0.94 and RMSE values below 0.02. It indicates their high degree of prediction accuracy and model reliability for the displacement demand estimations.
- The results showed that the seismic input energy is a valuable metric for predicting the structural displacement demands of SDOF systems, especially when integrated into machine learning algorithms.

This study contributes to the growing intersection between earthquake engineering and data science. By augmenting traditional analytical techniques, it demonstrates the potential of machine learning algorithms to improve seismic response predictions. Additionally, the following recommendations are proposed for future studies:

- Some additional intensity measures (e.g., PGA, PGV, Arias intensity) and earthquake metrics (e.g., significant duration, spectral shape indicators) should be introduced as input features to enhance model accuracy.
- The study should be extended to MDOF systems, which would yield a more complex and nonlinear relationship between the seismic input energy and displacement demands.
- Hyperparameter optimization techniques should be applied to further improve the models' prediction performance.
- To assess their applicability and robustness, the trained and tested machine learning models should be validated using experimental data from shaking table tests or real-world instrumented buildings.
- The use of hybrid or ensemble meta-models should be explored to combine the strengths of multiple machine learning algorithms for improved prediction stability.

Abstract. In modern engineering practices, finite element models of structures are generated using specialized structural analysis software, and simulations are conducted in computational environments. To ensure that these analyses accurately represent the actual structural behavior and produce realistic results, finite element models are calibrated using dynamic properties obtained from experimental modal analysis. In this study, five small-scale two storey one bay reinforced concrete specimens tested. Theoretical modal analysis results were obtained for these specimens using the SAP2000 software. Concurrently, the reinforced concrete specimens were excited using an impact hammer (modal hammer), and their dynamic responses were recorded using uniaxial accelerometers installed at specific floor levels. The force and acceleration signals collected during the experiments were processed in the frequency domain using dedicated signal processing software to derive transfer functions for the reinforced concrete models subjected to impact excitation. Through these analyses, the dynamic properties of the structures, including mode shapes, natural frequencies, and damping ratios, were determined. Then, the experimental modal analysis results for each reinforced concrete specimen were compared with the theoretical modal analysis results of the SAP2000 finite element model calibrated with the modulus of elasticity variation. Calibrating the analytical model with the experimental modal analysis results increases the reliability of the finite element model. This approach contributes significantly to accurately predicting structural behavior and provides a robust basis for more precise finite element modeling in future structural engineering research.

Keywords: Experimental modal analysis; Modal hammer; Finite element model; RC specimens

1. Introduction

In structural engineering, accurately predicting the behavior of designed systems under various external forces forms the basis of safe and functional designs (Chopra, 2017). In addition to static loads, dynamic loads—such as earthquakes, wind, traffic, or machine vibrations—have been shown to influence the response of structures significantly. These dynamic interactions are directly related to the fundamental properties of structures, such as mass and stiffness, and can lead to undesirable consequences like resonance, excessive oscillation, and structural damage.

At this stage, Modal Analysis is a critical method. This discipline, which involves the determination of a structure's vibratory properties through either experimental investigation or analytical modeling, facilitates the comprehension of structural dynamic behavior by characterizing its natural frequencies, damping ratios, and mode shapes (Ewins, 2000). Knowing these vibration properties is crucial for predicting and improving how structures respond to different dynamic forces.

Modal analysis is a methodology widely applied in various engineering disciplines. It is used in various fields such as civil engineering, automotive engineering, aeronautical engineering, astronautical engineering, electronics, and sports equipment design. The material properties specific to structures in these various engineering branches, combined with the variability of the environmental conditions to which they are exposed, often require various measurement techniques and data processing strategies.

Operational Modal Analysis (OMA) and Experimental Modal Analysis (EMA) represent two primary methodologies for identifying the dynamic properties of structures, which are fundamentally different from these models by the treatment of input excitation. OMA takes advantage of naturally occurring ambient or operational forces acting on a structure, where these input forces are not directly measured; the analysis focuses only on the

https://doi.org/10.31462/icearc2025_ce_eqe_748

golden light publishing

structural response. In contrast, EMA involves the application of a known and measurable input force to the structure, typically using instruments like modal hammers or shakers, allowing for direct input-output characterization of the system's dynamic behavior. This difference in input force measurement forms the core distinction between these two widely applied techniques in structural dynamics.

The practical difficulties of using impact hammers can make EMA challenging, especially when studying large structures. For this reason, OMA is often a more practical and effective method for understanding the dynamics of large-scale systems (Grosel et al., 2014). However, when analyzing smaller structures, both EMA and OMA have been shown to produce similar and reliable results.

Nowadays, EMA, especially when applied to impact testing, is a frequently used and preferred method for determining the vibration characteristics of structures. EMA has been widely accepted due to its advantages, such as low uncertainty in the applied force, a better understanding of the test conditions, easy applicability, fast results, and economy (Schwarz & Richardson, 1999; Zoltowski & Napieraj, 2017).

In current engineering design processes, finite element (FE) software is common, often relying on certain assumptions. The economic benefits of FE analysis frequently lead to its selection over physical experiments. However, it is important to recognize that real-world structural behavior may differ from theoretical predictions. Therefore, a reliable way to improve the validity and accuracy of FE analysis assumptions is to compare the outcomes of experimental studies with those from FE simulations. Many research projects have assessed the effectiveness of EMA on different structural materials and systems and how well its results align with analytical findings.

Prasad and Seshu (2008) conducted an experimental modal analysis on beams of different materials using an impact hammer. In their study, they compared their experimental results with theoretical analyses and FE software analysis results. Similarly, a study by Walunj et al. (2015) investigated the modal parameters of cantilever beams using the experimental modal analysis method. Sharma (2019) also presented a comparative study of theoretical and experimental modal analysis on beams.

Chandravanshi and Mukhopadhyay (2013) investigated the dynamic characteristics (frequency, mode shape, damping) of a two-story steel structure using experimental modal analysis. They then analyzed the same structure using the finite element method with the ANSYS program and subsequently compared the results obtained from the experimental and numerical approaches.

Bayraktar et al. (2010) experimentally obtained and investigated the dynamic parameters of three reinforced concrete buildings at different construction stages. Altunisik et al. (2013) applied analytical and experimental modal analyses to determine the dynamic characteristics of a scaled bridge model.

Arslan and Durmus (2014) conducted OMA experiments on single-story reinforced concrete frames to investigate the role of infill walls on the dynamic response of structures. These experiments tested both bare frames and frames with brick infill walls. A finite element model was also created and calibrated using the SAP2000 program.

Orlowitz and Brandt (2017) conducted a detailed comparison of EMA and OMA using a laboratory-tested plate. Their study aimed to evaluate the effectiveness and applicability of both methods under controlled conditions. The research examined the accuracy of identified dynamic properties and the practical aspects of each technique. This work provides knowledge of the relative merits of EMA and OMA for structural analysis.

Azmi et al. (2021) conducted an experimental modal analysis on a two-story reinforced concrete frame. In this study, they determined the structure's natural frequencies using impact testing and accelerometers. They compared the experimental results with the results from a finite element model they created using the HYPERWORK program. The findings showed that the natural frequencies measured experimentally were in significant agreement with those obtained through numerical modeling.

Filippoupolitis and Hopkins (2021) conducted a study investigating the dynamic behavior of damaged reinforced concrete beams. In their research, they utilized EMA to understand the effects of structural discontinuities on the vibration characteristics of these beams. Additionally, they employed Finite Element Methods (FEM) to support their experimental findings with numerical modeling.

In a study by Ahmed and Mohammad (2015), the EMA method was employed to understand the dynamic characteristics of reinforced concrete square plates. These researchers determined the plates' natural frequencies and mode shapes through experiments performed in a laboratory setting.

Sevim et al. (2011) collected experimental data on the dynamic properties of two historical arch bridges using ambient vibration tests, and they calibrated the finite element models created in the ANSYS program using this data. Günaydin et al. (2017) initially performed an analytical determination of the modal parameters of the reinforced concrete buildings constructed under laboratory conditions, employing the ANSYS software. Subsequently, they conducted ambient vibration tests to experimentally validate these parameters, utilizing the acquired data to refine the initial finite element models for increased accuracy.

Altunisik et al. (2024) updated the finite element models of the historical Santa Maria Church and its Guesthouse in Trabzon using the dynamic properties obtained from a non-destructive experimental investigation with ambient vibration testing.

Fig. 1. RC specimens

In this study, experimental modal analysis was performed on five reinforced concrete frame structures, as presented in Fig. 1. Using an impact hammer as an exciter, the natural vibration frequencies and corresponding mode shapes, which are the basic dynamic characteristics of the structures, were determined. In addition, the modal analysis of the same structural configurations was carried out analytically using SAP2000 software. A calibration process was applied to ensure the validity and predictive ability of the numerical models. In this process, the parameters of the analytical models were systematically adjusted by comparing them with the data obtained from the experimental modal analyses. The agreement between the analytical and experimental findings supported the overall reliability and validity of the numerical representations developed for the reinforced concrete frame structures.

2. Materials and methods

This study focuses on the experimental modal analysis of small-scale, two-story reinforced concrete structures, each featuring a story height of 20 cm and a span of 20 cm. Five distinct specimens were examined as part of this research. Three of these specimens were constructed with rectangular columns, each having a cross-sectional size of 25x25 mm (Fig. 2a). The remaining two specimens incorporated circular columns, each with a diameter of 20 mm (Fig. 2b).

(a)

(b)

Fig. 2. Two type of specimen having a) Rectangular column cross-section b) Circular column cross-section

At the beginning of this study, finite element (FE) simulations were performed before the experimental modal analysis to find the approximate natural frequency range of the structures. This frequency range obtained from the FE models was important in determining the necessary measurement settings (e.g., sampling frequency, frequency resolution) for the experimental modal analysis.

The reinforced concrete frame structures were stimulated with a calibrated modal impact hammer. The frequency content of the impact applied by the hammer depends on the hardness of the tip used; harder tips affect a wider frequency range. As stated in the literature by Avitabile (2001), selecting the appropriate tip is important to adequately excite all structural modes relevant to modal identification. Therefore, a modal impact hammer is used with appropriate sensitivity and linearity to accurately measure the force applied to concrete structures (Fig. 3a).

We used uniaxial accelerometers to study how structures vibrate (Fig. 3b). These special sensors generate electrical signals directly proportional to the movement of a small mass inside. These signals are converted from analog to digital, allowing us to obtain precise acceleration values at the points where the sensors are placed. In this way, we can comprehensively understand the dynamic behavior of structures.

In the experimental phase of this research, transient vibrational excitations generated in structural systems by the controlled impact forces of the modal hammer were recorded using three uniaxial accelerometers. The roving hammer technique was applied. Under this methodology, accelerometers were placed at strategic points in the structural frames to record linear acceleration components along the x and y horizontal axes.

(a) (b)

Fig. 3. Test setups a) Modal hammer b) Uniaxial accelerometers

The data obtained from the experimental studies was recorded using Dewesoft signal processing software installed on a personal computer. During this process, the force signal from the modal hammer was visualized as a force-time graph in the time domain. In contrast, the vibration response signals from the accelerometers were recorded as acceleration-time graphs. To accurately analyze these time-dependent data, they were transformed into the frequency domain using the Fast Fourier Transform (FFT) algorithm integrated within the software. Subsequently, Frequency Response Functions (FRFs) that characterize the dynamic properties of the structures were calculated.

The Frequency Response Function (FRF) mathematically describes how a structure responds to an applied force. This response is usually measured by acceleration, velocity or displacement. The FRF examines the components of both the applied force and the structure's response at different frequencies. To do this, we convert time-varying signals into the frequency domain using the Fourier Transform method. This allows us to see how much the structure increases or decreases the forces at different frequencies. The FRF is a complex number representing the magnitude ratio and phase difference between the input and output at each frequency. Notably, the specific mathematical points (poles) of the FRF indicate the structure's natural vibrational frequencies. The shape of the FRF around these points indicates the damping characteristics of the structure (how fast it dampens vibrations) (Avitabile, 2001).

In the calculation of the Frequency Response Functions (FRFs) by transforming the obtained time data into the frequency domain, the following fundamental frequency response function formula was used by the software. Here, H(ω) represents the Frequency Response Function; X(ω), the Fourier Transform of the output response; F(ω), the Fourier Transform of the input force; and ω, the Frequency.

$$H(\omega) = \frac{F(\omega)}{X(\omega)} \tag{1}$$

Through this mathematical relationship, the frequency domain response of the structure to the applied force is analyzed in detail, and the structural dynamic properties (natural frequencies, damping ratios, and mode shapes) are determined.

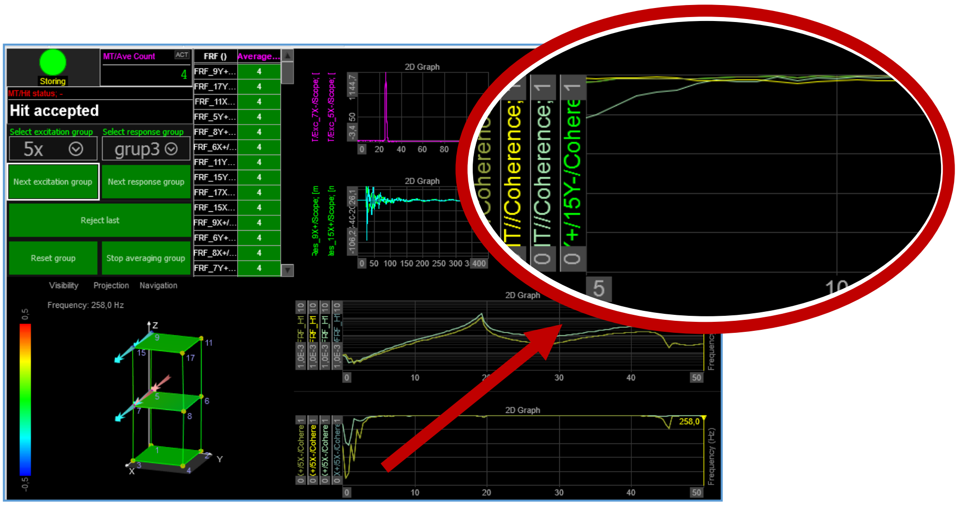

Fig. 4. Measurement screen and detail of coherence

In the experimental studies, various impact application points were used to ensure a comprehensive determination of the structures' dynamic behavior. The structures' corner points were excited in both x and y directions, as impacting the corner points facilitates the excitation of a larger number of modes compared to impacting the center point (Mali & Singru, 2018).

The coherence function was used to evaluate the data quality. This function shows how linearly the measured output is related to the applied input. Inconsistent pulses in the measurement can lead to variations in the resonance values. Therefore, four controlled and consistent pulses were applied to each point for reliable results. If the coherence value of the pulses at a point was between 0.7 and 1, that measurement was accepted (Fig. 4). This process aims to increase the reliability of the Frequency Response Functions (FRF).

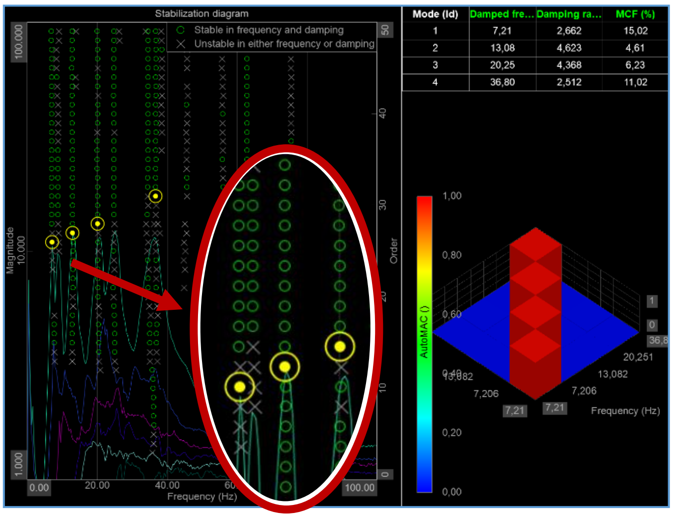

Fig. 5. Stabilization and AutoMAC diagram

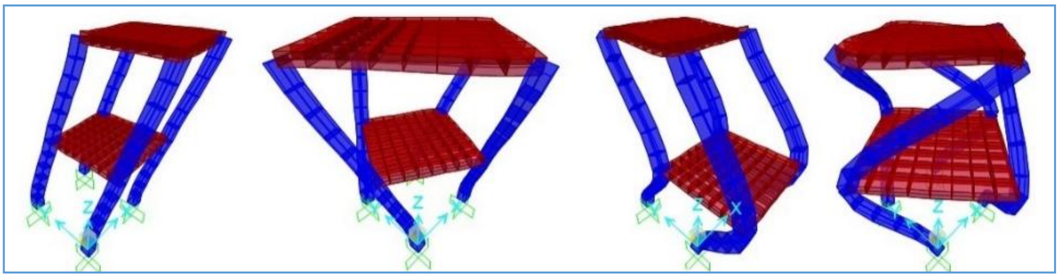
The Frequency Response Functions (FRFs) generated from the acquired measurement data were converted into stabilization diagrams using the software (Fig. 5). These diagrams visually illustrate the consistency of the structural vibration frequencies and damping characteristics calculated for different mathematical model complexities (model orders). As the model complexity increases, peak points that do not show a significant change in frequency and damping values, i.e., remain "stable," are marked on this diagram.

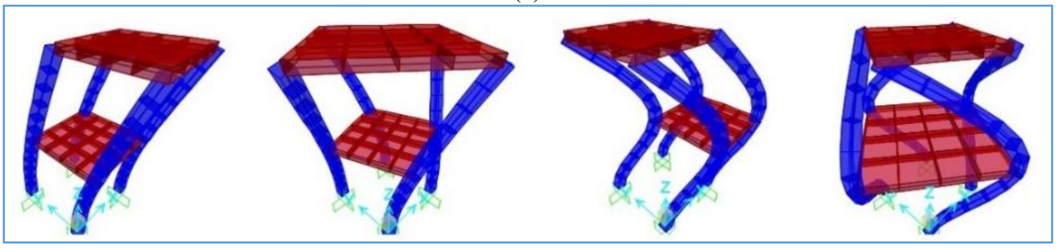
These stable peak points represent frequencies more likely to correspond to actual structural modes. Subsequently, these stable frequency values were used to generate the AutoMAC (Automated Modal Assurance Criterion) diagram. The AutoMAC diagram evaluates the similarity and consistency between the vibration patterns at different measurement points. This process helps identify "significant" physically meaningful " vibration modes, thus avoiding misleading results. These stages are crucial for enhancing the accuracy and reliability of the structural dynamic properties obtained from the experimental data (Dewesoft).

The SAP2000 models for samples given in Fig. 2a and Fig. 2b was developed using centroid lines of elements and midplanes for slabs. The models were generated separately for calibration. Calibration was made according to the modulus of elasticity of concrete of samples. The change in modulus of elasticity affects stiffness and also accounts for cracks as well. At first, the supports defined as fixed support and modulus of elasticity of concrete is taken as 24855 MPa, the default value. The effective flexural stiffness multiplier was taken as 0.7 for columns. The system is a flat slab building. The slab type definition is important for calibration, since the modal frequencies are affected by it. While “shell thin” makes column ends more like fixed ends. On the other hand, out of plane bending deformation of the slab does not accounted for the membrane, resulting decrease in the stiffness of columns. The theoretical modal analysis was done using the FE model at SAP2000 by eigenvalue analysis. In Fig. 6, the four mode shapes for different slab type definitions are given.

As can be seen from Fig. 6a and b, the nearly 90° angle of joints and “S” shape of columns can be observed from shell thin defined slab model mode shapes (Fig. 6a). On the other hand, it is more like free end for columns of membrane defined slab model mode shapes (Fig. 6b). This difference in behavior affects structural stiffness and the modal frequencies as well. Therefore, it was studied comparatively. The modal frequencies with automeshed slab models are given in Table 1.



(a)



(b)

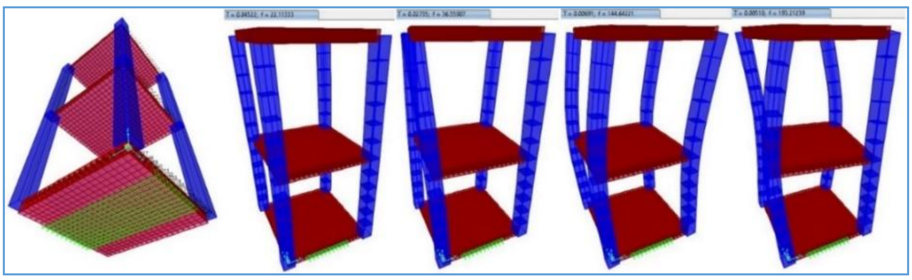
Fig. 6. SAP2000 theoretical mode shapes a) for slabs defined as shell thin b) for slabs defined as membrane

Table 1. Slab types and corresponding modal frequencies (Hz)

Slab Type	Mod 1	Mod 2	Mod 3	Mod 4
Shell Thin	62.44	86.9	203.43	268.23
Membrane	28.40	43.60	171.48	220.40

The construction of a small-scale low-strength building, like Fig. 2a and b, is a sensitive job. As a result, there are numerous governed cracks at slabs near joints. That is why membrane slab type is selected for model to describe reality. By increasing the mesh number of slab, as for shell thin model, the modal frequency is decreasing to a point. In that manner, the results given in Table 1 are obtained for 20x20 auto meshing of each slab. While gradually increasing the amount of mesh number, as for membrane, the slight change in modal frequency occurs only in torsional modes, the modal frequency for translational modes becomes constant.

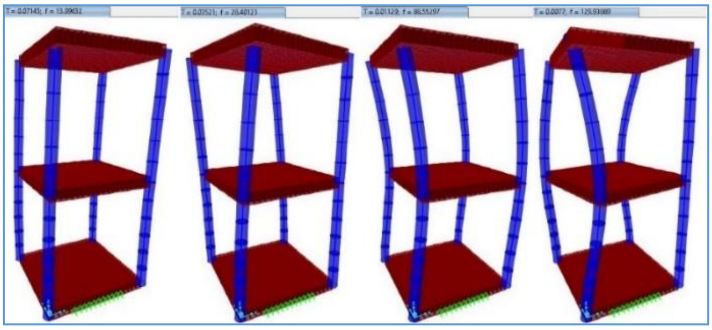
Aside from slab type, the support type should defined similar to the reality. The systems have a basement, and the basement sits on a steel I beam, as can be seen from Figs. 2 a and b while the measurements of EMA are taken. The column supports are the basement itself, meaning the boundary condition of bottom of columns provided by deformation of basement. Note that not the entire basement sits on the steel beam. This situation is taken into consideration in the SAP2000 model by adding a basement, dividing it into quads, and assigning pinned supports at the nodes corresponding to the mentioned I beam and basement intersection. The bottom perspective view of the basement can be seen in Fig. 7a. The basement defined by shell thin in order to the flexural behavior of the cantilever part of basement affect the boundary condition of bottom of columns. The mode shapes for Fig. 2a building are given in Fig. 7b, c, d, and e as well.



(a) (b) (c) (d) (e)

Fig. 7. SAP2000 model for rectangular column section samples a) realistic basement modeling of measured building and b) Mode 1 c) Mode 2 d) Mode 3 e) Mode 4

If one to compare Table 1 membrane defined model results with fixed support with Fig 7b, c, d, e, then the decrease in modal frequency can be observed. The basement support model provided in Fig 7a has less structural stiffness compared to fixed supported models. That is why, Fig 7 is taken as a more realistic support model and taken into account for the results in Table 2. The same procedure (membrane slab type and realistic support modeling) was done for modeling the samples with circular cross-sectional columns (Fig. 2b) since the only difference between Fig. 2a and Fig. 2b is the columns sections. The mode shapes and corresponding modal frequencies for the samples having circular column sections are given in Fig. 8.

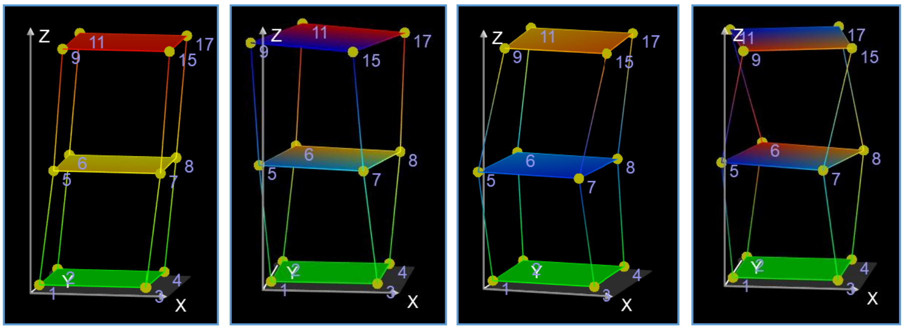


(a) (b) (c) (d)

Fig. 8. SAP2000 model for circular column section samples a) Mode 1 b) Mode 2 c) Mode 3 d) Mode 4

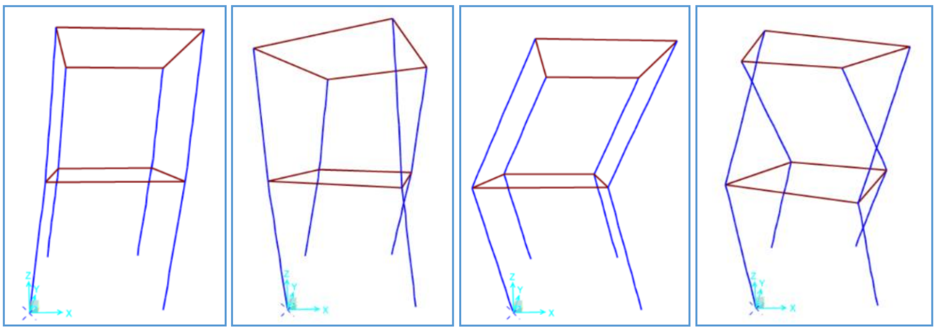
3. Results and discussion

The experimental analyses concluded by identifying four main vibration patterns (modes) for each small reinforced concrete structure we studied. This was done using special software. These fundamental modes, which show how the structures naturally vibrate, were consistently found in all samples.



(a) (b) (c) (d)

Fig. 9. Mode shapes (EMA) a) Mode 1 b) Mode 2 c) Mode 3 d) Mode 4



(a) (b) (c) (d)

Fig. 10. Mode shapes (SAP2000) a) Mode 1 b) Mode 2 c) Mode 3 d) Mode 4

The mode shapes obtained from the finite element program SAP2000 are presented in Fig. 10a, b, c and d. Observations indicate a significant overlap between the mode shapes derived from the experimental analyses and analytical results. For experiment and eigenvalue analysis, the first mode corresponds to primary translational mode (Fig. 9a and Fig. 10a), second mode corresponds to primary torsional mode (Fig. 9b and Fig. 10b), third mode corresponds to secondary translational mode (Fig. 9c and Fig. 10c) and forth mode corresponds to the secondary torsional mode (Fig. 9d and Fig. 10d). The order of these modes overlaps as EMA and FE analysis modes. This substantial agreement supports the accuracy of both the experimental methodology and the finite element model in effectively capturing the modal characteristics of the structural behavior. These modes are important for understanding how these reinforced concrete structures might behave when forces are applied to them.

Table 2. Frequency of modes (Hz)

Sample No	Analysis	Mode 1	Mode 2	Mode 3	Mode 4	Error (%)

[*1]EMA: Experimental Modal Analysis
[*2]SAP2000 noncalibrated results with membrane slab definition and more realistic basement modeling

In the comparison conducted, the frequency values obtained from the experimental and finite element analyses are presented in detail in Table 2. The percent error (percentage of relative error) was calculated for the most dominant –first-mode frequencies of FE and EMA analysis. The relative error is calculated by the ratio of absolute error, which is the difference between FE and EMA analysis, to the EMA analysis result (actual value). For the results of the rectangular cross-sectional model (Fig. 2a), the finite element analysis was compared with the experimental modal analysis results. Considering the dimensions of the reinforced concrete frame, its complex behavior, and the proximity of the support assumptions made in the finite element model to the actual structural behavior, these error percentages are evaluated to be within acceptable limits for the samples having rectangular cross-sectional columns.

On the other hand, for circular cross-sectional samples as Samples No. 4 and 5 (Fig. 2b), the percentage of error obtained is quite high. This is understandable due to the poor construction of circular cross-sectional samples relative to rectangular cross-sectional samples due to the constructional hardships of small-scale buildings. The flexibility of Samples 4 and 5 could be observed during the experiment as well.

The modal damping ratios corresponding to the different mode shapes of the two-story reinforced concrete frame obtained from the experimental analyses are presented in Table 3.

Table 3. Damping ratios (%)

Sample No	Mode 1	Mode 2	Mode 3	Mode 4
1	4,833	7,54	2,56	2,01
2	12,83	10,48	6,56	6,53
3	7,09	5,06	6,15	0,62
4	2,66	4,62	4,37	2,51
5	6,22	5,12	4,13	2,87

The calibration for both Fig 2a and Fig 2b buildings was done by changing the elastic modulus of concrete. The manual calibration was done based on mode number 1, the most dominant one. The non-calibrated model (with membrane slab and more realistic basement modeling), the calibrated model, and the obtained EMA results are given in Table 4.

Table 4 shows that while the calibrated FE model and EMA modal frequency of the first mode are nearly the same, the modal frequencies of the other modes differ. The calibration was done manually and for one independent variable, i.e., the elasticity modulus of concrete. However, the factors affecting translational and torsional modes differ. Multivariable calibration might be needed to calibrate modal frequencies more than one.

Table 4. Elastic modulus of uncalibrated and calibrated SAP2000 models and corresponding modal frequencies

Sample No	State	Elastic Modulus (MPa)	Mode 1(Hz)	Mode 2(Hz)	Mode 3(Hz)	Mode 4(Hz)

*1 Un-Calibrated: SAP2000 noncalibrated results with membrane slab definition and more realistic basement modeling
*2 Calibrated: SAP2000 calibration by changing the modulus of elasticity according to mode 1
*3 Experimental: Experimental modal analysis results

4. Conclusions

Within the scope of this study, the dynamic characteristics of two-story reinforced concrete structures were thoroughly investigated using experimental and analytical methods. In the experimental modal analysis conducted in a laboratory setting, the modal hammer excitation method was employed to determine the natural frequencies and mode shapes of the structures. Simultaneously, a finite element model of the same structures was created using SAP2000 software, and theoretical modal analyses were performed.

For the beamless (flat slab) frame samples, the slab type shows importance in theoretical modal analysis due to a significant change in modal frequencies. Since constructed small-scale buildings have cracks at slabs near joints and systems have defects, the joints are assumed to not be well stiff. In that regard, slabs are modeled as membranes. Even if the shell thin definition is less assuming, the membrane definition describes the real structure more suitably. This resulted in the first mode frequency decrease to %45 of it (decreased by almost half). Also, the bottom of columns is modeled not as fixed support but connected to a basement resting on a beam (with pinned supports at middle nodes). The flexural behavior of the cantilever part of the basement (outside of the steel beam) also results in a slight decrease in modal frequencies. The decrease percentage is %22. This is the pre-state of calibration changing the elastic modulus of concrete.

Manual calibration is done by changing the modulus of elasticity concrete to describe cracks in low-strength concrete. Decreasing the modulus of elasticity affects the stiffness matrix, and modal frequencies decrease as well. The first mode is considered for calibrating FE models, and Table 4 is obtained. The difference between EMA and FE modal frequencies increases with higher mode numbers. The modulus of elasticity the first three samples (rectangular cross-sectional) would be reasonable if the compressive strength of low-strength concrete is approximately 3-5 MPa.

On the other hand, the error obtained was significantly higher for Samples 4 and 5, which are circular column buildings. Due to improper construction and manufacturing difficulty, these two samples obtained way more flexible in reality than encountered in experimental results. There are some advanced calibration methods that are way more realistic. For example, in order to calibrate other modes, other calibration approaches, such as changing joint stiffness, can be evaluated. In addition, the modulus of elasticity samples can be obtained by test equipment and can be used for calibration.

The comparison of the experimental and analytical results shows that the methods used to determine the dynamic behavior of the structures and the assumptions made in the finite element model are generally consistent and reliable. In particular, the overlap in the mode shapes and the calibrated frequency values indicate that both approaches successfully capture the fundamental dynamic characteristics of the structures. Despite potential discrepancies due to the reinforced concrete frame's geometrical complexity and the material properties' idealization, the obtained agreement supports the use of the finite element model as an effective tool for the dynamic analysis of such structures. Future research can expand the knowledge in this area with different structural configurations and advanced modeling techniques.

Impact of infill walls and strengthening methods on the seismic behavior of rc buildings: A time-history approach

Özge Onat[1], Pınar Usta Evci*[1]

[1] *Isparta University of Applied Science, Department of Civil Engineering, 32200 Isparta, Türkiye*

Abstract. Time history analyses are a critical tool for understanding the behaviour of structures during earthquakes. Nevertheless, due to modelling challenges, infill walls are often excluded from seismic evaluation processes, which limits the realistic examination of structural behaviour. In regions where such structures are prevalent, a more comprehensive assessment of their impact on seismic performance is imperative. This study utilised the SAP2000 V25 finite element program to model and analyse a five-story reinforced concrete building located in Izmir. The building was evaluated under four different scenarios: without infill walls, with infill walls, strengthened with Fiber Reinforced Polymer (FRP) , and strengthened with a steel frame. The analyses utilised time history records from the Kahramanmaraş Pazarcık (Mw 7.7) and Elbistan (Mw 7.6) earthquakes that occurred on 6 February 2023, and the Izmir earthquake (Mw 6.6) on 30 October 2020. These records were modelled using acceleration-time graphs with peak ground acceleration values of 2178.72 cm/s² (Pazarcık), 635.45 cm/s² (Elbistan), and 179.31 cm/s² (Izmir). The results of the time history analyses were then compared. The effects of infill walls and strengthening techniques on parameters such as period, base shear force, interstory drift ratios, and story shear forces have been evaluated.

1. Introduction

Türkiye's geographic location within the Alpine-Himalayan seismic belt has rendered it highly susceptible to numerous devastating earthquakes throughout history. Moreover, the country continues to face significant seismic hazards. (Altindal et al., 2021; Karimzadeh et al., 2024). This vulnerability is further compounded by the convergence of the Arabian, Eurasian, and African tectonic plates, in conjunction with the presence of active fault zones, including the North Anatolian, East Anatolian, and West Anatolian Faults (Onat & Evci, 2024; Karimzadeh et al., 2018; Jiang et al., 2023). In particular, the Aegean Region has experienced a notable increase in seismic events, which have the potential to pose significant risks to the region's building stock (Askan et al., 2022; Usta et al., 2023). The substantial economic losses and widespread destruction resulting from past earthquakes have heightened the importance of seismic safety in Türkiye (Şahin & Kılınç, 2016). Given that reinforced concrete (RC) buildings constitute the majority of Türkiye's building inventory, it is imperative to assess their current conditions and seismic performance under strong ground motions (Yüksel, 2008). Conventionally, infill walls have been regarded as non-structural components, contributing solely to dead loads, and their effect on the overall structural behaviour has frequently been disregarded (Tekin et al., 2007; Akyürek et al., 2018). However, both field observations from past earthquakes and extensive academic studies have demonstrated that infill walls significantly enhance the lateral stiffness and load-carrying capacity of RC structures, while the absence of sufficient infill walls at ground floors often leads to severe damage (Uysal, 2023; Onat, 2022; Sancıoğlu et al., 2022). Consequently, realistic modelling of infill walls is imperative for accurate seismic performance evaluation (Onat, 2022). The Turkish Building Earthquake Code (TBDY-2018) advocates the utilisation of the equivalent diagonal strut approach for the modelling of infill walls, while concurrently providing the requisite parameters, including elastic modulus, compressive strength, and shear strength, for a range of infill materials (TBDY, 2018).

This section presents a review of previous studies focusing on the influence of infill walls and retrofitting techniques on the seismic performance of reinforced concrete buildings. Malekkianie (2006) constitutes a comprehensive analysis of the seismic performance of reinforced concrete (RC) frames with infill walls and frames retrofitted using carbon fibre reinforced polymer (CFRP). The research adopted both experimental and numerical approaches. Three full-scale specimens were tested: a bare frame, a frame with masonry infill, and a frame

golden light publishing

strengthened using diagonally applied CFRP strips. The specimens were subjected to cyclic lateral displacements in order to simulate earthquake loading. Furthermore, nonlinear finite element analyses were conducted using SAP2000 software to validate the experimental outcomes. The findings of the study demonstrated that the incorporation of infill walls significantly enhanced the lateral stiffness and strength of the RC frames, thereby augmenting the lateral load capacity by approximately fourfold in comparison with the un strengthened frame. The CFRP retrofitting further enhanced the lateral strength by approximately 30%, whilst also promoting a more uniform distribution of damage. This approach mitigated the risk of brittle failure and provided a pragmatic and non-intrusive retrofit solution, enabling strengthening without the necessity of vacating the building. Binici et al. (2007) presents a comprehensive analytical and experimental approach for the strengthening of reinforced concrete frames with hollow clay tile infill walls using fibre-reinforced polymer (FRP) composites. The authors draw attention to the common seismic vulnerability of mid-rise RC buildings in Türkiye, particularly due to insufficient lateral strength and inadequate detailing. In order to address this issue, a proposal has been put forward for an FRP retrofit system. This system has been designed to enhance the in-plane load-carrying capacity of infill walls. It does this by anchoring diagonal FRP ties to the surrounding RC frame. The method is designed to reduce inter-storey drift and enhance seismic performance without the necessity of occupant relocation. A simplified analytical model was developed based on a previously verified nonlinear model, and displacement-based design recommendations were provided. The methodology was validated through a case study on a deficient RC residential building in Istanbul. Pushover analyses revealed that the FRP retrofit approximately doubled the base shear capacity and reduced the number of collapsed columns by half. Furthermore, the retrofitted structure was found to be in accordance with the collapse prevention performance criteria outlined in the Turkish Earthquake Code. The findings indicate the efficacy of FRP systems as a seismic retrofitting solution for deficient RC buildings with masonry infill walls, characterised by their efficiency, minimal invasiveness, and structural effectiveness. Çöğürcü (2007) conducted a study on the enhancement of the seismic resistance of unreinforced masonry structures through the implementation of epoxy-based FRP along the horizontal mortar joints. Two masonry wall specimens were constructed identically, with one unreinforced and one reinforced with FRP sheets applied to the horizontal joints. Both specimens were then subjected to out-of-plane cyclic loading. The unreinforced specimen failed in a brittle manner with limited load capacity, whereas the fibre-reinforced polymer (FRP)-strengthened wall showed a significant improvement, exhibiting up to three times greater resistance to failure. The study emphasised that the utilisation of FRP in the reinforcement of horizontal joints can efficaciously augment the seismic resilience of masonry walls. Viswanath et al. (2010) conducted a study on the seismic behaviour of reinforced concrete (RC) frames retrofitted with steel bracings. A series of structural models were constructed and analysed using STAAD.Pro software, encompassing buildings with four, eight, twelve and sixteen storeys. In order to enhance the lateral load-carrying capacity of existing structures, X-type steel bracing systems were employed. The findings indicated that steel bracings significantly reduced lateral displacements in comparison to unbraced frames, with X-braced systems achieving approximately 74% reduction in drift for four-storey buildings. Furthermore, the integration of steel bracings resulted in a reduction of bending moments and shear forces in the columns, although it induced an increase in axial compression. However, given the inherent strength of RC columns in compression, this was not regarded as a structural issue. The study concluded that X-type steel bracing is an effective method for improving the seismic performance of multi-storey RC buildings. Sivri et al. (2015) conducted a study on the nonlinear seismic behaviour of RC frames with infill walls of varying compressive strengths (2 MPa, 4 MPa, and 6 MPa), as well as those retrofitted with steel bracing systems. In this study, the authors employed ANSYS finite element software to analyse a three-storey, two-bay RC frame under lateral loading conditions. The incorporation of infill walls resulted in a substantial enhancement of lateral stiffness and load-bearing capacity. However, brittle failures were frequently initiated within the masonry. Conversely, frames fortified with steel bracing exhibited a 234% surge in lateral strength while maintaining ductility. The findings of the study demonstrated that the integration of infill walls with steel bracing can lead to a substantial enhancement in seismic resilience without compromising deformation capacity. Parastesh & Saatcioglu (2017) presented a detailed analytical and numerical evaluation of RC frames retrofitted with FRP sheets applied to masonry infill walls. A 10-storey RC building model was analysed using SAP2000 with a nonlinear pushover approach. The infill walls were represented as diagonal struts, and the FRP strengthening was modelled using shell elements. Calibrated against experimental data from prior cyclic tests, the model showed that FRP retrofitting significantly increased lateral load capacity nearly threefold compared to unretrofitted specimens and enhanced overall stiffness. However, the retrofitting did not contribute to ductility improvement, as both masonry and FRP components behaved in a brittle manner. The study concluded that while FRP is effective in increasing elastic strength and stiffness, it may not prevent brittle collapse unless used in conjunction with ductility-enhancing techniques. Yu et al. (2024) examined the effect of fibre-reinforced polymer (FRP) retrofitting on the seismic resilience of low-ductility reinforced concrete (RC) frame structures. The finite element models of RC frames before and after FRP retrofitting were developed using OpenSEES software, and fragility functions were established. The assessment of seismic resilience indicators, encompassing repair costs, repair time, casualties, and carbon emissions, was conducted utilising PACT software in accordance with the FEMA P-58 methodology. The study demonstrated that

FRP retrofitting led to notable improvements, especially at low seismic intensities, reducing average annual repair costs by 5.32%, repair times by 6.90%, and carbon emissions by 7.16%. Furthermore, the implementation of FRP retrofitting measures has been shown to result in a significant reduction in fatalities, with a documented decrease of 57.6% in injury rates. Despite the effectiveness of retrofitting diminishing under very high seismic intensities, the findings emphasised the overall benefits of FRP application in enhancing seismic performance and resilience of low-ductility RC frames.

In this study, the seismic performance of a five-storey reinforced concrete building located in Izmir was investigated using the SAP2000 V25 finite element analysis software. The edifice was subjected to rigorous scrutiny under four distinct modelling configurations: (a) a configuration without infill walls, (b) a configuration with infill walls, (c) a configuration where infill walls were fortified with Fiber Reinforced Polymer (FRP), and (d) a configuration where infill walls were fortified with a steel bracing system. In order to assess the dynamic behaviour of the structure, nonlinear time history analyses were performed using acceleration records from three major earthquakes: the Kahramanmaraş Pazarcık (Mw 7.7) and Elbistan (Mw 7.6) earthquakes that occurred on 6 February 2023, and the Izmir earthquake (Mw 6.6) of 30 October 2020. The records were modelled on the basis of acceleration-time histories, incorporating peak ground acceleration (PGA) values of 2178.72 cm/s² for Pazarcık, 635.45 cm/s² for Elbistan, and 179.31 cm/s² for Izmir.

The structural and modelling specifics for the various configurations are delineated in Section 2. Section 3 focuses on the nonlinear time history analysis methodology employed to evaluate the seismic response of both strengthened and unstrengthened models. The fourth chapter of this study presents the key findings, and provides a comparative assessment of the building's seismic behaviour across the different strengthening strategies.

2. Building geometry and finite element modelling

The present study focuses on a reinforced concrete residential building located in Izmir, a city situated within Türkiye's seismically active Aegean Region. The architectural composition of the structure comprises a ground floor and four upper floors, thus amounting to a total of five storeys. The structure is notable for its absence of a basement, with continuous footings providing the primary means of support. The ground floor, with a story height of 3.65 m, serves commercial and administrative functions, including retail spaces and a janitor's office. The four upper floors, each 2.70 m in height, are residential, housing a total of 16 apartments arranged as four units per floor. The overall height of the building is 14.45 m. The local soil condition has been classified as type ZD in accordance with the Turkish seismic code standards.

The structural system incorporates nine reinforced concrete shear walls per floor, with a thickness of 20 cm. The edifice boasts three distinct column cross-sections, measuring 30x70 cm, 30x80 cm, and 30x90 cm, respectively. These dimensions undergo a systematic reduction of 10 cm from the lower to the upper levels of the structure. Two categories of beams have been incorporated into the design: internal beams measuring 20x50 cm and external beams sized 25x50 cm. The thickness of the slab is contingent upon its function. The dimensions for intermediate floors are 12 cm, 15 cm for other floors, and 20 cm for balconies. Fig. 1 provides a representation of the floor plan of the existing building.

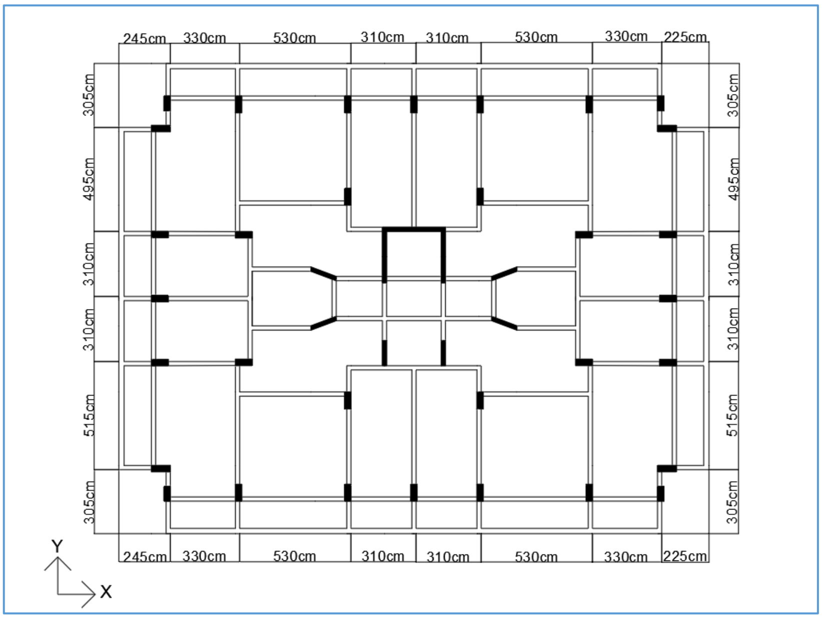

Fig. 1. Structural floor layout (Onat & Evci, 2024)

The material properties used in the model are based on actual structural test results. The compressive strength of concrete is taken as 8.27 MPa (designated as C8.27), and modelled in SAP2000 V25 using the formulation described in Section 5A.1 of the Turkish Building Earthquake Code (TBDY, 2018), which distinguishes between confined and unconfined concrete behaviour. Longitudinal reinforcement consists of deformed steel with a yield strength of 420 MPa, while transverse reinforcement is rated at 220 MPa. The modelling of these steel components was undertaken in accordance with the parameters specified in TBDY (2018), Section 5A.2.

