In this study, it is aimed to create an algorithm which can loop around a building without any help from a human. The algorithm will run on an unmanned ground vehicle equipped with distance sensors and LIDAR devices that will autonomously navigate around a building and create a database for digital twin creation by laser scanning. The robot will navigate with certain functions based on the maze algorithm. The vehicle will move counterclockwise and follow the walls with the left hand algorithm. In areas where the building walls or columns protrude and there are stones, sand piles or any other obstacles in the direction of the vehicle, the vehicle will activate the 'obstacle avoidance algorithm to overcome this situation and continue on its way. In cases where the building has a indendated architectural elements, the 'exit from the recess' algorithm will work. In cases where the walls continue straight and the robot's hand can move forward without touching the left wall for a while, the straight ahead algorithm will be active. The general flowchart and the specific algorithms that the vehicle will use while moving will be explained separately.

2.1. Explanation of algorithms

In the first step of the algorithm, before the vehicle starts looping, it requests the initial values to be assigned to the sensors. Once the data entry is complete, the mapping process will begin. At the beginning, the vehicle proceeds with the straight forward function and checks whether there are any obstacles, wall indentation or wall protrusions. As shown in Fig. 1, if the answer to the question “Are there any obstacle in the way?” is yes, the obstacle avoidance function is started in order to avoid the obstacle and continue the movement. After the obstacle is successfully overcome, the robot continues its path by activating the straight forward function again. It moves forward again by checking whether there is an obstacle, wall indentation or wall protrusion in front of it. The check whether there is a wall indentation or not is done with the question “Is there an indentation in the way?”. If the answer to this question is “Yes”, the robot moves to the relevant area and initiates the indentation escape function. This function will allow the vehicle to enter the indentation, scan the area inside and then return to the main route. After the indentation is completed, the vehicle moves forward again with the straight forward function. When each progress step is completed, it will ask the question “Is the building tour complete?”. If the tour around the building is complete, the mapping process is successfully completed, otherwise, the algorithm reverts back to the beginning and the steps are performed again. The flowchart presented in Fig. 1 shows the logical basis of the autonomous progression process based on the robot's environmental awareness and situation-based decision-making capabilities.