The structural model was developed using SAP2000 V25 finite element software. The beams and columns were defined as frame elements, the shear walls were modelled using shell elements, and the infill walls were represented through link elements based on the equivalent compression strut approach. The 3D structural model incorporates all pertinent geometrical and material characteristics, thereby ensuring a precise reflection of the actual building configuration.

The allocation of dead and live loads was conducted in accordance with the designated utilisation of each floor. The software automatically calculated floor self-weights and applied them as two-way distributed loads. A dead load of 2.0 kN/m² was applied to the intermediate floors, while the roof was assigned a dead load of 2.5 kN/m². The live loads were specified as 2.0 kN/m² for typical floors, 3.5 kN/m² for partitioned residential areas, and 1.5 kN/m² for the rooftop level. Furthermore, non-structural partition walls not included in the concrete frame design were considered as distributed line loads on the beams. The material and thickness of the masonry were taken into consideration in the definition of the load-bearing capacity. The former was categorised as 2.4 kN/m² for masonry 20 cm in thickness, and as 2.0 kN/m² for masonry 10 cm in thickness.

For infill walls, a macro modelling technique was adopted. The equivalent strut method was employed, whereby each infill wall was modelled as a compression-only link element. The stiffness parameters were derived using the empirical formulations provided in Appendix 15C of TBDY (2018), ensuring an accurate representation of their contribution to lateral stiffness.

The edifice was subjected to analysis under four distinct configurations: (1) without infill walls ; (2) with infill walls; (3) nfill walls strengthened with Fiber Reinforced Polymer (FRP); and (4) infill walls strengthened with a steel bracing system. Nonlinear time history analyses were conducted using strong ground motion records from the 6 February 2023 Kahramanmaraş Pazarcık (Mw 7.7) and Elbistan (Mw 7.6) earthquakes, as well as the 30 October 2020 İzmir (Mw 6.6) earthquake. The acceleration-time histories exhibited peak ground accelerations of 2178.72 cm/s² for Pazarcık, 635.45 cm/s² for Elbistan, and 179.31 cm/s² for Izmir. Table 1 presents a compendium of the characteristics of the earthquakes selected for time history analysis.

Table 1. Earthquakes used for time history analysis

Name	Earthquke Code	Date	Magnitude (MW)	Depth (km)	Epicenter	PGA (cm/s^2)	PGV (cm/s)
Izmir	3536	30 October 2020 11:51	6.6	14.9	Ege Denizi 17.26 km Seferihisar (Izmir)	179.31	22.53
Kahramanmaras (Elbistan)	4631	6 February 2023 10:24	7.6	7	Elbistan (Kahramanmaras)	635.45	170.79
Kahramanmaras (Pazarcık)	615	6 February 2023 01:17	7.7	8.6	Pazarcık (Kahramanmaras)	2178.72	212.94

The FRP retrofitting system was defined in the SAP2000 model using a material with a modulus of elasticity of 61 GPa, a Poisson's ratio of 0.22, and a shear modulus of 25 GPa. The strips were modelled as rectangular cross-section link elements with dimensions of 0.3 m in width and 0.0003 m in thickness, placed diagonally across structural bays to simulate the behaviour of externally bonded FRP applications. These elements were assigned compression-only properties in order to reflect the unidirectional behaviour that is typical of composite materials under seismic loads.

The steel bracing configuration was modelled using round cross-section S420-grade steel bars with a diameter of 100 mm. The elements were positioned diagonally between the beam-column joints within the selected bays, thus forming an X-shaped bracing system. The steel braces were defined as tension-compression members, thereby capturing their dual-directional capacity under seismic excitation. This approach facilitated a realistic depiction of the bracing effect on both stiffness and energy dissipation of the structural system under earthquake loading. The structural layouts of the four models (a) without infill walls ; (b) with infill walls; (c) infill walls strengthened with Fiber Reinforced Polymer (FRP); and (d) infill walls strengthened with a steel bracing system are depicted in Fig. 2.

3. Nonlinear Time History Analysis of Strengthened and Unstrengthened Structures

Prior to conducting the nonlinear time history analysis, a modal analysis was performed to evaluate the dynamic characteristics of the structural models. The period values of the models are presented in Fig. 3.

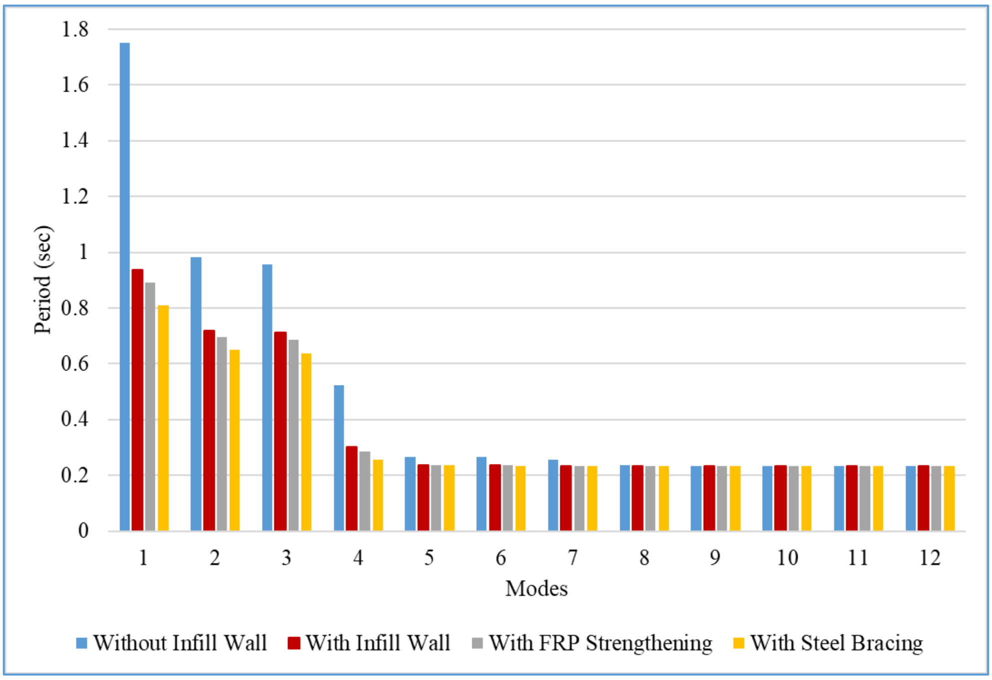

Fig. 3. The period values of the models

As demonstrated in Figure 3, the model without infill walls exhibited the highest period value of 1.75 seconds in the first mode, indicating the lowest lateral stiffness among all configurations.

The incorporation of infill walls resulted in a substantial reduction of the structure's natural period. When infill walls were modelled, the period in the first mode decreased to 0.94 seconds. In the FRP-strengthened model, a further reduction was observed, with the period dropping to 0.89 seconds, demonstrating an additional increase in stiffness through composite retrofitting. The steel-braced model demonstrated the most rigid behaviour, exhibiting a period of 0.81 seconds in the first mode.

Analogous tendencies were discerned in the second and third modes, where the period values underwent a gradual decline across the various strengthening types, from the unadorned frame to the steel bracing.

Nonlinear time history analysis was employed to calculate the total base reactions for each structural model in both the x and y directions. The results are presented in Fig. 4 and Fig. 5.

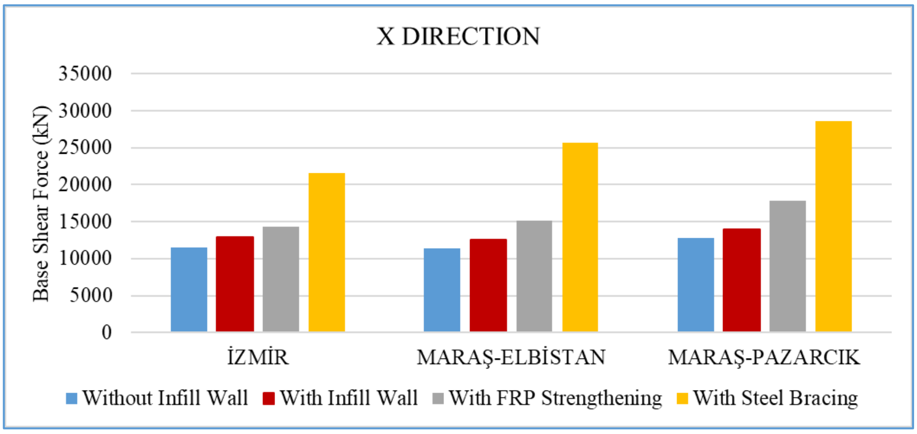

Fig. 4. Base shear forces of models in x-direction

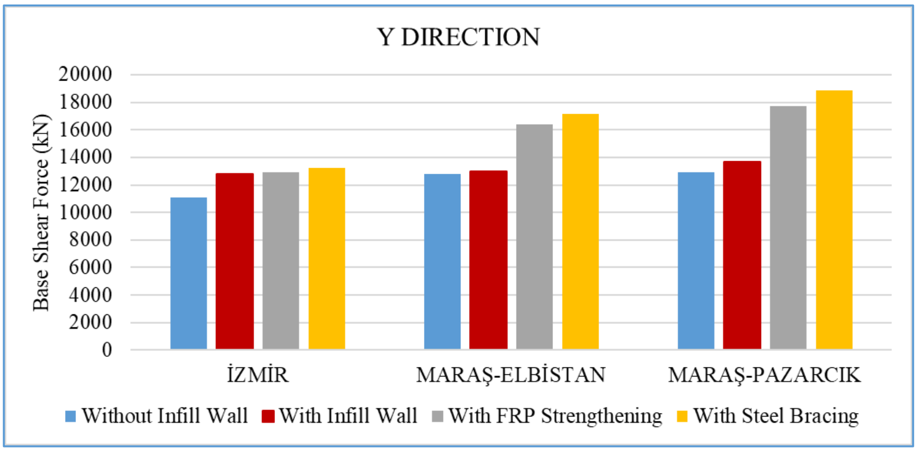

Fig. 5. Base shear forces of models in y-direction

In the x-direction, the highest base reaction was observed in the steel-braced model, particularly under the Kahramanmaraş (Pazarcık) earthquake, reaching 28,630.82 kN. This was followed by the same model under the Maraş-Elbistan record with 25,642.11 kN. The FRP-strengthened models also demonstrated notable performance, especially in the context of the Maraş-Pazarcık earthquake, during which they recorded a peak value of 17,820.58 kN. Models with infill walls exhibited moderate increases in base reactions when compared to bare frames. Conversely, models devoid of infill walls demonstrated consistently minimal base reactions across all earthquake scenarios.

In the y-direction, analogous trends were identified. The steel-braced configuration demonstrated the highest base reaction of 18,875.31 kN during the Maraş-Pazarcık earthquake, closely followed by the model strengthened with fiber reinforced polymer (FRP), which reached 17,727.41 kN.

Subsequent to the nonlinear time history analyses, interstorey drift values were calculated in accordance with the Turkish Building Earthquake Regulation (TDBY, 2018). Fig. 6, Fig. 7, Fig. 8 and Fig. 9 illustrate the variation in interstorey drift responses across different structural configurations and earthquake records. Positive drift values are indicative of displacement in the direction of ground motion, whilst negative values denote displacement in the opposite direction.

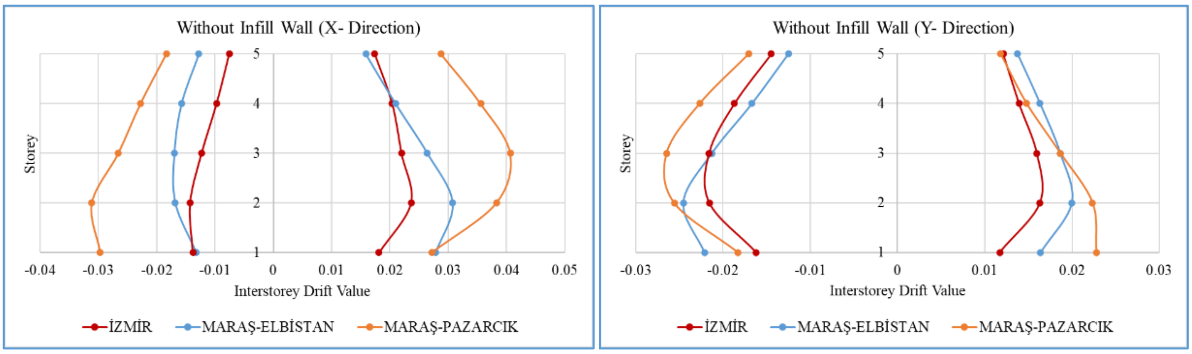

Fig. 6. Interstory shear value of the model without infill wall

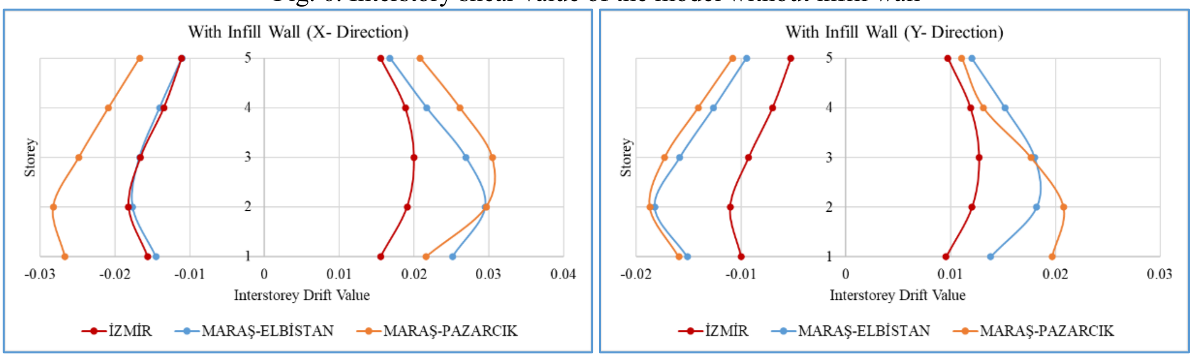

Fig. 7. Interstory shear value of the model with infill wall

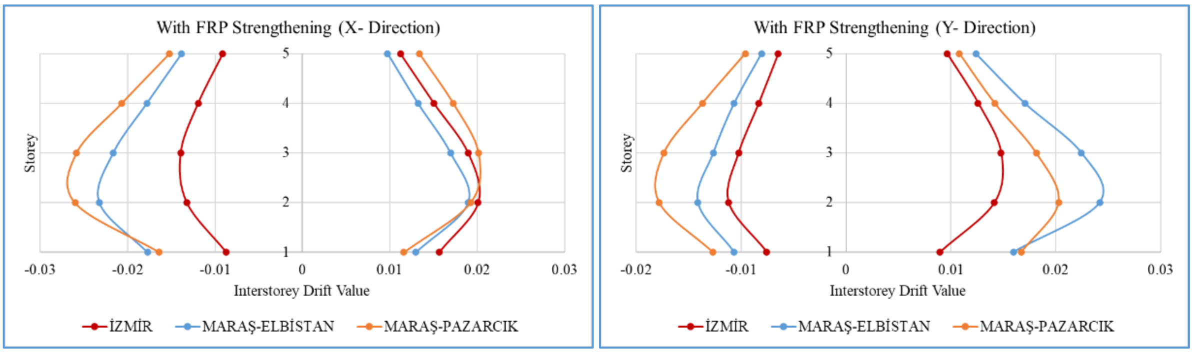

Fig. 8. Interstory shear value of the model with FRP strenghening

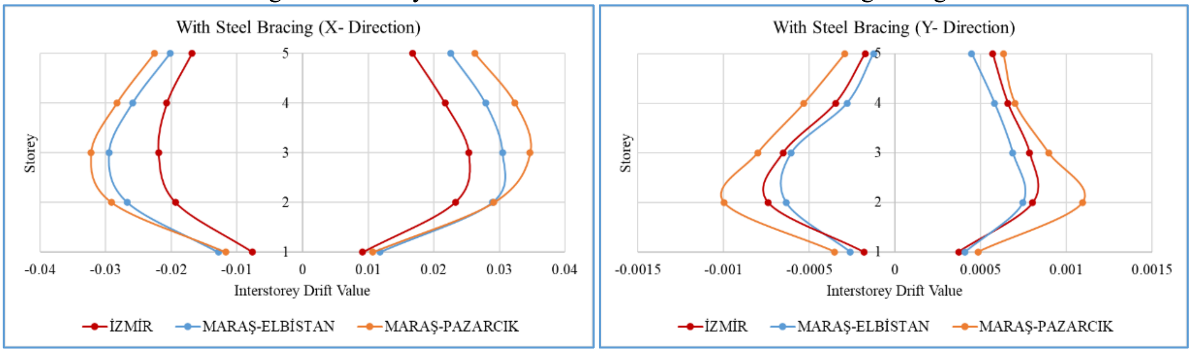

Fig. 9. Interstory shear value of the model with steel bracing

In the X direction, the without infill wall model experienced the highest average interstorey drift, reaching up to 0.03357 under the Maraş-Pazarcık earthquake, which is consistent with its high peak ground acceleration (PGA) of 2178.72 cm/s². Following the incorporation of infill walls, the maximum average drift reduced to 0.0303, indicating enhanced lateral stiffness. The FRP-strengthened model exhibited an enhancement in performance, yielding a maximum average drift of 0.0258, while the steel bracing system demonstrated the most significant performance, achieving a substantially reduced drift of 0.01995 under the same earthquake scenario.

In the Y direction, analogous patterns were identified. The without infill wall model exhibited the poorest performance, with a maximum drift of 0.02926 under the Maraş-Pazarcık motion. The model incorporating infill walls demonstrated a marked enhancement, with drift being constrained to 0.02779. This observation was further refined by the implementation of fiber reinforced polymer (FRP) strengthening, which led to a further reduction in drift to 0.0228. The most effective result was once again observed in the steel bracing system, where the average interstorey drift values were well below the code limit, with the highest recorded value being approximately 0.001096, demonstrating exceptional resistance to lateral displacements.

As stated in TDBY (2018), the maximum allowable interstorey drift for performance-based seismic design is 0.008. The findings unequivocally demonstrate that solely the steel-braced models adhered to the stipulated limit across all earthquake scenarios, while other configurations repeatedly exceeded the permissible threshold.

In accordance with the findings of the nonlinear time history analyses, the total story shear forces for each model were calculated. The shear force distributions for both the x and y directions are illustrated in Fig. 10, Fig. 11, Fig. 12 and Fig. 13.

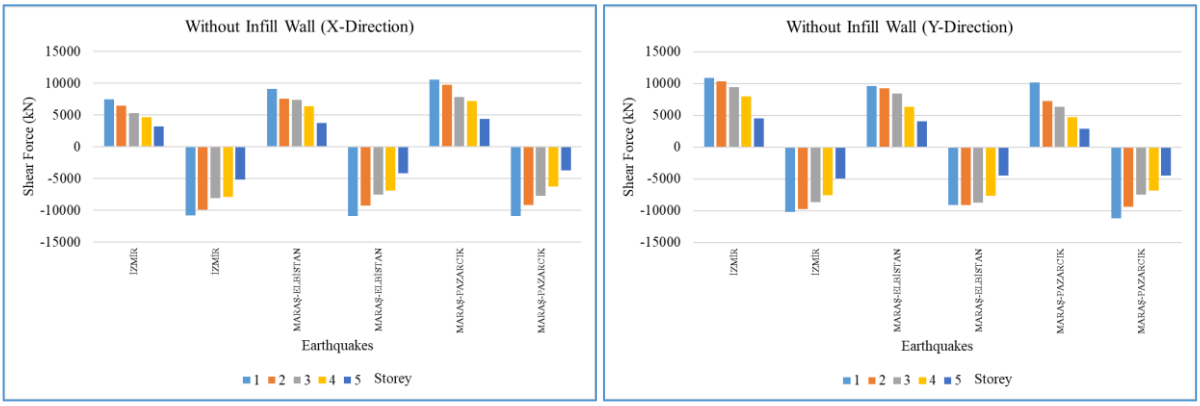

Fig. 10. Storey shear forces of the model without infill wall

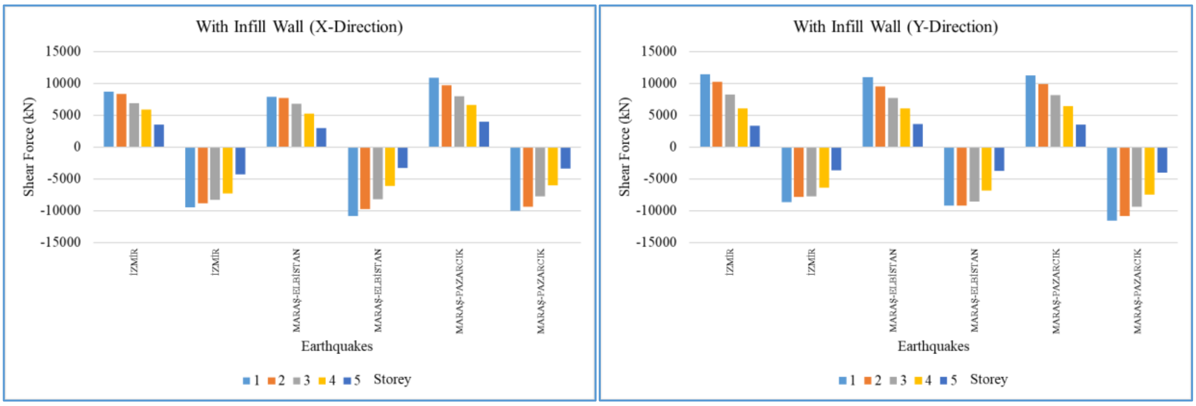

Fig. 11. Storey shear forces of the model with infill wall

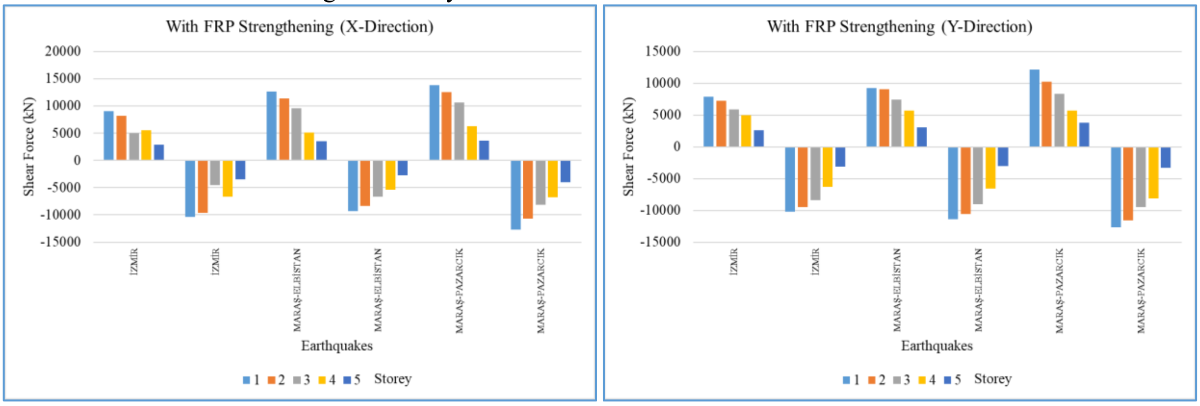

Fig. 12. Storey shear forces of the model with FRP strenghening

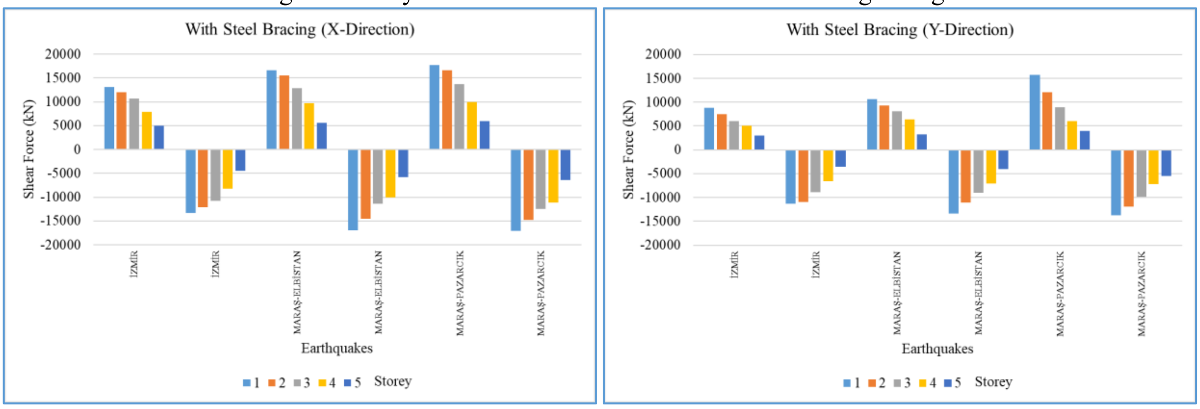

Fig. 13. Storey shear forces of the model with steel bracing

In the x-direction, the model devoid of infill walls exhibited the maximum shear force on the ground floor, measuring 10,534.83 kN, during the seismic event in Kahramanmaraş (Pazarcık). For the model incorporating infill walls, the maximum observed shear force was 10,888.29 kN, also during the Pazarcık earthquake. The model strengthened with fiber reinforced polymer (FRP) experienced a significantly higher shear force, reaching 13,856.30 kN under the same ground motion. The steel bracing model demonstrated the highest value, reaching a maximum of 17,705.75 kN, an outcome attributed to the seismic activity in Pazarcık.The following investigation is concerned with the comparative evaluation of the x-direction ground floor shear forces.The infill wall model exhibited an average increase of 23% in shear strength under Pazarcık compared to other seismic events.The FRP model exhibited a 31% increase in base shear under Pazarcık.The steel bracing model exhibited an average increase of 36%, thereby demonstrating the intensifying effect of the high peak ground acceleration from the Pazarcık earthquake.

In the y-direction, the highest storey shear force in the bare frame model was 10,146.08 kN on the ground floor during the Pazarcık earthquake. For the infill wall model, the corresponding value increased to 11,278.57 kN. In the FRP-strengthened model, the ground floor shear force reached 12,134.47 kN, while the steel bracing model displayed the highest value of all: 15,712.46 kN, again due to the Pazarcık earthquake.The evaluation of y-direction shear forces indicates:The infill wall model demonstrated a 22% increase in ground floor shear after the Pazarcık earthquake.The reinforced concrete structure exhibited an average increase of 29% in strength compared to non-reinforced structures during seismic events.The steel bracing model demonstrated an enhancement in stiffness and energy dissipation, resulting in a 37% increase in ground floor shear force following the Pazarcık event.

4. Conclusions

In this study, a five-storey reinforced concrete building was modelled using SAP2000 software with actual material properties, and nonlinear time history analyses were carried out based on the ground motion records of the 2023 Kahramanmaraş (Pazarcık and Elbistan) and İzmir earthquakes. Four structural configurations were considered in the analysis: (a) without infill walls ; (b) with infill walls; (c) infill walls strengthened with Fiber Reinforced Polymer (FRP); and (d) infill walls strengthened with a steel bracing system.

- The results of the modal analysis indicate that the without infill walls model exhibited the highest fundamental period of 1.75 seconds, suggesting that it possesses the lowest lateral stiffness. The incorporation of infill walls led to a 46% reduction in this value, thereby reducing the period to 0.94 seconds. In the FRP-strengthened model, the period decreased by 49% to 0.89 seconds, while the steel-braced model exhibited the highest stiffness with a 54% reduction to 0.81 seconds. Analogous trends were also observed in the second and third mode shapes, where the periods gradually decreased from the without infill walls configuration towards the steel-braced configuration.
- With regard to base shear reactions, the highest value in the x-direction was observed in the steel-braced model under the Kahramanmaraş (Pazarcık) earthquake, reaching 28,630.82 kN. This figure represents an approximate increase of 149% in comparison with the without infill walls model. The same model recorded 25,642.11 kN under the Elbistan record, corresponding to a 124% increase. The FRP-strengthened model demonstrated a maximum load of 17,820.58 kN under the Pazarcık record, exhibiting an 82% increase in load capacity. Models incorporating infill walls exhibited a mere 3% increase in comparison with the without infill walls. The without infill walls model demonstrated a consistent tendency to exhibit the lowest base reactions across all earthquake scenarios.
- A similar pattern was observed in the y-direction. The highest base shear was measured in the steel-braced model as 18,875.31 kN under the Pazarcık earthquake, representing an 86% increase compared to the without infill walls. The FRP-strengthened model demonstrated a 76% increase, reaching 17,727.41 kN, while the model with solely infill walls exhibited an 11% rise.
- The interstorey drift ratios were calculated in accordance with the Turkish Building Earthquake Code (TBDY, 2018), thereby demonstrating variations among structural configurations and earthquake records. In the x-direction, the without infill walls model exhibited the highest average drift ratio of 0.03357 under the Pazarcık earthquake, a phenomenon attributed to its elevated peak ground acceleration (PGA) of 2178.72 cm/s². The incorporation of infill walls resulted in a decrease to 0.0303 (a 9.7% reduction), and a subsequent further decrease to 0.0258 (a 23% reduction) in the FRP-strengthened model. The steel-braced model demonstrated the most significant enhancement, exhibiting a maximum average drift of 0.01995, which corresponds to a 40.6% reduction.
- In the y-direction, the maximum interstorey drift for the without infill walls model was 0.02926, while it decreased to 0.02779 in the model with infill walls. The FRP-strengthened model demonstrated a further reduction to 0.0228, and the steel-braced model exhibited a substantial limitation of drifts to 0.001096, signifying a reduction of over 95%. This outcome unequivocally substantiates the efficacy of the steel bracing system in constraining seismic displacements.
- TBDY (2018) asserts that the maximum allowable interstorey drift ratio for performance-based seismic design is 0.008. The findings indicate that solely the steel-braced configuration adhered to the stipulated limit across all earthquake scenarios, while the remaining models persistently exceeded the permissible threshold, thereby signifying a probable hazard of structural impairment.

In summary, infill walls contribute to enhanced stiffness by reducing natural periods and limiting displacements. The implementation of fiber reinforced polymer (FRP) strengthening measures has been demonstrated to engender a moderate enhancement in performance metrics. However, it should be noted that the efficacy of this approach is comparatively inferior to that of steel bracing. The utilisation of steel-braced systems has been demonstrated to consistently yield optimal performance in all analyses, thereby substantiating their efficacy as a highly effective solution for seismic safety enhancement.

Consequently, in instances where seismic retrofitting is imperative for extant structures, the implementation of steel bracing systems is emphatically advocated. In addition, subsequent studies should encompass a range of building types, varying story heights and infill wall materials, thereby facilitating more extensive and exhaustive parametric analyses.

Abstract. Cross-laminated timber (CLT) has emerged as an innovative construction material, offering advantages such as sustainability, low carbon emissions, and ease of application, making it a strong alternative to conventional building materials. By integrating the natural benefits of wood with advanced engineering techniques, CLT provides an environmentally friendly and structurally efficient solution for modern construction. However, the numerical analysis of CLT structures presents significant challenges due to the absence of standardized constitutive models for connections, the anisotropic behavior of wood, and the limited guidance provided by existing design codes. Consequently, experimental data plays a crucial role in the accurate development and validation of finite element models (FEMs) for such structures. This study investigates the structural behavior of 30 CLT panel groups with varying properties under dynamic loading conditions using experimental methods. The dynamic characteristics of the panels were identified through ambient vibration tests employing the Operational Modal Analysis (OMA) method. The FEM updating process was conducted exclusively based on experimental data obtained from dynamic tests, utilizing SAP2000 software to apply a frequency-based updating approach. The accuracy of the updated models was assessed by analyzing discrepancies between experimental and numerical fundamental natural frequency values. Furthermore, the influence of different material and boundary condition assumptions on model accuracy was examined.

Keywords: Finite element model; Model updating; Cross laminated timber; Operational modal analysis; Dynamic characteristics

1. Introduction

In engineering disciplines, problem-solving has traditionally relied on domain-specific expertise and experiential knowledge. Both experimental and numerical methods have been utilized in addressing complex challenges. Advances in computer technology have significantly enhanced the speed and efficiency of numerical analyses, leading to the development of various computational techniques. Among these, FEM, introduced in the mid-20th century, has emerged as a fundamental computational tool in engineering analysis. FEM provides high accuracy in the numerical modelling of various physical systems, offering comprehensive and reliable insights into the behaviour of structural components and materials (Madenci & Guven, 2015; Altunişik et al., 2018)

FEM is extensively employed in structural engineering applications such as structural analysis, health monitoring, and damage assessment. Despite its widespread use, FEM-based numerical models often fail to capture the full complexity of the physical and geometric characteristics inherent in real-world structures. As a result, discrepancies may arise between simulated outcomes and experimental observations obtained from static or dynamic testing. To minimize such inconsistencies and enhance the predictive capability of the numerical model, finite element model updating becomes essential. This process involves the calibration of model parameters based on experimental data, with the aim of reducing uncertainties and improving the overall accuracy and reliability of the model.

Initial FEMs frequently fall short in accurately reflecting the actual structural performance of a system, largely due to uncertainties inherent in the early modelling stages such as approximations in material characteristics,

[*]Corresponding author, E-mail: algihankasif.karahasan@avrasya.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_806

boundary condition definitions, and mesh discretization. To improve the model's predictive capabilities and ensure its consistency with experimental observations, it becomes necessary to update the initial FEM. This calibration process relies on referencing parameters obtained from experimental data, typically through static or dynamic testing, and adjusting uncertain model variables iteratively until a satisfactory level of accuracy is achieved (Günaydin et al., 2022; Butt & Omenzetter, 2014). Two principal methods are used for model updating: a manual approach based on trial-and-error, and an automated approach that leverages specialized computational tools. In the context of this study, the manual updating technique was implemented (Günaydin et al., 2022). Applying such model refinement strategies allows engineers to enhance the correlation between numerical and experimental results, ultimately leading to more precise structural assessments and more efficient detection and management of potential damage (Gurholt & Mikalsen, 2021).

Dynamic characteristics of engineering structures are widely utilized in the updating of FEMs (Brank & Carrera, 2000; Sunca et al., 2021; Altunışık et al., 2023; Oh et al., 2017). In addition, the experimental data employed during the model updating process may include various measurable quantities that can be directly compared with the numerical model. In this context, dynamic responses obtained through experimental studies are considered valuable data sources for enhancing the accuracy and reliability of FEMs.

Alongside the development of numerical modelling methods, the construction industry's interest in and application of timber-based materials has markedly increased. This growing trend is largely attributed to the inherent qualities of wood as an environmentally friendly and renewable resource. The use of timber has expanded in tandem with technological progress in adhesive and manufacturing techniques, as well as improvements in fire resistance strategies. Within the scope of innovative wood products, cross-laminated timber (CLT) has gained significant attention as a leading material (Wieruszewski & Mazela, 2017). Due to its ecological advantages and suitability for rapid construction, CLT represents a compelling alternative to conventional construction materials Öztürk et al., 2020).

CLT was first introduced in Europe during the early 1990s and has since achieved widespread recognition and acceptance within the construction industry (Espinoza et al., 2016). Often referred to as "mass timber," CLT represents a contemporary advancement among engineered wood products, contributing significantly to the evolution of timber usage in structural systems (Younis & Dodoo, 2022). Structurally, CLT panels are typically composed of an odd number of layers commonly three, five, seven, or more with the wood grain in each layer oriented orthogonally to that of adjacent layers (Fig. 1) (Gagnon & Pirvu, 2011). This crosswise configuration enables CLT to exhibit robust load-bearing capacities in both in-plane and out-of-plane directions, classifying it as a semi-rigid composite material in panel form. These mechanical characteristics make CLT a reliable and versatile option for a wide range of structural applications.

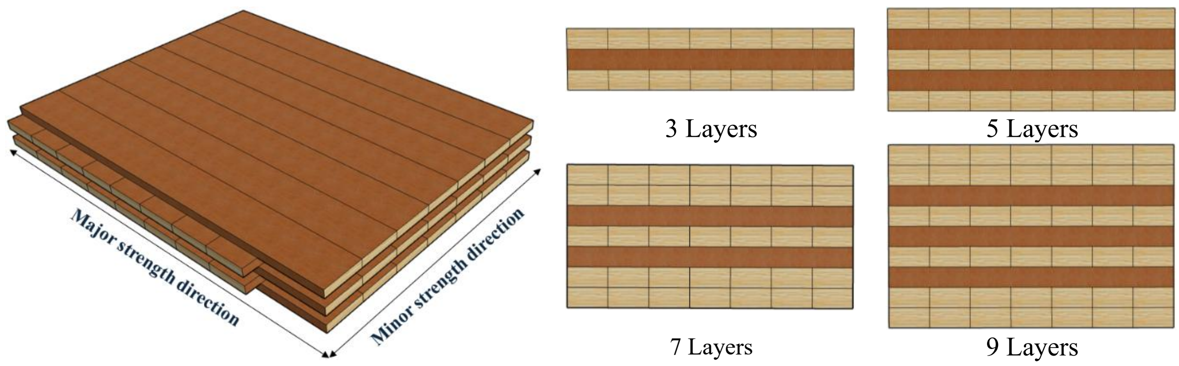

Fig. 1. Typical layer arrangement and fiber direction in CLT panels

FEM updating process plays a vital role in accurately predicting the dynamic responses of CLT structural components. To achieve this, modal tests are conducted on specimens to determine their natural frequencies and mode shapes. The discrepancies between the experimental data and the numerical models of the specimens are then reduced through FEM updating, ensuring the accuracy and reliability of the model (Kurent et al., 2024; Kurent et al., 2023; Aloisio et al., 2020).

2. Operational modal analysis (OMA)

Operational Modal Analysis (OMA) is a non-invasive method used to experimentally identify the dynamic properties of structures, including natural frequencies, mode shapes, and damping ratios, by analyzing their vibration responses. This approach is generally divided into two main types depending on the source of excitement: Ambient Vibration Testing and Forced Vibration Testing. In the present study, system identification was performed using ambient vibrations to determine the dynamic characteristics of the structures.

The equipment used for determining dynamic characteristics is presented below:

- B&K 4506 type three-axial accelerometer (Fig. 2 and Table 1)
- B&K 3560 data acquisition system with 17 channels (Fig. 3)
- PULSE software for signal processing (PULSE, 2006).
- OMA software to extract dynamic characteristics (OMA, 2006).

Fig. 2. B&K 4506 type three-axial accelerometer

Table 1. Properties of the accelerometers

Model	B&K 4506
Sensibility	0.5 V/g
Frequency range	0.3-2000 Hz
Maximum acceleration	±14g
Operating temperature	-54 to +100°C
Dimensions	17 x 17 x 17 mm
Total Mass	18 gr

Fig. 3. B&K 3560 C type 17-channel data acquisition unit

The structural response signals generated by environmental influences can be evaluated using both frequency-domain and time-domain algorithms. To extract modal parameters from these signals, a variety of techniques are available. These include Peak Picking (PP), Frequency Domain Decomposition (FDD), and Enhanced Frequency Domain Decomposition (EFDD) within the frequency domain, and methods such as Random Decrement, Recursive Techniques, and Stochastic Subspace Identification (SSI) within the time domain. In recent years, novel system identification techniques have also been proposed. Frequency-domain approaches focus on analyzing individual measurement points and the relationships between signals, whereas time-domain methods utilize the temporal progression of the signal or fit a mathematical model using correlation functions (Ramos, 2007; Ni & Zhang, 2019; Di Matteo et al., 2021; Russotto et al., 2022). Both categories are widely adopted for determining modal parameters. In the present study, system identification was performed using the EFDD technique, which is based on frequency-domain analysis.

The Enhanced Frequency Domain Decomposition (EFDD) method represents a refined version of the standard FDD technique. It identifies modal parameters by detecting peaks in the singular value decomposition (SVD) of the spectral density matrix. While the original FDD approach is limited in that it does not provide damping ratio information, it is effective in determining natural frequencies and mode shapes. In contrast, the EFDD method not only improves accuracy but also enables the estimation of damping ratios (Jacobsen et al., 2006). The mathematical relationship between the unknown excitation and the measured output within the EFDD framework is defined by Equation (1). Further explanation regarding the formulation and parameters of this equation can be found in previous studies (Brincker et al., 2000; Bendat & Piersol, 2011).

$$G_{yy}(j\omega) = H^{*}(j\omega) G_{xx}(j\omega) H^{T}(j\omega) \tag{1}$$

where the matrix Gxx represents the power spectral density of the input, where r denotes the number of inputs, while Gyy is the power spectral density matrix of the responses, with mmm indicating the number of responses. The matrix H(ω) is the frequency response function matrix, characterized by dimensions m×r.

Fig. 4 presents several images captured during the ambient vibration tests. In each test setup, a total of four accelerometers were employed two positioned at the upper corner locations (points 2 and 4), and the other two placed at the mid-height edge locations (points 1 and 3) of the CLT panels. Data acquisition was conducted over a 15-minute period, with raw signals recorded within the frequency range of 0–400 Hz.

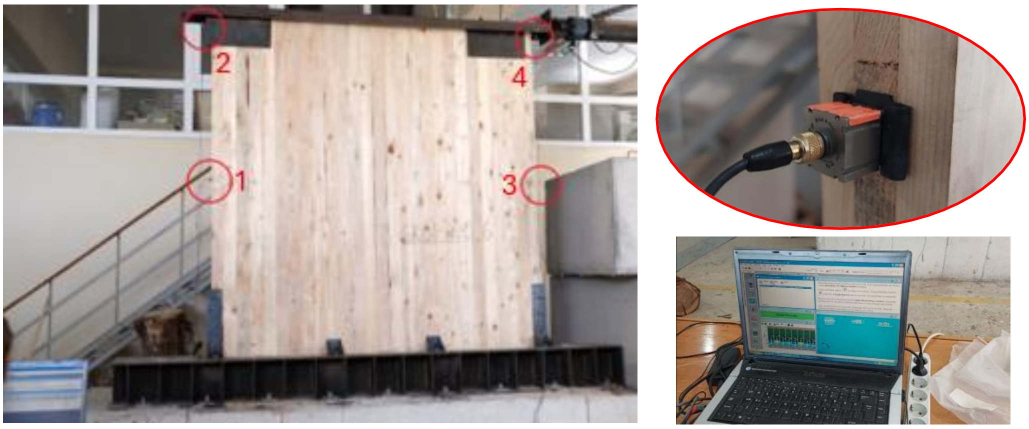

Fig. 4. Some view from the ambient vibration tests

Fig. 5 displays the spectral density matrices derived through the EFDD method. Due to page constraints, instead of presenting graphs for all 30 CLT panels, one representative graph from each material group is shown: spruce (Fig. 5a), alder (Fig. 5b), and hybrid (Fig. 5c). The analysis focused solely on the in-plane modes of the CLT panels, while out-of-plane modes were excluded from the scope of this study. Peak selections were made accordingly. Fig. 6 illustrates the first and second in-plane lateral modes identified from the experimental data. As similar mode shapes were consistently observed across all tests, only a single representative plot is provided. Table 2 summarizes the natural frequencies corresponding to the first two in-plane modes for each CLT panel.

3. Numerical studies

3.1. FEM of the CLT panels

FEMs of the CLT panels were developed using the SAP2000 software. In the modelling process, area, link, and spring elements were utilized, and a mesh size of 10 cm was selected based on the outcomes of convergence analyses. Each model consisted of 1875 nodes, 1728 area elements, and 1250 link elements. The two-dimensional area elements were employed to represent the CLT panels similarly to shell elements. Link elements were used to simulate the adhesive-like interaction between the individual layers of the panels. For the experimental setup, a steel H-profile was anchored prior to concrete casting in order to support the CLT panels on a reinforced concrete strip foundation constructed in the laboratory. Spring elements modelled the connection between the panels and the rigid foundation. To eliminate out-of-plane movement, a UPN 160 steel profile was installed at the top of the CLT panels, and this structural detail was also incorporated into the FEM. Fig. 7 provides a visual representation of the FEM layout for the CLT panels.

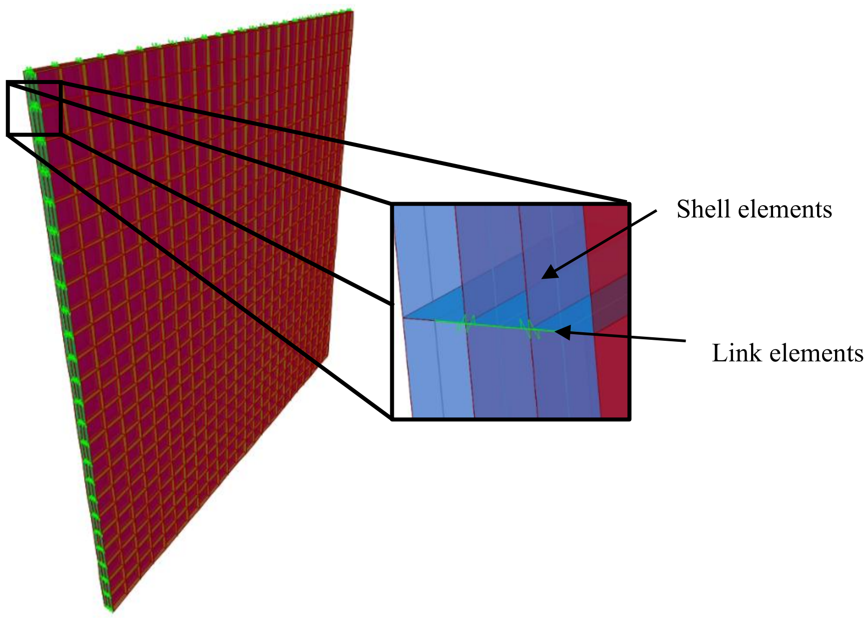

Fig. 7. Representation of the finite element model of CLT panels

A consistent finite element model was used across all cases, with adjustments made to reflect differences in material properties based on wood species, fiber orientations within the layers, and the stiffness of the springs positioned beneath the panels. The mechanical properties of the CLT panels were derived from EN 338 standards and are summarized in Table 3.