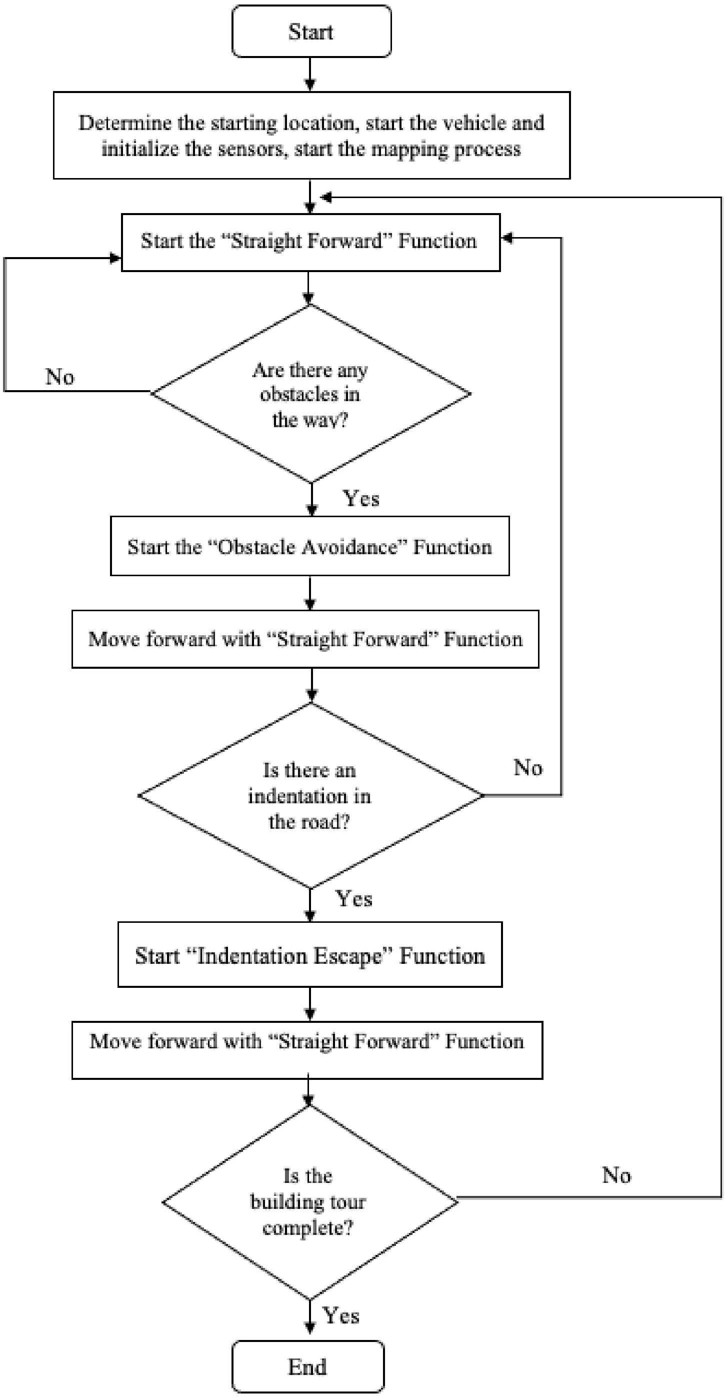

Fig. 1. Flowchart of the proposed algorithm

2.1.1. Straight forward function

In the "Straight Forward" function, the process starts by measuring the distance between the vehicle and the wall via the ultrasonic sensor. The vehicle then advances 5 cm, stops and scans its surroundings. During the scan, it checks whether the distance between its current position and the wall. If this distance is more than 50 cm, the vehicle rotates 5 degrees to the left to correct this deviation, assuming that the vehicle is moving away from the reference wall. Otherwise, if the distance is less than 50 cm, it is assumed that the robot is getting too close to the wall and the vehicle it rotates 5 degrees to the right to adjust the heading. After orientation, the vehicle is moved forward again and the process is repeated iteratively. Thanks to this approach, the robot can move in a linear and controlled manner, keeping the distance from the wall as close as possible to 50 cm. The flowchart of the straight forward function is as shown in Fig. 2.

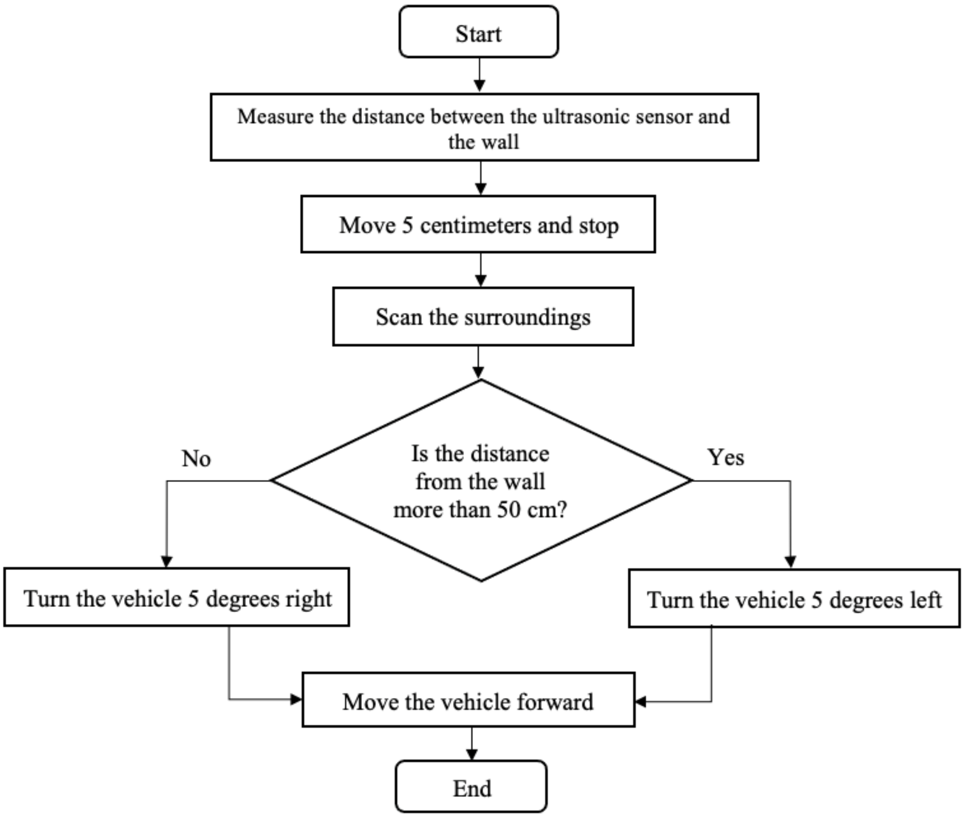

Fig. 2. Flowchart of the forward motion algorithm

2.1.2. Obstacle avoidance algorithm

If there is an obstacle in front of the vehicle, the "Obstacle Avoidance" function is activated and determines whether there is an obstacle on the road based on the distance between the front sensor and the wall or obstacle. If the distance measured by the front sensor is less than 50 cm, it will be assumed that there is an obstacle in front of the vehicle and the vehicle will turn 90 degrees to the right and start the obstacle avoidance maneuver. As the vehicle travels, the distance between the left sensor and the wall is continuously monitored and at the same time it is queried whether the distance increase is more than 1 meter. If the increase between consecutive distance measurement values is more than 1 meter, the vehicle has completed the obstacle avoidance maneuver. Since it moves away from the front face of the obstacle, it turns 90 degrees to the left in order to prevent losing its route and continues to move straight ahead by approaching the wall line again. While moving forward, the vehicle's left sensor distance increase will be queried again and if it is more than 1 meter, the vehicle will turn ninety degrees to the left and continue straight ahead. Finally, the front sensor distance is monitored and if the distance value decreases to 50 cm, the vehicle turns to the right and continues moving forward, thus overcoming the obstacle in front of it. This algorithm aims to realize a safe progress by enabling the vehicle to react autonomously to environmental obstacles. The flowchart of the algorithm is presented in Fig. 3.

2.1.3. Wall indentation exploration algorithm

In cases where the vehicle needs to enter narrow areas or inside a wall indentation, the "Indentation Escape" function is activated to scan the recessed area and exit the area correctly and safely. In this algorithm, firstly, the distance between the left sensor of the vehicle and the wall is monitored and the distance increase is queried and if the increase is more than 1 meter, the vehicle will turn 90 degrees to the left and the decision is made to proceed straight. This progress continues until the front sensor distance is 50 cm. When 50 cm is reached, the vehicle turns 90 degrees to the right and drives straight ahead. While moving forward, the front sensor distance is queried at every 5 cm step interval and when it drops to 50 cm again, the vehicle will once again turn 90 degrees to the right and move forward. Finally, the left sensor distance will be evaluated again and the distance increase will be checked and if the difference between 2 consecutive distance measurement values is more than 1 meter, the vehicle will turn 90 degrees to the left and continue with the straight ahead function and the process of exiting the recess will be completed. The flowchart of the algorithm is presented in Fig. 4.