Fig. 8 illustrates the first and second in-plane lateral modes obtained through FEM analysis. As the mode shapes showed high similarity across all analyses, only one representative plot is presented. A strong correlation was observed between the experimentally measured and numerically computed first two in-plane modes.

Table 4 summarizes the natural frequencies obtained from the initial finite element model (FEM), along with the corresponding experimental results for comparison. When the numerically and experimentally obtained frequency values were compared, significant discrepancies were observed up to 47.96% for the first mode and 79.89% for the second mode. These findings indicate a substantial inconsistency between the frequency responses of the initial FEM and the experimental data. Therefore, model updating was deemed necessary to ensure an accurate representation of the structural behavior through the FEM.

3.2. FEM updating using ambient vibration (dynamic) tests results

At this stage, the natural frequencies derived from ambient vibration tests were used as reference values, and the FEMs were updated by adjusting the stiffness of the spring elements at the support locations as the primary variable. Table 5 provides a comparison between the first two experimental natural frequencies and those obtained from the updated FEMs, along with the final values of the spring stiffnesses. Prior to model updating, the discrepancies in natural frequencies were as high as 79.89%, whereas post-update differences were significantly reduced to 7.09% for the first mode and 6.45% for the second mode. These results demonstrate a strong correlation between the experimental and numerical outcomes after the model updating process.

Table 5. The first two experimental natural frequencies with updated frequency-based FEM

4. Conclusions

In this study, the dynamic characteristics of 30 CLT panels with different properties were identified through ambient vibration tests, and FEMs were developed based on the experimental data. A frequency-based model updating approach was employed to enhance the accuracy of the numerical models. The analyses conducted yielded the following findings:

When the initial FEMs were compared with the experimental results, the differences in the natural frequencies of the first and second modes were found to reach up to 79.89% and 65.31%, respectively. This clearly demonstrated the necessity of performing model updating.

Following the frequency-based FEM updating, the discrepancies between the numerical and experimental natural frequencies were significantly reduced—down to 7.09% for the first mode and 6.45% for the second mode. These results indicate that the model updating procedure effectively improved the accuracy of the numerical representations.

In conclusion, the frequency-based model updating method contributed to obtaining finite element models that more accurately reflect the dynamic behavior of CLT panels. In this context, careful consideration of parameters such as support conditions, material properties of the panels, and boundary constraints is of critical importance for achieving consistency with experimental results.

The importance of evaluating building needs in retrofitting method selection

Muhammed Can Esen*[1], Kadir GÜLER[2]

Abstract: The 2023 Kahramanmaraş Earthquakes triggered a short-lived state of panic among residents in high-acceleration regions, particularly in areas specified by the Turkish Seismic Hazard Map 2018 (TDTH 2018). In response, many citizens sought to assess the seismic resistance of their buildings and retrofit them accordingly. In some of the implemented retrofitting projects, it was observed that despite the building having recently experienced an earthquake, the performance exhibited during the previous event was not evaluated. In some cases, expensive methods were chosen over more practical and cost-effective alternatives, while in others, retrofitting was carried out without conducting any static analysis to increase the element ductility (generally only applying FRP wrapping or steel jacketing to the existing reinforced concrete columns).Such practices can result in various negative outcomes, including failure to meet expected performance levels, which posing risks to human safety; over-design, leading to unnecessary expenses; and inefficient resource allocation, with retrofitting efforts focusing on adequate parts of buildings rather than addressing deficiencies. This study underscores the critical importance of selecting the appropriate retrofitting method for a building to prevent the financial and human losses. It demonstrates that retrofitting methods should be chosen based on the specific needs of the building. By evaluating retrofitting strategies within the framework of TBDY-2018 (Turkish Building Earthquake Code 2018), the study examines their outcomes in buildings with different deficiencies in Türkiye. Additionally, it provides recommendations for retrofitting approaches suitable for various structural weaknesses. In conclusion, the study emphasizes that retrofitting methods must be carefully selected based on a thorough evaluation of the reinforced concrete building's deficiencies and specific needs.

Keywords: Retrofitting methods; TBDY-2018; Seismic resistance; Cost-effective retrofitting; Structural weaknesses

1. Introduction

The need for strengthening buildings may be for buildings moderately damaged after an earthquake, or to increase the seismic performance of existing buildings. In 2023, two major earthquakes occurred in Kahramanmaraş in the same day of 6th February, the first measuring 7.7 Mw and the second 7.6 Mw. After the earthquakes, many buildings were evaluated as heavily damaged, while some were classified as moderately damaged. (Altıok, Şevik, & Demir, 2024)

In some of the moderately damaged buildings, the owners opted for demolition and reconstruction, while in others, repair and retrofitting methods were preferred. In some of the buildings where retrofitting was decided, it was observed that the applied methods were chosen without considering the needs of the building, and in some cases, retrofitting was carried out without any structural system analysis (CAEES/ACGPS, 2023)

Such improper practices lead to unnecessary costs, causing financial losses to citizens who are already facing economic difficulties due to the earthquake, and in some cases, they mislead the public, posing risks to life safety. This study emphasizes the importance of evaluating the needs of the building when selecting a retrofitting method and discusses various methods that can be applied for different level of deficiencies.

2. Retrofitting methods

When it comes to strengthening buildings, system and element strengthening should be understood together. However, element strengthening is mostly used and understood in the sense of strengthening the building/structure. This is not true. Because in the existing building stock, in addition to the lack of sufficient wrapping in columns

*Corresponding author, E-mail: esen22@itu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_824

golden light publishing

in buildings, lateral rigidity is also not sufficient. Due to the lack of sufficient wrapping effect in columns (insufficient stirrups, 90-degree hooks and easy opening of these hooks, buckling of column longitudinal reinforcements and crushing of core concrete, severe damage to columns, reaching strength loss), the earthquake behavior of frame system buildings does not occur as expected. In order to repair and strengthen damaged columns and as a structural system strengthening in existing buildings, columns are mostly tried to be wrapped. However, this application means increasing the ductility of the element. In very few cases, element strengthening may include structural system strengthening. Some of the options for element and system level strengthening are given below. This section discusses the various retrofitting methods and their benefits. The methods to be examined include Fiber Reinforced Polymer (FRP) retrofitting, Reinforced Concrete Jacketing, Retrofitting by Adding Shear Walls, Steel Jacketing/Strip Retrofitting, and Retrofitting with Steel Braces (including buckling restrained braces, BRB).

2.1. Retrofitting with fiber-reinforced polymer (FRP)

In the FRP retrofitting method, structural elements are strengthened using materials made from glass, aramid, or carbon fibers by wrapping or strip application. These materials consist of fiber and resin. The mechanical properties of the material vary depending on the type of fiber used.

Glass fibers are recommended for elements where high load-bearing is not crucial and where large deformations are not expected, while carbon fibers are recommended for elements where high load-bearing is essential and significant deformation is expected (İlki, Demir, & Cömert, 2023). Aramid fibers offer high tensile strength but are less commonly used due to higher costs (Jibu & Joseph, 2022).

Retrofitting by FRP can be applied in two ways: wrapping or strip application. The main difference is that wrapping provides a confinement effect due to its continuity, resulting in an increase in the axial load capacity of the element. The main advantages of this method are fast application, minimal reduction in usable space, increased ductility of the element, and significant improvement in shear strength depending on capacity. (Antoniou, Fibre – Reinforced Polymers (FRPs), 2022). Wrapping application is much effective in low strength concrete circular and squared column sections. Strip application of FRP is used to increase the flexural rigidity (at beams and slabs) and shear resistance of columns and beams.

Fig. 1. CFRP strip application to increase the flexural rigidity of slabs (SİKA, 2024)

2.2. Retrofitting with reinforced concrete jacketing

In this strengthening method, it is assumed to increase the bending rigidity and ductility by increasing the sizes of the section from one side to four sides. It is important to fix the longitudinal reinforcements to the foundations in the sheathing and to ensure their continuity at the floor slab levels. To improve the bond between the existing and new jacketing sections, it is important to perform the surface roughness and chemical anchorage of reinforcement between existing and new sections.

As a result, it improves the ductility, axial load, and shear capacity of the element and enhances the overall structural stiffness. However, the drawbacks include reduction in usable space and long, labor-intensive application processes (Sichko & Sezen, 2017).

Fig. 2. RC column jacketing application (Structville, 2023)

2.3. Retrofitting with reinforced concrete shear walls
This method involves adding new shear wall elements in the direction where they do not already exist in the building, enhancing stiffness and enabling the building to resist significant lateral forces. These elements can be added either between frame columns, or by connecting to existing columns independently. In retrofitting buildings with adding shear walls, at least three shear walls should be used and their axis should not intersect at one point. The location of shear walls should not disturb the architectural functions of the building. Continuity of the shear walls between slabs is important.

By adding shear walls, the building's stiffness is significantly improved, and it becomes more capable of resisting shear forces in the direction of the walls located. Although this is a difficult and laborious process, when shear walls are placed within infill walls, they may not reduce usable space. (Antoniou, New Reinforced Concrete Shear Walls, 2022)

Fig. 3. Adding shear walls to existing structural system (Seismosoft, 2022)

2.4. Retrofitting with steel jacketing/straps
In this method, existing structural system elements (columns and beams) are retrofitted using steel members with various mechanical properties, either by jacketing or by attaching strip-shaped steel elements.

Similar to FRP, this method allows relatively easy application. Jacketing increases both axial load and shear force capacity, while strip application mainly improves the shear force capacity. It also enhances the ductility of the column or beam applied.

This method does not significantly reduce usable space and is relatively fast to apply. However, the material and labor costs are high, and corrosion susceptibility depends on the type of steel used. (Chong, ve diğerleri, 2024). It is recommended to perform an economic analysis with that of FRP wrapping for increase in shear capacity.

Fig. 4. Steel jacketing (Kaplan & Yilmaz, 2012)

2.5. Retrofitting with steel bracing (BRB)
In this method, buckling-restrained steel braces are added externally or internally to increase the structural system's stiffness. Similar to adding rc shear walls, this method enhances the stiffness. Although it is costly, it can save time and enable the building to continue to provide service.

To apply this method, the amount of concrete compressive strength of the structural elements is important. In case of low concrete strength, in addition to the need for steel jacketing on columns, jacketing of some beams may also be required to meet in-plane effects. . (Güler, 2022)

Fig. 5. Buckling restrained braces application (Arfenbrb, 2022)

3. Selecting retrofitting methods based on structural needs

In Türkiye, buildings are predominantly constructed according to the seismic codes of 1975, 1997, 2007, and 2018, These codes have evolved over time due to changing conditions, advancements in technology, capacity design principles and practical applications. The requirements on capacity design principles, structural irregularities and reinforcement details are given in 1997 seismic code. Earthquake codes generally include rules regarding the design of structural systems under vertical and lateral loads with a strength-based approach. Rules regarding the seismic performance assessment and strengthening of existing buildings are included in the 2007 and 2018 earthquake codes.

In addition to changes in seismic codes, inspection mechanisms and engineering software have also improved over time, contributing to today's standards. At this point, analyzing the deficiencies and needs of buildings resulting from past mistakes is crucial for proper retrofitting.

Deficiencies in the existing buildings can be classified as element level and system level.

Element level deficiencies include insufficient strength, rigidity and ductility. The most critical system level deficiency in the existing buildings is inadequate lateral stiffness and insufficient confinement for columns. For that reason, only element level strengthening cannot be sufficient, at the same time the system level retrofitting is required to prevent collapse the buildings and save human life.

Below is a table showing the effects of various retrofitting methods for commonly encountered deficiencies.

Table 1. Effectiveness of various retrofitting methods

Retrofitting Method	Cost	Labor & Time	Contribution to Axial Load Strength (Element-Level)	Contribution to Shear Strength (Element-Level)	Contribution to Stiffness (System-Level)	Contribution to Ductility
Retrofitting with FRP	+	+*	+ (only for wrap)	+*	-	+*
Retrofitting with RC Jacketing	+*	-	+	+	+	+
Retrofitting with RC Shear Wall	-	-	~	~	+*	-
Retrofitting with Steel Jacketing/Strips	-	+	- (For strip)	+*	~	+*
Retrofitting with Steel BRB	-*	+	-	-	+*	-

+ good, +* very good, ~ partial contribution, - costly/ineffective, -* very costly
*BRB = buckling restrained brace

4. Importance of selecting retrofitting methods based on needs using a sample building

In this section, the outcomes of a building retrofitted using fiber-reinforced polymer (FRP) were examined.
The building consists of beam and column elements, frame system, and does not contain any reinforced concrete shear walls.

The building has a ground floor and six typical stories. It was constructed using concrete with a compressive strength of 20 MPa and S420 grade deformed reinforcement. Carrying out nonlinear analysis, it was observed that four columns experienced collapse, and FRP retrofitting was decided upon to prevent the failure of the building.

The results obtained after the retrofitting process are as follows:

The ductility capacity, shear and compressive strength of reinforced concrete columns were improved through FRP wrapping. Additionally, in cases where the lap splice length of longitudinal reinforcement at bottom ends of the columns was insufficient, FRP wrapping can enhance the bond strength of the reinforcement.

The displacement capacity of columns was increased with FRP wrapping. Before FRP wrapping, 142 mm displacement is calculated, 83 structural elements showed significant damage level and 4 columns collapsed level. After the wrapping, the number of collapsed elements was reduced to zero, and the structural safety was ensured. In fact, story drifts did not changed, they were in acceptable limits.

The wrapping of the structural system with FRP material, the shear capacity of the structural system elements was increased to the Vmax limit defined by the seismic code 2018. However, in order to classify the building as shear-safe, it was determined that some columns and beams needed to be strengthened by rc jacketing. This is due to the code limitation that the maximum shear capacity of FRP-wrapped members cannot exceed Vmax.

Due to the current building conditions, some columns are weaker than the beams, resulting in the building behaving like a limited ductility system, so earthquake loads are increased and existing lateral rigidity is insufficient. In order to upgrade the system classification to a high-ductility system, jacketing of some columns is required.

While the building initially exhibited collapse performance, with FRP wrapping and the additional jacketing of necessary structural elements, the building achieved the desired Controlled Damage performance level according to TBSC 2018.

Despite these improvements, the FRP wrapping method caused almost no reduction in usable space compared to other retrofitting techniques.

FRP retrofitting remains an active area of research, and codes from different countries impose varying limitations.

For example, in the Turkish Building Earthquake Code 2018 (TBDY-2018):

a) In order to enhance the axial compressive strength of columns via FRP wrapping, the ratio of the longer side to the shorter side of the column cross-section must not exceed 2.5.

b) To improve the ductility of columns using FRP wrapping, the same aspect ratio condition (≤2.5) must also be satisfied.

c) For columns with a cross-section aspect ratio greater than 2 or longitudinal reinforcement with plain bars, confinement is inadequate, and FRP wrapping cannot be used to strengthen the lapped splice regions.

If some elements in the building do not meet the above requirements, another suitable retrofitting method must be selected. This alternative method can be used in combination with other techniques as part of a composite approach.

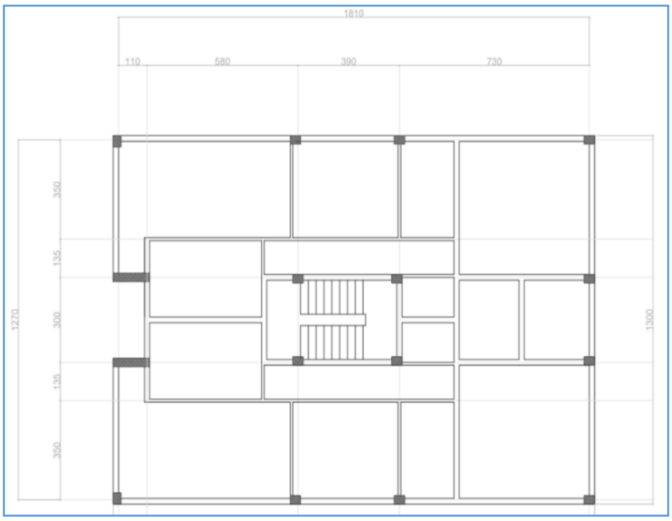

Fig. 6. Floor plan

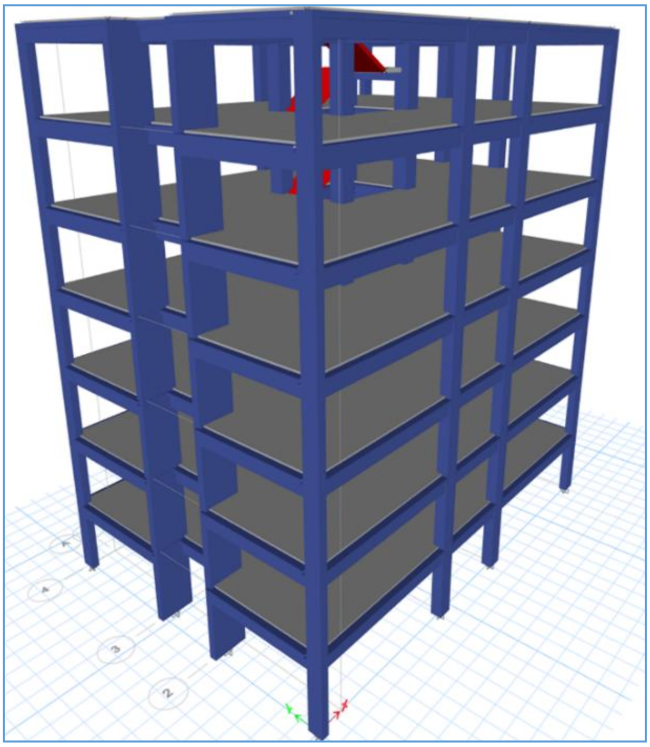

Fig. 7. 3D model of building

Table 2. Evaluation of Retrofitting Methods According to Structural Deficiencies

Structural Deficiency	Retrofitting Method	Contribution of the Method
Inadequate shear strength	FRP wrapping	Increases shear capacity; fast and space-saving
	Steel strip	Increases shear capacity; cost-effective depending on conditions
Inadequate axial load capacity	RC jacketing	Increases shear, axial, and ductility capacities
	RC jacketing	Increases axial and shear strength, improves ductility
	Steel jacketing	Increases axial and shear capacity
	FRP wrapping (full wrapping)	Increases axial capacity through confinement
Inadequate ductility	RC jacketing	Enhances ductility and energy dissipation capacity
	Steel jacketing	Enhances ductility
	FRP wrapping	Enhances ductility
Inadequate structural stiffness	Adding shear walls	Increases stiffness and lateral load capacity
	Steel bracing	Increases stiffness; shorter application time

Damper and base isolation strengthening techniques are not considered in this study.

5. Conclusions

The need for retrofitting is specific in the strengthening of damaged buildings, and the strengthening system can be decided accordingly. However, determining the earthquake performance of the existing buildings and deciding on the strengthening system requires professional experience. A decision should be made on the applicable and economical reinforcement technique according to the reinforcement need on a system level and, if any, on an element level. Each retrofitting method has its own advantages and disadvantages. During retrofitting processes, the negative aspects of the building should be evaluated, and the most effective method for addressing these should be chosen.

There is no obligation to use a single retrofitting method, hybrid methods may be applied. Sometimes, one method may not be sufficient to address all deficiencies, and multiple methods may need to be combined.

For example, after increasing the stiffness of a building by adding new shear walls to the existing structural system, for element level deficiencies can be resolved using FRP wrapping or jacketing of some columns.

- For the elements of columns with insufficient axial load, shear strength, or ductility, if the required capacities defined in the code are met, the use of FRP is recommended. If not, reinforced concrete jacketing is advised.
- If the shear strength of columns needs to be increased within the capacity limits of the element, either FRP or steel strips can be used. The choice between these methods may depend on cost, labor, and retrofitting time.
- For buildings with structural system level deficiencies, new shear walls or steel braces can be used depending on the building's needs, cost, and timeline. To use the steel braces, the concrete compressive strength in the frame system must be sufficient (not less than 15MPa). Both methods require compatibility with the building's slab plan and locations of columns without changing the architectural functions of the building.

Evaluation of strengthening RC building with X steel cross elements

Gürkan Tam*[1], Burak Yön[1]

[1]Munzur University, Department of Civil Engineering, 62000 Tunceli, Türkiye

Abstract. In this study, a building with C12 concrete strength, unchanged column and beam dimensions, S420 reinforcement steel and 250 mm transverse reinforcement spacing was modeled. Then, this building was strengthened with X steel diagonal elements to form a total of two buildings. Nonlinear static and incremental dynamic analyses were performed to evaluate the seismic response of the buildings. 11 different earthquake records were selected for incremental dynamic analyses. These records were applied to the structures with 0.1 increments between 0.1g and 1.0g. As a result of the analyses, the capacity curves of the buildings, interstory drifts and hysteretic curves of some selected columns were obtained. According to the results obtained, it was determined that as a result of the strengthening using X-steel diagonal elements, the interstory drifts and displacements in the columns of the strengthened structure were significantly reduced compared to the existing structure, and the base shear forces that the strengthened structure faced compared to the current situation increased approximately 4.3 times.

1. Introduction

Türkiye is situated in one of the most seismically active regions globally, resulting in a significant earthquake hazard across the nation. Active faults, particularly the North Anatolian Fault Zone, East Anatolian Fault Zone, Bitlis Thrust Zone, and Aegean Depression System, induce significant earthquakes. Numerous lives and properties were lost due to significant disasters, including the 1999 Kocaeli Earthquake, the 2011 Van Earthquakes, the 2020 Elazığ and İzmir Earthquakes, and the 2023 Kahramanmaraş Earthquakes. In Turkey, consistently susceptible to earthquakes, field research conducted post-quake uncovered numerous deficiencies, including the utilization of low-strength concrete in transverse reinforced concrete structures, design flaws, inspection-related issues, and excessive spacing of confinement reinforcement. Reinforced concrete structures with such defects, when subjected to significant ground movements, result in substantial loss of life and property. Consequently, the seismic performance of the current reinforced concrete building inventory at different danger levels must be assessed and fortified employing suitable techniques (Yurdakul et al., 2021; Rizvan et al, 2021).

The objective of seismic design is to avert loss of life by ensuring that structures exhibit appropriate behavior under lateral loads during an earthquake, maintain structural damage within repairable limits and most critically, prevent structural collapse (Gunel & Ilgin, 2007). Nevertheless, older buildings, constructed in accordance with previous design rules and standards, are unable to satisfy the performance criteria established by contemporary regulations (Alkhayyat & Ozay, 2024; Villar et al, 2020; Beiraghi et al, 2022; Sidika et al, 2020; Doğan et al, 2021; Pohoryles et al, 2022). As a result, the imperative to enhance the seismic performance of these structures arises (Tam, 2024). The option of reinforcing with steel cross members is emerging as a cost-effective and efficient method to enhance structural performance and provide stability against lateral loads. These support parts confer stiffness and stability to the structure, particularly in high-rise buildings (Hassan & Al-Wazni, 2023; Patil & Angalekar, 2021). The implementation of cross member systems is an effective strategy to mitigate structural damage, interstorey drifts and storey displacements during seismic events (Ahiwale et al, 2023; Kirruti & Balkıs, 2020).

This numerical study employed static pushover analysis and incremental dynamic analysis to examine the impact of steel cross member reinforcement on the seismic performance of retrofitted concrete structures.

Capacity curves, average interstorey drifts, and hysteretic curves for specific columns were derived for the selected structures.

2. Material and method

The current 5-storey symmetrical reinforced concrete structure was used as the benchmark for the numerical analysis. The height of each floor is designated as 3 meters. The building's total height was established at 15 m, the floor thickness at 12 cm, the concrete grade at C12, and the steel grade at S420. All columns of the reference structure measure 400x400 mm, all beams measure 250x500 mm, and the existing building is modeled with confinement reinforcement spacing of 250 mm for both columns and beams. During the second phase of the project, the existing structure was reinforced by including X steel cross members. A comparison of the seismic performance of the two simulated structures was conducted. The Mander confined concrete model (Mander et al, 1988) was selected for concrete, the Menegotto-Pinto model (Menegotto & Pinto, 1973) for steel, and the SHS 150x8 mm material model (Seismostruct, 2024) for the X steel cross reinforcement element. The SeismoStruct V24 structural analysis software (Seismostruct, 2024) was utilized for the analysis. Fig.s 1-3 present the floor plans and perspectives of the existing and retrofitted structures utilized in the numerical analysis, while Table 1 provides the specifications of the columns and beams.

The static pushover analysis approach was initially employed in the study to assess the nonlinear behavior of both existing and retrofitted structures. Static pushover analysis involves the determination of demand-capacity curves through the estimation of plastic hinges and displacements. The investigation investigates the development of plastic hinges under progressively increasing lateral strains (Ueda & Takewaka, 2007; Rodriguez et al, 2024; Ruggieri & Uva, 2020; Prince et al, 2023). The second technique employed in numerical analysis is the incremental dynamic analysis method. This method involves doing a series of nonlinear time history analyses to assess the structural response to dynamic loads (Prince et al, 2023; Verki & Preciado, 2022). This technique delivers insights into structural demand levels, including damage status in structural components, maximum peak displacement, and interstory drift for earthquake data of varying amplitudes (Karaşin, 2023). The relative storey drifts derived from dynamic analyses were compared with the threshold values established for various performance levels in the HAZUS program, a nationally standardized risk assessment methodology in the United States administered by the FEMA-2000 (Federal Emergency Management Agency) natural disaster risk assessment initiative. The limit values utilized in the investigation are presented in Table 2 for framed constructions.

3. Findings and discussion

This section presents capacity curves derived from the non-linear analysis of the analyzed structures, average interstorey drifts, and hysteresis curves observed in selected columns.

3.1. Capacity Curves

Static pushover analyzes of the selected buildings were carried out according to the DD-2 earthquake level and ZD local soil class criteria, taking into account the earthquake forces and the additional eccentricity effect. Continuously increasing lateral force was applied to the models until the roof displacement reached 3% of the building height. The comparison of the obtained capacity curves between existing and retrofitted buildings is presented in Fig. 4.

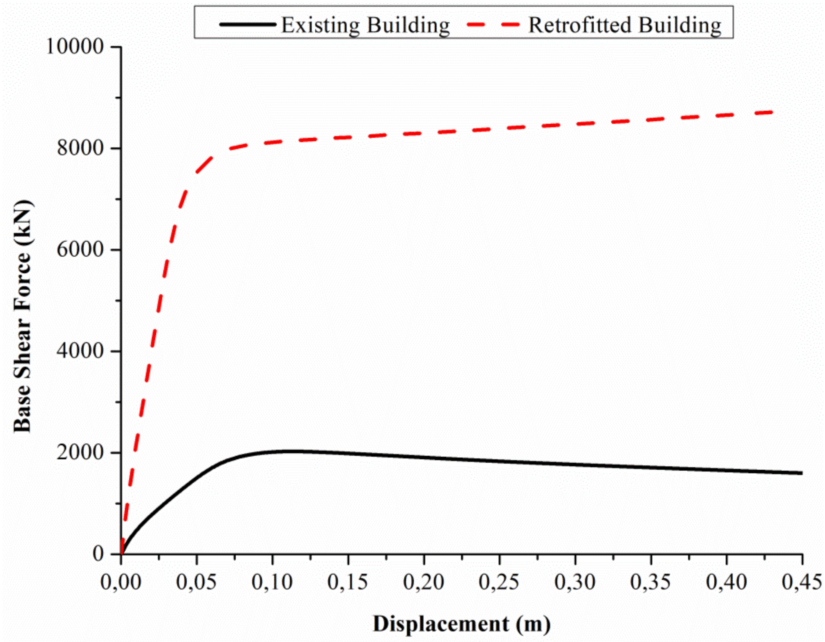

Fig. 4. Comparison of capacity curves

Upon examination of Fig. 4, it is evident that the capacity curve of the retrofitted structure significantly surpasses that of the existing building. The maximum base shear force resisted by the retrofitted building was 8748 kN, while the original building resisted a maximum base shear force of 2028 kN. The capacity values of the building reinforced with X steel cross members rose by over fourfold compared to the capacity value of the existing structure. Furthermore, the horizontal load-bearing capacity of the existing building diminished following a displacement of 0.10 m, but no reduction was noted in the capacity of the retrofitted structure.

3.2. Interstorey drift ratio

The average of the interstorey drift ratios obtained according to the acceleration amplitudes of the two buildings that were numerically analyzed was compared with the limit values specified for different performance levels in the HAZUS program, based on earthquake amplitudes of 0.1g-1.0g (Fig. 5-6).

Fig. 5 presents the average interstory drifts of the existing building based on a total of 11 earthquake records ranging from 0.1g to 1.0g. The relative storey drift ratios of the building were assessed to be between moderate and heavy damage at 0.1g and 0.2g, between heavy damage and collapse at 0.3g, and beyond the collapse threshold at higher acceleration amplitudes.

The average of the interstorey drift ratios of the retrofitted building calculated according to a total of 11 earthquake records between 0.1g-1.0g is given in Fig. 6. Accordingly, for 0.1g acceleration amplitude, the building is below the light damage level, for 0.2g and 0.3g acceleration amplitudes, it is between slight damage and moderete damage level, for 0.4g-0.7g, it is between moderete damage and heavy damage level, for 0.8g, For acceleration amplitudes of 0.9g and 1.0g, it was determined that it remained between the levels of severe damage and collapse.

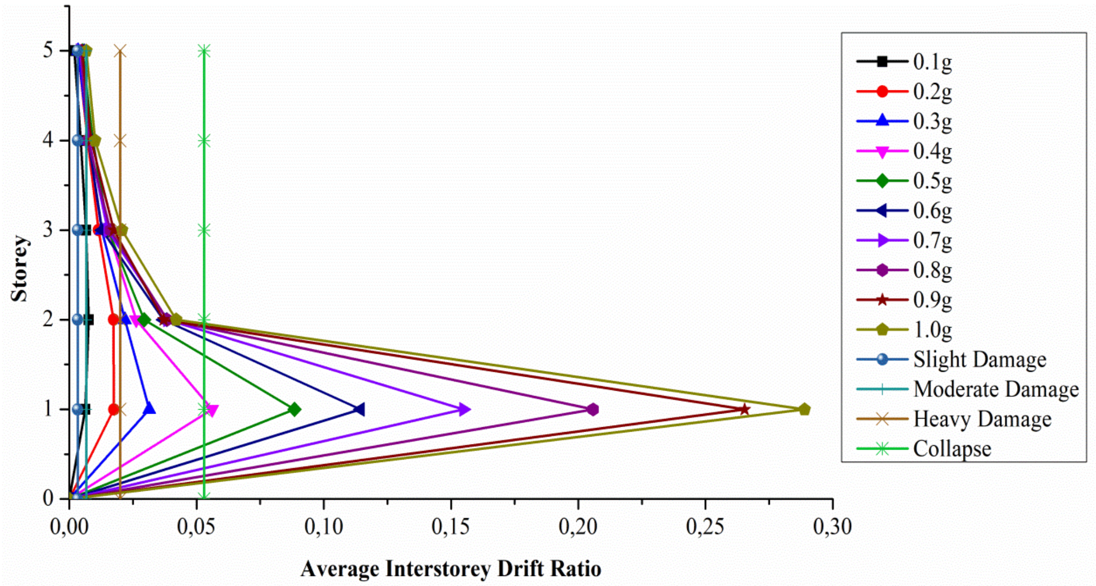

Fig. 5. Average interstorey drift ratios of the existing building under earthquakes with accelerations of 0.1g-1.0g

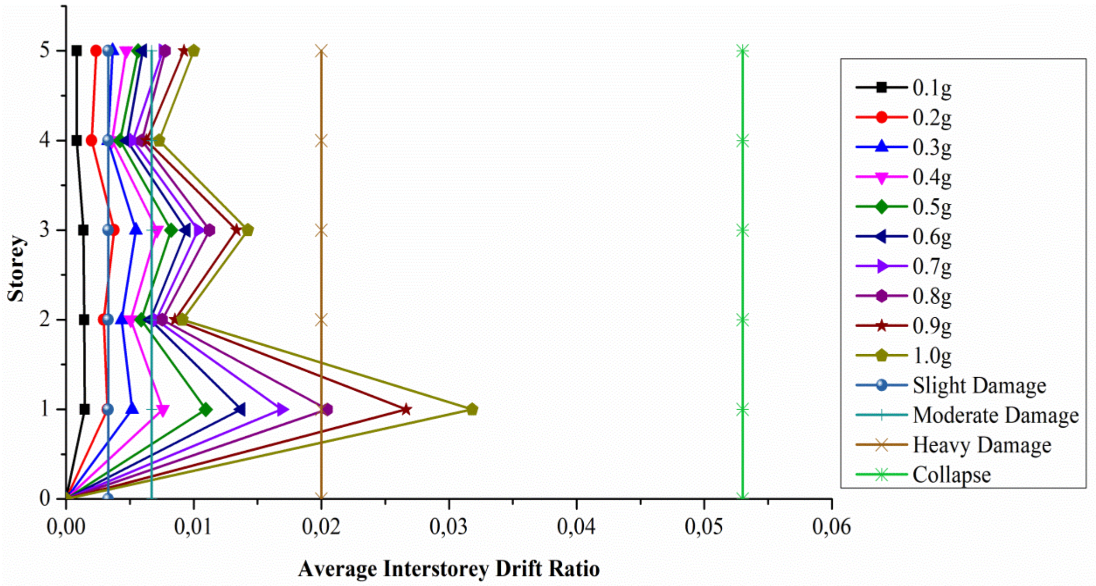

Fig. 6. Average interstorey drift ratios of the retrofitted building under earthquakes with accelerations of 0.1g-1.0g

3.3. Hysteresis curve

The hysteretic curves obtained as a result of nonlinear analyzes using the 0.7g amplitude acceleration record of the Bingöl earthquake for some selected columns in the examined buildings are given in Figs. 7-9.

Upon examining Fig. 7, the maximum displacement value for the ground floor S13 column is 0.024 meters in absolute terms, whereas the maximum lateral shear force is around 1400 kN. Following the fortification of the structure, the peak displacement value for the identical column diminished to 0.0096 meters in absolute terms, although the highest shear force escalated to 5898 kN.

In the first floor S21 column, the current maximum displacement value was 0.042 meters in absolute value and the largest lateral shear force was approximately 1419 kN. After the building was strengthened, the maximum displacement value for the same column decreased to 0.006 meters in absolute value, while the maximum shear force increased to approximately 5900 kN (Fig. 8).

In the S3 column on the second floor, the maximum displacement value is 0.03 meters in absolute terms, and the peak lateral shear force is approximately 1500 kN. Conversely, in the retrofitted structure, the maximum displacement value for the same column is 0.011 meters in absolute terms, with the highest shear force reaching approximately 5900 kN.

4. Conclusions

This study conducted static pushover and incremental dynamic analyses of chosen building models to investigate the impact of X steel cross members on the reinforcement of reinforced concrete structures. A structure with a confinement reinforcement spacing of 250 mm and a concrete strength of C12 was modeled for this purpose. This building, subsequently modeled, was reinforced with X steel cross members, resulting in a total of two models. The investigations yielded capacity curves for the modeled buildings, average relative floor drifts, and hysteresis curves for chosen columns. The findings derived from the investigation are presented below.

- The assessment of capacity curves indicates that the lateral load-bearing capacity of the building reinforced with X steel cross members has grown to roughly 4.3 times that of the existing structure. Nevertheless, the horizontal load-carrying capacity of existing structures diminished following a displacement of 0.10 m, although no reduction was noted in the capacity of rtrofitted structures.
- The evaluation of the average interstorey drifts from 11 earthquake records with acceleration amplitudes ranging from 0.1g to 1.0g revealed that the interstorey drift rates for the existing building surpassed the collapse threshold at acceleration amplitudes exceeding 0.3g. The retrofitted structure exhibited average interstorey drifts that fluctuated between severe damage and collapse thresholds for acceleration amplitudes of 0.8g, 0.9g, and 1.0g.
- As a result of examining the 0.7g amplitude Bingöl earthquake data, hysteresis curves were obtained for the specified columns. When these curves were evaluated, it was determined that steel cross members reduced the maximum displacement in the columns by more than two times and increased the shear forces encountered by the columns by four times.

The investigation concluded that the strengthening using X steel diagonal members postponed the performance limit values to high amplitude acceleration levels, significantly reduced column displacements and significantly increased the base shear force resisted by the building.

Progressive Collapse and the Turkish Earthquake Code 2018: a review for precast industrial buildings

Samwel Amumpeire*[1], Aydın Demir[2]

[1] Sakarya University, Institute of Applied Sciences, 54050, Sakarya, Türkiye
[2] Sakarya University, Department of Civil Engineering, 54050, Sakarya, Türkiye

Abstract
Progressive collapse represents a severe structural safety issue, particularly for precast reinforced concrete industrial buildings in seismic zones. Observations from the 2023 Kahramanmaraş earthquakes revealed widespread damage with over 60% of Türkiye's precast industrial structures severely affected. This study provides a succinct review of progressive collapse mechanisms, design methodologies, and the relevant provisions of the Turkish Building Earthquake Code 2018 (TEC 2018). While TEC 2018 emphasizes seismic resilience of the structure through ductility and joint integrity, it lacks explicit guidance on progressive collapse mitigation for precast RC buildings. Drawing from international standards, the review identifies significant gaps in the code and highlights advanced design approaches, including Alternate Path and Enhanced Local Resistance methods. The findings emphasize the need for integrated strategies combining seismic and progressive collapse design to ensure structural safety under multi-hazard scenarios. The study proposes a unified framework for updating TEC 2018, informed by recent case studies and international best practices. These recommendations aim to enhance the resilience of Türkiye's industrial infrastructure, mitigating future risks and fostering sustainable development.

Keywords: Progressive collapse; Turkish Earthquake Code; Precast concrete; Industrial buildings; Structural resilience.

1. Introduction

Progressive collapse, such a catastrophic chain reaction that is initiated by a localized structural element's failure, has been a topic of growing concern following serious events such as that of the Ronan Point Apartment, Fig. 1(a), collapse in 1968, the terrorist attack on the World Trade Center in 2001, and the bombing of Alfred P. Murrah – Federal Building, Fig. 1 (b**)**, in 1995. These incidents underscored the disproportionate outcomes of minor failures in structural elements, particularly in precast reinforced concrete systems that rely extensively on the joint integrity and modular connections. Precast RC buildings are considered a preferred choice for industrial applications in Türkiye due to their rapid and construction-effectiveness (Demir & Sezen, 2024). However, their modular nature introduces unique vulnerabilities, particularly under abnormal loading scenarios such as explosions, impacts, and seismic events (Ghaderi et al., 2020; Z. Xu & Huang, 2024).

Progressive collapse can be briefly defined as a situation where the local failure of a key structural element leads to a series of cascading failures, consequently resulting in the collapse of an entire building or a large portion of it (GSA, 2016; UFC 4-023-03, 2009). The UFC (2009) code based on ASCE 7-05 code of practice, further highlights progressive collapse as "the expansion of initial local collapse from an element into another element of the structure which eventually leads to the entire or part of it in a disproportionate way." (UFC 4-023-03, 2009).

In Türkiye, the February 2023 earthquakes devastated the industrial zones, revealing systematic weaknesses in the application of the Turkish Building Earthquake Code (TEC) 2018 to precast reinforced concrete systems. These events demonstrated the need for robust design strategies not only to mitigate the seismic actions but also progressive collapses that might arise in multi-hazard situations. According to a seismic performance study on industrial buildings by Demir & Sezen (2024) following the 2023 Kahramanmaraş Türkiye earthquakes, it is indicated that the highest levels of damage and collapses were reported in precast RC buildings (Demir & Sezen, 2024). Although these buildings were designed as per the seismic code requirements, Xu et al. (2024), highlight that whereas the traditional aseismic and seismic designs focus at enhancing a structure's strength and deformability, allowing a structure to absorb and dissipate part of seismic or impact energy mainly through plastic deformation, their suitability in multi-hazard scenarios is not certain (G. Xu et al., 2024).

*Corresponding author, E-mail: samwel.amumpeire@ogr.sakarya.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_863

This means that, if there is no explicit consideration for progressive collapse design, the structures' integrity in such extreme situations remain unpredictable. The latest Turkish Building Earthquake Code, TEC 2018, provide comprehensive design specifications for ductility and deformability in reinforced concrete and precast structures. However, there is not a single specific guideline/ specification provided by this code of practice regarding the explicit design for extreme instances of progressive collapse (Demir, 2022). The code emphasizes the integrity of joints, including the beam-to-column, and column-to-foundation connections. These joint specifications are undoubtedly critical for seismic performance response and can indirectly influence the progressive collapse resistance of a structure. On contrary, with no clear specification and guideline, the performance of these joints in arresting progressive collapse cannot be guaranteed.

In fact, most codes of practice including the Turkish Building Earthquake Code 2018, do not have provisions explicitly considering the design and mitigation criteria for progressive collapse. Only a few like the BS EN 1991-1-7 do highlight some design philosophies that indirectly might mitigate disproportionate collapses by consideration of extra lateral and vertical reinforcing ties. However, the US Department of Defense (DoD)'s GSA(GSA, 2016) and UFC(UFC 4-023-03, 2009) codes have published analysis guidelines with an attempt at addressing the progressive collapses in buildings. The analysis philosophies in the UFC (Unified Facilities Criteria) 4-023-03, include entirely three methods; Tie forces, Alternate path, and Enhanced local resistance methods.

It is however worth noting that the American code of practice, ASCE 7-05,(ASCE, 2006) which also provides guidelines for designing against progressive collapse, encompasses only two general approaches: Direct, and indirect approaches. The direct design approach explicitly considers the building's resistance to progressive collapse during the design stages. This strategy combines the alternate path method (AP) and the Enhanced local resistance (ELR) methods. Whereas the direct design approach achieves the resistance to progressive collapse implicitly through regulation of least levels of resistance, continuity and ductility in frames play a critical role (Delfian & Hassanipour, 2020).

The alternate path (AP) method of progressive analysis stands out to be the commonly employed practice. This is evidenced by its adoption by both the GSA and UFC codes of practice. However, in this analysis technique only single critical element failure is investigated one at a time. Yet, questions continue to arise about the effectiveness of the approach in addressing the far extreme failure scenarios of multi-column failures in a structure, more so its adaptability to precast modular systems.

Fig. 1. Some of critical progressive collapse instances: a) Ronan Point apartment (Juinio, 2018), b) Alfred P. Murrah (FBI, 1995).

Moreover, precast systems in Türkiye are particularly attractive due to their rapid assembly and cost-efficiency yet their performance under multi-hazard scenarios such as seismic and progressive collapse risks, remain a significant concern (Demir & Sezen, 2024). By critically analyzing both local and international design practices, this review seeks to offer a concise understanding of progressive collapse in precast reinforced concrete industrial buildings. Drawing from the recent studies and real-world implementations of the Turkish Building Earthquake

Code (TEC) 2018, the paper provides a succinct overview of the vulnerabilities and mitigation techniques for such structures. It aims to relay future directions for enhancing structural resilience in seismically vulnerable areas by synthesizing current research and recent case studies.

1.1. Mechanisms of progressive collapse

Whereas the continuous disproportionate collapse of a building is generally referred to as progressive collapse, it is important to note that there are differing mechanisms through which this disproportion does occur. The typology of progressive collapse was first brought to attention by Starossek back in 2007 (Starossek, 2007). According to Starossek, in order to lessen the progressive collapse analysis and its related prevention design, it is of great need to first understand the underlying mechanisms through which the catastrophe happens. Thus, the author did summarize these collapse mechanisms into six groupings that is; Pancake-type, Zipper-type, Domino-type, Instability-type, and the Mixed-type as further discussed. All these mechanisms are identified and characterized by features with which they occur.

1.1.1. Pancake-type collapse

Pancake-type collapse, Fig. *2*(a)**,** is one of the most catastrophic forms of structural failure that is characterized by a sequential and vertical progression of collapse. It begins with the failure of critical vertical load-bearing elements such as columns or walls, often triggered by localized damages like fires, impact, or explosions. Then upper sections of the structure then lose support and fall onto the lower sections, converting all the potential energy to kinetic energy. The resulting impact then creates extreme forces far exceeding the structural reserve capacity of the lower levels which results in their collapse. The process continues until the entire structure is compromised with gravity acting as the driving force. A famous example of pancake-type collapse is the collapse of The World Trade Center Towers, where the weight and velocity of falling debris caused catastrophic failure of successive floors (Starossek, 2007).

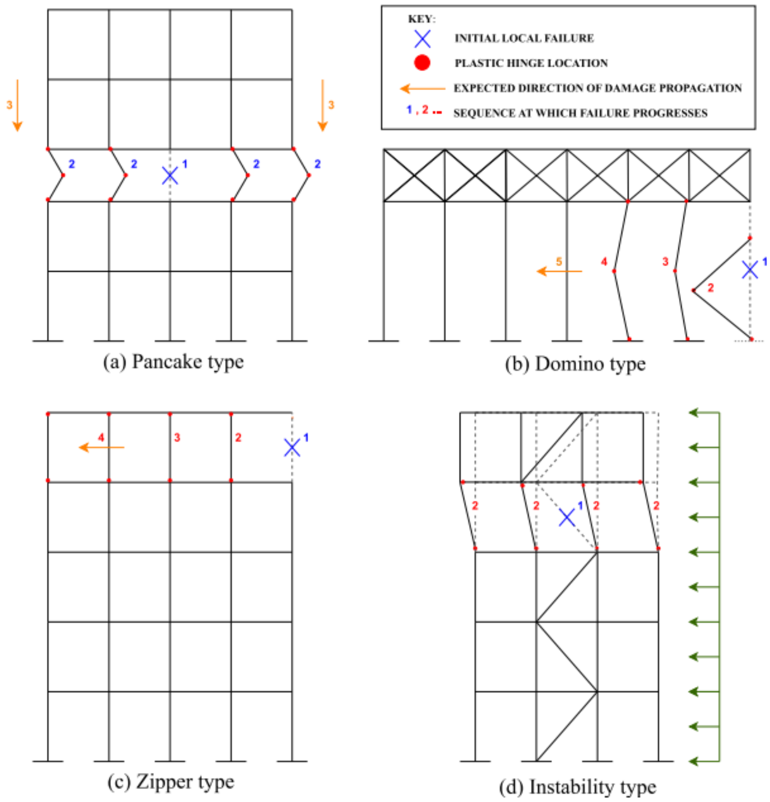

Fig. 2. Different progressive collapse mechanisms (Elkady et al., 2024)

1.1.2. Zipper-type collapse

Except for the initial failure of tension elements, the zipper-type collapse mechanism, Fig. *2*(c), is unconstrained. It is one of the common types of collapse because it can occur in almost any structural arrangement. Zipper-type collapse is usually distinguished by force redistribution into alternate paths, impulsive loading caused by sudden element failure, and static and dynamic force concentration in elements that will fail next. The propagating action caused by the failure of one element is the inverse of the force present prior to failure, acting as an impulsive loading at the point of failure. Unlike the pancake-type, impact forces are rarely encountered (Starossek, 2007).

1.1.3. Instability collapse

Instability-type of collapse mechanism, Fig. *2*(d), arises from the failure of stabilizing elements, leading to instability in load-carrying members. It starts with the loss of bracing or stiffening components, which destabilizes the primary members during compression. Small perturbations such as minor loads or imperfections, can cause destabilized members to collapse. Unlike other collapse mechanisms, instability-type does not always result in a cascading failure. However, in some cases, losing a single critical member, such as a truss leg, can cause immediate global collapse. Truss towers and pipelines are two examples where the failure of bracing elements may result in buckling or large deformations in the main structure. This form of collapse mechanism emphasizes the importance of maintaining stability through proper bracing and stiffness.

1.1.4. Section-type collapse mechanism

Section-type collapse occurs within the cross-section of structural elements such as beams or columns, and is characterized by progressive failure though stress redistribution. When a portion of a cross-section fails, the remaining section experiences an increase in stress which may exceed its reserve capacity, causing further rupture. This process continues until the entire cross-section is compromised. Section-type of collapse is analogous to zipper-type but confined to the scale of a single element. Examples include; weld or splice failures in steel or reinforced concrete components, where localized damage propagates through the section. This mechanism of collapse underscores the importance of uniform stress distribution and robust detailing to prevent localized weaknesses that might otherwise trigger a chain reaction of failure.

1.1.5. Domino-type mechanism

Domino-type of collapse, Fig. *2*(b), occurs when structural elements overturn sequentially, resembling the fall of a row of dominos. This mechanism commences with the overturning of one element, often triggered by horizontal forces such as winds, impact or an explosion. The falling element then strikes an adjacent component, transferring the horizontal forces that may cause it to overturn as well. This sequence continues, propagating a collapse horizontally through the structure. Domino-type collapse is extremely dynamic, this means that it involves the conversion of potential energy into kinetic energy, which magnifies the impact forces. An example of this mode of collapse is the cascading failure of overhead transmission towers, where the tension in connecting cables transmits forces that lead to the sequential toppling of towers. This type of collapse highlights the critical importance of lateral stability and robust connections between structural elements.

1.1.6. Mixed-type collapse

This type of collapse combines the features of multiple collapse mechanisms, creating a system of complex and unpredictable progression patterns. This mechanism often arises in real-world scenarios where structural systems have diverse load paths and interconnected components. For instance, a structure may exhibit features of pancake-type collapse such as vertical progression, alongside domino-type characteristics such as horizontal propagation through horizontal forces. Mixed-type collapse is indeed challenging to analyze due to the interplay of various forces and failure modes. An example is the Murrah Federal Building collapse, Fig. 1(b), where both vertical and horizontal forces contributed to the progressive failure. Mixed-type collapse underscores the need for comprehensive design approaches that account for multiple potential failure modes and their interactions.

1.2. Design philosophies of progressive collapse

Progressive collapse resistance involves designing structures capable of withstanding localized failures without undergoing catastrophic chain reactions. Since progressive failure mechanisms have catastrophic implications, design philosophies for progressive collapse resistance are a focal point of structural engineering research and practice. These philosophies have evolved over the years, shaped by incidents like the Ronan Point collapse (1968) and the World Trade Center attacks (2001).

The Unified Facilities Criteria code (UFC 4-023-03, 2009), alongside other guidelines like the U.S. General Services Administration code (GSA, 2016), provides detailed design philosophies and methodologies aimed at achieving this resilience. The integration of robust alternate path analysis, material optimization, and advanced performance-based methods continue to shape the field, ensuring resilient structural systems in the face of unforeseen disasters. These philosophies are central to structural engineering for mitigating progressive collapse occurrences. Some of the common and emerging progressive collapse resistance design philosophies include;

1.2.1. Alternate path approach

The alternate path method (AP) emphasizes structural redundancy, enabling load redistribution when a critical element is lost. This philosophy is widely applied in modern codes, including UFC 4-023-03 and GSA 2016. The approach involves simulating column removal scenarios, Fig. 4 to evaluate a structure's ability to form alternate load paths. Alternate path method ensures a robust load redistribution mechanism, preventing localized damage from escalating into global failure. In this philosophy, nonlinear dynamic analysis is commonly employed to test alternate path capacities. Several studies show that ductility and connection integrity are important factors that influence alternate path formation (Singh & Mohit Bhandari, 2024).

1.2.2. Enhanced local resistance approach

The enhanced local resistance (ELR) or specific local resistance approach (SLR), focuses at enhancing the resilience of critical elements to prevent initial failure. The UFC 4-023-03 code of practice, specifies reinforcement and detailing requirements for structural components prone to progressive collapse. This philosophy ensures components, such as columns and joints, are overdesigned to withstand abnormal loads. According to a number of studies, materials such as fiber-reinforced polymers (FRP) and high-strength steels are increasingly being used to improve component capacities (Kiakojouri et al., 2022). Furthermore, the numerical studies emphasize that increasing reinforcements in joints regions do facilitate mitigation of the initial failures that could otherwise propagate progressive collapse of a structure (Elkady et al., 2024).

1.2.3. Tie force approach

The Tie Force Method (TF) ensures structural elements are interconnected to maintain integrity under abnormal loads. The UFC 4-023-03 code mandates horizontal and vertical ties to sustain residual capacity after localized failures as shown in Fig. 3. Tie force method relies on developing continuous tension and compression ties through the structure. Studies like those of (Kiakojouri et al., 2022), do highlight the effectiveness of the tie forces approach in arresting the progressive collapse propagation especially in precast concrete structures.

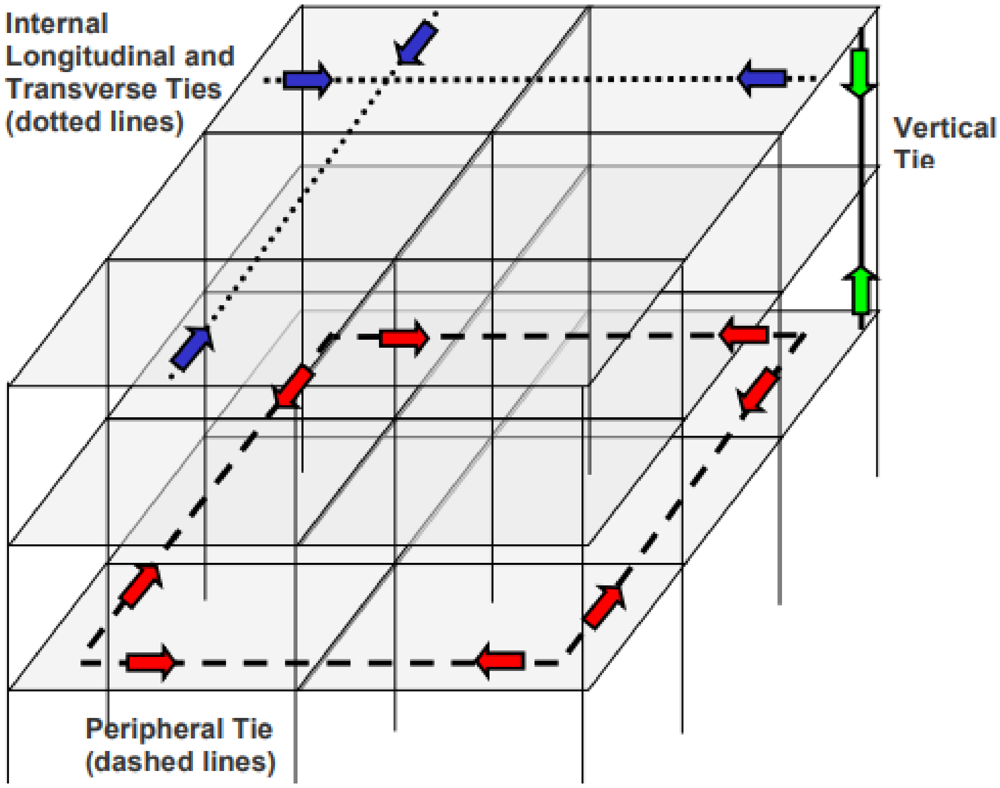

Fig. 3. Tie forces in a frame structure (UFC 4-023-03, 2009).

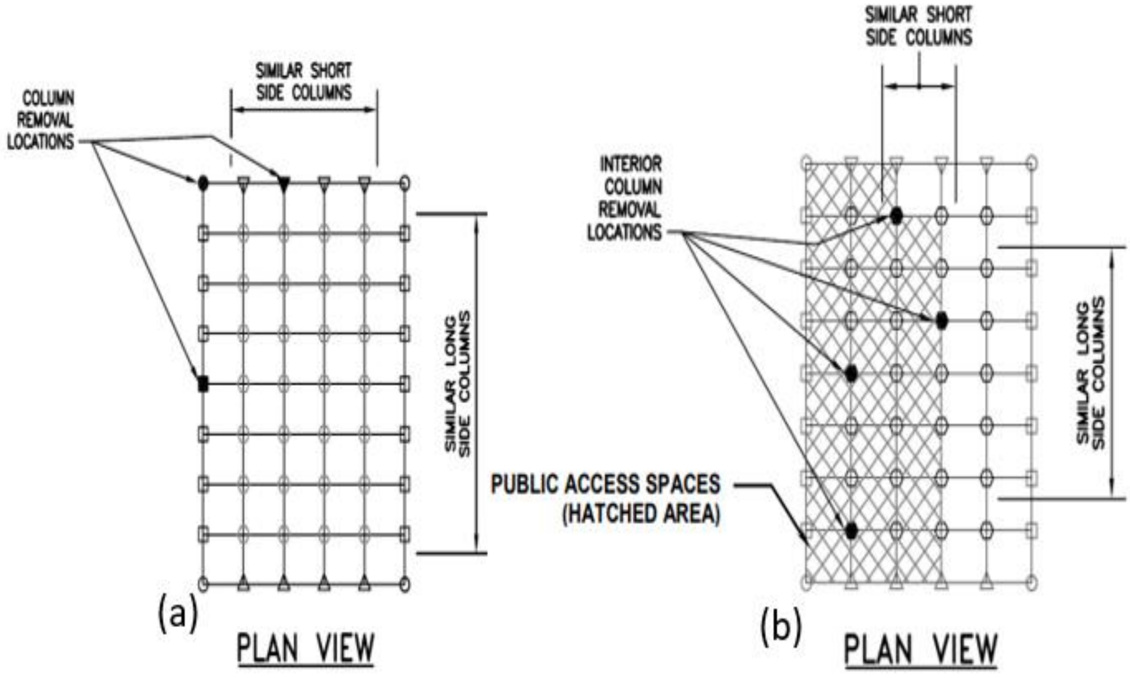

Fig. 4. Critical locations for column removal in AP approach (UFC 4-023-03, 2009).

1.2.4. The mixed design approaches

The Mixed Design Approach combines Alternate Path and Enhanced Load Resistance approaches to address both system-level and component-level vulnerabilities. The UFC 4-023-03 code, highlights the importance of this integrated strategy, particularly for large and complex structures. By addressing redundancy and local resistance simultaneously, the mixed approach ensures robust overall performance. Experimental observations indicate that that hybrid designs (such as those of prestressed joints combined with ductile reinforcements) out performs singular strategies (Singh & Mohit Bhandari, 2024).

1.2.5. Ductility-based design approach

The ductility-based designs aim to enable structures to undergo significant deformations without losing load-bearing capacity. The UFC 4-023-03's specifications emphasize ductility in beam-column joints which are critical for progressive collapse resistance. Studies indicate that connections with high ductility allow energy dissipation during extreme events. Moreover materials such as high-performance concrete (HPC) and shape memory alloys (SMAs) are being used to achieve high ductility in designs (Elkady et al., 2024). Additionally, the dynamic tests indicate that ductile designs significantly delay collapse onsets in structures (Singh & Mohit Bhandari, 2024).

2. The Turkish Earthquake Code (TEC) 2018 provisions for precast systems

The Turkish Earthquake Code (TEC, 2018), is a comprehensive guideline tailored for seismic resilience in building structures. Chapter 8 of this code specifically focuses on precast reinforced concrete (RC) buildings, addressing critical aspects like material properties, joint configurations, and diaphragm behaviors under seismic forces. While progressive collapse resistance isn't explicitly stated, many provisions in Chapter 8 indirectly may enhance a structure's capacity to prevent disproportionate failure after localized damage.

2.1. Precast RC structural elements and connections

The chapter begins with an overview of precast RC components and their connection requirements (section 8.2.1). Precast buildings are made up of factory-produced elements like beams, columns, walls, and slabs that are assembled on-site with mechanical or cast-in-place connections. The code explicitly highlights key provisions for two joint connections.

2.1.1. Moment resisting connections (MAB)

These connections are designed to transfer moments and exhibit ductile behavior under seismic and other extreme loads (Section 8.4.1). This ensures the structure retains its integrity during localized failures. The code specifies that these joints must sustain high moments without degradation ensuring stability under dynamic loads.

2.1.2. Pinned connections (MFB)

Primarily used in non-moment-resisting systems, pinned connections transfer axial and shear forces while minimizing rotations (Section 8.3.1). The friction forces at these connections are neglected, emphasizing the importance of mechanical stability. The shear capacity provided by the code for pinned connections is computed from the equation;

$$V_r = 0.7n\phi^2\sqrt{f_{cd}.f_{yd}} \quad (1)$$

Where V_r: shear capacity, n: number of joints, f_{cd}: compressive strength of concrete, f_{yd}: yield strength of pins, and ϕ: pin diameter.

The design emphasis on robust joint performance and load transfer mechanisms is essential for mitigating progressive collapse. The moment-resisting connections ensure that alternate load paths are maintained after an element failure, while the pinned connections provide stability against shear forces that could otherwise trigger disproportionate collapse.

2.2. Material specification

Section 8.2.3 of TEC 2018 defines the threshold material properties for precast elements and their connections. The C30 concrete quality class is mandated as the minimum grade, ensuring sufficient compressive strength to resist abnormal loads. Moreover, high-strength, non-shrinking grout (grout for connections) is required for joint connections. The code requires that the compressive strength of this grout be at least equal to that of the connected elements.

The code's specification for high-strength materials aims to reduce the risk of brittle failures, particularly at critical joints. By ensuring the grout's strength matches or exceeds that of the precast components, the code minimizes weak points that could compromise structural integrity during extreme events.

2.3. Ductility and redundancy requirements

The chapter emphasizes ductility in structural elements and connections, as describe in sections 8.2.2 and 8.4 of the code. The code highlights two possible ways on how ductility can be achieved in a structure: through detailing and redundancy.

2.3.1. Ductile detailing

The code specifies that columns, beams, and connections must be designed for high or limited ductility, depending on their roles in the structural system (Sections 7.3 and 7.7).

2.3.2. Redundancy

The code provision requires that behavior factors, denoted by (R), be assigned based on the ductility level and connection type to ensure sufficient redundancy in load distribution. Ductile detailing enables elements to deform without losing their load-bearing capacity. This is critical for maintaining alternate load paths after localized damage in a structure. Additionally, redundancy ensures that no single failure leads to a cascading collapse that might give rise to the collapse of the entire structure. The material behavioral factor, R, is generally given by an expression;

$$R = \frac{Q_u}{Q_d} \quad (2)$$

Where Q_u is the ultimate strength parameter, and Q_d is the design strength parameter.

Behavioral factor, R, ensures that structure has an adequate reserve capacity. Table 4.1 of TEC2018 provides a descriptive summary of these behavioral factors for easy application in analysis and design.

2.4. Dynamic and performance-based design

Section 8.2.2.3 of TEC2018 incorporates advanced performance-based analysis and design approaches;

2.4.1. Performance targets

The code requires that structures be evaluated for controlled damage under severe earthquakes (DD-1) and limited damage under moderate earthquakes (DD-3).

2.4.2. Nonlinear dynamic analysis

The code specifies this analysis requirement for critical components, considering load combinations beyond seismic forces.

Generally, the performance-based design evaluates structures for failure scenarios like column removal, aligning with global collapse mitigation standards.

2.5. Diaphragm and load transfer provisions

Section 8.6 of the TEC 2018 provides specific requirements for diaphragms in precast systems. These diaphragms are broadly discussed as composite and reinforcement diaphragms.

2.5.1. Composite diaphragms

The code describes these diaphragms as those that constitute of floor and roof, and must integrate precast and cast-in-place elements to ensure effective lateral force transfer.

2.5.2. Reinforcements

The code provides a specification that requires that, reinforcement ratios be such that they prevent separation or failure under seismic forces. By this specification, the code aims at emphasizing a rigid diaphragm that holds together all the frame elements they by enhancing the frame rigidity and collapse resistance. The general diaphragm shearing force is provided by a relation;

$$V_d = A_s . f_y \tag{3}$$

Where V_d denotes diaphragm shearing forces, A_s denotes the reinforcement area, and f_y denotes the yield strength of the reinforcements.

It is worthy to note that, well-designed diaphragms ensure strong connectivity between structural elements. This is a key factor in redistributing loads in cases of a primary element failure, a critical requirement for progressive collapse mitigation. Moreover, the integration of cast-in-place toppings improve the structural rigidity and continuity in precast structural systems.

3. The state of industrial infrastructure in Türkiye

The industrial infrastructure forms the backbone of the Türkiye's economic activities, encompassing manufacturing plants, warehouses, and logistical hubs. Precast concrete structures have increasingly gained prominence due to their efficiency, durability, and adaptability (Akduman et al., 2024; Arslan et al., 2024). These pre-fabricated systems align with the nation's rapid urbanization and industrialization goals. However, challenges such as seismic risks and adoption limitations continue to hinder their potential.

3.1. Overview of precast structures in Türkiye

Precast concrete structures are prefabricated components manufactured off-site and assembled on location, offering faster construction times and consistent quality. Türkiye has seen a consistent increase in the use of these systems, particularly in industrial projects, driven by their cost-effectiveness and resilience (Gumusburun Ayalp & Ay, 2021). Historical analysis highlights their evolution as a preferred choice for industrial facilities, especially in regions prone to rapid urbanization (Demir & Sezen, 2024). Despite their advantages, the adoption of precast concrete systems remain uneven across the country, often influenced by regional policies and economic factors.

3.2. Seismic resilience of precast structures

Seismic activity poses a significant challenge to Türkiye's industrial infrastructure. The devastating 2023 Kahramanmaraş earthquakes highlighted vulnerabilities in existing precast buildings. Studies reveal that industrial facilities with precast structural frameworks experienced varying levels of severe damage depending on design and construction quality (Arslan et al., 2024; Demir et al., 2024). Adopting advanced materials such as fiber-reinforced concrete and improving connection technologies are among the tremendous efforts that need to be made to improve the seismic performance of precast structures. Additionally, collaborative efforts between academia and industry continue to propose innovative solutions to reduce these risks and ensure structural integrity under seismic loads (Akduman et al., 2024).

Moreover, during the Kahramanmaraş earthquakes, joint failures and inadequate roof connections were frequently observed as reported by field studies (Sagbas et al., 2024). These failures underscore the need for enhanced joint detailing and dynamic performance evaluations in these infrastructures.

3.3. Challenges in adoption of precast structures

The adoption of precast systems in Türkiye faces several barriers. A 2021 study identified key limiting factors, including lack of technical expertise, regulatory constraints, and high initial costs (Gumusburun Ayalp & Ay, 2021). According to the authors, these difficulties are exacerbated by perceptions that prefabrication is a low-quality option, despite evidence to the contrary. In fact, a survey conducted by the authors revealed that 65% of Turkish contractors cite high initial costs as the primary barrier to precast adoption.

However, Government support and strategic policy interventions could address these barriers. For instance, incentives for precast manufacturing facilities and standardized building codes could enhance adoption rates. The available comparative studies from neighboring countries already demonstrate the economic and operational benefits of such policies (Ogaili & Abdulrahman, 2022).

3.4. Innovations and future trends

The recent advancements in precast technology demonstrate a promising revolutionary in the industrial construction sector of Türkiye. The integration of geopolymer concrete, a sustainable alternative to traditional materials, offers environmental and performance advantages (Akduman et al., 2024). Moreso, the incorporation of automation in the prefabrication processes has greatly improved precision and reduced labor dependency (Batalha et al., 2019).

Additionally, the precast systems are also exponentially gaining traction in disaster-resilient construction. Modular designs and demountable systems are being tested for their adaptability to post-disaster scenarios, ensuring continuity of operations in industrial facilities (Sagbas et al., 2024). According to a study by Batalha et al., (2019), advanced automation in precast manufacturing revolutionizes the industry by reducing human error and improving precision. According to the author, robotic assembly techniques have been shown to reduce production times by 25% while ensuring consistent quality (Batalha et al., 2019). These innovations are in a sync with the Türkiye's broader goals for enhancing infrastructure resilience and sustainability.

It is thus critical to note that, Türkiye's industrial infrastructure, supported by precast structures, has enormous potential for modernization and growth. While challenges such as seismic vulnerabilities and adoption barriers persist, ongoing innovations and policy support can transform the sector. By addressing these issues, Türkiye can harness the full benefits of precast systems, ensuring sustainable and resilient industrial development.

4. Conclusion

Progressive collapse remains a critical yet under-addressed vulnerability in Türkiye's precast industrial buildings, as starkly revealed by the 2023 Kahramanmaraş earthquakes. While the Turkish Building Earthquake Code (TEC) 2018 provides robust guidelines for seismic resilience – emphasizing ductility, joint integrity, and material strength, it lacks explicit provisions for mitigating cascading failures triggered by abnormal loads. This gap leaves structures compliant with TEC 2018 susceptible to disproportionate collapse, particularly in multi-hazard scenarios.

Key findings from this review highlight the unique risks posed by precast modular systems, such as their reliance on joint performance and susceptibility to pancake or zipper type collapse mechanisms. Although TEC 2018's focus on redundancy and dynamic analysis indirectly supports progressive collapse resistance, its omission of internationally recognized strategies like the Alternate Path (AP) method or Enhanced Local Resistance (ELR) approaches limits its applicability. Case studies from U.S. standards (UFC 4-023-03, GSA 2016) demonstrate that the hybrid design philosophies – integrating ductility, advanced materials (e.g., fiber-reinforced polymers), and performance-based analysis can significantly enhance resilience.

The implications of these findings are twofold. Theoretically, this work bridges the divide between seismic and progressive collapse engineering, advocating for multi-hazard design frameworks. Practically, updating TEC 2018 to address cascading failures could safeguard Türkiye's industrial infrastructure, reducing economic and human losses in future disasters. However, this study is limited by its reliance on post-earthquake observational data rather than experimental validation, and it does not fully address regional challenges such as barriers or uneven technical expertise in adopting advanced precast systems. To address these gaps and advance the field, the following recommendations are proposed:

- Revise TEC 2018 to incorporate progressive collapse mitigation strategies, including AP and ELR methodologies, with localized adaptations for Türkiye's industrial building typologies.
- Promote hybrid systems combining geopolymer concrete, demountable connections, and automation to enhance sustainability and multi-hazard resilience.
- Invest in empirical research, including large-scale testing of precast joints under combined seismic and abnormal loads, to refine performance-based design criteria.

Conclusively, as Türkiye continues to industrialize, harmonizing seismic and progressive collapse design principles is no longer optional, it is a societal imperative. By integrating global best practices and fostering innovation in modular construction, Türkiye can transform its industrial infrastructure into a model of resilience, ensuring that future seismic events become catalysts for advancement rather than catastrophe.

Abstract: Fires are catastrophic events that can severely degrade the seismic performance of buildings. High temperatures weaken concrete and steel, reducing their strength. This can lead to premature collapse and increased damage during earthquakes. The duration of the fire, the temperature reached, and the extent of structural damage all influence the seismic performance negatively. Ignoring the fire effects in seismic assessment can severely underestimate the risk and thus jeopardize safety. Unfortunately, some fire-damaged reinforced concrete buildings continue their service life without any repair or strengthening intervention. On the other hand, it is possible for reinforced concrete buildings to be reused safely if properly repaired or strengthened following a fire. Thus, accurate assessment of fire-damaged buildings is crucial to determine their remaining capacity and identify the need for strengthening or demolition. In this study, the seismic performance of a benchmark reinforced concrete building exposed to fire is examined according to the TBDY-2018, Turkish Building Earthquake Code, considering its nonlinear behavior. For this purpose, the structure is modeled considering the parameters defining the relationship of the material with temperature mentioned in TS EN-1992-1-2, structural fire design code, and using the temperature-time curve given in ISO-834, fire resistance tests code. The occurrence of fire on ground floor was considered and nonlinear static pushover analyses were performed considering the capacity losses of the structural elements under the influence of a typical 120 minute duration. The results of the seismic performance assessment are presented in comparison with the building condition that is not exposed to fire.

Keywords: Reinforced concrete building, Fire, Nonlinear structural analysis, Seismic performance assessment

---

1. Introduction

Reinforced concrete structures, like all other building types, have the potential to cause significant loss of life and property in the event of disasters if adequate fire safety precautions are not taken. Compared to the earthquake disaster, the phenomenon of fire is considered to have a higher probability of occurrence than earthquakes in terms of frequency. This is because the timing, intensity, and recurrence intervals of earthquakes, which are natural events, are less predictable compared to fires. In developed countries, the fire resistance of structures is mandated through building codes, similar to seismic resistance. This approach is considered an integral part of structural safety. Notably, in the aftermath of fires occurring in residential buildings, sometimes damaged structural elements are continued to be used without employing any repair or strengthening procedures. Such structural deficiencies can negatively impact the performance these buildings would exhibit during an earthquake.

Reinforced concrete structures demonstrate superior performance against fire compared to steel structures. The duration of this resistance, assuming the concrete has been properly cast, is directly related to the concrete cover thickness over the reinforcement. The primary reason for this is that steel material experiences sudden and significant losses in strength at critical temperatures. In this context, having sufficient concrete cover is critically important for assuring the fire safety of reinforced concrete structures. The methodology in this study is mainly adopted from Hacıemiroğlu (2014) with the primary exception that the seismic performance evaluations are made according to the current seismic building code, namely Turkish Building Earthquake Code, TBDY (2018).

2. Structural Modelling

2.1. Building geometry

In this study, a fire model for a structure (Figure 1) is developed, featuring four bays in both directions (6 meters between each axis) and a storey height of 4 meters. In this model, assuming a 120-minute fire occurred on the ground floor, the strength losses in the cross-sections were determined using the finite element method. The structure has a symmetric configuration with respect to both the X and Y axes. The column and beam elements have the same dimensions on each floor; the column dimensions are set as 50 cm x 50 cm and the beam dimensions as 40 cm x 50 cm. The concrete class is C25 (f_{ck}=25 MPa) and reinforcement steel class is S420b.

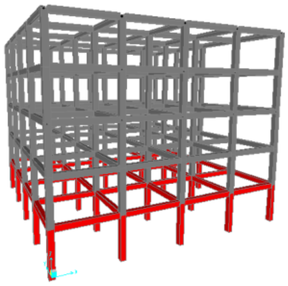

Fig. 1. 3D view of the benchmark building with ground floor affected by fire.

2.2. Fire scenario

The structural design of the existing building was performed assuming a concrete cover thickness of 2 cm for columns and beams. The seismic performance of the existing condition was compared with the seismic performance after a 120-minute fire resistance period. Nonlinear static pushover analyses were employed. The details regarding the scenarios considered are provided in Table 1.

Table 1. Details of the fire scenarios

Scenario#	Scenario Name	Fire Effect #	Cover for Column	Cover for Beam	Fire Duration (min)
1	With Fire	Ground Floor	2 cm	2 cm	120
2	Without Fire	-	2 cm	2 cm	-

2.3. Earthquake design parameters

The earthquake design parameters used in the design of the structural system designed according to TBDY-2018 are given in Table 2 where DD2 is the 475 year return period design earthquake level and F_s and F_1 are the soil influence parameters for local soil class ZC.

Table 2. Earthquake design parameters of the benchmark building

Building Use Class (BKS)	BKS = 3 – TBDY-2018, Table 3.1
Building Importance Factor (I)	I = 1.00 – TBDY-2018, Table 3.1
Spectral Acceleration Coefficients for DD2	$S_s = 1.223$ and $S_1 = 0.337$
Design Spectral Acceleration Coefficients for DD2	$S_{DS} = S_s \times F_s = 1.223 \times 1.2 = 1.468$ $S_{D1} = S_1 \times F_1 = 0.337 \times 1.5 = 0.506$
Earthquake Design Class (DTS)	for $S_{DS} = 1.468 > 0.75$ and BKS = 3 DTS = 1 – TBDY-2018, Table 3.2
Building Height Class (BYS)	for 17.5m < $H_N \leq 28$ m and DTS=1 BYS = 5 – TBDY-2018, Table 3.3

2.4. Loading details

The load per unit area of the external walls (20 cm thick and plastered) is calculated as 3.8 kN/m². This value for the internal walls (10 cm thick and plastered) is 2.5 kN/m². The additional load created by the plaster and coating layers on the surface of the structure is calculated as 1.5 kN/m². The live load is assumed as 5 kN/m² and the snow load that the structure may be exposed to is calculated as 0.75 kN/m². In addition to these loads, the self-loads from the self-weight of the elements are taken into account during the analysis. The reinforced concrete unit volume weight is accepted as ρ=25 kN/m³.

2.5. Change of material properties with high temperature

2.5.1. Change of concrete material properties with temperature
In order to reliably assess the behavior of structures under fire conditions, it is necessary to accurately determine the temperatures to which the constituent materials of structural elements are exposed during a fire and their material properties at these temperatures. Although concrete is classified as A1 class ('non-combustible') in terms of flammability, the high temperatures encountered during a fire and the duration of exposure to these temperatures may still cause significant changes in the mechanical, physical, and thermophysical properties of concrete. These effects become particularly pronounced at temperatures of 600°C and above. Currently, the effect of high temperatures on the reduction in compressive strength of normal and high-strength concrete is included in standards covering structural fire design principles. In these standards, the stress-strain relationships, physical, and thermal properties of normal strength concrete under high temperatures are expressed with different values and empirical relationships depending on the type of aggregate used (Yüzer & Özçiftçi, 2006). Furthermore, it is stated that the thermal properties defined for normal strength concrete can also be used for high-strength concrete. These standards, available for use by designers, also provide temperature distributions (temperature profiles) within structural elements depending on the exposure temperature and duration (Bingöl & Gül, 2009).

2.5.2. Change in concrete stress-strain curve
The change in the concrete stress-strain curve with temperature must be known to determine the load-bearing capacity of a structure after fire exposure and its behavior during an earthquake. The strength and deformation properties of concrete subjected to uniaxial compression at high temperatures are given in EN 1992-1-2:2023 as the stress-strain relationship for concrete made with siliceous aggregate. The stress-strain relationship of concrete is expressed with two parameters: the compressive strength $f_{c,\theta}$ and the corresponding strain, $\varepsilon_{c1,\theta}$. Linear interpolation is applied for intermediate temperature values. The stress-strain relationship for concrete subjected to compression at high temperatures is given in EN 1992-1-2:2023, Table 5.1. In the internal regions of fire-damaged elements, where the temperature has not changed, the material properties of concrete at normal temperature (20 °C) are taken as the values given for normal temperature design in EN 1992-1-1, Eurocode 2: Design of concrete structures. The change in the modulus of elasticity of concrete with temperature is obtained using the relationships regarding the change in the modulus of elasticity of concrete with temperature provided in EN 1992-1-2 (Eren & Gençoğlu, 2012).

2.5.3. Change of reinforcement steel properties with temperature
As a result of a research study in which the yield strength of reinforcement steel was tested, the yield strength loss curve showing the temperature-dependent change in yield strength, along with the condition of uninsulated reinforcement used in the high-temperature test before being exposed to high temperatures, have been shared. It is observed in the study that the yield strength losses of the steel material start to decrease after 300 °C, and this decrease is much more rapid in the uninsulated specimen (Ünlüoğlu, Topçu & Yalaman, 2007). Within the scope of this study, while utilizing the test results, the strength of the reinforcement steel in a non-corroded state were taken into consideration. The reason for this is that when calculating the temperature reached by the reinforcement of column and beam elements subjected to section analysis, the extent to which the ambient temperature raised the temperature of the reinforcement within the section over time was calculated.

2.5.4. Change of mechanical properties of reinforcement steel with temperature
Reinforcement steel temperature has been assumed to be equal to the concrete temperature at the depth of the reinforcement. The temperature values of the flexural reinforcement and stirrup reinforcement were calculated separately depending on the concrete cover thickness and the duration of fire exposure. It can be assumed that the density of the reinforcement steel, ρ_s=7850 kg/m^3, does not change at high temperatures (EN 1992-1-2:2023). The coefficient of thermal expansion of steel, α_s, has been calculated according to the equations given in EN 1992-1-2:2023 (Öztürk & Yavuz, 1995). The high-temperature value for the parameters related to hot-rolled and cold-worked reinforcing steel is given in EN 1992-1-2:2023. Within the scope of this study, parameters for cold-worked steel, which is widely used in Turkey, are included. The high-temperature steel strength and deformation properties are given as stress-strain relationships in EN 1992-1-2:2023, Table 5.2 and Table 5.3. The strain corresponding to the proportional limit $f_{sp,\theta}$ is expressed as $\varepsilon_{sp,\theta}$, the strain corresponding to the maximum stress level $f_{sy,\theta}$ is expressed as $\varepsilon_{sy,\theta}$ and the slope of the linear elastic part is expressed as $E_{s,\theta}$.

3. Material properties after fire effect
The temperature values reached by each 1 cm layer of concrete cover from the outermost layer inwards for column and beam elements exposed to fire effect were calculated using the software SAFIR and DIAMOND. When creating the finite element model in SAFIR (Gernay & Franssen, 2011), silica aggregate concrete with a compressive strength of 25 MPa and 3% water content was used. The density of concrete at normal temperature

was taken as 2500 kg/m³. In Figure 2, images showing the fire direction and temperature distribution for the column and beam cross-sections used for thermal analysis are shared, along with images demonstrating the layer-by-layer cross-section definition in SAP2000 and XTRACT software.

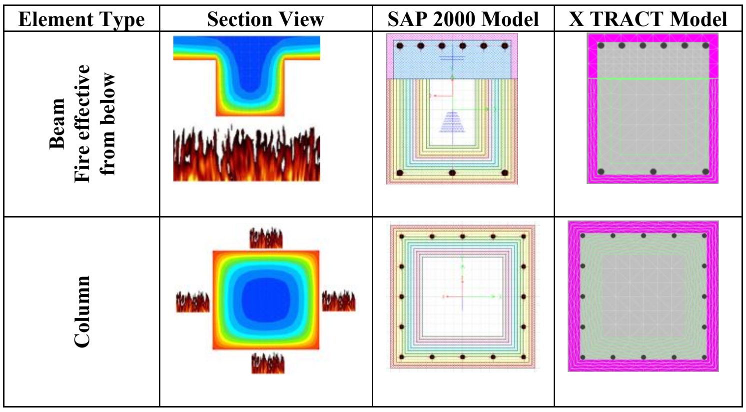

Fig. 2. Sample column and beam section fire model.

The column section with dimensions of 50 cm x 50 cm was defined in SAFIR with quarter symmetry. The time-dependent temperature change in the diagonal direction from the corner of the column is given in Figure 3.

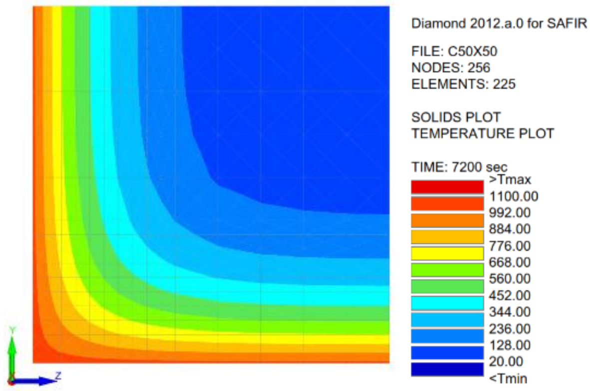

Fig. 3. Temperature change with time for a 50cm x 50cm column under fire effect for 120 minutes.

In order to calculate the confined concrete model of the elements exposed to fire, the concrete temperature was obtained from the outermost to the innermost. Depending on these temperature values, material properties were calculated for 1 cm layers. The values used for the columns are given in Tables 3 and 4.

Table 3. Temperature reached by each 1 cm concrete layer of a 50 cm x 50 cm column after a 120-minute fire and corresponding concrete mechanical properties.

4. Analysis

XTRACT v3.0.8 software (Chadwell, 2002) was used to calculate the plastic hinge properties of columns and beams required for nonlinear static pushover analysis.

4.1. Column section analysis

In the existing structural system, all column sections contain 16Φ16 longitudinal reinforcement and Φ10/10/20 four-legged stirrups. The hooks of the stirrups are arranged with a 135° bend as special seismic stirrups defined in TBDY-2018. Therefore, confinement effect is present in the columns. For use in nonlinear elastic analyses, yield surfaces under biaxial bending and axial force effects for column sections were obtained using XTRACT . After obtaining the yield surfaces for the columns, these values were defined in the axial load and biaxial bending hinges created in SAP2000 where, the yield surfaces were defined at 0 and 45 degree angles; 0 and 90 degrees are symmetrical. When assigning hinge properties in SAP2000, the axial load-moment interaction surfaces were defined as convex. After obtaining the yield surfaces for the columns, the demands obtained from the nonlinear analyses were compared with the strain capacities provided for each damage limit. Axial load-curvature diagrams were created to determine the performance of the structural system at the cross-sectional level. Using the considered strain capacities, axial force – total curvature diagrams were generated. The plastic hinge lengths of the columns were used in the analyses as half of the section depth in the direction of action, as defined in TBDY-2018. The plastic hinges were defined at the ends of the clear spans of the columns. The sample compressive strength – strain diagrams under different temperature effects for the confined and unconfined concrete models used in the column section analyses are presented in Figure 5. The plot showing the change in reinforcement steel property with temperature is given in Fig. 6.

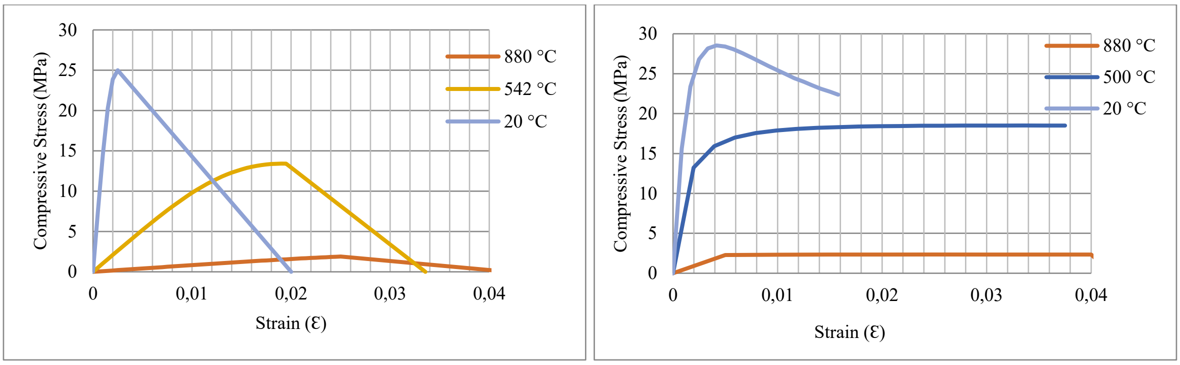

Fig. 5. (a) Unconfined concrete stress-strain plot for 50 cm x 50 cm column section (b) Confined concrete stress-strain plot for 50 cm x 50 cm column section

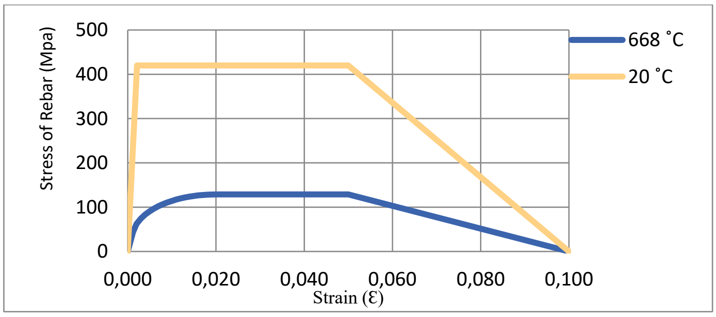

Fig. 6. Temperature-dependent stress-strain plot of reinforcement steel for a 50 cm x 50 cm column section

4.2 Beam section analysis

In the structural system of the building, all beams have dimensions of 40x50 cm but the reinforcement layout varies according to the beam types. The beam stirrups are specified as Φ10/10 for all beams and are designed as two-legged stirrups. It is assumed that the stirrup hooks are bent at 135° and are arranged as special seismic stirrups as defined in TBDY-2018. Therefore, capacity calculations have been performed assuming the presence of confinement effect in the beams. Moment-curvature relationships for the beam sections were obtained using XTRACT . The calculated moment-curvature analysis results were idealized and transferred to the SAP2000. The plastic hinge lengths of the beams were considered in the analyses as half of the effective section depth, as defined in TBDY-2018. Plastic hinges were defined at the ends of the clear spans of the beams. From the plastic rotation demands obtained in the final step of the pushover analysis, total curvature demands were calculated. From the moment-curvature relationship, the strain demands corresponding to the total curvature demand were found, and these values were compared with the strain capacities defined for each damage limit to determine the section damage level. For the confined and unconfined concrete models used in the beam section analyses, several different stress – strain plots under temperature effects for unconfined concrete are presented in Fig. 7(a). The plot showing the variation of reinforcement steel property with temperature is presented in Fig. 7(b).

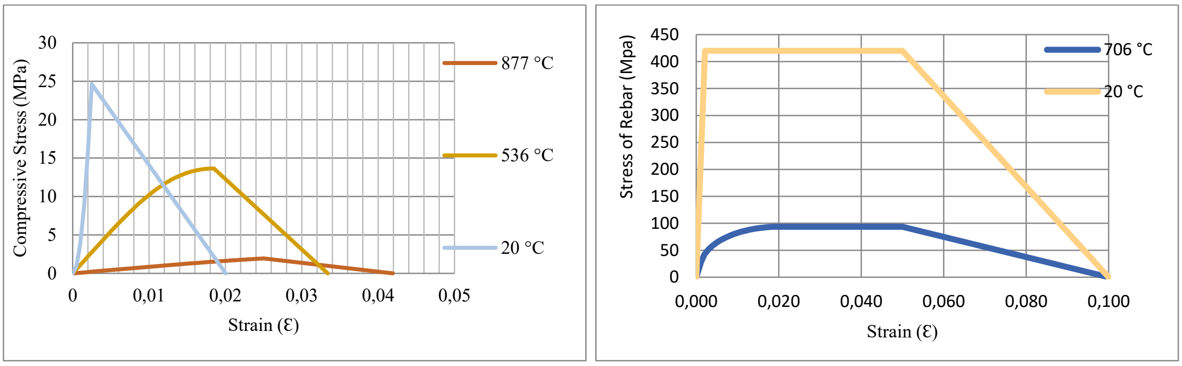

Fig. 7. (a) Unconfined concrete stress-strain plot of a beam section with dimensions 40cm x 50cm (b) Temperature-dependent stress-strain plot of shear reinforcement in a 40cm x 50cm beam

4.3. Nonlinear static pushover analysis

The definition of pushover analysis in TBDY-2018 is the performance under the effect of equivalent seismic loads that are monotonically increased step-by-step, proportional to the first (dominant mode) vibration mode shape, up to the seismic demand limit. In each step of the pushover analysis following the vertical load analysis, the displacements, plastic deformations, and internal force increments occurring in the structural system, as well as their cumulative values and the maximum values corresponding to the seismic demand in the final step, are calculated. To perform pushover analysis, it is first necessary to determine the lateral load distribution, i.e., the equivalent seismic loads, which will be gradually increased in the analysis. In SAP 2000, the distribution of equivalent loads at each story level was achieved by selecting modal analysis as the initial condition (Celep, 2007). The distribution of these loads is determined using the dominant mode shape amplitudes in the analysis direction of the building and the story masses. Changes occur in the dominant mode shape of the building due to the plastic sections formed during the pushover analysis. In this case, the load distribution is defined to be proportional to the value obtained by multiplying the mass associated with the first (dominant mode) natural vibration mode shape amplitude, calculated for linear elastic behavior at the beginning of the analysis. In buildings where floor slabs are idealized as rigid diaphragms, the amplitudes of the first natural vibration mode shape are considered as the two orthogonal horizontal translations at the center of mass of each story and the rotation about the vertical axis passing through the center of mass. According to TBDY-2018, there are conditions that must be met for the Incremental Equivalent Seismic Load Method to be used in pushover analysis. The buildings examined in this study are symmetric in plan in terms of both stiffness and mass. Therefore, torsional effects do not occur. The effective mass ratio of the first (dominant) vibration mode, calculated based on linear elastic behavior in the considered earthquake direction, to the total building mass must be at least 0.70. In analyzed scenarios, this ratio is in the order of 0.85.