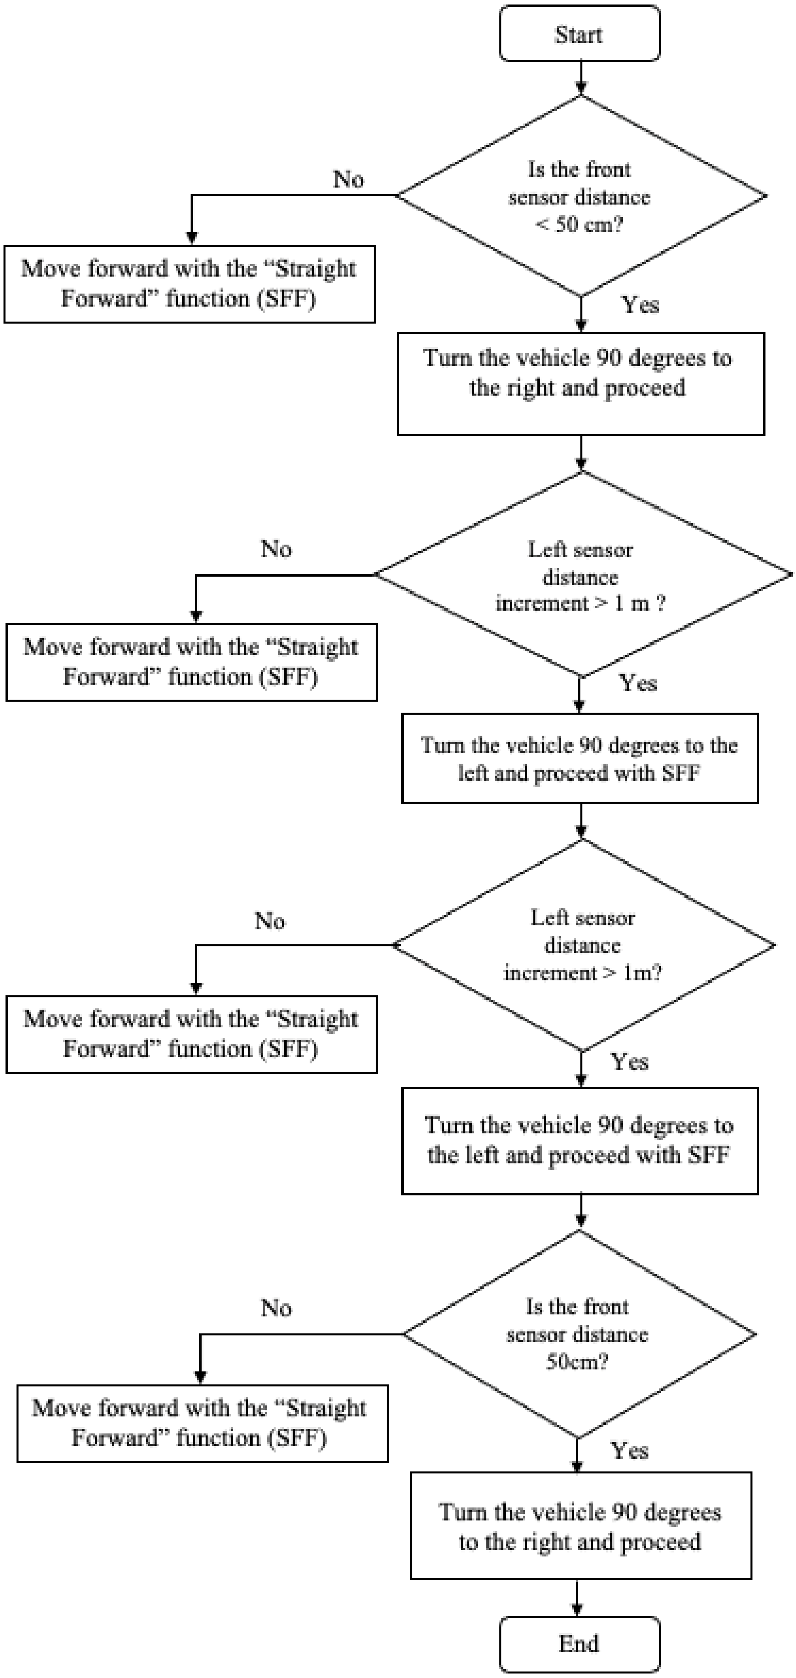

Fig. 3. Flowchart of the obstacle avoidance algorithm

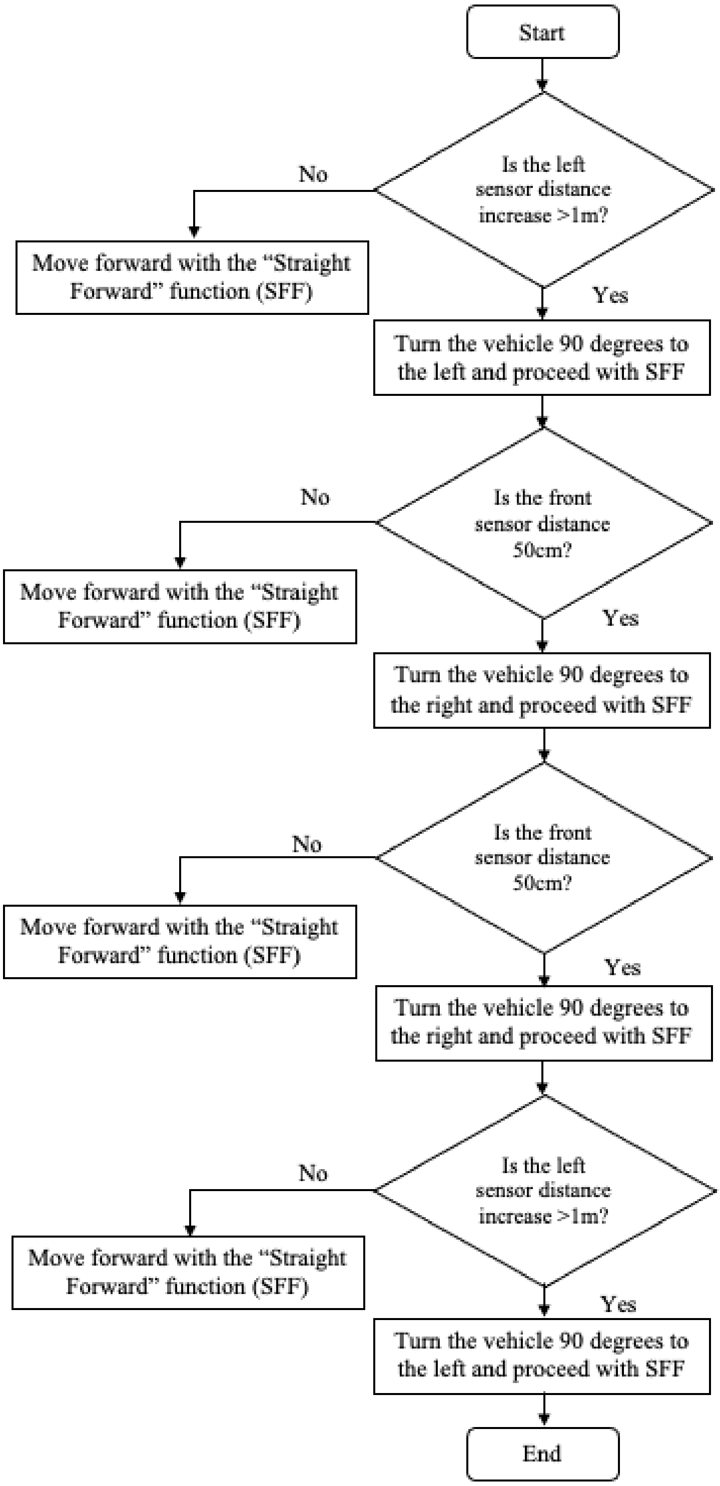

Fig. 4. Flowchart of the wall indentation exploration algorithm

3. Case study

The study, in which a sample environment model is created and the algorithm mentioned above is applied in a simulation environment, is described in detail in this section.