4.4. Determination of effective bending stiffness ratios

The effective cross-sectional stiffness of columns and beams modeled according to lumped plasticity behavior were calculated according to TBDY-2018 as defined by Equations (1) and (2). These equations are calculated in relation to the effective yield moments of the plastic hinges at the member ends. M_y and θ_y represent the average of the effective yield moments and yield rotations of the plastic hinges at the ends of the bar element. L_s indicates the shear span, h indicates the section depth, Φ_y indicates the effective yield curvature at the plastic hinge section, d_b indicates the average diameter of the reinforcing steel anchored to the support, and f_{ce} and f_{ye} indicate the average compressive strength of concrete and yield strength of steel, respectively. According to TBDY-2018, η is taken as 1 in beams and columns. $(EI)_e$ is the effective section stiffness of columns and beams modeled according to plastic behavior and $(EI)_g$ is the gross section stiffness of columns and beams.

$$(EI)_e = \frac{M_Y}{\theta_Y}\frac{L_S}{3} \tag{1}$$

$$\theta_y = \frac{\Phi_y L_S}{3} + 0.0015\eta\left(1 + 1.5\frac{h}{L_S}\right) + \frac{\Phi_y d_b f_{ye}}{8\sqrt{f_{ce}}} \tag{2}$$

Table 7. Effective stiffness values of structural elements

	Element	Width m	Depth m	L_{net} m	L_s m	M_y kN.m	Φ_y 1/m	$(EI)_e/(EI)_g$
Ground Floor	Column	0.5	0.5	3.5	1.75	405	0.00765	0.19
First Floor	Column	0.5	0.5	3.5	1.75	376	0.00765	0.18

Note: The effective section stiffnesses of the beams with the same section size but five different reinforcement configurations.

4.5. Determination of target displacement

Performance points for the scenarios were determined based on the peak displacement - base shear force curves (pushover curve, capacity curve). The procedure for the determination of the building performance point that is explained in detail in TBDY-2018 is followed. For the Design Earthquake level with a 10% probability of exceedance in 50 years (DD2), the peak displacement demand was calculated. As a result of the structure being a frame system and the stiffnesses being significantly reduced, the dominant periods in the scenarios are calculated to be larger than that considered normal for a 5-story building. Given that the dominant periods are larger than the characteristic period of the earthquake, the equal displacement rule is valid. This allows the nonlinear spectral displacement to be taken as equal to the linear elastic displacement. Table 8 presents the calculated peak displacement values for the scenarios. The periods and consequently the peak displacement demands of the models analyzed based on the material properties of the elements exposed to fire effects show differences. T_x represents the natural vibration period of the first mode, Φ_{Nx1} represents the amplitude in the x direction of the variable mode shape, which is updated with free vibration analysis at each pushover step at the N^{th} story, Γ_{x1} represents the modal participation factor calculated based on the fixed mode shape determined in the first pushover step for the earthquake direction and not changed throughout the pushover analysis, M represents the mass, C_r represents the spectral displacement ratio, and u_{Nx1} represents the displacement calculated at the top of the building in the x-axis direction at the pushover step for the earthquake direction.

Table 8. Target displacement calculation table for scenarios.

#	Scenario Name	T_x sec.	Φ_{Nx1}	Γ_{x1}	Ɣx %	$\sum M$	Cr	u_{Nx1} m	$V^{(i)}_{x1}$ kN
1	With Fire	2.790	0.0221	58.85	0.884	4023	1	0.349	3415.9
2	Without Fire	2.795	0.0233	58.85	0.885	4023	1	0.311	4093.0

The obtained nonlinear spectral displacement values are equal to the modal displacement demand. The modal displacement demands calculated for the equivalent single degree of freedom system are converted to the peak displacement demand of the multiple degree of freedom system through appropriate coordinate transformation. The peak displacement demands for the X-direction of the building are given in Table 8. These obtained values were transferred to SAP2000, and each scenario's analytical model was pushed up to the calculated displacement demand. In the final step, some results pertaining to all demand magnitudes obtained at the last step were examined.

5. Results

The results of the analyses presented in this section have been evaluated under two main headings. Firstly, the general results were examined, covering the findings for two scenarios and a comparison of these findings. Secondly, the focus was on element-level results, and within this scope, a comparison was made between the internal forces developed in beams and columns and the capacities specified in TBDY-2018. These results, obtained using the nonlinear incremental pushover method, are presented for the current state of the structure and the defined scenarios. The obtained data were compared in Figure 8 through base shear force-roof displacement relationships and modal capacity curves.

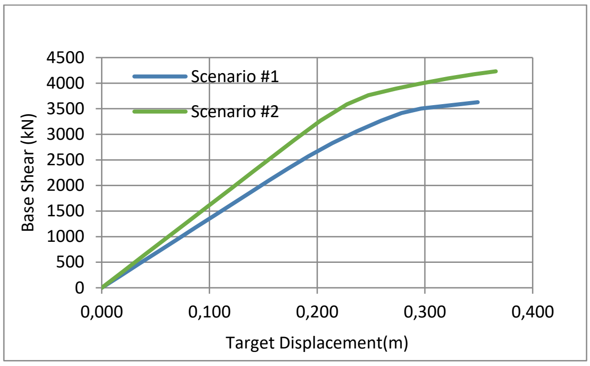

Fig. 8. Base shear force-peak displacement curves of scenarios

In the plots above, the base shear forces at the final stage of the static pushover analysis are compared for the existing condition and the fire condition. In cases affected by fire, the decrease in structural stiffness can be explained as a corresponding decrease in the lateral load-carrying capacity of the system. The reason for this reduction is the loss of material strength due to the effect of fire, and consequently, the formation of plastic hinges at lower deformations compared to the existing condition. On the other hand, the decrease in the stiffness of structural elements due to the fire effect increased the target displacement value by approximately 12% compared to the existing condition.

Based on the conducted analyses, the plastic strain demands on column elements were compared with the defined deformation capacities for various damage limits. According to the results of the uniaxial pushover analysis, almost all columns on all floors of the building are in the Limited Damage (LD) range for original state, i.e. Scenario 2. In Scenario 1, representing a fire on the ground floor, it is observed that all columns transition from the Limited Damage to the Controlled Damage (CD) range.

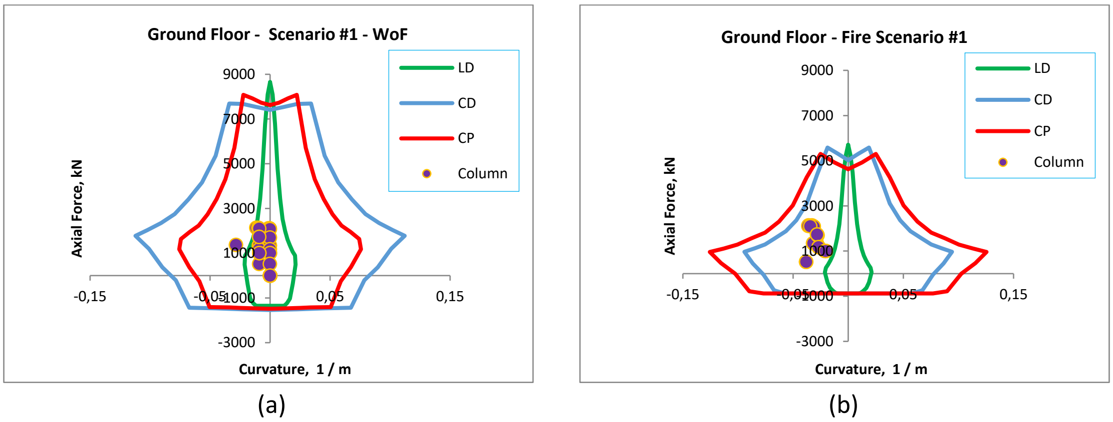

Fig. 9. (a) Ground Floor Column Results Scenario #2 (b) Ground Floor Column Results Scenario #1 (Note: LD-Limited Damage, CD-Controlled Damage, and CP-Collapse Prevention).

6. Conclusions

The analysis results presented in this section were obtained using the nonlinear static pushover method and compare the effects of different fire scenarios on the global and structural element behavior of an existing structure with the capacities specified in TBDY-2018. The overall results indicate that a fire occurring on the ground floor causes significant reductions in base shear force and a decrease in structural stiffness, thereby reducing the lateral load bearing capacity. At the component level, it was concluded that columns which were initially in the limited damage zone were transitioned to the controlled damage zone as a result of the ground floor fire.

In light of the results obtained from this study, further studies will be conducted considering fire conditions on different floors, different concrete cover, and different fire durations.

Investigation of the effect of different wall layouts on B1 irregularity in buildings

Abdulkadir Solak[*1], Amissou M. Pamom[1], Mehmet Kamanlı[1]

[1] *Konya Technical University, Department of Civil Engineering, 42250, Konya, Türkiye*

Abstract. Infill walls can be partially or completely removed at different floor levels of reinforced concrete framed structures for a variety of reasons, including architectural requirements. However, this can have a substantial impact on the seismic behaviour of the structure, potentially leading to irregularities in the stiffness distribution (B1 type). The present study was conducted with the objective of quantitatively evaluating the effects of different infill wall arrangements on the structural performance, with a particular focus on analysing the risk of soft story irregularities. In this study, an 11-storey reinforced concrete frame structure is modelled in accordance with the TS500 and TBEC-2019 standards. A total of eight distinct configurations were analysed in this study, representing partial or complete removal of infill walls. These configurations were analysed using ETABS v22, a software program designed for structural analysis and design. The structural parameters analysed in this study included foundation period, base shear, displacement and soft story irregularity coefficient (ηki). The findings indicated that the implementation of infill walls resulted in an augmentation of structural stiffness, consequently diminishing the necessity for foundation periods and, in certain instances, precipitating an escalation in roof displacements. The findings emphasise the importance of incorporating infill walls into the design process and suggest that additional measures should be implemented when infill walls are removed in successive storeys.

Keywords: Infill wall; Reinforced concrete structures; ETABS; B1 irregularity; Soft story

1. Introduction

Advances in construction technology, innovations in material science and accumulated experience in engineering-architecture disciplines have resulted in structural system designs and structural planning solutions which are becoming increasingly diversified. In buildings of differing architectural design and constructed for different purposes, non-bearing infill walls are not applied at different floor levels due to architectural requirements. It is a common occurrence to observe the presence of commercial units situated on the ground floors of various buildings within the built environment (Fig. 1).

In addition to these cases, there are many structures in which the infill walls of the structure are damaged even if the structural system is not severely damaged by the earthquake effect. (Fig. 2) In case of damage to the infill walls, the infill walls will be dysfunctional in load transfer in new earthquake conditions that will affect the structure.

In engineering design, the contribution of infill walls to the stiffness of reinforced concrete framed buildings is often overlooked. The primary factors contributing to this oversight can be attributed to the intricacy and challenge inherent in the development of calculation models that encompass the contribution of infill walls. This complexity arises from the absence of standardised calculation methodologies to evaluate this contribution at the project design stage. Additionally, the exclusion of the infill wall effect from calculations is driven by a desire to maintain a cautious approach, thereby ensuring safety (Sayın, 2003). However, infill walls are widely used in both interior and exterior sections of reinforced concrete structures. These walls are important structural elements that separate the building from the external environment and provide the creation of architecturally different spaces (Luo et al., 2024). Despite their classification as non-structural elements, they contribute to the structure's energy absorption capacity and stiffness by working in conjunction with the frame under earthquake loads.

Fig. 1. Designs without infill walls at different floor levels

The effect of infill walls makes it necessary to produce solutions that will both meet architectural requirements and comply with engineering design principles. In the literature, there are many theoretical and experimental studies investigating the effect of infill walls on structural behaviour (Korkmaz and Ucar, 2006; Tekin et al., 2007; Balık, 2012). Mainstone (1974) proposed the method of equivalent pressure bars to facilitate the analysis of frames with infill walls and developed various formulations to calculate the widths of these bars. Sivri (2003) showed that infill walls increase the stiffness of the structure and reduce the structural period and lateral displacements. Smith (1962) showed that the lateral stiffness and strength of frames with infill walls depend on the wall dimensions, physical properties and contact length with the column. Similarly, Beklen (2009) stated that infill walls have significant effects on parameters such as stiffness, period, horizontal displacement and base shear force and directly affect building behaviour.

This study was carried out to investigate the effect of infill walls on building behaviour in more detail. An 11-storey framed building with sections dimensioned in accordance with TS500 and Turkish Building Earthquake Code (TBEC-2019) is modelled in ETABS v22 analysis software. These analyses were carried out in order to understand the contribution of infill walls to building performance and to make more informed decisions in design processes.

Fig. 2. Collapse of infill walls on some floors under earthquake effect (Kamanli et al., 2023)

2. Materials and methods

In this study, a reinforced concrete frame structure with ground + 11 normal storeys is analysed. The characteristics of each analysed building model are given in Table 1. The structure and structural system elements are dimensioned in accordance with TS500 and Turkish Building Earthquake Code (TBEC-2019). C25 concrete class and S420 reinforcement class were used in material definitions. The soil class was determined as ZC. As a result of the equivalent earthquake analysis, the elastic first mode natural vibration period of the 11-storey solid frame was calculated as T1=1.309 s.

In the design and modelling, all storey heights were taken as 3.00 m, except for the ground floor with a height of 3.5 m, for the structures whose section plans are given in Figure 1 (a-h). Slab thickness is 12 cm, beam dimensions are 25x40 cm and column dimensions are 30x45 cm. Table 1 shows the different building models (Types) and Figure 3 shows the geometry of the structure in plan.

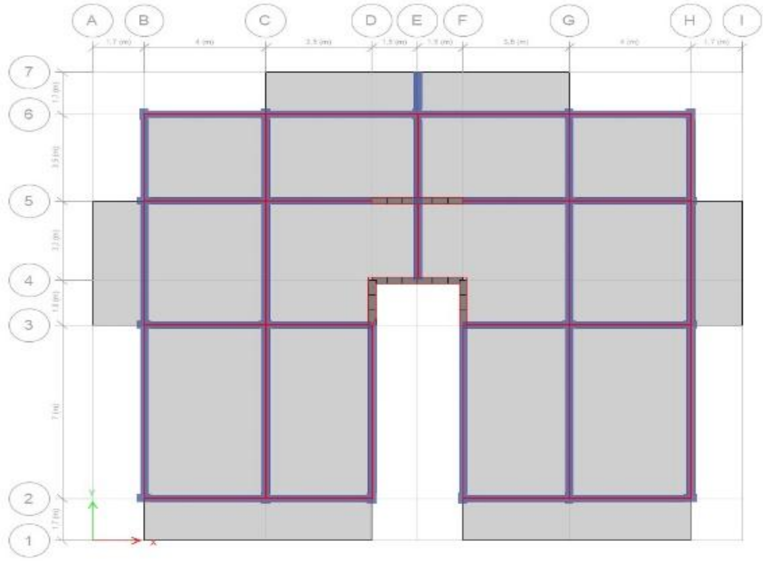

Fig. 3. Plan of the building

The frame system has been designed to exhibit a high level of ductility, with the behaviour coefficient of the structural system set at R=8 for bond beam shear walls in the Y direction and R=7.5 for hollow walls in the X direction. In the process of dimensional analysis, the live load of 2 kN/m² was applied to slabs and 5 kN/m² to balconies. These values were derived from the live load table, which is specified in TS498 [ts498] and is based on the intended use of the building. Panels with a thickness of 20 centimetres were modelled to represent the infill wall, whereas 20 centimetres was taken for both interior and exterior walls.

In the study, parameters such as periods, earthquake shear forces, displacements, relative storey drifts and soft storey irregularities of the structures under the same earthquake effect, by removing the infill walls at different floors, were evaluated separately for each case.

3. Results and discussion

3.1 Investigation of period changes

The analysis results indicate that the configuration of infill walls exerts a substantial influence on the structural period. The fully infilled system (Type 1) demonstrates the most rigid behaviour, exhibiting a period of 1.309 s. In contrast, the completely wallless configuration (Type 8) exhibits a period value of 2.134 s, which is the highest observed. These findings are consistent with the fundamental period formula relationship expressed in Hooke's Law (Westergaard, 1952). In cases involving the removal of walls in a single floor (Type 2, Type 4, Type 6), the observed period increase remained within the range of 7-12%. In contrast, the configuration involving three consecutive floors without walls (Type 3) resulted in a substantial period increase of 34.5%. The elimination of all barriers (Type8) resulted in a significant surge of 63% (Table 2).

Table 1. Structure models

Model	Configuration Image	Description	Model	Configuration Image	Description
Type 1		Full infill: All stories have infill walls	Type 5		8th-11th stories infills removed
Type 2		Ground story infills removed	Type 6		6th story infills removed
Type 3		Ground + first 2 stories infills removed	Type 7		4th-7th stories infills removed
Type 4		11th story infills removed	Type 8		Bare frame: All infills removed

Table 2. Period values and rates of change

Model Type	Periyot (s)	Change (%)
Type1	1.309	Reference
Type2	1.459	+11.5
Type3	1.760	+34.5
Type4	1.400	+7.0
Type5	1.440	+10.0
Type6	1.463	+11.8
Type7	1.617	+23.5
Type8	2.134	+63.0

3.2. Distribution of base shear forces

An analysis of the base shear forces acting on the structure revealed that the fully filled system (Type 1) yielded a maximum shear force of 1534.15 kN, while the wallless configuration (Type 8) generated a 6% lower shear force of 1445.18 kN. In alternative wall configurations, it was observed that the distribution of the base shear forces occurring in the structure was at a lower level (Table 3).

Tablo 3. The maximum earthquake shear forces

Model Type	Shear Force (kN)	Change (%)
Type1	1534.15	Reference
Type2	1512.82	-1.4
Type3	1499.31	-2.3
Type4	1511.72	-1.5
Type5	1498.82	-2.3
Type6	1512.96	-1.4
Type7	1499.21	-2.3
Type8	1445.18	-5.8

3.3. Total deformation

According to the peak displacements of the structure, the maximum displacement, which was 57.31 mm in the reference system, reached 117.24 mm (104.7% increase) in the configuration without walls. The variation in floor levels where the walls are not present has been shown to significantly affect the peak displacement value. For instance, the wall-less configuration near the ground floor (Type 2) resulted in an 11.8% increase in displacement, the wall-less configuration in the middle floors (Type 6) resulted in an 8.0% increase in displacement, and the wall-less configuration in the upper floors resulted in a 4.9% increase in peak displacement (Type 4). The findings of this study demonstrate that the storey level of the wallless floors exerts an influence on the deformation behaviour of the structure (Table 4).

Table 4. Maximum displacement values

Model Type	Max. Displacement (mm)	Change (%)
Type1	57.31	Reference
Type2	64.07	+11.8
Type3	75.38	+31.6
Type4	60.10	+4.9
Type5	66.00	+15.2
Type6	61.90	+8.0
Type7	72.70	+26.9
Type8	117.24	+104.7

3.4. Soft storey irregularity analysis

Although the Type B2 Coefficient of Irregularity (Soft Storey) specified as

$$\mathrm{\eta ki} = (\Delta \mathrm{i}(X)/\mathrm{hi})\mathrm{ort}/(\Delta \mathrm{i} + 1(X)/\mathrm{hi} + 1)\mathrm{ort} > 2.0 \tag{1}$$

$$\mathrm{\eta ki} = (\Delta \mathrm{i}(X)/\mathrm{hi})\mathrm{ort}/ (\Delta \mathrm{i} - 1(X)/\mathrm{hi} - 1)\mathrm{ort} > 2.0 \tag{2}$$

in TBEC-2019 was achieved in all models, the models with wallless configuration in the middle floors (Type6-Type7) gave the closest results to the limit value with ηki = 1.279-1.450. In the ground floor wallless case (Type2), ηki = 1.185. These findings indicate that the risk of soft storey formation should be carefully evaluated, especially in wall removal operations in the middle floors (Table 5).

Table 5. Soft story irregularity coefficients

Model Type	ηki
Type1	1.204
Type2	1.185
Type3	1.186
Type4	1.102
Type5	1.187
Type6	1.279
Type7	1.450
Type8	1.195

The findings of this study provide quantitative evidence for the critical effect of infill walls on structural behaviour. The findings of the present study demonstrate that the presence of walls exerts a direct influence on the stiffness of the structure. It has been observed that the effect of wall configuration on shear force distribution is limited. With regard to displacement behaviour, it is understood that the location of the wall-less floors is decisive on the structural performance. It is imperative that the soft storey irregularity coefficient is subjected to meticulous analysis, with particular emphasis on its manifestation in the middle storeys of wallless configurations. The results of all analyses obtained from this study are presented in Table 6.

Table 6. Comparative analysis results for all models

Model Type	Period (s)	Shear Force (kN)	Max. Displacement (mm)	ηki
Type1	1.309	1534.15	57.31	1.204
Type2	1.459	1512.82	64.07	1.185
Type3	1.760	1499.31	75.38	1.186
Type4	1.400	1511.72	60.10	1.102
Type5	1.440	1498.82	66.00	1.187
Type6	1.463	1512.96	61.90	1.279
Type7	1.617	1499.21	72.70	1.450
Type8	2.134	1445.18	117.24	1.195

4. Conclusions

All papers must include a Conclusions section. The main findings of the study must be given there. Bullets must In this study, the effects of different infill wall configurations on the structural behaviour of an 11-storey reinforced concrete frame structure are evaluated. The results of the analyses can be summarised as follows:

- Inclusion of infill walls in the structure causes a significant decrease in the structural periods. Especially in completely unfilled systems, longer period values occur compared to fully filled systems.
- The absence of infill walls in more than one consecutive storeys has more adverse effects than the wallless configurations in single storeys and significantly reduces the stiffness of the structure.
- The storey level at which the wall-less configuration is located influences the dynamic characteristics of the structure. Wall-less configurations at upper storeys show more limited effects compared to lower storeys.
- Infill walls have a limited effect on the shear force distribution of the structural system.
- The absence of infill walls increases the horizontal displacements in the structure. Especially the configurations without walls in the lower storeys cause larger displacements than the upper storeys.
- In terms of soft storey irregularity, all configurations are within acceptable limits, but especially the wallless configurations in the middle storeys are found to reach values closer to these limits.

The findings indicate that the impact of infill walls on the structural system should not be disregarded. It is imperative to note that the absence of walls, particularly in lower and consecutive floors, has the potential to adversely impact the seismic performance of the structure. Consequently, the implementation of supplementary engineering measures is crucial in designs involving such configurations. Moreover, it is imperative to enhance the prevailing analysis methodologies so as to more accurately depict the behaviour of infill walls in structural analyses, with a view to ensuring structural safety.

Effects of seismic isolators on the structural behavior of reinforced concrete buildings

Hacer Tülen*[1], Hakan Öztürk[2], Hilal Meydanlı Atalay[1]

[1] Kocaeli University, Department of Civil Engineering, 41001 Kocaeli, Türkiye
[2] Sakarya University, Department of Civil Engineering, 54050 Sakarya, Türkiye

Abstract. Seismic force is a critical parameter in the design and performance evaluation of buildings. In the field of earthquake engineering, seismic isolators, which are developed to reduce structural damage and enhance the seismic performance of buildings, are increasingly used in modern building systems. The primary function of seismic isolators is to reduce the seismic forces acting on a building by increasing its natural period of the building. In this study, it is aimed to investigate the effect of the use of seismic isolators on the structural behavior of reinforced concrete buildings with varying period. For this purpose, five-storey, seven-storey and nine-storey reinforced concrete frame systems without irregularities, selected to change the mass, were designed in accordance with the 2018 Turkish Building Earthquake Code (TBEC-2018). Six models were established to evaluate the seismic performance of buildings under different support conditions. Structural analyses were performed using the linear time history analysis method and 11 different ground motion records were selected to compare the effects of different scaling methods on the structural response. Simple and geometric scaling methods were used to scale these records in accordance with the spectral matching criteria specified in TBEC-2018. Both horizontal components (X and Y directions) of each scaled earthquake record were applied to the structural models and linear time history analyses were performed. The results of the analyses were compared in terms of building period, roof displacement ratio and story acceleration. The results show that the use of seismic isolators positively affects the seismic behavior of buildings and significantly reduces the story acceleration.

Keywords: Seismic isolators; Reinforced concrete buildings; Scaling method; Time history analysis; Seismic performance.

1. Introduction

Earthquakes in the past years have caused loss of life and economic losses. This situation has given rise to the concept of earthquake-resistant structural design.There are two approaches to earthquake-resistant structural design. The traditional method aims to reduce structural damage and to have the damage occur in the predicted places.The implementation of seismic isolation aims to increase the structural period and improve the overall seismic performance of the structure. Rubber isolators and friction surface isolators are frequently used in seismic isolation systems (Meral,2021). The effects of seismic isolation systems on structures behavior have been addressed by many researchers for various parameters. The effect of the use of isolation systems in regular and irregular buildings on the structural behavior was examined by Özer (2022), Öztürk (2022) and Meral (2021). Türk (2019) investigated the effects of different isolator types and number of stories on the behavior and stated that structures with seismic isolators become safe. Özkan et al. (2023) investigated reinforced concrete buildings with varying ground storey heights and number of stories, and reported that interstory drifts were significantly reduced in seismically isolated structures.

Codes recommend that analyses of structures with isolators be performed in the time history. There are various criteria in determining the earthquake records to be used. In TBEC-2018, regarding scaling, the condition that the average of the resultant horizontal spectrum values of the earthquake record should be greater than 1.3 times the design spectrum in the specified period range is included. No details are given regarding the method to be used in scaling the earthquake records. The effect of the scaling method on the structures behavior has been studied by many researchers. Shome et al. (1998) adopted the concept of scaling ground motions by matching the spectral acceleration of the structure's target spectrum. However, there are many parameters affecting the structures period, a scaling method has been developed within a specific period range. Stewart et al. (2001) and Huang (2008) used

https://doi.org/10.31462/icearc2025_ce_eqe_883

the geometric mean scaling method in their studies.When determining appropriate scaling factors for earthquake records, it is recommended that the scale factor not be greater than 4. In the literature, studies related to scaling often consider structures with fixed-base supports. However, studies conducted for isolator structures are limited. When examining the effect of changing the number of stories on the behavior of the structure in isolator structures, a single scaling method is often used. In this study, building models with 5, 7 and 9 storeys fixed supports and lead core rubber isolators were subjected to linear analysis in the time history using earthquake records scaled with two different methods. As a result of the analysis, structures periods, roof displacements ratio and story acceleration values changes were examined.

2. Material and methods

In this study, the changes in the behavior of reinforced concrete structures with a fixed and isolated base depending on the story height and the earthquake record scaling method were investigated. The buildings were modeled as 5, 7 and 9 storeys and the floor heights were determined as 3 m. The plan area was kept the same for all buildings. The buildings were designed in accordance with the design principles in TBEC-2018. Building models consist of a typical column-beam system. The bay spacing in the X and Y directions were chosen as 4 m. In the load-bearing system, all column sections are 45x45 cm, beam sections are 25x50 cm, and the floor thickness is 15 cm. The plan used in all buildings is given in Figure 1 and the 3D view of the 7-storey building is given in Figure 2. In all structures, the concrete compressive strength is defined as 25 Mpa (C25) and the yield strength of the reinforcement is defined as 420 Mpa. A rigid diaphragm was defined at every story in all models. The dead and live loads on the slabs were considered as 3.75 kN/m^2 and 2.0 kN/m^2 (1.5 kN/m^2 on the upper floors), respectively. A load of 4.5 kN/m was applied to the beams as infill wall load, except for the beams located on the roof floor. SAP2000 that is a structural analysis program was used in modeling and time history analysis of buildings.

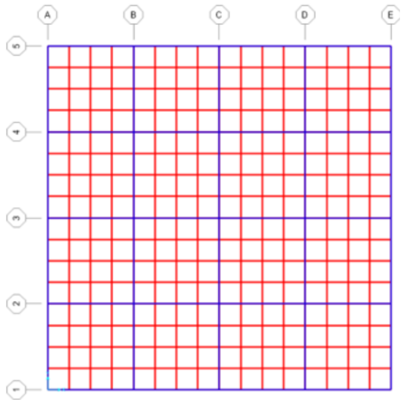

Fig. 1. Plan for all buildings

2.1. Lead rubber bearings

Lead-core rubber bearings are commonly used to improve structural behavior. These isolators are created by combining rubber and steel plates. İn addition to, there is one or more lead cores in its center. The lead core provides the necessary damping (Komodromos, 2000). A representative image of the isolator and the force-displacement relationship are given in Figure 3. The design parameters used for the isolated building models are given in Table 1.

Fig. 3. (a) Lead rubber bearing (Özpalanlar, 2004), (b) Force-displacement relationship (TBEC,2018).

Table 1. Design parameters of models with isolators

Parameters	5 storey	7 storey	9 storey
Shear modulus (Mpa)	0.5	0.5	0.5
Lead core diameter (mm)	140	160	175
Rubber diameter (mm)	850	950	1000
Total rubber layer thickness (mm)	336	336	312
Post-yield stiffness (kN/m)	821	1024	1220
Post-yield stiffness / Elastic stiffness	0.1	0.1	0.1
Effective yield strength (kN)	154	201	240
Elastic stiffness (kN/m)	1083	1350	1573

2.2 Scaling of earthquake ground motions

In the study, the reinforced concrete building models were subjected to linear time history analysis. It was assumed that the buildings were located in Kocaeli and the soil class was determined as ZC. In selecting the earthquake records in determining, a moment magnitude (M_w) of the earthquake records was chosen between 6.5 and 7.6, a distance to the fault rupture(R) between 0 and 20 km, and a shear wave velocity in the top 30 meters of soil between 180 and 360 m/s were considered. These parameters affect the analysis sensitivity. Eleven earthquake record sets in the analyses were selected through the Pacific Earthquake Engineering Research Center (PEER) database. Selected records are given in Table 2.

In the study, the resultant horizontal spectrum was determined by taking the Square Root of the Sum of the Squares of the two horizontal components (SRSS) of each earthquake. The method in which the scale coefficient is determined according to the design spectrum is determined as the first method. As the second method, the geometric mean scaling method developed by Huang et al. (2008) was used. It was investigated how the scaling method affects the behavior of isolator structures with different number of floors. In the first method, the horizontal components of each earthquake are determined. The horizontal spectrum is obtained by taking the square root of the sum of the squares of the horizontal components. The average of the combined horizontal spectra of all records is taken. The scale factor is determined by harmonizing the obtained combined spectrum with the horizontal design spectrum. In the geometric mean scaling method, first the horizontal components of the selected records are determined and the resultant horizontal spectrum is created by taking the geometric mean. In order to minimize the difference between each resultant horizontal spectrum and the design spectrum, the amount of error is calculated and the first scale factor is determined. In the next stage, the horizontal spectrum is obtained by averaging the root mean square sum (SRSS) of the spectrum curves scaled by the first scale factor. The compatibility between the design spectrum and the resultant spectrum is examined, and the second scale factor is determined. The final scale factor is determined by multiplying the two scale factors. For scaling, DD-1 earthquake ground motion was taken into account. Scaling coefficients were calculated for a 3 s period in the range of $0.5T_m$-$1.5T_m$. The scaling of both horizontal components is used with the same scale coefficients.

Table 2. Information and scaling coefficients of earthquake records

Earthquake No	Earthquake Name	Station	M_w	R (km)	Component	ScaleFactor M1	ScaleFactor M2
1	Imperial Valley	El Centro Array #4	6.5	7.1	230 140		3.36
2	Imperial Valley	El Centro Array #6	6.5	1.4	230 140		2.1
3	Chi-Chi	CHY101	7.6	9.94	E N		2.3
4	Chi-Chi	TCU110	7.6	11.6	E N		2.07
5	Chi-Chi	TCU065	7.6	0.6	E N		1.58
6	Kobe	Takatori	6.9	1.5	000 090	1.6	1.08

3. Analysis Results

The period values of the structures, roof displacement ratios, and story accelerations obtained from the linear time history analyses were evaluated for 11 different earthquake records and two scaling methods.

3.1 Comparison of the Natural Vibration Periods of the Structures

The natural vibration periods obtained as a result of the analysis of the building models with fixed supports and isolators are given in Table 3. The difference in scaling coefficients don't cause a any change in the structural periods. The periods of structures modeled with isolators are larger than the periods of fixed-supported structures.

Tablo 3. Structural periods

Number of Floors	Mod	T_{fixed}(sn)	$T_{isolator}$(sn)
5	1	0.6	1.71
7	1	0.86	1.89
9	1	1.12	2.08

3.2 Comparison of Roof Displacement Demands

As a result of the analysis, the roof displacement ratios obtained are presented in Figure 4 for 11 earthquake records and 2 different scaling methods. Roof displacements were normalized by dividing by the building heights. In the figure; FIXED indicates fixed supported structures, ISO indicates isolated structures, 1 and 2 indicate the scaling method, and the numbers indicate the number of floors. Since the comparison was made with the fixed supported models, the roof displacements were determined by subtracting the isolator displacements in the isolated structures. When the average of maximum roof displacement rates of 11 earthquake records was examined, it was seen that the displacement demand decreased in isolated structures.

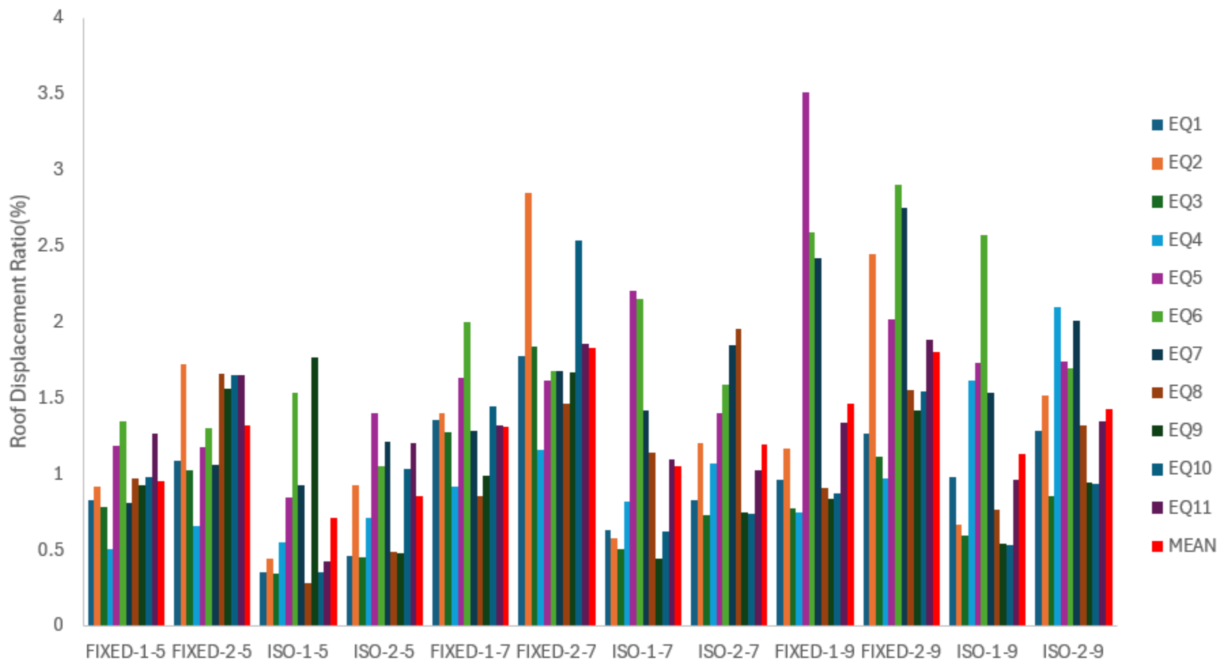

Fig 4. Roof displacement ratios

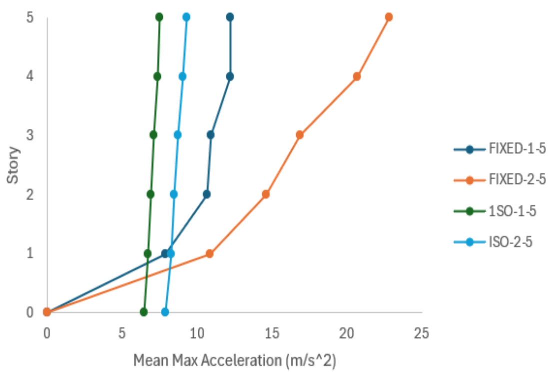
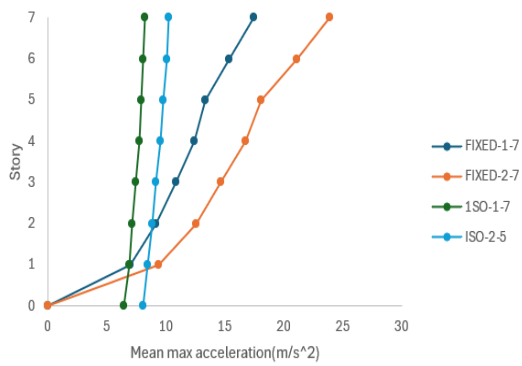
3.3 Story accelerations

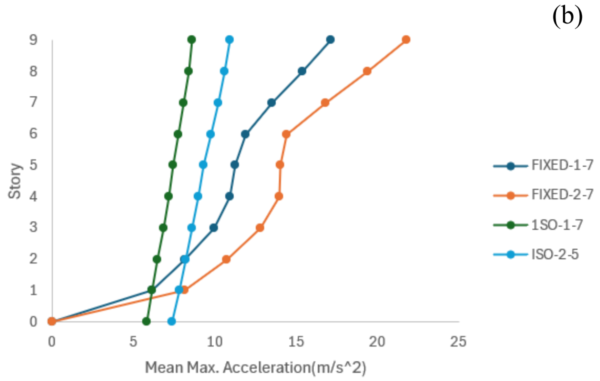
The average maximum acceleration values obtained as a result of the analyses are shown in Figure 5 for 5-storey, 7-storey and 9-storey buildings. When the graphs were examined, it was seen that were greater the story accelerations in the buildings with fixed support. Additionally, there is less acceleration difference between floors in isolated structures. When compared in terms of scaling methods, it was observed that the floor accelerations were greater in the analyses made using the second method.



(a)



(b)



(c)

Fig 5. Maximum floor accelerations, (a) 5 story , (b) 7 story , (c) 9 story

4. Conclusions

In the study, building models with different number of stories, incorporating fixed-support and lead-core rubber isolators, were subjected to linear time history analysis using 11 earthquake records. The records used in the analysis were scaled using two different methods. As a result of the analysis, structural periods, roof displacement rates and changes in floor accelerations were examined.

- When examining the structural periods, it was observed that the periods of the isolated structures increased. However, the scaling method has no effect on the period of structural.
- In terms of the mean maximum roof displacement ratios, it was found that the roof displacements of isolated buildings were smaller than fixed-supported buildings. Comparing the scaling methods, it it was observed that the geometric scaling method resulted in greater roof displacements in both fixed support and isolated buildings.
- The story acceleration values were lower in isolated structures compared to fixed support buildings. In fixed supported buildings, floor acceleration values increased as the number of stories increased. It is observed that the acceleration values on the floors in isolated buildings are closer to each other. This shows that a significant section of the earthquake demands are damped at the isolator interface.

The use of isolators in structures leads to an increase in structural periods and a reduction in seismic demands. The application of two different scaling methods resulted in differences in roof displacement ratios and story accelerations. Therefore, careful consideration should be given to the selection of the scaling method for earthquake records and its application to the building.

Abstract. Progressive collapse is a process initiated by the sudden loss of load-carrying capacity of a local structural element, leading to the propagation of damage to other elements and resulting in significant structural damage or collapse. In this study, the progressive collapse behavior of reinforced concrete frames under middle column removal scenarios was investigated. Within the scope of the study, two different types of frames are evaluated: a frame designed according to the Turkish Building Earthquake Code 2018 (seismically detailed) and a frame with low concrete strength, smooth reinforcing bars and insufficient transverse reinforcement (lacking seismic detailing). The main objective of the study is to examine the development of progressive collapse mechanisms in these frames and compare their structural responses. For this purpose, the progressive collapse behavior of reinforced concrete frames was simulated using finite element modeling in ABAQUS software. As a result of the analyses, the resistance capacities of the frames against progressive collapse were obtained. In addition, changes in axial forces at the ends of the beam were determined to gain a better understanding of the load transfer mechanisms. Furthermore, the effects of concrete strength and variations in stirrup spacing on the load-carrying capacity were examined in detail through numerical models.

Keywords: Progressive collapse; RC frames; Seismic detailing; Finite element analysis

1. Introduction

Progressive collapse is a failure mechanism initiated by the sudden damage of a local structural element, which subsequently propagates to other elements, potentially resulting in the partial or total collapse of the entire structure (GSA, 2016). This type of collapse first drew attention with the failure of the 22-story Ronan Point apartment building in London in 1968, and later gained global prominence following the tragic collapse of the World Trade Center in 2001 (Elkady et al. 2024). In the aftermath of these events, various design methods and guidelines have been developed to enhance structural resistance against progressive collapse. The United States General Services Administration (GSA, 2016) published practical design guidelines for federal buildings, while the U.S. Department of Defense (DoD, 2024) issued a comprehensive manual outlining design criteria aimed at preventing progressive collapse.

In addition to the development of such guidelines, extensive experimental and numerical studies have been conducted to better understand the underlying mechanisms of progressive collapse. These investigations have primarily been carried out on scaled models such as beam-column frames or beam-slab subassemblies, often under column removal scenarios that simulate the sudden loss of a vertical load-carrying element. In reinforced concrete (RC) structures, progressive collapse is typically triggered by the loss of a column, and in such cases, the prevention of collapse progression depends on the effective redistribution of loads to adjacent members and the formation of alternative load paths (Adam et al., 2018). To examine the contribution of alternative load paths to mitigating collapse, various experimental tests have been performed (Yu et al., 2013; Yi et al., 2008; Xiao et al., 2015). Several studies have also investigated the force transfer mechanisms at beam-column connections, particularly in beams with axial restraints (Forquin and Chen, 2017; Lim et al., 2017). Moreover, the influence of parameters such as transverse reinforcement ratio, seismic detailing level, and span-to-depth ratio of beams on progressive collapse behavior has been explored through both experimental and numerical approaches (Qian & Li, 2013; Kang & Tan, 2015; Yap & Li, 2011; Choi & Kim, 2011; Yu & Tan, 2013).

This study investigates the progressive collapse behavior of reinforced concrete frames with and without seismic detailing through numerical modeling. In this context, frames with identical geometries but different reinforcement details were modeled using the ABAQUS software. The models were analyzed under middle column removal scenarios to determine their force transfer mechanisms, which were then compared. The comparison revealed the effect of seismic detailing on the progressive collapse resistance of RC frames.

2. Numerical modeling of reinforced concrete frames

In this section, the progressive collapse behavior of reinforced concrete (RC) frames under middle column removal scenarios was investigated through numerical analyses using the ABAQUS software. Within the scope of the analysis, the influence of seismic and non-seismic detailing on the structural response was evaluated. Based on widely adopted approaches in the literature, a prototype building was first designed, and subsequently, a representative frame from this building was selected and modeled at scale.

The prototype building features a span length of 4500 mm in both directions and a story height of 3000 mm (Fig 1). The critical frame used in the progressive collapse analysis was extracted from this prototype building and modeled in detail. To ensure computational efficiency and representativeness in the numerical simulations, 1/3 scale models were employed.

The RC frames were designated as RCF-1, RCF-2, RCF-3, and RCF-4. The geometric properties of the prototype building and frames are provided in Table 1. In the prototype building, columns measure 600×600 mm and beams measure 450×600 mm, whereas in the scaled frames, columns are 200×200 mm and beams are 150×200 mm.

The four frames used in this study share the same geometric characteristics but differ in concrete strength class and stirrup spacing. Material properties and reinforcement details of the RC frames are given in Table 2. Specifically, RCF-1 and RCF-2 frames utilize C30 (concrete with characteristic cylinder compressive strength 30MPa) concrete, while RCF-3 and RCF-4 employ C14 (concrete with characteristic cylinder compressive strength 14MPa) concrete. Additionally, 8 mm diameter stirrups spaced at 50 mm were used in the RCF-1 and RCF-3 frames, while 8 mm diameter stirrups spaced at 200 mm were used in the RCF-2 and RCF-4 frames. In all frames, column longitudinal rebar consists of 4⌀12 bars, and beam longitudinal rebar consists of 2⌀10 bars at both the top and bottom, with B420C (rebar with yield strength of 420 MPa) rebar grade employed. The reinforcement details of the frames are presented in Fig. 2, where the reinforcement layouts of the frames with 50 mm and 200 mm stirrup spacing are shown in detail.

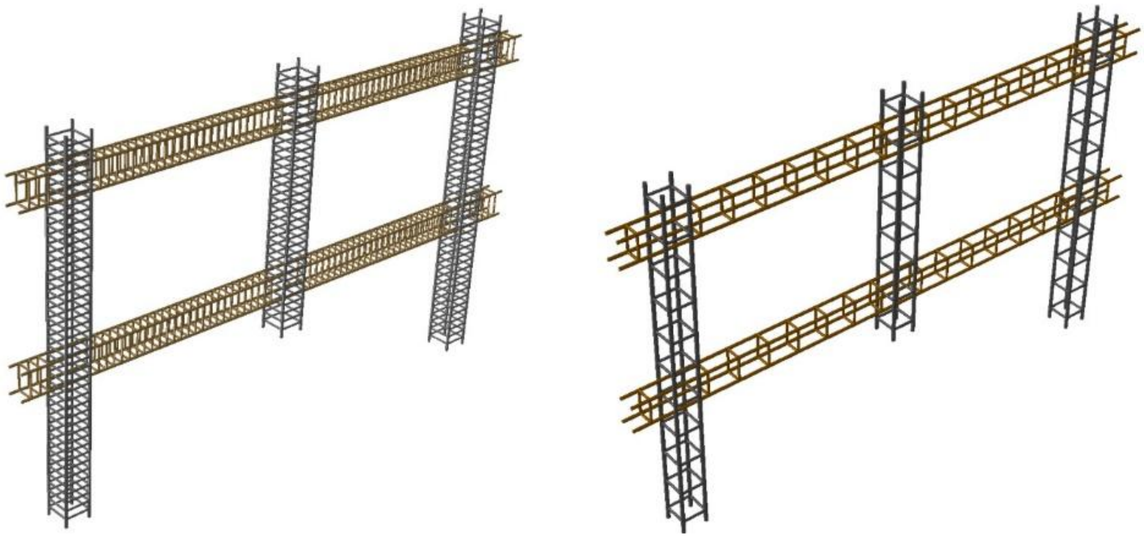
Frame ID	Concrete grade	Stirrup diameter (mm)	Stirrup spacing (mm)	Column longitudinal rebar	Beam longitudinal rebar
RCF-1	C30	8	50	4ø12	2ø10 (top and bottom)
RCF-2	C30	8	200	4ø12	2ø10 (top and bottom)
RCF-3	C14	8	50	4ø12	2ø10 (top and bottom)
RCF-4	C14	8	200	4ø12	2ø10 (top and bottom)



(a) Frame with 5cm stirrup spacing (b) Frame with 20cm stirrup spacing

Fig. 2. Reinforcement detailing of RC frames

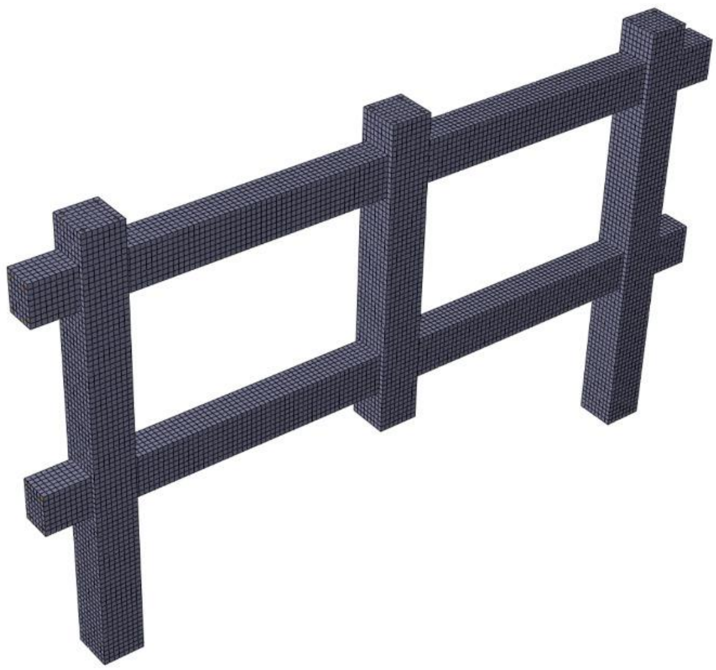


Fig. 3. Abaqus model of RC frames

In the ABAQUS software, the columns and beams were modeled using three-dimensional solid elements, while the reinforcements were represented as wire elements. To ensure a high level of analysis precision, the mesh size was set to 25 mm (Fig. 3). The other parameters of the ABAQUS model were selected based on the study by Qingfu (2020). An axial force of 240 kN, corresponding to 20% of the axial load-carrying capacity of the columns, was applied on top of the edge columns and kept constant throughout the analyses. The frames are supported at the ends of the beams on either side of each span and only rotations are allowed at these points. These boundary and loading conditions were established to realistically capture the progressive collapse mechanisms that may occur under the middle column removal scenario. Subsequently, a displacement-controlled axial force was applied incrementally on the middle column, starting from zero. To monitor the development of progressive collapse behavior and to assess the damage in the beam–column joint regions, the Simplified Damage Plasticity (SCDP) equation proposed by Hafezolghorani et al. (2017) was employed. This numerical approach enabled the evaluation of the progressive collapse behavior of RC frames and the investigation of the effects of various design parameters on the collapse mechanisms.

3. Results and discussion

This study has revealed the progressive collapse behavior of four different reinforced concrete frames (RCF-1, RCF-2, RCF-3, RCF-4) under middle column removal scenario. The load-carrying and deformation capacities of the frames were evaluated using load–displacement and horizontal reaction force graphs (Fig. 4–7), while the damage mechanisms that developed during this behavior were illustrated through damage distribution visualizations (Fig. 8–11).

Fig. 4 and 5 present the vertical load–displacement relationships, highlighting the effects of concrete strength and stirrup spacing on load-carrying capacity and ductility. Among the C30 concrete frames (RCF-1, RCF-2), the RCF-1 frame with 50 mm stirrup spacing exhibited a notably higher load-carrying capacity compared to RCF-2. In RCF-1, following the initial flexural action stage, a maximum load of 183 kN was recorded, after which the frame exhibited pronounced ductile behavior during the development of compressive arch and catenary action stages, dissipating a significant amount of energy prior to collapse. In contrast, the RCF-2 frame displayed no substantial difference in maximum load during the initial flexural action stage compared to RCF-1; however, due to the 200 mm stirrup spacing, ductility and energy dissipation capacity were reduced during the compressive arch and catenary action stages, leading to an earlier onset of collapse.

A similar trend was observed in the C14 concrete frames: RCF-3 (50 mm stirrup) demonstrated superior load-carrying and deformation capacity relative to RCF-4 (200 mm stirrup). The concrete class comparisons in Figure 5 clearly show that the frames with C30 concrete grade are superior to the frames with C14 concrete grade in terms of both load-carrying and ductility. Fig. 6 and 7 present the axial force variations in the edge beams of the frames, as derived from the horizontal reaction force–displacement graphs. During the initial loading phase, significant axial compressive forces developed only in the first-floor beams, while the second-floor beams experienced only limited compression. Furthermore, as the vertical displacement increased, the axial forces in the first-floor beams transitioned from compression to tension, indicating the formation of the catenary action stage in the beams.

(b) Horizontal reaction force–displacement curve for RCF-4 frame

Fig. 7. Horizontal reaction force-displacement relationships at beam ends of reinforced concrete frames with concrete grade C14

The load-carrying and deformation behaviors obtained from the vertical load–displacement and horizontal reaction force graphs of the RC frames were directly correlated with the damage distribution visualizations (Figures 8–11). In the RCF-1 frame (C30, 50 mm stirrup spacing), concrete damage was observed at the beam–column joints at a displacement of 158 mm, followed by the initiation of the catenary action stage, and ultimately, at the maximum displacement of 452 mm, extensive damage occurred at the joints. The confinement effect provided by the closely spaced stirrups delayed the formation of plastic hinges and enhanced the ductility of the system. In contrast, in the RCF-2 frame (C30, 200 mm stirrup spacing), damage at the beam–column joints began to appear at 60 mm displacement, while at 399 mm, pronounced plastic deformations, core concrete crushing, and local failures at the joints were observed.

In the C14 concrete frames, the RCF-3 frame with 50 mm stirrup spacing exhibited joint concrete damage at 80 mm displacement, and severe damage was noted at 315 mm. Despite the lower concrete strength, the use of closely spaced stirrups delayed the progression to collapse. In the RCF-4 frame (C14, 200 mm stirrup spacing), the earliest collapse behavior was observed; concrete damage at the joints initiated at 40 mm displacement, and severe joint damage developed at 281 mm. The damage distribution visualizations clearly revealed the underlying mechanisms responsible for the behaviors observed in the load–displacement and horizontal reaction force graphs.

4. Conclusions

This study investigated the progressive collapse behavior of seismically and non-seismically detailed reinforced concrete (RC) frames under middle column removal scenario through numerical analyses. Based on the results obtained, the following key conclusions can be drawn:

- Seismically detailed RC frames (C30 concrete, 50 mm stirrup spacing) exhibited significantly higher load-carrying capacity, ductility, and energy dissipation performance compared to non-seismically detailed frames (C30 concrete, 200 mm stirrup spacing).
- Although low-strength concrete (C14) frames showed weaker performance compared to high-strength concrete (C30) frames, the use of closely spaced stirrups still improved progressive collapse resistance by delaying the onset of catenary action and ultimate collapse.
- Axial force redistribution was primarily observed in the first-floor beams; as displacement increased, compressive forces in the beams transitioned to tensile forces, indicating the activation of compressive arching and catenary mechanisms that are critical for maintaining structural integrity following column removal.
- The numerical results highlight the importance of proper seismic detailing, particularly in terms of stirrup spacing and concrete strength, in enhancing the strength and robustness of RC frames against progressive collapse.

Comparative analysis of Kahramanmaraş Earthquakes for old and new buildings

Kevser Damlar[1], Hakkı C. Demir[1], Mehmet Palanci[*1], Rojda Orman Subaşı[1]

[1] *Istanbul Arel University, Department of Civil Engineering, 34537 Istanbul, Türkiye*

Abstract. In this study, acceleration and displacement response spectra were calculated using earthquake simulations using earthquake records recorded in the Kahramanmaraş and Hatay regions during the Kahramanmaraş earthquake sequences. Considering the general topology of the regions, low- and mid-rise reinforced concrete buildings were analyzed. Using these general structural characteristics of these buildings, earthquake loads affecting these buildings due to recorded earthquakes were calculated. For the comparison, the former Turkish Earthquake Code (TEC) 2007 and recent Turkish Building Earthquake Code (TBEC) 2018 were considered, and code-based elastic forces and displacement were computed. During the comparisons, the earthquake loads affecting these buildings were compared using the earthquakes codes, such as 2007 and 2018 regulations. Thus, a force-based evaluation of the buildings was performed. Following the force-based evaluation, displacement spectra were used to determine the ductility demands in the buildings, and the ductility demands demanded from the buildings were evaluated. The force-displacement damage relationship was evaluated by comparing the obtained data with the post-earthquake damages.

Keywords: Kahramanmaraş earthquakes; Force-based evaluation; Seismic codes

1. Introduction

Many natural disasters, such as earthquakes, floods, and storms, cause loss of life and property, as well as major destruction both around the world and in our country. In the last 100 years, Türkiye has experienced 20 earthquakes with a magnitude of 7 and above, highlighting that Türkiye is an active, earthquake-prone country. On February 6, 2023, two earthquakes with magnitudes of Mw7.7 and Mw7.6 occurred in our country, with epicenters located in the Pazarcık and Elbistan districts of Kahramanmaraş. These earthquakes directly influenced the 11 provinces, resulting in significant loss of life and property. Additionally, the cost of the destruction and the severely damaged energy and communication infrastructure to our country was 103.6 billion dollars. This situation reveals that Turkey is one of the countries most severely affected by earthquakes (Presidency of the Republic of Türkiye Strategy and Budget Presidency, 2023).

From an earthquake engineering perspective, the intensity of the earthquake, the examination of structures under the influence of earthquakes with experimental and theoretical methods, and the interpretation of the obtained data from these empirical models are among the important topics of study. These topics allow us to focus on the development of the design of earthquake-resistant structures and the strengthening of existing structures against earthquake effects. In addition, the characteristics of ground motion records are an effective parameter in examining the behavior of structures under the earthquake excitations. Ground motion records vary depending on various parameters such as the magnitude of the earthquake, the duration of the earthquake, local soil conditions, the type of faulting, and the distance between the epicenter and the recording station. Therefore, the ground motion record to be used in the analyses will directly determine the design or performance evaluation to be made, as it will affect the analysis results to be obtained (Demir, 2015).

With the performance-based design approach, realistic results can be obtained regarding the amount of deformation that a new or existing building will undergo under the effect of an earthquake, the type and condition of damage it will receive, and the general performance of the structure. Although different methods are applied in many codes in the world, a common perspective is based on the performance-based design principle. In this design approach, the deformation demands of the structural elements must be determined first. To obtain these demands, the analysis of structures or systems in the time history domain is widely adopted. There are many studies in the literature using these methods.

Ruiz-García & Miranda, (2006) comprehensively investigated the magnitude and distribution of the permanent drift demand of a 12-story, single-span frame system. Nonlinear analysis was performed using 40 scaled acceleration records for the analysis. As a result of the study, the effects of parameters such as ground motion intensity, vibration period, number of floors, and system strength on the permanent drift behavior were statistically examined. It was explained that the permanent relative drift demand should also be taken into consideration in the performance evaluation.

Fahjan et al., (2011) performed linear and nonlinear analysis of a 12-story reinforced concrete building using 10 scaled real earthquake records. It was emphasized that at least 7 earthquake records should be used, and the average of the obtained results should be taken as a basis to obtain reliable results.

İnel et al., (2011) compared the three-dimensional models of 2-, 4-, and 7-story reinforced concrete buildings representing the existing building stock in Türkiye, considering the single degree of freedom (SDOF) models. 19 real acceleration records were used in the nonlinear elastic analyses. It was stated that the roof drift demands of the SDOF models were higher than the three-dimensional models. Hamsici (2019) investigated the effects of earthquake ground motion spectra calculated within the scope of TEC 2007 (TEC, 2007) and TBEC 2018 (TBEC, 2018) codes on base shear force and maximum relative story drifts. Seismic analysis of 4-, 7-, and 10-story structures under 4 different soil types located in different earthquake zones was performed using the FEM program according to principles of both codes. The analysis results showed that as the number of stories increased, the base shear force values calculated according to TBEC 2018 decreased compared to TEC 2007. On the other hand, the maximum effective story drift values increased significantly compared to the former code.

Çoruh, (2024) compared the earthquake design spectra of a school building according to different earthquake codes. The contents of the codes, soil classes, and horizontal elastic design spectra were examined, and graphical comparisons were made for different soil types. As a result, it was stated that there were similarities between the codes as well as significant differences and deficiencies, especially regarding the consideration of soil conditions. Keyik (2019) investigated the different parameters adopted by TBEC 2018 and ASCE 41-17 (ASCE/SEI 41-17, 2017) codes when making performance-based evaluations. It was explained that while TBEC 2018 strain values play an important role in determining performance levels. Meral (2021) compared the seismic demands of 3, 6, and 9-story reinforced concrete buildings, obtained as a result of linear elastic and linear inelastic time history analyses using 12 earthquake records. It was observed that base shear force demands are prominent in linear analyses, while displacement demands are prominent in nonlinear analyses.

In this study, the acceleration and displacement response spectra of low and medium-rise (3, 5, and 7-story) reinforced concrete residential buildings were compared with the records of the Kahramanmaraş earthquake sequences (Kahramanmaraş and Hatay) by the TEC 2007 and TBEC 2018 codes. Then, the ductility demands and the force-displacement relationship obtained from the displacement spectra were examined.

2. Typical building models

In this study, three different residential buildings with 3, 5, and 7 stories were considered, and it was assumed that these buildings were designed according to TEC 2007, which uses capacity design principles. The height of the first floor was 3.5 m, and the height of the other floors were taken as 3 m. The concrete quality was taken as C25, and the reinforcement quality was assumed as S420. In 3- and 5-story buildings, the cross-sectional dimensions of beams and columns were taken as 30x60cm, while in the 7-story building, columns were 40x70cm and beams were 30x60cm. It was assumed that the reinforced concrete buildings are located in the first degree earthquake zone and on Z3 class soil, according to TEC 2007. Buildings were designed as high ductile buildings with beam-column frame systems. Typical representation and designed residential buildings are plotted in Fig. 1.

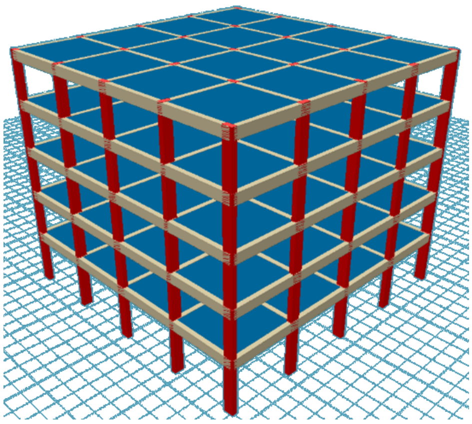

Fig. 1. Three dimensional representation of typical buildings considered

Buildings were considered as regular in plan and height. The buildings have five axis and four bays in plan, and the width of the bays were taken constant as 4.50 m. As a result of the modal analysis, the periods of the 3-, 5-, and 7-story buildings were found to be 0.538 s, 0.839 s, and 0.938 s, respectively. Using these period values, the elastic earthquake forces and displacement demands acting on the buildings are analyzed, assuming that the buildings are located in the Hatay and Maraş regions. To consider Kahramanmaraş sequences, the location of accelerometer 3129 in Hatay was taken into consideration since the maximum accelerations were recorded in Hatay province for a magnitude of Mw=7.7, and the location of accelerometer 4612 in Kahramanmaraş was taken into consideration since the maximum accelerations measured were in Maraş province for the earthquake with a magnitude of Mw=7.6.

2.1. Calculation of target elastic acceleration spectra for Hatay and Kahramanmaraş regions

The comparison of the target spectra calculated according to the TEC2007 and TBEC2018 codes for Hatay and Maraş provinces and the earthquake spectra obtained from corresponding stations (i.e., 3129 and 4612 stations) are shown in Fig. 2.

The location of the 3129 station is in Hatay-Antakya, and this location is in the 1st degree earthquake zone according to TEC-2007. Therefore, the effective ground acceleration coefficient (A_0) is taken as 0.40. In addition, the location of 4612 station is in Maraş-Göksun, and this location is in the 3rd degree earthquake zone according to TEC-2007, and so, effective ground acceleration coefficient (A_0) is considered as 0.20 for TEC-2007. For the elastic target spectrum, similar analyses were also made for TBEC 2018, and based on the location of stations, local soil class (according to NEHRP site classification), local soil coefficients (F_S and F_1), and response acceleration parameters (S_S, S_1, S_{DS}, S_{D1}) were calculated. The parameters during the calculation of the target spectra for both seismic codes are provided in Table 1. It is worth noting that target elastic spectral accelerations were computed for a design earthquake that has a return period of 475 years, which corresponds to the 10% probability of exceedance in 50 years.

In addition to target spectra determined from the seismic codes, the spectral acceleration spectrum of recorded ground motions recorded at the 3129 and 4612 stations for both components, such as east-west (EW) and north-south (NS), were considered. These spectral accelerations are plotted in Fig. 2 to make a comparison of target and recorded real ground motions. It can be seen from the figure that spectral accelerations of TBEC are higher than TEC at low periods ($T < 0.6$ s), and spectral accelerations tend to get similar with increasing periods. Spectral acceleration of TBEC is slightly lower than TEC in Hatay when $T > 0.6$ s. Figure also clearly demonstrates that spectral acceleration of record motion in NS and EW components is higher than both seismic codes. Especially recorded motions in Hatay are highly observatory for periods ($T < 1.2$ s). When the recorded motion in Kahramanmaraş is observed, it can be said that spectral acceleration of TBEC and recorded motions are very close when $T < 1.0$ s. On the other hand, spectral acceleration is greatly diverged from the seismic codes when $T > 1.2$ s. For periods of considered residential buildings, it can be said spectral acceleration of record motion at these periods are generally higher, which will cause higher lateral shear forces.

Table 1. The parameters for the calculation of elastic target spectrum for TEC-2007 and TBEC-2018

Parameters		Soil type	A_0	I	T_A	T_B
TEC-2007	Hatay	Z2	0.4	1.0	0.15	0.4
	Kahramanmaraş	Z3	0.2	1.0	0.15	0.6
Parameters		Soil type	S_s	S_1	T_A	T_B
TBEC 2018	Hatay	ZC	1.064	0.276	0.065	0.324
	Kahramanmaraş	ZD	0.688	0.178	0.093	0.464

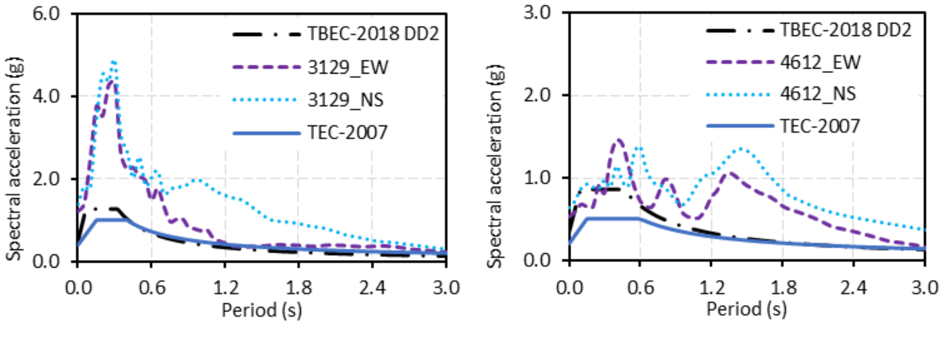

Fig. 2. Comparison of spectral accelerations computed for seismic codes and recorded real ground motions in the stations (Left: Hatay, Right: Maraş)

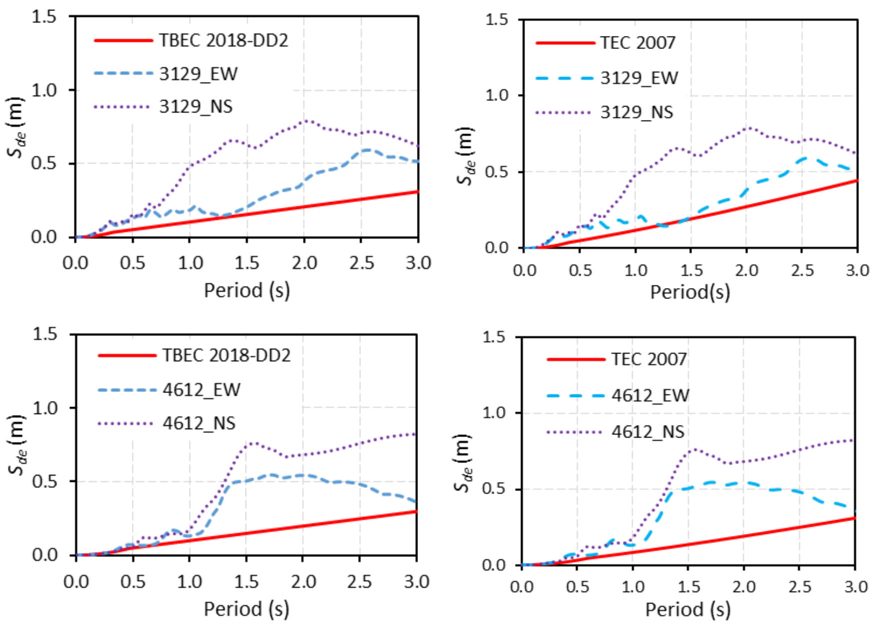

Fig. 3. Displacement spectrum of seismic codes and recorded ground motion in Hatay (up) and Kahramanmaraş (bottom)

2.1. Calculation of displacement spectra for Hatay and Kahramanmaraş regions

To make displacement-based comparison, displacement spectra of seismic codes and recorded ground motions were made. The determination of displacement spectra will allow to make displacement-based evaluation of demands for the considered buildings. In this way, displacement based and force based comparisons will be made for considered building topologies.

Since spectral acceleration of seismic codes are computed, these accelerations can be converted to spectral displacement based on Equation 1. Linear time history analysis were made to compute spectral displacement of recorded ground motions. A comparsion of the spectral displacement of recorded motion considering both components and seismic codes are plotted in Fig. 3. This clearly demonstrates that not only spectral acceleration but also displacement demands determined from recorded motions are higher than seismic codes. Numerical comparisons will also be made to make a comparative assessment between shear forces and displacement demands.

$$S_{de}(T) = \left(\frac{T^2}{4\pi^2}\right) S_{ae}(T) \tag{1}$$

3. Analysis results

3.1. Force-based assessment using seismic codes

In order to make force-based comparisons, base shear demands are determined from the target spectral acceleration for each seismic code. An example calculation is given in Table 2 for TEC-2007 and Table 3 for TBEC-2018, considering Hatay and Kahramanmaraş (Maraş) city.

Table 2. Calculations of base shear force according to TEC-2007 for 3-story building

Building	Parameters		Hatay	Maraş
	Effective ground acc.	A_0	0.4	0.2
	Period	T_1 (s)	0.538	
	Soil type		Z2	Z3
	Importance factor (I)		1	
3 story	Ductility	R_a	8	
	Building weight	W (t)	2258.36	
	Spectral coefficient	S(T)	1.97	2.50
	Elastic spectral acc	S_{ae}(T) (g)	0.79	0.50
	Base Shear Force	V_{te} (t)	222.70	141.15

Table 3. Calculations of base shear force according to TBEC-2018 for 3-story building

Building	Parameters		Hatay	Maraş
3 story	Map spectral coefficients	$S_S;S_1$	1.064;0.276	0.688;0.178
	Period	T_1 (s)	0.538	
	Soil type		ZC	ZD
	Importance factor (I)		1	
	Ductility	R	8	
	Building weight	W (t)	2258.36	
	Horizontal spectral acc.	$S_{ae}(T)$ (g)	0.77	0.74
	Reduced hor. spectral acc.	$S_{aR}(T)$ (g)	0.096	0.093
	Base Shear Force	V_{te} (t)	217.37	209.36

Using the similar procedure given in Table 2 and Table 3, base shear force (V_{te}) acting on all 3, 5 and 7 story residential buildings is calculated considering TEC2007 and TBEC2018 regulations, and results are given in Table 4. It can be seen from the table that base shear force demands obtained from TEC-2007 are higher than TBEC-2018 in Hatay, whereas TBEC-2018 is higher than TEC-2007 for Maraş city.

Table 4. Comparison of base shear forces for 3-, 5- and 7-story building according to TEC-2007 and TBEC-2018

Number of story	Hatay		Maraş	
	TEC-2007 (t)	TBEC 2018 (t)	TEC-2007 (t)	TBEC 2018 (t)
3	222.70	217.37	141.15	209.36
5	267.92	239.11	185.29	230.45
7	358.70	313.07	248.07	301.73

3.2. Force-based assessment using recorded ground motions

In order to make force-based comparison between seismic codes and recorded motions, base shear demands must also be determined from the recorded motions. For this purpose, building periods corresponding to spectral acceleration ($S_{ae}(T)_{EQ}$) of recorded ground motions are obtained. An example calculation for the determination of $S_{ae}(T)_{EQ}$ is sketched in Fig. 4. The example is plotted for 5-story building, which T=0.839 s, and spectral acceleration at this period for NS and EW directions were obtained as 1.80g and 1.04g, respectively. Based on these spectral accelerations, base shear demand for these components were calculated 503.28 t and 871.23 t (see Table 5) for NS and EW directions in Hatay, respectively. Similar computations were also made for other buildings and Maraş city.

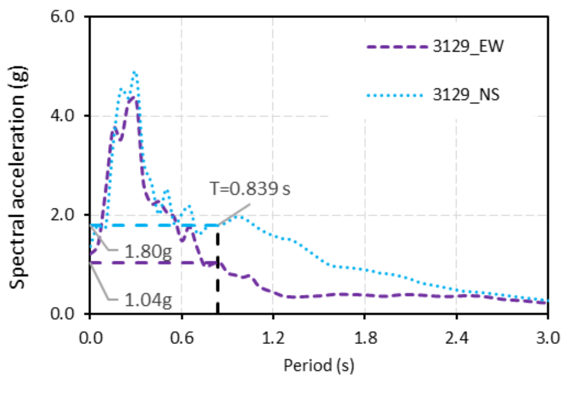

Fig. 4. Calculation of $S_{ae}(T)_{EQ}$ for sample building considered for Hatay city

Table 5. Calculation of base shear force from recorded motions for 5-story building considering Hatay city

Building	Parameters		EW	NS
5 story	Period	T_1 (s)	0.839	
	Soil type		ZC	
	Importance factor (I)		1	
	Ductility	R	8	
	Building weight	W (t)	3876.62	
	Horizontal spectral acc.	$S_{ae}(T)_{EQ}$ (g)	1.04	1.80
	Reduced hor. spectral acc.	$S_{aR}(T)_{EQ}$ (g)	0.130	0.225
	Base Shear Force	V_{te} (t)	503.28	871.23

3.3. Comparison of elastic force-based results

Using this base shear force demand obtained in Section 3.2 and Section 3.1, code-based and earthquake based shear demands for 3.5 and 7-story buildings are compared in Table 6. Comparisons are made in terms of ratios. For example, base forces of seismic codes are found to make code based assessments in terms of ratios. Similar ratios were also computed for both components. In addition, base shear demands are divided to code based shear forces to understand shear demanded by the recorded motion in corresponding stations.

It can be seen from Table 6 that base shear demand ratios for seismic codes change depending on the region considered. For example, the ratio of TBEC 2018 to TEC 2007 is lower than 1.0 and it is found 0.98, 0.89 and 0.87 for 3-, 5- and 7- story buildings, respectively. On the other hand, these ratios are higher than 1.0 such as 1.48, 1.24 and 1.22 for 3-, 5- and 7- story buildings, respectively, indicating that TBEC shear demands are higher than TEC 2007.

Since the Turkish Building Earthquake Code is currently in practice, earthquake demands are proportioned by taking this code into account, and base shear demands determined from the recorded motions are divided to TBEC based base shear forces. It can be observed from Table 6 that code based shear demands are lower than those of record motions, the lowest ratio is 1.29 and the highest ratio is obtained as 4.39. The lower ratios are obtained from Kahramanmaraş city for a 3-story building when considering the east-west direction of recorded motion, but when the NS component is considered, this ratio increases to 1.63.

When the obtained results are investigated for Hatay city, it can be said that a higher ratio (see Table 6, i.e., 4.39) is obtained from Hatay city for a 7-story building when considering the north-south direction of recorded motion, but when the EW component is considered, this ratio decreases to 1.83. Based on the above results, it can be said that code based forces are lower than recorded motions, indicating that designed buildings may undergo elastic displacement, and hence nonlinear deformation may be needed.

One may also think that buildings may be inadequate when only shear forces are considered. On the other hand, it is worth keeping in mind that code-based design allows buildings to behave in a nonlinear phase since code-based spectral accelerations are obtained under uncertainties involved in seismic hazard analysis. Accordingly, obtained results clearly indicate that buildings should have certain ductility when shear forces are exceeded to ensure their performance level, which is Life Safety for ordinary buildings.

3.4. Comparison of elastic displacement-based results

In the earlier section (section 2.1), elastic spectral displacement versus periods were computed for both seismic codes and recorded ground motions. Based on the results, elastic spectral displacement demands corresponding to buildings periods were obtained. Using these elastic displacement values, the ratio of displacement demands were calculated and results are provided in Table 7.

It can be seen from Table 7 that as calculated displacement ratios are identical with force-based ratios, the calculations behind displacement for the seismic code is based on Eq. 1. Accordingly, displacement demands are proportional to spectral accelerations and hence, displacement ratios are the same as ratios obtained from accelerations. When displacement ratios determined from the real earthquakes are compared, it can be said that ratios differ.

Table 6. Comparison of code- and recorded earthquake- based base shear demands for buildings considering Hatay and Kahramanmaraş cities

Building Story	TBEC 2018/ TEC 2007 Hatay	TBEC 2018/ TEC 2007 Maraş	3129EW/ TBEC 2018	3129NS/ TBEC 2018	4612EW/ TBEC 2018	4612NS/ TBEC 2018
3	0.98	1.48	2.58	2.60	1.29	1.63
5	0.89	1.24	2.10	3.64	2.01	1.75
7	0.87	1.22	1.83	4.39	1.51	1.60

Table 7. Comparison of code- and recorded earthquake- based ratio of horizontal elastic design displacement for DD2 level considering Hatay and Kahramanmaraş cities

Building Story	TBEC 2018/ TEC 2007 Hatay	TBEC 2018/ TEC 2007 Maraş	3129EW/ TBEC 2018	3129NS/ TBEC 2018	4612EW/ TBEC 2018	4612NS/ TBEC 2018
3	0.98	1.48	2.56	2.55	1.28	1.65
5	0.89	1.24	2.10	3.72	2.00	1.75
7	0.87	1.22	1.81	4.54	1.50	1.61

It can be observed from the Table 7 that code based displacement demands are lower than those of record motions and lower ratio is 1.28 and the highest ratio is obtained as 4.54. The lower ratios are obtained from Kahramanmaraş city for 3-story building for the east-west direction, but when the NS component is considered, this ratio increases to 1.65.

The obtained results from Hatay city indicate that the highest ratio is 4.54 for a 7-story building when considering the north-south direction of recorded motion. For the same station, this ratio decreases to 1.81 for the EW component. Based on the above displacement results, it can be said that code based displacement demands, once again, are lower than recorded motions.

When displacement based results are compared with force-based results, it can be said that buildings are expected to undergo beyond the elastic phases. One may bear in mind, that the nonlinear behavior of these buildings are not investigated, even in the elastic phase, even for displacement and acceleration based results. In addition, obtained results revealed that not only force-based but also displacement based evaluations must not be overlooked by practicing engineers, and displacement based evaluation is needed and as important as elastic spectral acceleration to understand building behaviour.

3.5. Nonlinear displacement based evaluation

Based on the elastic-based analysis results, nonlinear dynamic analysis is performed. For this purpose, simple structures idealized as single-degree of freedom (SDOF) buildings are considered to consider the real building characteristics. SDOF structures are identified by stiffness (k), damping (c), mass (m), and strength (Fy). In this study, four T values with increments of 0.2 s (e.g., 0.4, 0.6, 0.8, and 1.0) were considered. It is worth noting that these values also cover the period values corresponding to 3-, 5-, and 7-story buildings used in this study and mainly represent low- to mid-rise buildings.

SDOF systems were represented by Fy/W, and they were taken as 0.1, 0.2, and 0.3 according to consideration of various studies (Akkar et al., (2005); Ucar et al., (2015); Palanci et al., (2021)). Low strength ratios (i.e., 0.1) can be attributed to structures that do not have sufficient stiffness and strength according to modern seismic codes. Finally, elastic-perfectly plastic (EPP) model is used to represent structural behavior. Typical presentation of the SDOF system is shown in Fig. 5. The general equation of motion of an inelastic SDOF system subjected to an earthquake excitation can be solved by Equation 2.

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = -m\ddot{x}_g(t) \tag{2}$$

To make code-based comparison, the maximum displacement demands of each SDOF system were obtained using acceleration records obtained from 3129 stations in Hatay and 4612 stations in Maraş. Later, acceleration records were obtained for each station according to TBEC 2018 (11 acceleration records) and TEC 2007 (7 acceleration records), and using these records, the average maximum displacement demands were obtained for relevant seismic code. For code-based record selection, a stochastic optimization software developed by Kayhan et al., (2022) and later improved by Demir et al., (2025) is used. Details about the selected records are not discussed here, readers are suggested to see relevant studies for more information. Finally, the maximum displacement demands obtained from the stations were compared with the average maximum displacement demands obtained from the selected ground motions based on the target spectral shape of relevant seismic codes.

The maximum displacement demands of SDOF systems obtained from 3129 and 4612 stations are plotted in Fig. 6. It can be seen from the figure that nonlinear displacement values determined from 3129-NS is dramatically higher than 3129-EW values. In general, nonlinear displacement values are higher than 40 cm. Note that nonlinear displacement values are also dramatically higher than displacement values determined from elastic displacement curves. For Kahramanmaraş city (4612 station), maximum displacement values determined from 4612-NS is higher than 4612-EW component.

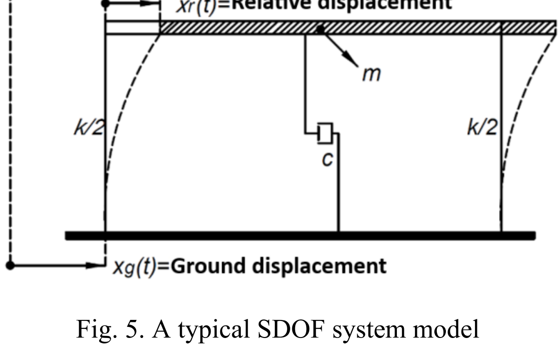

Fig. 5. A typical SDOF system model

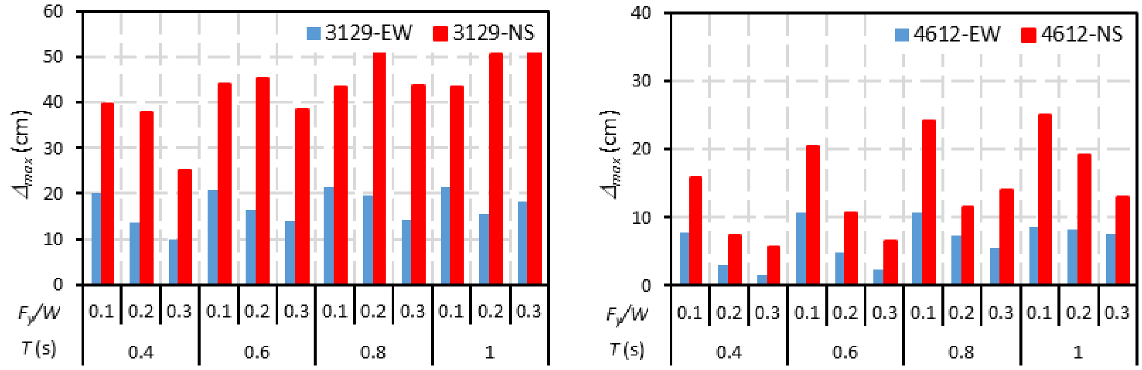

Fig. 6. Maximum nonlinear displacement values calculated for left: 3129 (Hatay) and right: 4612 (Maraş) and stations

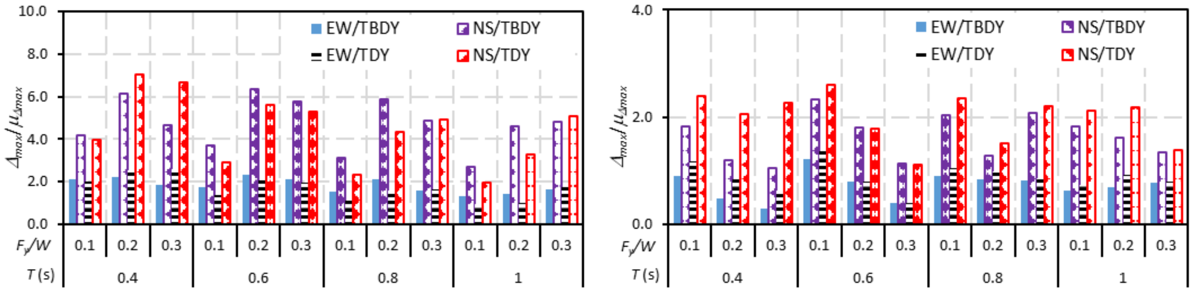

Fig. 7. Ratios of maximum displacements (Δ_{max}) of recorded earthquake motions (Left: 3129 and right: 4612) to average displacement ratios ($\mu_{\Delta max}$) determined according to code-based record selection for Hatay (left) and Maraş (right) cities

The displacement ratios of recorded earthquake motions (D_{max}) to average displacement ratios (m_{Dmax}) determined according to code-compatible record selection for Hatay and Maraş cities are obtained from nonlinear dynamic analysis using different lateral strength ratios and periods, and results are plotted in Fig. 7. It can be seen from the figure that the ratios may up to 7 times (mainly higher than 4.0) when nonlinear responses are considered, especially for buildings with lateral strength ratios higher than 0.2 in Hatay city for NS direction of the 3129 station. Meanwhile, figures implies that ratios may be up to 2.5 times in Hatay city for the EW direction of the 3129 station.

When the ratios for the Kahramanmaraş case (right side in Fig. 7) are investigated, it can be said that the ratios mainly range between 1.06 and 2.61 depending on the lateral strength ratio and building period. Nevertheless, it can be said that nonlinear displacements determined from the Maraş earthquakes are still higher than code-based nonlinear displacements. This situation highlighted that majority of buildings are subjected to high displacement ratios rather than shear forces when the nonlinear behavior of buildings is considered.

4. Damage measures and implications from the Kahramanmaraş sequences

Analysis results have shown that building damages is not only attributed to shear forces but also displacement demands mostly dominate the behavior. To overcome displacement demands, buildings must dissipate energy and energy demand, and hence displacement can be overcome considering capacity-design principles such as strong column-weak beam and ductility concepts. Ductility of members can be increased by application of appropriate details dictated by seismic codes (i.e., TBEC-2018 currently in force), and practitioners must comply with the rules such as the length of the confinement regions, confinement reinforcement with sufficient wrapping including stirrups and crossties, and appropriate reinforcement arrangements like 135-degree hooks. These details and concepts are necessary to ensure ductility demands, which are required to meet earthquake demands.

Analysis results also demonstrated that if common mistakes are made, it is natural to obtain such damages resulting from mistakes made during the design or in the construction process. Many field reconnaissance studies also confirm the results obtained in this study, and these studies revealed that existing reinforced concrete structures still suffer from common mistakes given above (İnce, (2024); Ivanov & Chow, (2023); Vuran et al., (2025); Avcil et al., (2024)) and the majority of buildings suffer from deficiencies resulting from inadequate ductility and bad applications in Türkiye.

In Fig. 8 and Fig. 9, some bad applications and engineering practices are demonstrated. These examples are taken from various studies after Kahramanmaraş earthquake sequences (Ince, (2024); Ivanov and Chow, (2023); Vuran et al., (2025); Avcil et al., (2024)). The picture in Fig. 8 (left) shows insufficient transverse reinforcement, which can be seen in common in field observations (Ince, 2024), and the picture on the right side shows the differences in structural behaviour between the adjacent buildings due to the impact of engineering practices and quality. It can be seen that buildings are in the same location, and so they undergo the same seismic, but they have distinct responses and damages (Ivanov and Chow, (2023)).

In Fig. 9 (left) collapsed post-2000 building is observed by Vuran et al., (2025). It was mentioned that buildings presumably stem from bond-slip failure, which may have possibly resulted from a lack of adequate length of the confinement regions, which implies bad construction practice. The other damage failure observed in the field is shown in Fig. 9 (right) and the main reason for this damage was mentioned by lateral collapse mechanism as a result of the formation of plastic hinges in the columns due to construction of strong beams, weak columns, not paying attention to the confinement of stirrups, and poor concrete quality by Avcil et al., (2024).

Despite the bad application and construction practices, one could observe the good practices that performed well after Kahramanmaraş earthquake sequences, as seen in Fig. 10 (Erbaş et al., (2025)), which highlight the importance of the capacity-design principles and ductility concepts.

Fig. 8. Some bad applications and engineering practices (Left: Insufficient transverse reinforcement (Ince, (2024)); Right: Two buildings in the same location (Ivanov and Chow, (2023))

Fig. 9. Some collapsed buildings stemming from formation of plastic hinges primarily in the columns, insufficient reinforcement, low-strength material, and RC frame insufficiency stemming from bad construction practices (Left: presumably bond-slip failure due to lack of adequate length of the confinement regions (Vuran et al., (2025)); Right: Lateral collapse (accordion) damages (Avcil et. al., (2024))

Fig. 10. Some well performed buildings examples (Erbaş et. al., (2024))

4. Conclusions

In this study, the displacement response spectra of residential buildings with varying floor heights, presumed to be located in Hatay and Kahramanmaraş provinces, were derived according to TEC 2007 and TBEC 2018 codes and compared with earthquake records obtained from Kahramanmaraş and Hatay. The results can be summarized as follows:

- In Hatay, the base shear force acting on 3, 5, and 7-story residential buildings of the TEC 2007 is higher than that of the TBEC 2018. However, in Kahramanmaraş, the base shear forces calculated according to the TEC 2007 were lower than those of the TBEC 2018.
- When force-based comparisons are made, the base shear force demands obtained from earthquake records are higher than the base shear forces calculated according to the 2007 and 2018 codes.
- It was seen that all buildings exceeded the elastic displacement limits and required inelastic deformation. Thus, emphasizing that not only force-based but also displacement-based approaches should be considered during the evaluation of structures.
- It can be said that nonlinear displacements determined from Maraş earthquakes are still higher than code-based nonlinear displacements.
- Kahramanmaraş earthquake sequences illustrated that distinct damage could be observed for the buildings at the same location even if they were exposed to the same seismic effects. The reasons behind this situation was observed as bad application and construction practices, such as poor concrete quality, not paying attention to the confinement of stirrups, weak columns, etc.

Acknowledgments

The authors express their thanks to Dr. Ahmet Demir for providing seismic code compatible real ground motion records.

Abstract. Structural Health Monitoring (SHM) plays a critical role in ensuring the safety and long-term performance of engineering structures by continuously assessing their dynamic behavior and detecting potential anomalies. With advancements in cloud computing and web technologies, the integration of SHM systems into cloud-based platforms has become increasingly feasible, allowing for real-time data processing, remote access, and improved decision-making. This study presents the development of a cloud-based website designed for monitoring the structural health of engineering structures. The platform is designed to collect, process, visualize, and analyze real-time sensor data from various SHM systems installed on structures such as bridges, dams, and high-rise buildings. Key features of the system include real-time data streaming, automated anomaly detection using machine learning algorithms, and an intuitive user interface for remote monitoring. The cloud-based infrastructure enables scalable data storage and computational efficiency, ensuring seamless access for engineers and decision-makers. The proposed platform is tested using sensor data from case studies involving large-scale civil infrastructure, demonstrating its effectiveness in identifying changes in modal parameters and potential structural anomalies. The results indicate that cloud integration significantly enhances the accessibility and efficiency of SHM systems while reducing on-site computational demands. This study highlights the potential of cloud-based SHM platforms in transforming traditional structural monitoring approaches by providing real-time insights and predictive maintenance capabilities. Future developments will focus on enhancing the system's AI-based diagnostics and expanding its application to a broader range of engineering structures.