3.1. Facade modeling and design for autonomous vehicle integration

In the first phase of the study, a building façade was modeled for the vehicle to navigate around and extract its digital twin. This was done using the SketchUp program, which allows three-dimensional (3D) modeling. In this context, an environment presented in Fig. 5 was designed with various obstacle situations that the vehicle may encounter as it travels. In this building environment model, the building is assumed to have straight walls with protruding and indentationed architectural areas. These regions are considered separately and algorithms are generated for each situation in order for the vehicle to navigate autonomously. In particular, the model includes a combination of facade surfaces enriched with indentations and protrusions, and building components that run straight. This diversity was chosen in order to test the vehicle in different situations. The geometry of the building façade is detailed to be suitable for sensor detection, taking into account volumetric differences, depths and edge lines that can be read by Lidar sensors and cameras. Indentations and protrusions are added to the model to enable the vehicle's sensor systems to detect the boundaries and form of the structure more effectively. These architectural elements have the potential to serve as reference points in the robot's pose estimation, distance measurement and environment mapping processes. Sections of the model with flat surfaces are important areas for evaluating the vehicle's ability to move without deviating from a certain direction. These surfaces can also be preferred as reference planes when creating a digital twin of the building.

3.2. Creation of simulation environment and implementation of autonomous navigation algorithms

In the second phase of the study, a simulation environment was designed to display the building façade in three dimensions and allow an autonomous ground vehicle to navigate around the building. The main goal of the simulation is to enable the vehicle to develop environmental awareness based on the building geometry, detect the façade and determine its route accordingly. This digital environment allows testing algorithms, evaluating vehicle-building interaction and testing data collection processes.

The environment used in the simulation is based on a three-dimensional model of the building facade modeled in SketchUp software. The model is adjusted to reflect the real environment conditions in terms of surface details and change of direction points that the autonomous vehicle will interact with. Geometric variations on the façade, such as indentations, recesses, flat surface transitions and corner points, are crucial for the vehicle to analyze sensor data and map its surroundings. In the simulation, the algorithm detailed above, which is based on the wall tracking method used in maze solving, was used. The algorithm allows the vehicle to change direction at each decision point by evaluating the obstacles in front and to the sides.

This simulation environment was a useful test platform for developing the data collection infrastructure for the digital twin formation process. The data acquired by the autonomous vehicle will be integrated into the digital twin model of the building and will form the basis for the reconstruction of the building envelope under real environmental conditions. At the same time, this environment will increase the applicability of the system by enabling the algorithms to be tested on different building typologies and facade geometries.