Keywords: Arch dam; Cloud-based website; Operational modal analysis; Structural health monitoring

1. Introduction

In the field of civil engineering, the design and analysis of structures are increasingly relying on computer-aided methods, facilitating the process of creating efficient and reliable structural systems. However, during the design phase, it is often challenging to perform analytical solutions, especially for complex structures, due to the computational effort required. To mitigate this challenge, numerical methods such as Finite Element Method (FEM) and Finite Difference Method (FDM) are employed to assess structural behavior, including modal, static, dynamic, linear, and nonlinear responses. Despite these advanced techniques, the assumptions made during the design phase may not always align with the actual conditions encountered during construction or over time, due to factors such as cracks, fatigue, foundation settlement, or other external influences. This divergence can lead to discrepancies between the expected and actual performance of the structure.

To address these uncertainties and ensure the continued safety and functionality of engineering structures, Structural Health Monitoring (SHM) systems play a critical role in providing real-time data on structural conditions. SHM systems enable the continuous assessment of structural health by monitoring key parameters, such as displacement, deformation, and strain, through the use of various sensors. These systems can detect potential damage and predict future issues, thus preventing significant losses in both human lives and property.

In the last twenty years, Structural Health Monitoring (SHM) has significantly grown with the advancement of sensor technologies, important progress in computing, and the inclusion of structural control approaches (Basu et al., 2014; Aydın et al., 2020). The SHM system generally consists of three main components: sensors, a data processing unit, and a data interpretation system (Amezquita and Adeli, 2016). SHM involves collecting data from precise sensors placed at predetermined points of the structure, storing and processing these data within a system,

* Corresponding author, E-mail: yesevi@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_893

and interpreting them to identify potential damages in the structure. In SHM, both local and global methods are used for damage detection or structural condition assessment (Doebling, 1998). Local methods help in identifying or monitoring regional damage in structural elements (Shih, 2009). The most commonly used local methods include ultrasonic testing, eddy current, liquid penetrant testing, radiography, acoustic emission, visual inspection, etc. Global methods provide information about the overall condition of the structure and are used to detect the presence of damage. Various global methods, such as optical inspection, optoelectronic scanning, 3D laser scanning, and vibration-based methods, are used. Vibration-based methods are among the most widely used because they are greatly influenced by changes resulting from behavioral differences in the structure, regardless of its complexity (Boscato, 2019). Vibration-based methods are divided into Ambient Vibration Testing (AVT) and Forced Vibration Testing. The most commonly used method is Ambient Vibration Testing (AVT). In AVT, algorithms are used in the frequency and time domain for data processing to obtain dynamic characteristics of the structure. Many studies in the literature aim to interpret the data obtained from long-term monitoring of the dynamic characteristics of the structure through sensors (Rageh et al., 2018; Ono et al., 2019; Huseyno et al., 2020; Jayasundara et al., 2020; Vega & Yu, 2022; Zhang et al., 2022). These valuable studies are important for the development of SHM systems.

Given the increasing size and complexity of infrastructure projects, there is a growing need for scalable and efficient systems to manage and interpret the vast amounts of data generated by SHM systems. Cloud computing and web-based platforms have emerged as promising solutions, providing a centralized, accessible framework for real-time monitoring and data analysis. These platforms enable remote access, enhanced decision-making, and the integration of AI-driven diagnostics to improve the overall performance and maintenance of engineering structures.

This study presents the development of a cloud-based SHM platform designed to monitor and assess the structural health of various engineering structures. A web-based software has been developed, which can store raw signals and generate time-dependent visual graphs, provide alerts when signals reach predefined threshold levels, automatically track frequencies for obtaining dynamic characteristics, determine the confidence interval of uncertainties arising from changing environmental conditions using Bayesian Neural Networks, and perform anomaly detection through a deep learning-based methodology with an autoencoder. The platform utilizes real-time sensor data to detect anomalies and provide valuable insights for decision-makers. By integrating these developed algorithms, the SHM system aims to transform traditional SHM approaches and provide a more efficient and proactive solution for ensuring the safety and longevity of critical infrastructure.

2. Cloud-based structural health monitoring system

The online monitoring of signals that represent the current state of engineering structures, which can vary depending on various environmental factors such as ambient temperature, humidity, and wind speed, is facilitated through a web-based Structural Health Monitoring Platform. This platform enables the processing, interpretation, graphing, reporting of data, and easy access to data from any desired date. Deep learning-based methodologies have been developed for the automatic processing of dynamic characteristic data and for anomaly detection in the continuously obtained signals. Additionally, a study has been conducted to determine the confidence interval using Bayesian Neural Networks under uncertainties caused by changing environmental conditions, and this has been integrated into the platform. ASP.NET MVC, C#, Python, Grafana, and PostgreSQL were used in the development of the platform and its database.

With the Structural Health Monitoring platform, in addition to having 24/7 access to all data related to ongoing work and obtaining information about the structure at any desired time, the following can also be achieved:

- Continuous monitoring can be provided through sensors placed on the structure.
- Signals from the structures can be transferred to the main server, stored, and processed for evaluation.
- Processed data can be displayed systematically with date and time, and comparisons can be made with new data received during the monitoring process.
- Data processing algorithms can be applied during the monitoring process.
- Changes in structural behavior can be presented in real-time, and emergency intervention can be facilitated in extreme situations.
- Site members can access their structures at any time of the day with their personalized passwords, and emergency alerts can be sent via email.

The main entry screen of the Cloud-Based Structural Health Monitoring Platform developed in this study is shown in Fig. 1. This platform includes a dedicated page for each monitored structure. Authorized individuals, as defined by the requesting party, can access the structure's page using the designated password (Fig. 2). On this page, graphs of signals received 24/7 from sensors placed on the structure, as well as information about the current condition of the structure and reports, can be accessed (Fig. 3).

2.1. Structural health monitoring in multi-storey reinforced concrete building

Within the scope of long-term structural health monitoring study in a multi-storey reinforced concrete building located in Yomra District of Trabzon Province, sensor installations were carried out and data transfer was provided to the web-based site. The building consists of a ground floor and 20 additional floors, with a net floor height of 2.95 meters for each floor. The total height of the building, starting from the ground floor, is approximately 65 meters. For vibration-based Structural Health Monitoring in the multi-story reinforced concrete building, two three-axis accelerometer sensors have been placed at the north-west and south-west corner points of the top floor. The data has been integrated into the Cloud-Based Structural Health Monitoring Platform. The SARA SL06 model has been used as the three-axis accelerometer sensor. FiG. 4 shows the placement and installation visuals of the accelerometer sensors. Fig. 5 shows the main visual screen of the data obtained from the web-based structural health monitoring platform. Fig. 6 shows the change of automatically obtained frequencies with respect to time.

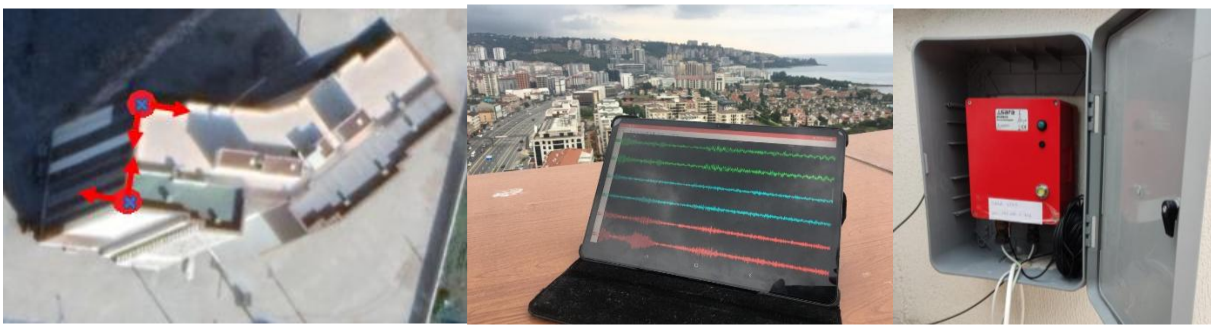

Fig. 4. Visual of the accelerometer sensor placement and sensor installations of the structure

Fig. 5. Main visual screen of the structure on the cloud-based structural health monitoring platform

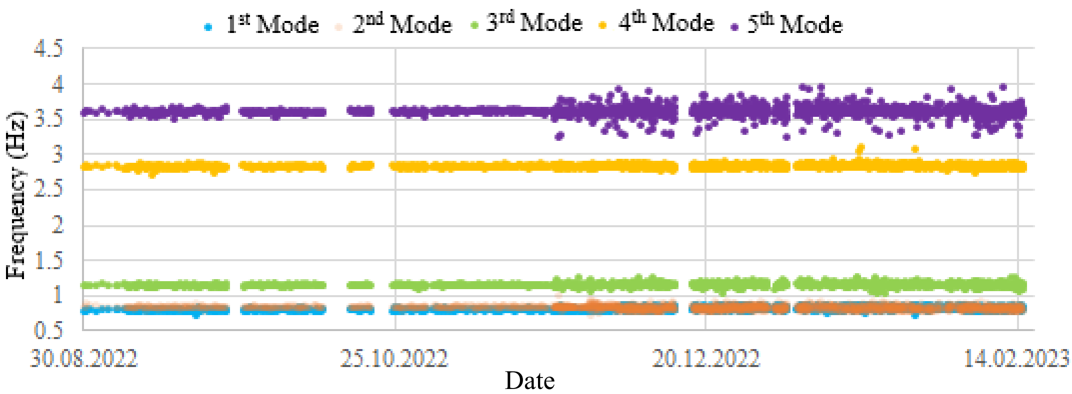

Fig. 6. Change of frequencies obtained automatically within the scope of the developed platform according to time

2.2. Structural health monitoring in Tekkale Viaduct

Within the scope of long-term structural health monitoring study in Tekkale Viaduct located in Yusufeli District of Artvin Province, sensor installations were carried out and data transfer was provided to the web-based site. The bridge was constructed with the balanced cantilever technique and consists of 5 spans with span distances ranging from 53 to 175 m. The total length of the bridge is 628 m. The superstructure width and the highest pier length of the bridge are 14.5 m and 144 m, respectively. A total of three sensors were placed in the middle of the main span, one in four and one on the column, in the section where the structural health monitoring based on vibration of the Tekkale Viaduct is the largest. The data has been integrated into the Cloud-Based Structural Health Monitoring Platform. The SARA SL06 model has been used as the three-axis accelerometer sensor. Fig. 7 shows the placement and installation visuals of the accelerometer sensors. Fig. 8 shows the main visual screen of the data obtained from the web-based structural health monitoring platform. Fig. 9 shows the change of automatically obtained frequencies with respect to time.

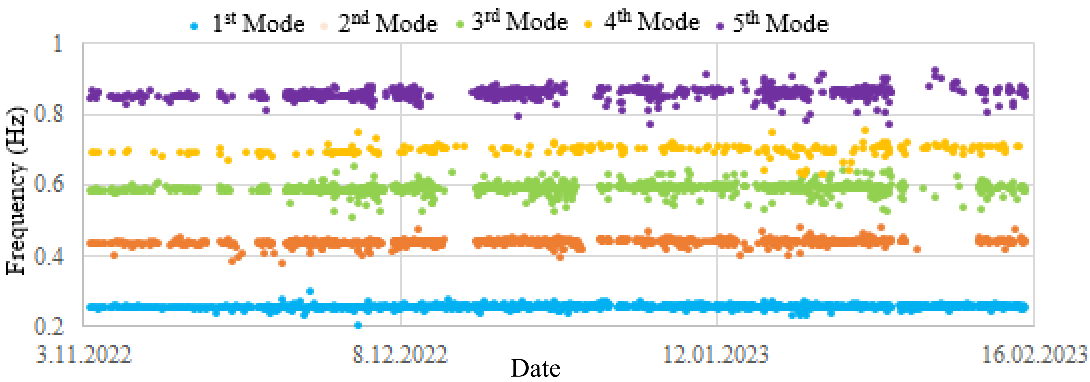

Fig. 9. Change of frequencies obtained automatically within the scope of the developed platform according to time

2.3. Structural health monitoring in Rize-Artvin Airport technical block tower building

Within the scope of long-term structural health monitoring study in Tekkale Viaduct located in Pazar District of Rize Province, sensor installations were carried out and data transfer was provided to the web-based site. The Technical Block Tower Building has a core reinforced concrete shear wall structural system designed with concentric walls, and it has a height of approximately 30.5 meters from the foundation level. The thicknesses of the outer and inner shear walls are 40 cm and 30 cm, respectively, while their diameters are 7.10 meters and 3.50 meters, respectively. The building features a reinforced concrete staircase that connects the two cores and spirals upwards along the height of the core. The tower building consists of a total of 8 floors, including the ground floor and 7 additional floors. In the Technical Block Tower Building, a total of 7 three-axis accelerometer sensors are installed: one on the ground floor, and two on the 2nd, 4th, and 7th floors. The three-axis accelerometer sensor used is the SENSEBOX 7043-D model. Additionally, a meteorological data measuring sensor is installed on the rooftop. Fig. 10 shows the placement and installation visuals of sensors. Fig. 11 shows the main visual screen of the data obtained from the web-based structural health monitoring platform. Fig. 12 shows the change of automatically obtained frequencies with respect to time.

3. Conclusions

This study presents the development and implementation of a cloud-based Structural Health Monitoring (SHM) platform designed to monitor the dynamic behavior and structural integrity of engineering structures. By leveraging advanced technologies in cloud computing, web-based platforms, and deep learning methodologies, the system provides a comprehensive solution for real-time monitoring, data processing, and anomaly detection. The key findings of this study include:

- The platform facilitates continuous monitoring of engineering structures through the integration of various sensors, enabling real-time data acquisition.
- The collected sensor data is transferred, stored, and processed in a centralized cloud environment, providing easy access to engineers and decision-makers.
- The system incorporates deep learning techniques for automatic anomaly detection, ensuring early identification of potential structural issues.
- Bayesian Neural Networks are utilized to determine confidence intervals, taking into account uncertainties arising from environmental changes, enhancing the reliability of the data.
- The platform's user-friendly interface allows for seamless visualization of structural data, historical comparisons, and the ability to respond to emergency alerts promptly.

In conclusion, the developed cloud-based SHM platform significantly enhances the accessibility, efficiency, and accuracy of structural health monitoring systems. It represents a shift toward more proactive, data-driven decision-making in the maintenance and safety of critical infrastructure. Future work will focus on expanding the system's capabilities to include more advanced AI-driven diagnostics and its application to a broader range of engineering structures, ensuring its scalability and adaptability to evolving industry needs.

Hysteretic behaviour of aluminium foam filled double-skin steel sections

Gulshen Shukurova[1], Emre Ozyurt*[2]

[1] Gümüşhane University, Graduate Education Institute, Gümüşhane, Türkiye
[2] Gümüşhane University, Faculty of Engineering and Natural Science, Department of Civil Engineering, Gümüşhane, Türkiye

Abstract. This study uses the non-linear finite element method to evaluate the hysteretic behaviours, energy absorbation capacities, and ductility ratios of corrugated and non-corrugated double-skin sections under cyclic loads. The double-skin sections consist of layers (inner and outer skins) in different combinations of aluminium foam filling. Also, the concrete-filled columns are modelled as a reference column. The investigated sections include configurations where both inner and outer skins are flat (without corrugations), only the inner skin is corrugated and the outer skin is flat, or only the outer skin is corrugated and the inner skin is flat. In the parametric analyses using the validated Finite Element (FE) models, the hysteretic behavior, energy dissipation capacity, plastic strain distributions, and ductility ratios of the composite columns are evaluated. The results revealed that increasing the wall thickness of the concrete-filled columns increased the strength and the ductility. In addition, the configurations with outer surface corrugated generally exhibited better cyclic performance for each fi. As for the aluminium foam-filled columns, their load-bearing capacity was less than their corresponding concrete-filled specimens, but they had higher energy dissipation capacity and ductility ratios. It may be possible to use aluminium foam-filled corrugated members in seismic regions because of their high energy dissipation capacity and the advantage of lightweight.

Keywords: Aluminium foam; Concrete filled; Corrugated; Energy absorbation capacity; Hysteretic behaviour.

1. Introduction

In recent years, the demand for lightweight yet high-performance structural materials has significantly increased in the field of civil engineering. Structural efficiency, cost-effectiveness, and material sustainability have become critical factors in the selection of construction materials. Corrugated structures, known for their superior strength-to-weight ratio, have been widely used in various applications, including aerospace, automotive, and civil engineering. These structures offer enhanced mechanical properties due to their unique geometry, which provides excellent load-bearing capacity and energy absorption characteristics. However, while numerous studies have been conducted on concrete-filled corrugated panels, limited research has been devoted to exploring the potential of foam-filled configurations, particularly under cyclic loading conditions.

Foam-filled structures present a promising alternative to traditional concrete-filled systems by offering significant weight reduction while maintaining structural integrity. The integration of foam as a filling material has the potential to improve energy dissipation, stiffness, and overall durability, making them suitable for seismic and impact-resistant applications. However, the structural response of foam-filled corrugated systems under cyclic loading remains largely unexplored. Understanding the mechanical behaviour of these systems is crucial for assessing their viability in real-world engineering applications.

The behavior of concrete filled double skin steel tube (CFDSST) members under cyclic loading has become a subject of significant interest in recent years. The researchers have explored various aspects of these structures, including their mechanical properties, failure mechanisms, and potential applications in structural engineering. Fan et al. (2024) evaluated the failure mechanism under cyclic loads by performing low-cycle fatigue tests of CFDSST specimens under different loading conditions and evaluated the effects of parameters such as clearance, slenderness and shear rate, revealing that low fatigue life is related to defects and stress levels. Zhou et al. (2022); (2016) studied the failure mechanism of CFDSST beam-columns under cyclic bending loading, evaluated the

*Corresponding author, E-mail: emre.ozyurt@gumushane.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_896

effects of design parameters on ductility, energy dissipation capacity and ultimate moment capacity, verified the accuracy of existing design methods and showed that the strain hardening of stainless steel and the limiting effect of tubes on concrete should be taken into account in the design. Lu et al. (2022) assessed the effects of various parameters on the torsional capacity of CFDSST columns and suggested accurate design formulas to predict the torsional capacity. Wang et al. (2024) analyzed the effects of different parameters (void ratios, axial compression ratios, infill material types) on the hysteretic performance of CFDSST columns with non-standard D/t ratios, and proposed a moment resistance model that takes into account the tensile strength of ECC.

Additionally, the innovative form of concrete filled corrugated steel tube (CFCST) members have been studied. Zou et al. (2023) proposed a new formulas to predict the ultimate axial strength of CFCST columns, investigated the confinement mechanism of multicellular steel tube columns by axial compression tests and 3D finite element modeling. Fang et al. (2024) examined the torsional hysteretic behavior in detail by testing nine specimens under cyclic torsional loads. Tong et al. (2024) performed axial compression tests of 20 CFCST columns, proposed a theoretical formula for the axial bearing capacity of CFCST columns. Fang et al. (2021) examined the failure modes, axial load-axial strain curves, plastic strains and stress failures in detail by performing monotonic and cyclic axial compression tests on CFCST specimens with large helical angles. Farahi et al. (2016) further analyzed the compressive behavior of concrete-filled double-skin sections consisting of corrugated plates, emphasizing their mechanical efficiency.

Furthermore, several studies have focused on the behavior of aluminium foam filled steel tube (AFST) members under various loading conditions. Duarte et al. (2018); (2015) investigated the static and dynamic axial crush performance of in-situ AFST, demonstrating the potential of these structures for energy absorption applications. Yanjun et al. (2023) and Li et al. (2018) conducted experimental and numerical studies AFST, analyzing their mechanical behaviors and crashworthiness properties. Moreover, Seitzberger et al. (1997) investigated the crushing behavior of axially compressed AFST, contributing to the understanding of impact resistance.

This study aims to investigate the cyclic behavior of double-walled corrugated structures reinforced with foam filling. The primary objectives include analyzing the stiffness, energy dissipation capacity, and load-bearing performance of foam-filled panels and comparing their behavior with conventional concrete-filled structures. Hence, this study evaluates whether foam-filled members can be applicable as a viable alternative to heavier and more rigid concrete-filled designs.

2. Verification of numerical model

In this study, the numerical modeling of the compressive behaviour of double-skin steel sections with concrete filling was validated. The results of the experimental studies conducted by Farahi et al. (2016) were used for validation study. A nonlinear finite element (FE) method was used, for simulating the experimental study. In double-skin steel sections, the interaction between the steel surface and the concrete filling significantly affects the overall behaviour of the composite member. Therefore, the interaction definitions was one of the most important issues of the numerical modeling. In addition, the appropriate material models were selected to represent the actual behaviour of steel and concrete materials.

The numerical stability of the FE simulations is another important issue to be considered, especially during loading step. Events such as the onset of local buckling in steel walls, crushing and contact interactions in concrete can cause sudden strength decreases and local instabilities. In such cases, it may be necessary to use dynamic analysis methods instead of static analysis methods. In this study, ABAQUS/Explicit dynamic analysis method was used to model the compressive behavior of CFDST columns accurately.

2.1. Detail of numerical model

Fig. 1 illustarates geometrical configurations of CFDST columns of Farahi et al. (2016). A constant length and steel wall thickness of 1000 mm and 3 mm were used in their test, respectively. The outer and inner widths of the columns are also presented in Fig. 1. Table 1 summarizses the geometrical parametes of the corrugated steel plates. Accordingly, the columns are categorised into two types, namely IC1 and OC1, based on positioning of the corrugations on the inner or outer surface. Fig. 2 illustrates the typical geometry of the cross-section of a corrugated steel plate. The geometry consists of alternating inclined and flat segments, forming a repetitive zig-zag pattern. Key geometrical parameters include the inclined length *(l)*, horizontal length *(a)*, vertical depth *(b)*, plate thickness *(t)*, and angle of inclination *(α)*.

The boundary conditions were defined to ensure that the numerical model accurately replicated the experimental setup. The bottom of the column was rigidly fixed in all directions to prevent any translational or rotational movements. The top of the column, on the other hand, was allowed to move along the vertical direction, providing the necessary freedom for axial deformation under the applied loads.

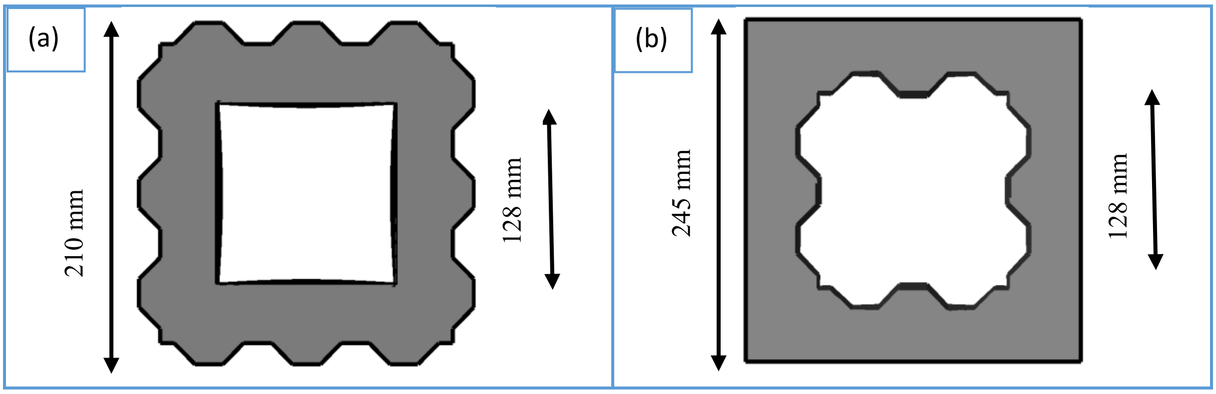

Fig. 1. Geometrical configurations; (a) OC1 from the test of Farahi et al. (2016), (b) IC1 – from the test of Farahi et al. (2016)

Table 1. Geometrical parameters of the corrugated steel plate

	α (°)	a	h	t	l	d	c	b
Type1	45	20.00	15.00	3.00	70.00	15.00	21.21	210.00

2.2. Material models

In this study, the Concrete Damaged Plasticity (CDP) model in Abaqus software was used to model the behaviour of concrete. This model allows us to define the behaviour of concrete under compression and tension separately. In the model, the rules of increasing the strength (hardening) and decreasing the strength (softening) of the concrete and the development of the scalar damage variable in compression and tension were developed based on the model of Han et al. (2001). Both the increase/decrease in strength and the development of the damage variable were defined depending on the plastic deformations (crushing and cracking strain) of the concrete after crushing and cracking, respectively. The ultimate compressive strength, Young's modulus and Poisson's ratio of the concrete were 40 MPa, 31350 MPa and 0.2, respectively.

Table 2. CDP model parameters

Dilation angle	Eccentricity	f_{b0}/f_c*	K	Viscosity Parameter
10	0.1	1.137	0.87	0.008

*f_{b0}/f_c: Ratio of the compressive strength under biaxial loading to uniaxial compressive strength

*K: Ratio of the second stress invariant on the tensile meridian to that on the compressive meridian

For steel material, 250 mild-steel flat plates were used in the specimens of Farahi et al. (2016). The steel material properties used in the numerical model are adapted as follows: The proof stress, tensile strength and strain conrresponding to the tensile strength were assumed to be 280 MPa, 410 MPa and 23%, while Young's modulus and Poisson's ratio of the concrete were 200000 MPa and 0.3, respectively.

2.3. Contact and element details

The rigid plates were attached to the both ends of the columns using tie function in Abaqus. Reference points were also defined at the centre of the rigid plates to apply loading and boundary conditions. Furthermore, the interaction between the steel plates and the concrete core was modeled using contact elements, which were carefully defined to represent the real bonding conditions between the two materials. In the numerical simulations, surface-surface contact was defined to model the interaction between the concrete core and the steel tube. Coulomb friction model with a friction coefficient of 0.25 was used for the tangential behavior of the contact interaction. This value represents the shear resistance between the concrete and the steel. The normal behavior was defined as 'hard contact'. This prevents the contact surfaces from penetrating each other and allows the transfer of pressure forces. In defining the contact interaction, the node-surface formulation of the surfaces was used.

Fig. 2 presents the finite element mesh details applied to the reference samples IC1 and OC1 columns. In the modeling of the steel plates, four-node, reduced integration shell elements (S4R) were used. The infill concrete was represented by eight-node, reduced integration linear brick elements (C3D8R). As a result of the mesh sensitivity analyses performed, the maximum mesh element size for the column models used in the simulations was determined as 10 mm.

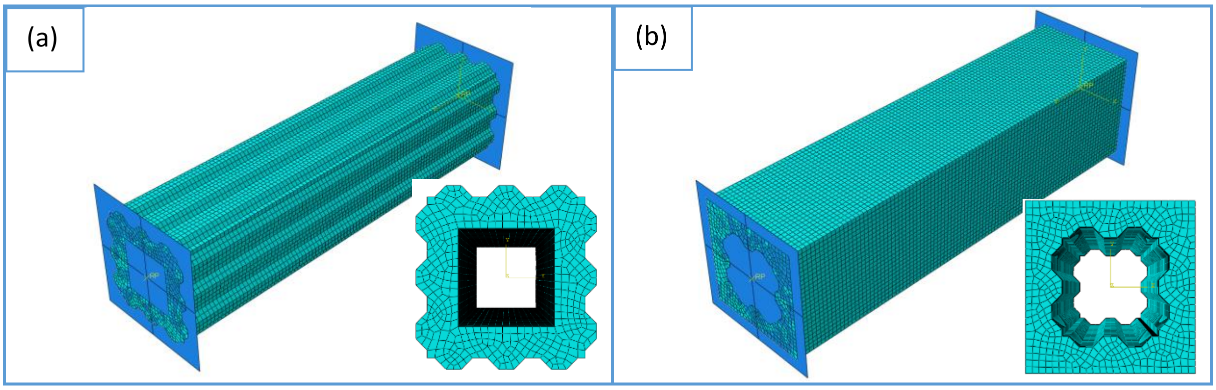

Fig. 2. Mesh layouts; (a) OC1, (b) IC1

2.4. Verification results

After the completion of the numerical modeling procedure, experimental results for reference specimens IC1 and OC1 were used to verify the accuracy of the developed finite element models. Comparison of the failure modes of OC1 and IC1 presented in Fig. 3 reveals that the numerical models show a high level of similarity with the experimental observations. Furthermore, examination of the load-nominal axial strain curves in Fig. 4 shows that all numerical models can predict the elastic behavior of the column specimens with considerable accuracy. The ultimate strength values obtained from the numerical simulations also show good agreement with the values obtained from the experimental studies. It is anticipated that the approach used in this validation study may also provide reliable results in the parametric studies of composite steel columns, both with concrete fill and aluminum foam fill.

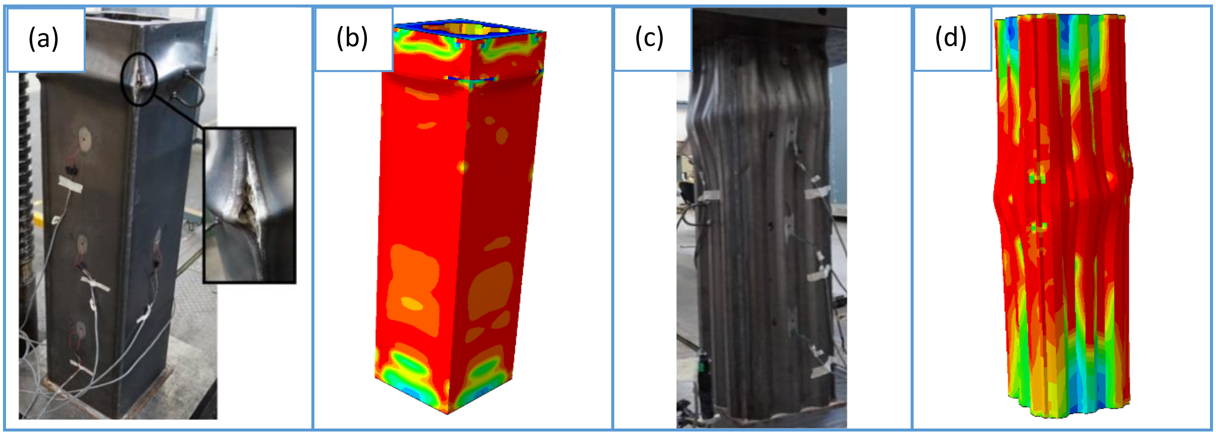

Fig. 3. Comparison of the failure modes; (a) IC1 – Test results of Farahi et al. (2016), (b) IC1 – FE results, (c) OC1 – Test results of Farahi et al. (2016), (d) OC1 – FE results

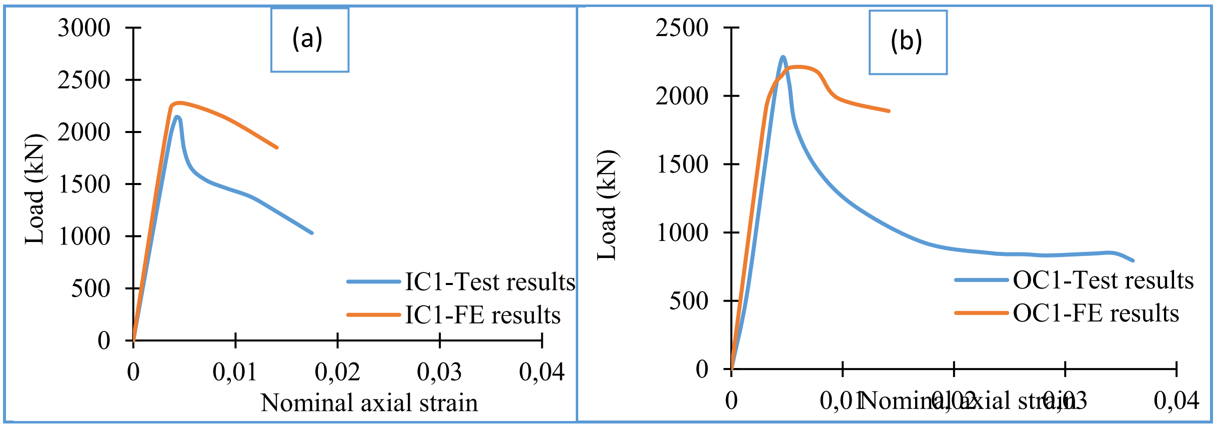

Fig. 4. Comparison of the nominal axial strain-load curves; (a) IC1, (b) OC1

3. Parametric study

In this study, the behavior of double-skin steel corrugated columns under cyclic loads was investigated with a parametric approach. In the numerical analyses, the effects of parameters such as the positioning of the corrugations on the inner or outer surface, the wall thickness of the steel walls and the type of filling material (concrete or aluminum foam) on the structural behavior were evaluated comprehensively. In the parametric analyses, the wall thicknesses of the steel walls were taken into account in three different values as 3 mm, 5 mm and 7 mm.

The effects of those parameters on energy absorption capacities, ductility ratios and damage mechanisms of concrete-filled columns or aluminum foam-filled columns were compared. Each column specimen examined in the parametric study was numbered with a unique code indicating the position of the corrugated plate ('O' outer, 'I' inner surface), the infill material ('C' concrete, 'A' aluminium foam) and the steel wall thickness in mm; for example, 'OC1-3' refers a column with corrugated outer surface, concrete infill and 3 mm wall thickness, and 'IA1-5mm' is a column with corrugated inner surface, aluminium foam infill and 5 mm wall thickness.

3.1 Definition of loading protocol

The loading protocol used in the parametric study was designed in two stages in order to reflect the realistic behaviour of the structural members. In the first stage, the axial load carrying capacity (P_u) of each finite element model was determined. This capacity represents the maximum strength of the composite columns under axial loads. In the second stage, a constant axial load was applied to the column. This axial load was set as 20% of the determined P_u value.

Under the constant axial load, the columns were subjected to lateral cyclic loading. The details of the applied cyclic loading are shown in Fig. 5. Based on the yield displacement (Δ_y) estimated by FE analysis, it was applied at $0.25\Delta_y$, $0.5\Delta_y$ and $0.75\Delta_y$ levels. After the yield strength was reached, the displacements were increased to Δy, $1.5\Delta_y$, $2\Delta_y$, $2.5\Delta_y$, $3\Delta_y$, $5\Delta_y$ and $7\Delta_y$ levels. One cycle was applied at each displacement level. The smilar cycling loading proccess was also used by previous researchers (Mashaly et al., 2011; Ozyurt & Gunaydin, 2024; Seitzberger et al., 1997; Xia et al., 2017).

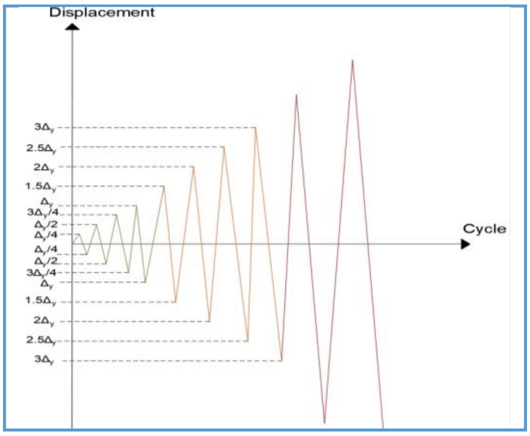

Fig. 5. Horizontal loading protocol

3.2 Hysteretic behavior

The loading protocol used in the parametric study was designed in two stages in order to reflect the realistic behaviour of the structural members. In the first stage, the axial load carrying capacity (P_u) of each finite element model was determined. This capacity represents the maximum strength of the composite columns under axial loads. In the second stage, a constant axial load was applied to the column. This axial load was set as 20% of the determined P_u value. Fig. 6 comparatively illustrates the hysteretic behavior of columns with corrugated plates on the outer (O) or inner (I) surfaces, filled with concrete (C) or aluminum foam (A) and with different wall thicknesses (3, 5, 7 mm).

Fig. 6(a) presents the hysteretic curves of the OC1-3) and IC1-3 columns, both concrete filled and 3 mm wall thickness. It is understood that the IC1-3 column exhibits wider hysteretic loops and therefore can dissipate more energy. In addition, the maximum load level reached by the IC1-3 column is higher than that of the OC1-3 column. Increasing the wall thickness in the concrete-filled composite columns significantly exhibited the wider hysteretic loops, indicating a more stable behavior under cyclic loading, while columns with internal corrugated surfaces tend to offer higher strength and energy dissipation capacity compared to those with external corrugated surfaces at the same wall thickness.

Fig. 6(d) compares the hysteretic curves of the OA1-7 and IA1-7 columns with aluminum foam filling instead of concrete filling and having a wall thickness of 7 mm. It is observed that the hysteretic loops of the aluminum foam filled columns are narrower and the maximum load levels they reach are significantly lower compared to the concrete filled columns. However, it is observed that the IA1-7 column has a slightly better energy dissipation capacity and can carry higher loads than the OA1-7 column.

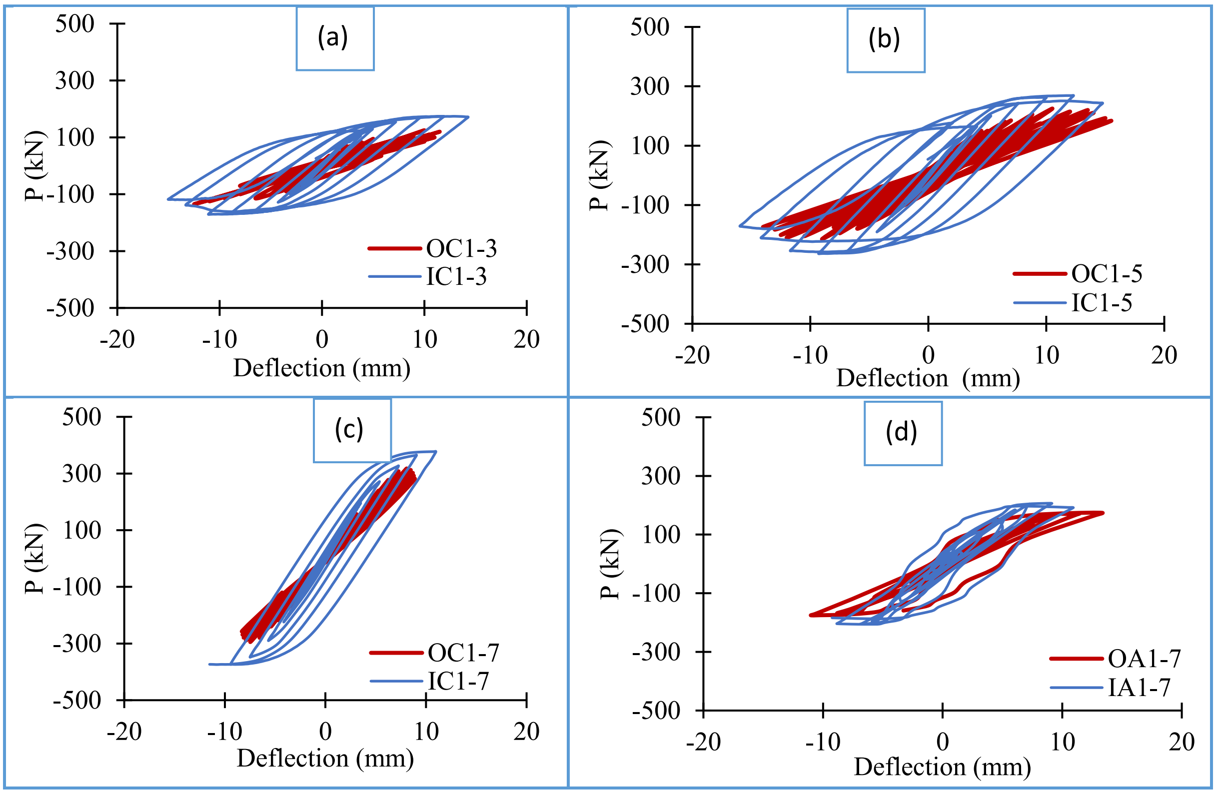

Fig. 6. Hysteretic curves of composite columns; (a) OC1-3&IC1-3, (b) OC1-5&IC1-5, (c) OC1-7&IC1-7, (d) OA1-7&IA1-7

3.3 Energy dissipation capacity

In this section, the normalised energy dissipation capacities (E/E_y) of composite columns with different configurations under cyclic loads are assessed. Fig. 7 show the change in the energy dissipation capabilities of the columns as the number of cycles progresses. Here, E represents the energy dissipated in each cycle and E_y represents the energy dissipation capacity at the initial yield stress. The energy dissipation capacity of composite columns are evaluated using the area under the load-displacement hysteretic curves.

The columns with corrugated inner surfaces and especially aluminum foam filled columns can reach much higher energy absorption capacities according to the normalised energy dissipation. In the concrete filled columns, increasing the wall thickness and positioning the corrugated plate on the outer surface positively affect the energy absorption capacity. The high energy absorption potential of the aluminum foam filled columns indicates that such lightweight composite structural elements can be a promising alternative to increase the performance of structural systems under dynamic loads.

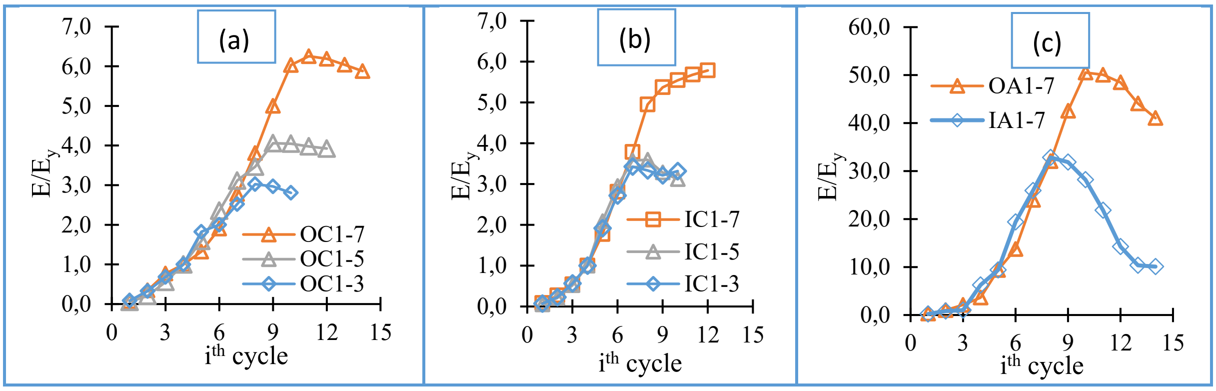

Fig. 7. Comparison of normalised energy dissipation capacity of composite columns; (a) OC1, (b) IC1, (c) OA1&IA1

Fig. 8 presents the plastic equivalent strain (PEMAG) distributions of the FE results of composite columns with aluminum foam filling and 7 mm wall thickness, with corrugated outer and inner surfaces. It can be seen that the position of the corrugated plate has a significant effect on the plastic deformation mechanism and distribution. While the plastic deformation in the IA1-7 column with the corrugated inner surface remains more localised and at lower levels, the plastic deformation in the OA1-7 column with the corrugated outer surface is more widespread and severe. The reason for that the presence of the corrugated plate on the outer surface may increase the yielding area of the column by dissipating higher energy with the aluminum foam filling.

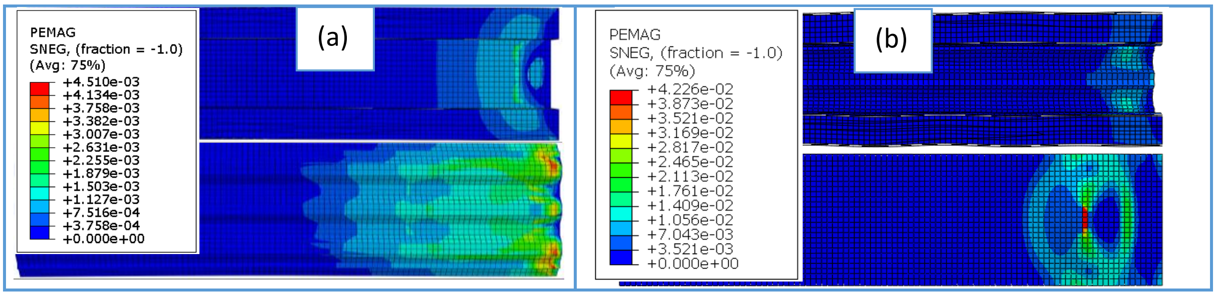

Fig. 8. Comparison of plastic equivalent magnitude of composite columns; (a) OA1-7, (b) IA1-7

3.4 Ductility

The effects of the steel wall thicknesses and infill materials on the ductility ratios (μ) of the composite columns are examined. The ductility ratio is the displacement at failure (δ_u) to the displacement at yielding (δ_y) ($\mu = \delta_u/\delta_y$). Fig. 8 compares the ductility performances of the composite columns with outer surface corrugated (O1) and inner surface corrugated (I1) configurations for the concrete filled (CF) and aluminum foam filled (AF) columns at different steel wall thicknesses.

It can be noted from Fig. 8 that there is an increasing tendency in the ductility ratios of O1 and I1 columns with increasing in the steel wall thickness. In addition, the O1 column provides a better ductility performance than the corresponding I1 column because of larger yielding areas. As for the AF columns, they exhibit significantly higher ductility ratios compared to the corresponding concrete filled columns. In particular, the ductility ratio of the O1 aluminum foam filled column is the highest. Moreover, the I1 AF column also exhibits significantly higher ductility than its CF counterparts.

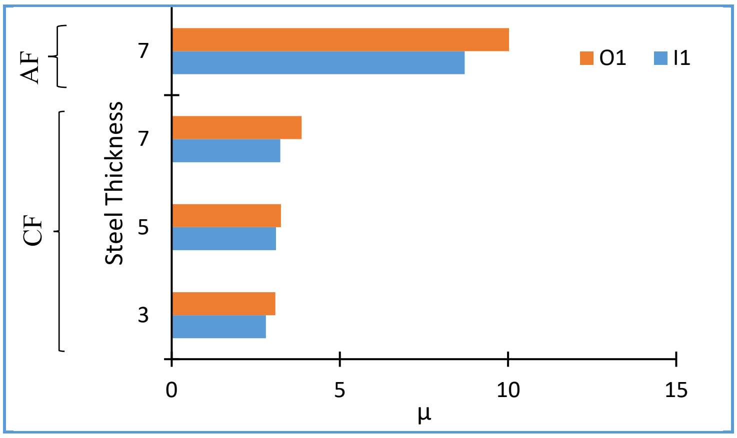

Fig. 8. Comparison of ductility ratios of composite columns with various steel thicknesses and fillings

4. Conclusions

This study comprehensively examines the structural behavior of double-walled corrugated composite columns under cyclic loads by the numerical methods. The obtained hysteretic curves showed that the energy dissipation capacities and ductility ratios, the location of the corrugated plate, the steel wall thickness and the type of infill material (concrete or aluminum foam) have significant effects on the performance of the composite columns. In the concrete-filled columns, increasing wall thickness generally increases the load-carrying capacity and energy dissipation, while the configurations with external corrugated surfaces exhibited superior cyclic behavior compared to those with internal corrugated surfaces. In terms of ductility, while increasing wall thickness in concrete-filled columns tended to cause an increase in ductility ratios, the columns with external corrugated surfaces provided better performance than those with internal corrugated surfaces. Although aluminum foam-filled columns had significantly lower load-carrying capacities compared to concrete-filled columns with the same wall thickness, they showed significantly superior performance in terms of energy dissipation capacities and especially ductility ratios. In particular, the columns with corrugated aluminum foam filler on the outer surface reached the highest ductility values. Plastic deformation analyses revealed that the location of the corrugated plate significantly affects the damage mechanisms and deformation distribution. In conclusion, this study emphasizes the critical role of material selection and geometric configuration in the design of lightweight and high-performance composite structural elements. In particular, the high energy dissipation and ductility potential of aluminum foam filled corrugated columns offers a promising alternative for seismic and impact resistant applications.

A comprehensive assessment of the as-built projects of severely damaged or collapsed residence in Malatya after Feb 6, 2023, Kahramanmaraş earthquakes

Onur Onat*[1], Şenol Albayrak[1]

[1] *Inonu University, Department of Civil Engineering, 44280, Malatya, Türkiye*

Abstract. The basic purpose of this study is to evaluate design parameters of as-built blueprint residence project in Malatya. This study includes theoretical investigation on the base of as-built projects. For this aim, 41 projects were investigated in detail and then selected features were presented with suitable graphs. These selected features were construction year, earthquake regulations in force in the year the structure was built, target concrete compressive strength, target steel grade, thickness of foundation and deep foundation level (excavation from ground surface), total height and settlement area of residences, numbers of column in transvversal and longitudinal directions of the plan, minimum distance of shear reinforcement in column and beam, minimum tension reinforcement in beam and minimum reinforcement in colum section was evaluated.

Keywords: Kahramanmaraş earthquakes; Building stock of Malatya; Design evaluation; Blueprint project

1. Introduction

On February 6, 2023, a pair of earthquakes with magnitudes Mw 7.7 and Mw 7.6 struck the Eastern Anatolian Fault Zone, centered in the Pazarcık and Elbistan districts of Kahramanmaraş Province, an event which was later described as the "Disaster of the Century." These two powerful earthquakes, occurring 9 hours apart, affected 11 provinces in Eastern and Southeastern Anatolia, resulting in 50,783 fatalities, 107,204 injuries, and causing an economic loss of 178 billion USD. Despite being located 165 km from the epicenter of the Pazarcık-centered earthquake and 100 km from the Elbistan-centered earthquake, the province of Malatya was the third most affected, with 6,444 injuries and 1,237 fatalities. Although the loss of life was not as severe, Malatya experienced extensive damage, including heavy structural damage to 44,000 buildings. Therefore, significant destruction occurred in Malatya, with a large number of reinforced concrete buildings being either destroyed or severely damaged. The first of them occurred at 04:17 local time at Kahramanmaraş-Pazarcık. Nine hours later, at 13:24 local time, Kahramanmaraş-Elbistan triggered another earthquake. The measured PGA of the first earthquake was reached to 2.05 g (Onat et al. 2024). The earthquake exceeded the highest design level, which defied the Turkish Building Earthquake Code 2018 (TBEC, 2018). The two shocks inflicted significant damage, leading to a total of 53537 casualties. 39441 structural systems completely collapsed, while 206907 structural systems suffered heavy damage. The heavy damage distribution of old and new building stock from the epicenter to 165 km away from the Elbistan earthquake is mystery. This study given an emphasis to a different perspective of heavy damage distribution of building stock in Malatya in terms of code based design requirements. In the content of this manuscript, the statistical evaluation of heavily damaged and destroyed buildings has been conducted based on various parameters. Subsequently, using selected parameters from 41 different projects with varying construction years, a statistical analysis was performed to assess whether there were deviations from the design standards. Architectural conditions and minimum requirements in the relevant regulations were taken into account when determining the design parameters. The goal is to investigate and propose new inter-floor displacement limits for existing buildings.

2. Literature review of Kahramanmaraş Earthquakes

On February 6, 2023, the Kahramanmaraş earthquakes were extraordinarily strong ground motions that gave emphasis to the design of the earthquake level, whose return period is 2475 years and effected eleven cities, 124 town and 6929 villages as presented in Fig. 1.

*Corresponding author, E-mail: onur.onat@inonu.edu.tr

https://doi.org/10.31462/icearc2025_ce_eqe_898

Fig. 1. Earthquake effected cities during Feb 6, 2023

These earthquakes did not make up for the lack of knowledge in design and basic theory in far-fault territories, including classic and non-engineered structures. For this reason, after field observations in different cities, different results were registered in the literature. For instance, Vuran et al. (2024) investigated structural damages into two categories pre 2000 and post 2000. They emphasized that pre-2000 buildings could not satisfy the ductility requirements and updated basic calculations. İnce (2024) emphasized that the effective use of reinforcement, the hammer effect, and the discontinuous frame that resulted in damages and collapse in Adyaman. Kazaz et al. (2024) underlined the failure reasons as followed: i) production of shear wall system, ii) wall position, and iii) insufficient seismic detailing of new RC residences that resulted in total collapse of new buildings in Hatay. Tura et al. (2024) reported that missing confinement detail on site, mis bending of crossties, unexpected and early loss of moment capacity resulted in a severe damage beyond collapse prevention damage levels. Ozdemir (2024) prepared a list for an evaluation of the post-earthquake damages of 2790 buildings in the Antakya stock. They underlined that the construction year, building typologies, number of floors, ground level, and load-bearing systems as the primary factors contributing to damage. Sezgin et al. (2024) performed field observations in İskenderun to identify main reasons for damage and failure. The basic problem is identified as liquefaction in İskenderun and Hatay, problems with material quality, aggregate and gradation, the effect of humidity on concrete and reinforcement, problems with design and application, loose detailing of main bearing elements, stairs that don't have enough bearing capacity, and finally not following the rules about irregularities that aren't allowed in seismic codes. Sevim et al. (2024), Erbaş et al. (2024) and Yön et al. (2025) highlighted the conventional damages that occurred, particularly in old building stock constructed during the out-of-date seismic codes. After these valuable field observations and numerical studies, there is a question: What is the problem related to accepted projects from the local municipality? This study is devoted to clarify this questions on the base of design parameters.

3. Materials and method

In the current study, the parameters that were considered for the evaluation of the examined structures according to their blueprint projects are as follows:

a) The project regulations for the structure and the site boundaries,
b) Foundation and soil characteristics,
c) Material properties,
d) Architectural features,
e) Structural load-bearing system.

The evaluation was carried out based on these headings. Subsequently, the parameters evaluated have been explained in detail. Additionally, the subheadings under the specified main headings are as follows: reinforced concrete damage states of the structures; location, municipal regulations, construction year, number of floors, concrete class, steel class, total building height (m), settlement area (m²), soil type, foundation type, foundation thickness (cm), existence of a basement, foundation excavation depth, ground floor height, short shear wall ratio, long shear wall ratio, short column count, long column count, smallest column dimensions, beam dimensions, plan irregularity, vertical irregularity, presence of mezzanine, number of cantilever beams, column reinforcement ratio, shear wall reinforcement ratio, minimum beam reinforcement, beam ratio in tension zones, beam reinforcement ratio, column stirrup spacing (cm), beam stirrup spacing, and other similar mechanisms have been examined.

4. Results and discussion

4.1. The earthquake regulations in force and the administrative boundaries at the time the structure was designed
In this subsection, the regulations in force during the years when the structures were initially designed have been identified, with the specific regulations being the 1968, 1975, 1998, 2007, and 2018 codes. A total of 41 projects were examined according to these regulations, with the number of structures analyzed for each regulation being 3, 10, 8, 14, and 6, respectively, thus generating quantitative data as seen in Fig. 2.

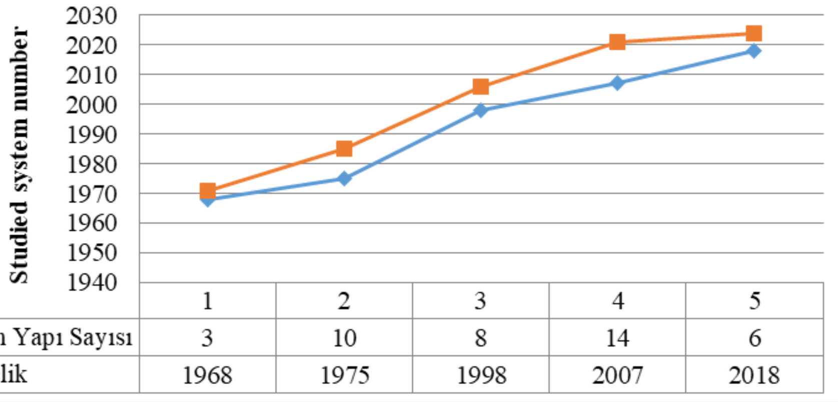

Fig. 2. The regulations under which the examined structures were designed and the number of structures analyzed

Under the aforementioned regulations, the construction years of the examined structures are as follows: For structures designed according to the 1968 regulation, the construction years range from 1971 to 1974. Structures designed under the 1975 regulation were built between 1976 and 1997. Buildings designed according to the 1998 regulation were constructed between 1998 and 2000. Structures designed under the 2007 regulation were built between 2015 and 2018. Lastly, buildings constructed according to the 2018 regulation were built between 2018 and 2021. Regarding the administrative boundaries, Malatya gained metropolitan status in 2012 with the Municipal Law, and it remained as Malatya province under the 1968, 1975, 1998, and 2007 regulations. However, when the 2018 regulation was enacted, Malatya province was divided into two districts: Yeşilyurt and Battalgazi. Our study focused on the structures within the boundaries of Yeşilyurt, where the seismic impact is the most destructive.

4.2. Foundation and soil characteristics
In this subsection, the foundation and soil characteristics of the structures designed under the regulations in force during their construction years are evaluated. It was found that the buildings designed according to the 1968 and 1975 regulations were of lower height, while those designed according to the 1998, 2007, and 2018 regulations were taller. Additionally, there were no basements in buildings designed under the 1968 regulation, whereas basements began to be constructed starting from the years following the 1975 regulation. The foundation thicknesses have gradually increased over time, as the regulations required thicker foundations for enhanced structural integrity. In terms of foundation types, buildings designed under the 1968 regulation generally used individual (single) foundations, while those under the 1975 and 1998 regulations employed continuous (slab) foundations. In contrast, buildings designed according to the 2007 and 2018 regulations were found to predominantly use raft foundations. The temporal changes in these parameters can be attributed to the increasing need for safer and more robust structures as buildings became taller, leading to a growth in the physical dimensions of the buildings.

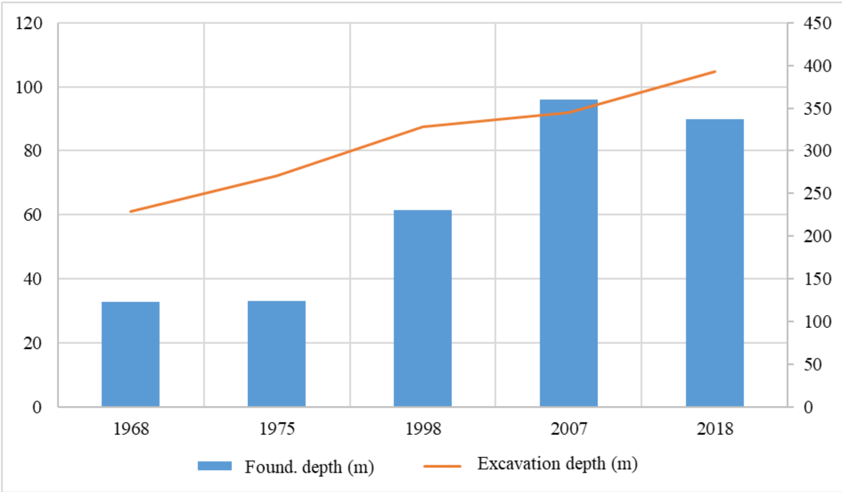

Fig. 3. The foundation excavation depth and foundation thickness of structures under the regulations

4.3. Material properties

In this evaluation step, it was observed that as the physical dimensions of the structures examined increased within the framework of the mentioned regulations, there has been a consistent increase in concrete and steel grades over time. This trend can be attributed to the fact that, in an effort to save costs, people began to build taller structures by coming together, which in turn necessitated improvements in the quality of concrete and steel grades. This conclusion is supported by the numerical data obtained from the analysis.

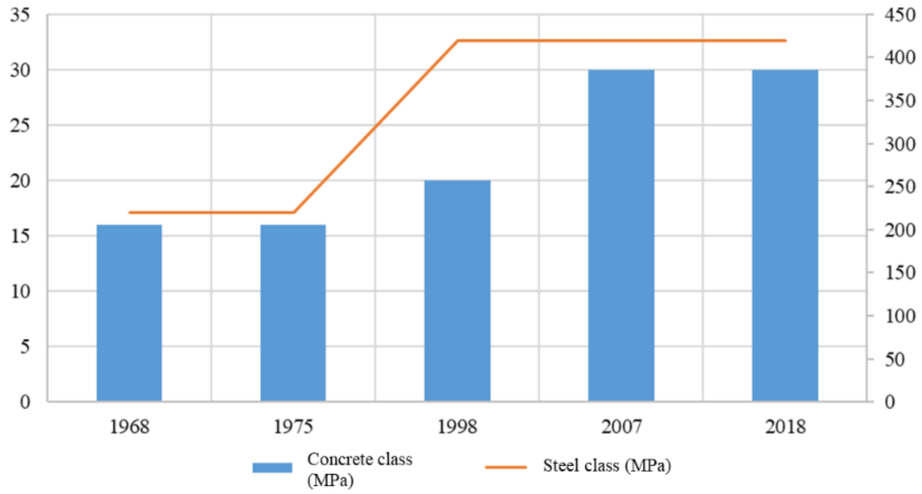

Fig. 4. Changes in concrete grade and steel grade according to the regulations

4.4. Architectural features

In terms of architectural features, when evaluating the structures based on the regulations for each respective construction year, it was observed that the footprint areas, total building heights, and the number of floors of buildings designed from the 1968 regulation to the 2018 regulation have progressively increased. In this context, it was also assessed that the increasing living standards of people have led to a growing need for higher buildings and more floors, reflecting the changes in the coefficients and total heights of the buildings over time.

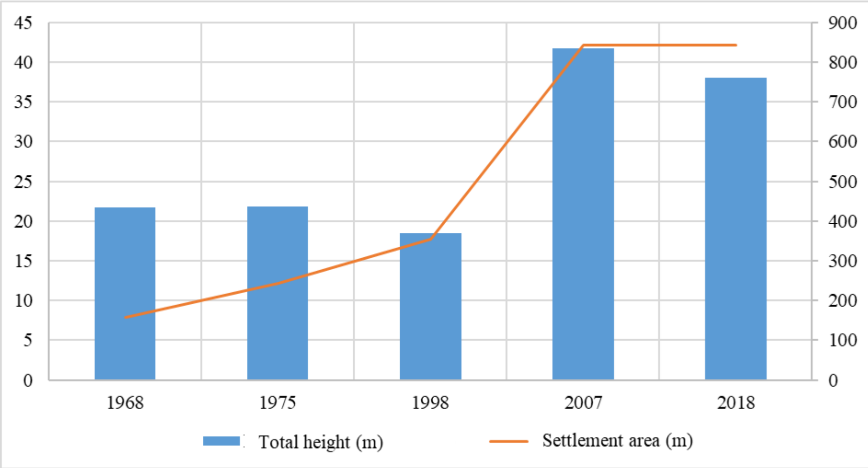

Fig. 5. The relationship between the construction area in m^2 area and total building height according to the regulations

When considering the physical dimensions of buildings designed under the 1968 regulation, it was observed that the number of tie beams was low, and mezzanines were not constructed. In contrast, for buildings designed according to later regulations, the number of tie beams increased, and mezzanines were built until the 2007 regulation. However, no mezzanines were included in buildings designed according to the 2018 regulation. Additionally, it was found that there were no vertical or plan irregularities in structures designed under the 1968 regulation. In buildings designed according to the 1975 and 1998 regulations, soft-story irregularities were observed. For buildings designed under the 2018 regulation, there were no mezzanines or vertical and plan irregularities. Furthermore, the ground floor heights have also increased over time, in accordance with the physical dimensions of the buildings, reflecting the changes in the regulations from the past to the present.

4.5. Main bearing structural system
According to the average project data based on the relevant regulations, the smallest beam size is 20x60 cm, and the smallest column size is 25x60 cm. The number of columns in both the long and short directions has increased with the regulations, which can be attributed to the increased footprint area of the buildings. The wall ratio in the long and short directions was found to be nonexistent in buildings designed under the 1968, 1975, and 1998 regulations. However, for buildings designed according to the 2007 and 2018 regulations, the average wall ratios were calculated as 0.26 and 0.0085, respectively. In structures designed under the 1968 regulation, the number of columns in both the short and long directions was lower compared to those designed under later regulations. Between the 1975 and 1998 regulations, the number of columns in the long direction remained stable, but it increased again in buildings designed according to the 1998, 2007, and 2018 regulations. The number of columns in the short direction, however, increased from the 1968 regulation until the 2007 regulation, with a subsequent decrease under the 2018 regulation.

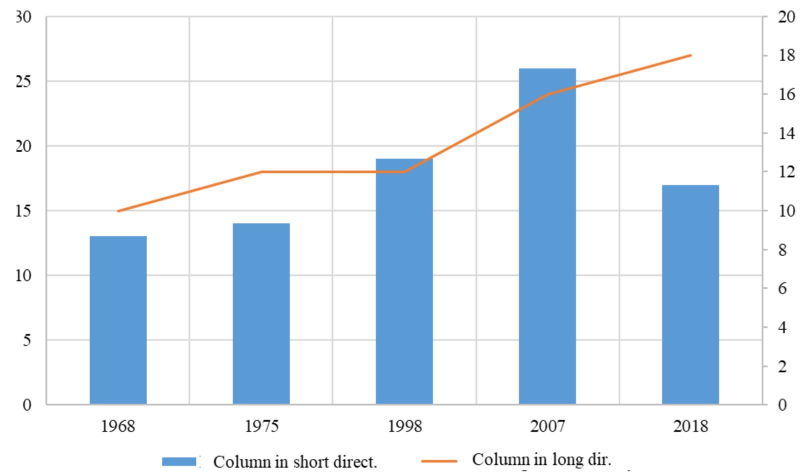

Fig. 6. The relationship between the number of columns in the short direction and the number of columns in the long direction for structures designed according to the regulations

It was observed that in the 1968 and 1975 regulations, there was no increase in the spacing of beams, columns, and stirrups. However, in structures built under subsequent regulations, the spacing was adjusted according to the regulations. This indicates that the concept of ductility was incorporated into the seismic behavior of buildings through the regulations.

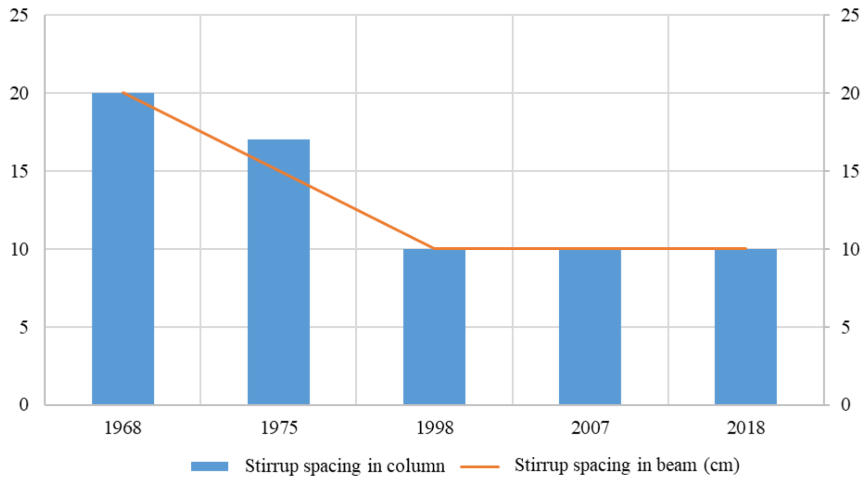

Fig. 7. Changes in the beam stirrup spacing and column stirrup spacing for structures designed according to the regulations

It was also observed that the beam stirrup spacing decreased from 20 cm to 10 cm according to the regulations. The same situation applies to the columns, where the spacing also decreased from 20 cm to 10 cm. When analyzing the reinforcement ratio in beams, it was found that the regulations set a minimum limit for the reinforcement in the tension zone. These values changed from the minimum value prescribed by the regulations to a value of 0.0062.

In terms of column reinforcement ratio, according to the TBDY 2018 regulations, the longitudinal reinforcement area in columns should not be less than 1% and should not exceed 4% of the gross cross-sectional area. It was observed that the average column reinforcement ratio remained around 0.875% for buildings designed according to the 1968 and 1975 regulations, while it increased slightly above 1% after the 1998 regulation.

The dimensions of both columns and beams increased as a result of the physical dimensions of the structures. The number of columns increased according to the long and short directions of the building. The beam reinforcement ratio, tension region beam ratio, and minimum beam reinforcement values were at their minimum level under the 1968 regulation, whereas in later regulations, the values remained within the limits prescribed by the regulations.

Regarding the wall reinforcement ratio, it was found that there were no walls in structures designed according to the 1968, 1975, and 1998 regulations. However, in buildings designed according to the 2007 and 2018 regulations, the numerical values of the wall reinforcement ratio met the minimum conditions prescribed by the regulations.

5. Conclusions

Although many field studies and reports have been conducted regarding the earthquakes centered in Pazarcık-Elbistan, Kahramanmaraş on February 6, 2023, there have been no studies where criteria were set based on project data. However, this seminar aimed to address this gap, focusing solely on the province of Malatya. In this context, selected buildings were specifically studied and examined at the provincial level.

In this regard, in order to investigate the deficiencies in the design of reinforced concrete structures, a study of 41 building projects was conducted. The findings revealed that for structures built according to newer regulations, design errors related to vertical load-bearing were rarely observed. However, the presence of tie beams and non-continuous elements that did not form frames was noteworthy. It was also concluded that nonlinear analyses based solely on vertical loads and equivalent seismic loads were insufficient for buildings taller than 30 meters, and that performance-based design had become a necessity. Alongside design, factors such as unqualified workmanship, the use of unsuitable materials, and flaws in inspection mechanisms were emphasized as influential elements in this study.

Compressive behaviour of CFRP- and SFRP-confined concrete: A performance assessment

Biçimlendirilmiş: Aralık Önce: 24 nk, Sonra: 12 nk

Nisreen Salameh[1], Raafat El-Hacha*[1]

[1] *University of Calgary, Department of Civil Engineering, 2500 University Drive NW, Calgary, Alberta, Canada*

Abstract. This study presents a comparative assessment of the compressive behaviour of concrete cylinders confined with Carbon Fibre-Reinforced Polymer (CFRP) and Steel Fibre-Reinforced Polymer (SFRP) jackets. While the differences in compressive behaviour between CFRP- and SFRP-confined cylinders have been extensively explored in terms of ultimate axial strength, ultimate axial strain, and load-deformation behaviour, this research shifts focus to other critical performance metrics. These include dilation behaviour, CFRP and SFRP confinement effectiveness coefficient, strain ductility index, and energy ductility index. Forty-two cylinders were tested under uniaxial compression with varying concrete strengths, FRP types, and jacket thicknesses.
Experimental results reveal significant distinctions in the performance of CFRP and SFRP confinement systems. CFRP demonstrates superior confinement effectiveness due to its high stiffness and strength, significantly enhancing compressive strength and controlling dilation. In contrast, SFRP exhibits distinct advantages in strain and energy ductility, attributed to its metallic properties that enable greater deformation capacity and energy absorption. The study also provides insights into the interaction between the confining jacket and the concrete core, focusing on dilation behaviour as a key factor in confinement mechanics.
The findings underscore the importance of balancing strength and ductility in designing FRP-confined concrete systems. A comparative framework highlights the unique benefits of CFRP and SFRP, offering guidelines for optimizing material selection based on specific structural requirements. This research contributes to advancing the understanding of FRP-confinement mechanics and offers practical recommendations for enhancing the performance of confined concrete under axial loads.

Keywords: FRP-confined concrete; Compressive behaviour; Ultimate axial strength, Ultimate axial strain, Stress-strain behaviour

1. Introduction

The use of Fiber Reinforced Polymer (FRP) composites for strengthening and retrofitting concrete structures has seen significant advancements since their introduction in the late 1980s. Initially developed in Europe and Japan and later adopted in North America, FRP composites, including Carbon Fiber-Reinforced Polymer (CFRP) and Steel Fiber-Reinforced Polymer (SFRP), have become key materials for addressing structural deficiencies in civil infrastructure, particularly in seismic zones (Bank, 2006). The appeal of FRP composites lies in their high strength-to-weight ratios, corrosion resistance, and ease of installation compared to traditional methods like concrete and steel jacketing.

While traditional methods such as concrete and steel jacketing effectively enhance structural performance, they are often associated with significant drawbacks. Concrete jacketing increases the weight and cross-sectional area of structural members, while steel jacketing, though robust, is labour-intensive, costly, and prone to corrosion. In contrast, FRP composites provide an efficient solution, delivering enhanced structural performance with minimal weight addition, superior durability, and adaptable installation techniques. These advantages have driven extensive research into their use for concrete confinement (Fahmy & Wu, 2010).

Among FRP systems, CFRP has been widely studied, with its high stiffness and tensile strength enabling significant improvements in the compressive strength and ductility of confined concrete. The effectiveness of CFRP confinement has been well-documented, highlighting its ability to enhance ultimate axial strength, axial strain, and overall load-deformation behaviour (Lam & Teng, 2003; Li, 2006; Xiao & Wu, 2000). SFRP, on the other hand, offers unique advantages, combining the tensile strength of steel fibres with the lightweight and corrosion-resistant properties of polymer matrices. Recent studies, such as those by Mashrik (2011) and Abdelrahman (2011), have demonstrated the inherent ductility and cost-effectiveness of SFRP, although its application in concrete confinement remains underexplored.

Despite the significant body of research on the axial strength and strain capacity of FRP-confined concrete, certain key performance metrics have received comparatively less attention. Metrics such as dilation behaviour, strain efficiency, confinement effectiveness, and ductility indices are crucial for understanding the mechanics of FRP-confinement systems (Chen, 1982). Additionally, parameters such as FRP jacket thickness, type, and compressive strength of unconfined concrete significantly influence the performance of confined concrete.

This study addresses these gaps by providing a detailed comparative analysis of CFRP and SFRP-confined concrete under uniaxial compression. By focusing on metrics like dilation behaviour, strain efficiency, and ductility indices, this research aims to advance the understanding of FRP-confinement mechanics and inform the optimization of material selection based on specific structural requirements.

2. Methodology

2.1 Experimental program overview

The experimental program was designed to investigate the compressive behaviour of concrete cylinders confined with Carbon Fiber-Reinforced Polymer (CFRP) and Steel Fiber-Reinforced Polymer (SFRP) under monotonic uniaxial compression. The study variables included the concrete compressive strength and the type and thickness of the FRP jacket. The concrete cylinders were divided into two groups based on target unconfined concrete compressive strengths of 35.0 MPa and 45.0 MPa. Each group included three unwrapped control cylinders as benchmarks, alongside various CFRP and SFRP confinement configurations.

In total, 42 circular small-scale unreinforced concrete cylinders were prepared and tested, consisting of 18 specimens wrapped with SFRP, 18 specimens wrapped with CFRP, and 6 unwrapped control specimens. All cylinders had an outer diameter of 150 mm and a height of 300 mm. The specimens were cast in two batches with different concrete mix designs to achieve the desired compressive strengths. A summary of the experimental program and cylinder configurations is detailed in Table 1.

The designation system assigned to cylinders referred to hereafter in all subsequent discussions and graphical plots, is presented next. The designation system adopted takes the following general form:

C(F)-FBR(N)

where;

C = Cylinder;

F = Concrete 28-day specified compressive strength;

FBR = Fibre type;

N = Number of plies;

It should be noted that when N=0, when the specimen is unwrapped, the notation FBR(N) will be simply replaced by UW notation.

Table 1. Summary of test cylinders

Cylinder ID	No.	Confinement Configuration			Cylinder ID	No.	Confinement Configuration		
		f_c' (MPa)	Fibre Type	No. of FRP Layers			f_c' (MPa)	Fibre Type	No. of FRP Layers
C37.3-UW	3	37.3	-	-	C42.4-UW	3	42.4	-	-

2.2 Material properties

2.2.1 Concrete

Normal-strength concrete was used for all specimens. The mix design for both batches are summarized in Table 2.

2.2.2 SFRP sheets

The SFRP sheets used were 3×2-20-12, manufactured by Hardwire LLC. The typical properties of SFRP composite are detailed in Table 3.

2.2.3 CFRP sheets

The CFRP sheets used were SikaWrap® Hex 230C, manufactured by Sika Canada Inc. The typical properties of carbon cured laminate with Sikadure 330 Epoxy are presented in Table 4.

Table 2. Summary of concrete mix design

Mix Design	Units	Batch

2.3 Instrumentation

2.3.1 Strain gauges

Conventional foil strain gauges with a resistance of 120 Ω and a gauge length of 6.35 mm were employed. Unwrapped specimens were equipped with four strain gauges (two vertical and two radial), while wrapped specimens were equipped with two strain gauges (one vertical and one radial).

2.3.2 Linear strain converters (LSCs)

Wenglor high-performance distance sensors were utilized to measure axial and lateral displacements.

2.3.3 Digital image correlation (DIC)

High-resolution cameras were used to capture strain behaviour along the entire height of the cylinders. Images were taken every 5 seconds during testing and processed with GeoPIV software via Matlab.

2.4 Test setup and loading

The test setup involved positioning the cylinders within a 9 MN loading frame, equipped with high-resolution cameras and work lights to ensure a well-lit environment. Axial compressive loading was applied using a load control mechanism at a rate of 0.15 MPa/s to 0.35 MPa/s until complete failure. This testing protocol ensures precise and reliable measurement of the compressive behaviour of FRP-confined concrete cylinders, offering valuable insights into the performance variations between different FRP confinement configurations.

3. Results

3.1 Ultimate axial strength

The average ultimate axial strength for the tested cylinders is presented in Table 5, showing significant improvements for both CFRP- and SFRP-confined concrete compared to unconfined concrete. SFRP-confined cylinders outperform CFRP-confined ones, with C37.3-SFRP3 achieving a 421% strength increase compared to 147% for C37.3-CFRP3. For higher-strength concrete (C42.4), SFRP3 achieves a 373% increase, while CFRP3 reaches 123%. These results highlight the superior confinement effectiveness of SFRP, particularly with additional layers, though the relative strength gains are reduced for higher-strength concrete.

Table 5. Ultimate axial strength of CFRP- and SFRP-confined concrete cylinders

	Ultimate Axial Strength				Ultimate Axial Strength		
Confinement Configuration	Avg. (Mpa)	f'_{cu}/f'_{co}	Strength Increase (%)	Confinement Configuration	Avg. (MPa)	f'_{cu}/f'_{co}	Strength Increase (%)
C37.3-CFRP1	51.4	1.4	38	C42.4-CFRP1	59.6	1.4	40
C37.3-CFRP2	69.5	1.9	86	C42.4-CFRP2	75.8	1.8	79
C37.3-CFRP3	92.4	2.5	147	C42.4-CFRP3	94.6	2.2	123
C37.3-SFRP1	94.5	2.5	153	C42.4-SFRP1	98.8	2.3	133
C37.3-SFRP2	146.8	3.9	293	C42.4-SFRP2	153.9	3.6	263
C37.3-SFRP3	194.6	5.2	421	C42.4-SFRP3	200.4	4.7	373

3.2 Ultimate axial strain

The average ultimate axial strain, measured from strain gauges at the mid-height of the cylinders for each of the three nominally identical tested cylinders, is presented in Table 6. The results demonstrate a substantial increase in ultimate axial strain across all 18 cylinders compared to the axial strain of unconfined concrete. Notably, SFRP-confined cylinders exhibit superior strain capacity compared to CFRP-confined cylinders. For example, the strain increase for C37.3-SFRP3 reaches 2682%, significantly exceeding the 1199% observed for C37.3-CFRP3. Increasing the number of FRP layers enhances confinement effectiveness for both CFRP and SFRP systems. However, for higher-strength concrete C42.4, the ultimate strain values are consistently lower than those for C37.3, suggesting that FRP confinement is less effective in improving strain capacity for higher-strength concrete, which inherently has lower ductility.

Table 6. Ultimate axial strain of CFRP- and SFRP-confined concrete cylinders

	Ultimate Axial Strain				Ultimate Axial Strain		
Confinement Configuration	Avg. (με)	$\varepsilon_{cu}/\varepsilon_{co}$	Strain Increase (%)	Confinement Configuration	Avg. (με)	$\varepsilon_{cu}/\varepsilon_{co}$	Strain Increase (%)
C37.3-CFRP1	14652	7.5	648	C42.4-CFRP1	10659	6.1	507
C37.3-CFRP2	19265	9.8	884	C42.4-CFRP2	11491	6.5	554
C37.3-CFRP3	25440	13.0	1199	C42.4-CFRP3	15525	8.8	784
C37.3-SFRP1	32088	16.4	1538	C42.4-SFRP1	27007	15.4	1437
C37.3-SFRP2	43674	22.3	2130	C42.4-SFRP2	33227	18.9	1791
C37.3-SFRP3	54495	27.8	2682	C42.4-SFRP3	47361	27.0	2596

3.3. Ultimate lateral strain

Table 7 shows the ultimate lateral strain results, indicating that SFRP-confined cylinders achieve significantly higher lateral strain values compared to CFRP-confined ones. For example, C37.3-SFRP1 reaches 1478%, far exceeding the 664% observed for C37.3-CFRP1, demonstrating the superior strain capacity of SFRP. However, the lateral strain values decrease for higher-strength concrete C42.4, highlighting the reduced effectiveness of confinement in enhancing lateral strain for stiffer concrete cores.

Table 7. Ultimate lateral strain of CFRP- and SFRP-confined concrete cylinders

Confinement Configuration	Ultimate Lateral Strain			Confinement Configuration	Ultimate Lateral Strain		
	Avg. (με)	$\varepsilon_l/\varepsilon_{co}$	Strain Increase (%)		Avg. (με)	$\varepsilon_l/\varepsilon_{co}$	Strain Increase (%)
C37.3-CFRP1	-10491	7.6	664	C42.4-CFRP1	-10024	9.0	801
C37.3-CFRP2	-12632	9.2	820	C42.4-CFRP2	-11268	10.1	913
C37.3-CFRP3	-13419	9.8	878	C42.4-CFRP3	-10009	9.0	800
C37.3-SFRP1	-21655	15.8	1478	C42.4-SFRP1	-18714	16.8	1583
C37.3-SFRP2	-14896	10.9	985	C42.4-SFRP2	-12491	11.2	1023
C37.3-SFRP3	-15085	11.0	999	C42.4-SFRP3	-14722	13.2	1224

3.4 Load-deformation behaviour

Stress-strain curves for CFRP- and SFRP-confined concrete cylinders for each confinement configuration are plotted in Figure 1, respectively. For comparison, the stress-strain curves of the corresponding unconfined concrete are also included. As depicted in the figures, all FRP-wrapped cylinders exhibit a bilinear ascending stress-strain behaviour up to the point of FRP failure.

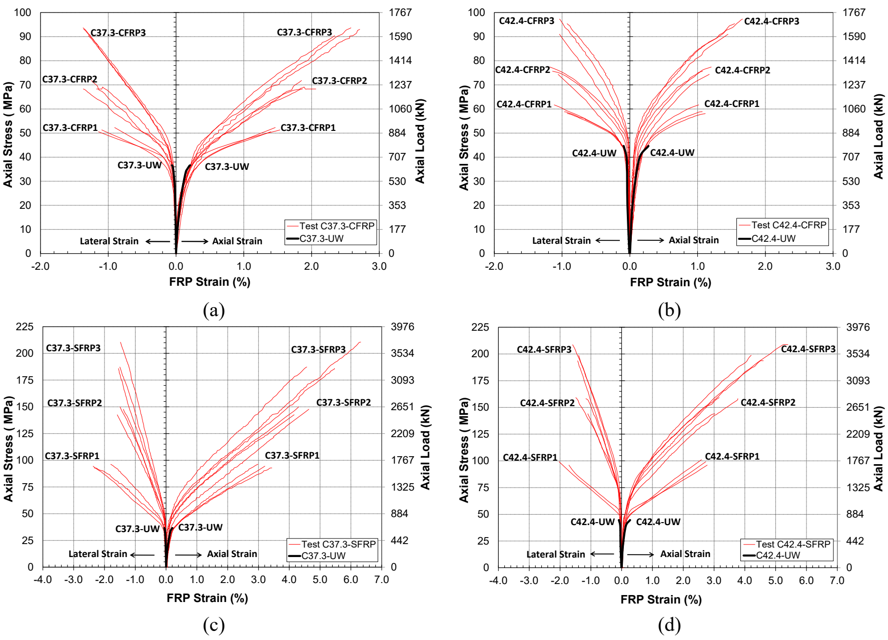

Fig. 1. Stress-strain curves for (a) C37.3-CFRP (b) C42.4-CFRP (c) C37.3-SFRP (d) C42.4-SFRP

3.5 Dilation behaviour

Axial stress data, used for plotting axial stress-volumetric strain curves shown in Figure 2, were calculated by dividing the loads obtained from the data acquisition system by the cylinder's cross-section area. Volumetric strain,

ε_v, which is defined as the volume change per unit volume [8], is calculated from Equation 1 using axial strain, ε_c, and lateral strain, ε_l, both obtained from the foil strain gauges installed at the mid-height of each cylinder.

$$\varepsilon_v = \frac{\Delta V}{V} = \varepsilon_c + 2\varepsilon_l \tag{1}$$

—where ΔV is the change of volume, and V is the original volume.

Biçimlendirilmiş: Girinti: İlk satır: 0,32 cm

The plots highlight distinct dilation and compaction behaviours for CFRP and SFRP-confined concrete, illustrating the influence of confinement type and concrete strength on volumetric response under axial loading.

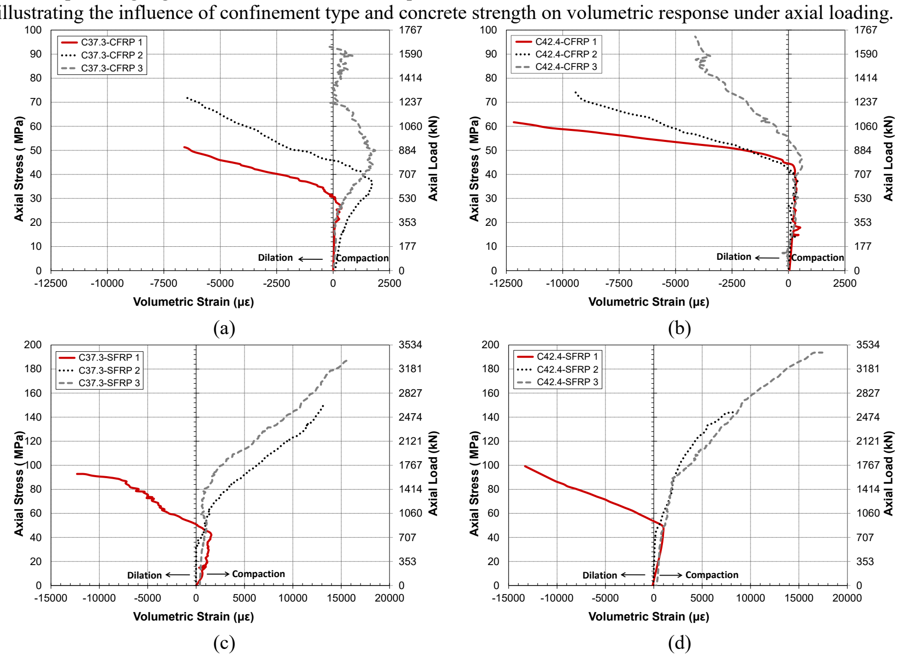

Fig. 2. Dilation behaviour for (a) C37.3-CFRP (b) C42.4-CFRP (c) C37.3-SFRP (d) C42.4-SFRP

4. Performance ~~Comparison~~ comparison between CFRP- and SFRP-~~Confined~~ confined ~~Cylinders~~cylinders

The performance of CFRP- and SFRP-confined concrete was compared by examining the confinement effectiveness coefficient, strain ductility indices, and energy ductility indices.

The experimental confinement effectiveness coefficient, k_l, is calculated utilizing the formula originally developed by Richart et al. (1928), as shown below:

$$k_l = \frac{(f'_{cu} - f'_{co})}{f_{lu}} \tag{2}$$

The strain ductility factor, μ_{cu}, measures the ability of a structural member to undergo large inelastic deformation without significant loss in strength. It is defined as the ratio of the FRP ultimate axial strain at rupture, ε_{cu} over the axial strain corresponding to unconfined concrete at peak, ε_{co}. It is calculated as per the following equation:

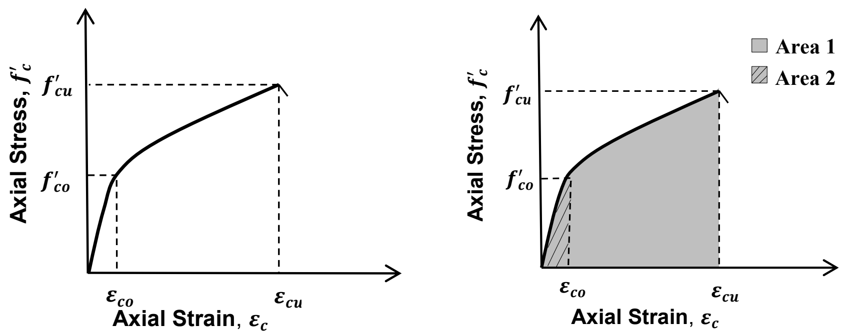
$$\mu_{cu} = \frac{\varepsilon_{cu}}{\varepsilon_{co}} \tag{3}$$

The energy ductility index, ω_{cu}, is defined as the area under the stress-strain curve up to the failure of the FRP jacket over the area under the stress-strain curve corresponding to the unconfined state. It expresses the ability of the structural member to dissipate energy during inelastic deformation.

$$\omega_{cu} = \frac{Area_1}{Area_2} \tag{4}$$

Different parameters of ductility indices for bilinear stress-strain response are illustrated in Figure 3.

Table 8 compares the confinement effectiveness coefficient, kl, and ductility indices, μ_{cu} and ω_{cu}, for different confinement configurations of CFRP- and SFRP-confined cylinders. The results show that SFRP-confined cylinders achieve higher ductility indices compared to CFRP-confined cylinders. For instance, C37.3-SFRP3 achieves a strain ductility index, μ_{cu}, of 27.8 and an energy ductility index, ω_{cu}, of 107.9, significantly outperforming C37.3-CFRP3, which has values of 13.3 and 26.0, respectively. This highlights SFRP's superior deformation and energy absorption capacity due to its metallic properties. However, the confinement effectiveness coefficient (k_l) is slightly higher for CFRP-confined cylinders (up to 4.08) compared to SFRP systems (ranging from 3.33 to 3.63), reflecting CFRP's higher stiffness. Overall, while CFRP provides better confinement effectiveness, SFRP excels in enhancing strain and energy ductility, making it more suitable for applications requiring greater deformability.



(a) Strain ductility index (b) Energy ductility index

Fig. 3: Definition of ductility indices: (a) Stain ductility index (b) Energy ductility index

Table 8. Confinement effectiveness and ductility indices for CFRP and SFRP-confined concrete

Configuration Designation	Lateral Confinement Parameters					Ductility Indices	
	Lateral Conf. Pressure	Conf. Ratio	Lateral Stiffness (MPa)	Lateral Stiffness Ratio	Confinement Effectiveness Coefficient	Strain Ductility Index	Energy Ductility Index
	f_{lu}	f_{lu}/f'_{co}	$(2Et/D)$	$(2Et/Df'_{co})$	k_l	μ_{cu}	ω_{cu}
C37.3-CFRP1	4.54	0.12	332	8.9	3.10	7.5	9.6
C37.3-CFRP2	9.08	0.24	664	17.8	3.54	9.8	15.8
C37.3-CFRP3	13.62	0.37	997	26.7	4.04	13.0	26.0
C42.4-CFRP1	4.54	0.11	332	7.8	3.40	6.1	11.0
C42.4-CFRP2	9.08	0.21	664	15.7	3.68	6.5	14.3
C42.4-CFRP3	13.62	0.32	997	23.5	3.83	8.8	24.2
C37.3-SFRP1	15.78	0.42	1058	28.4	3.63	16.4	32.8
C37.3-SFRP2	31.55	0.85	2115	56.7	3.47	22.3	66.6
C37.3-SFRP3	47.33	1.27	3173	85.1	3.33	27.8	107.9
C42.4-SFRP1	15.78	0.37	1058	24.9	3.57	15.4	40.6