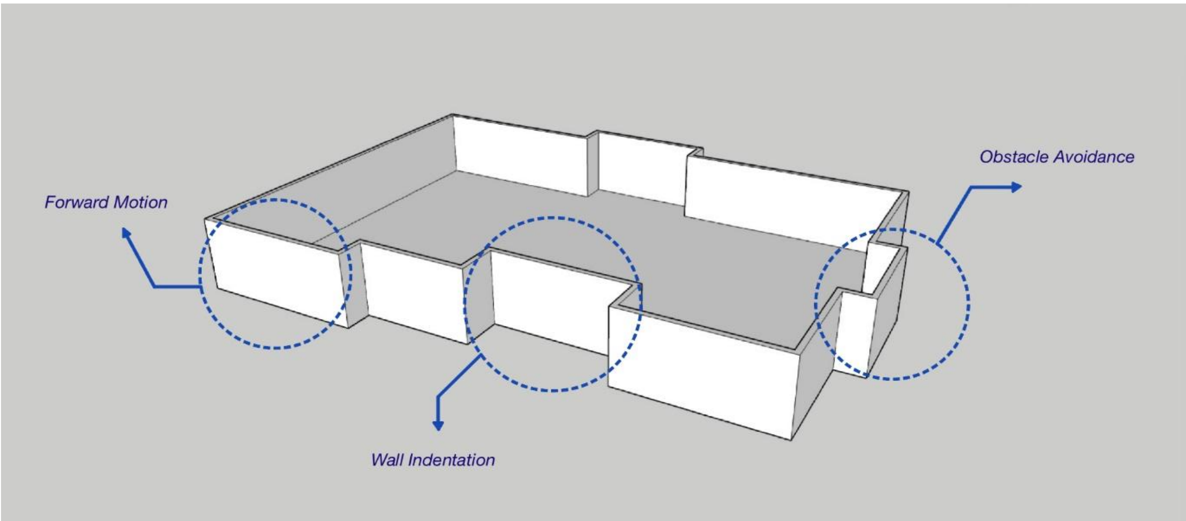

Fig. 5. Fictitious building façade

3.3 Simulation outputs

3.3.1. Forward motion example

By applying the forward motion function in the simulation environment, the images in Figure 6 are generated. The vehicle starts its movement at the starting point of a straight wall (Fig. 6a). While moving forward, the vehicle also tracks the distance between the left sensor and the wall and when it detects that it is more than 50 cm away from the wall, it changes its heading angle by 5 degrees to the left and continues its movement (Fig. 6b). When the vehicle is closer than 50 cm to the wall, as shown in Figure 6c, it turns 5 degrees to the right, moves away from the wall and continues its movement straight ahead again at a distance of 50 cm (Fig. 6d-e).

3.3.2. Obstacle avoidance example
Fig. 7 shows the results of testing the obstacle escape function in the simulation. The vehicle detects that there is an obstacle in front of it when the front sensor distance, which it monitors continuously, reaches 50 cm (Fig. 7a). In order to go around the obstacle, it turns 90 degrees to the right and continues moving forward (Figure 7b). At the same time, the vehicle also monitors the left sensor distance and when it detects a value of more than 1m, it turns 90 degrees to the left and starts moving parallel to the wall again (Fig. 7c-d-e). When it reaches the end of the wall, it detects a high value for the left sensor distance and moves 90 degrees to the left (Fig. 7f-g). It analyzes the front sensor values again and when it reaches 50 cm, it detects the presence of a wall in front of it and continues its movement by turning 90 degrees to the right and thus successfully overcomes the obstacle (Fig. 7h- i- j).

3.3.3. Example of escape from an indentation
While moving forward, the vehicle scans the building facade with the LIDAR device on the vehicle and exhibits the behavior shown in Fig. 8 when it encounters an indentation. The vehicle detects that it will enter an indentation when the left sensor distance is more than 1 meter and initiates the exit function (Fig. 8a-b). It first turns left and moves into the recess, and when the front sensor distance is 50 cm, it detects that there is a wall in front of it and which prevents it to move further. Therefore it continues its movement by turning 90 degrees to the right (Fig. 8c-d-e). It continues until the front sensor distance is 50 cm again, at which point it turns right once more and exits the recess (Fig. 8f-g). Finally, in order not to move away from the wall but to follow it, it continues its movement by turning left when the left sensor distance is greater than 1 m (Fig. 8 h-i-j).

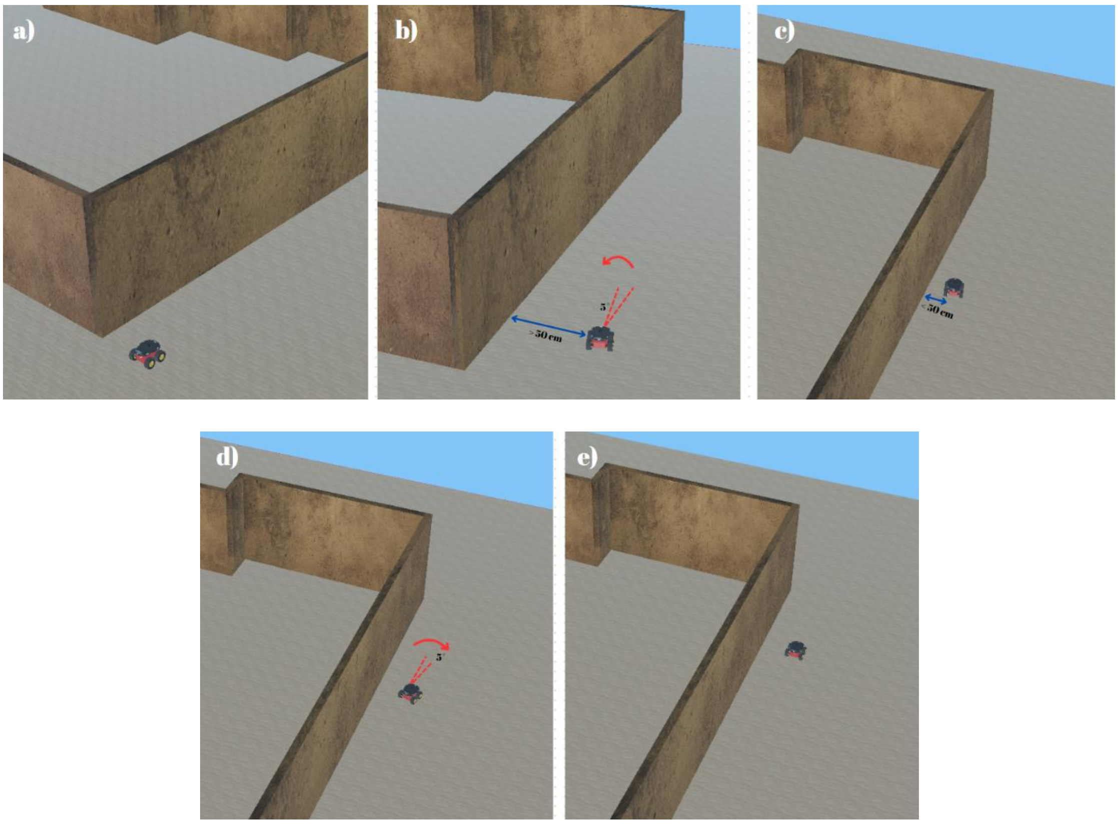

Fig. 6. Simulation outputs of the forward motion algorithm

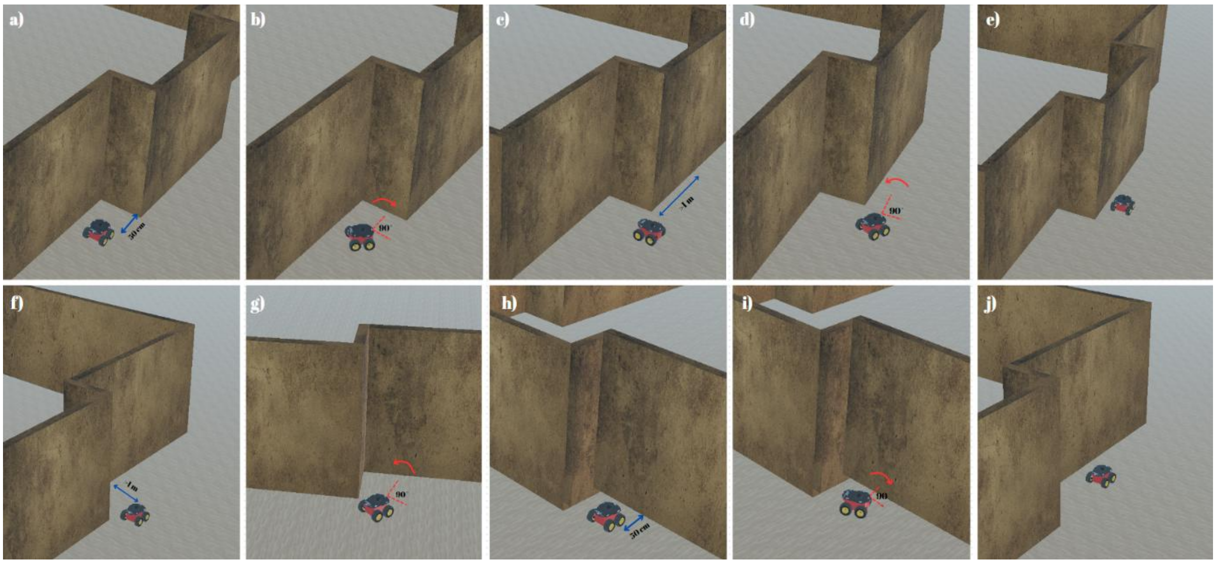

Fig. 7. Simulation outputs of the obstacle avoidance algorithm

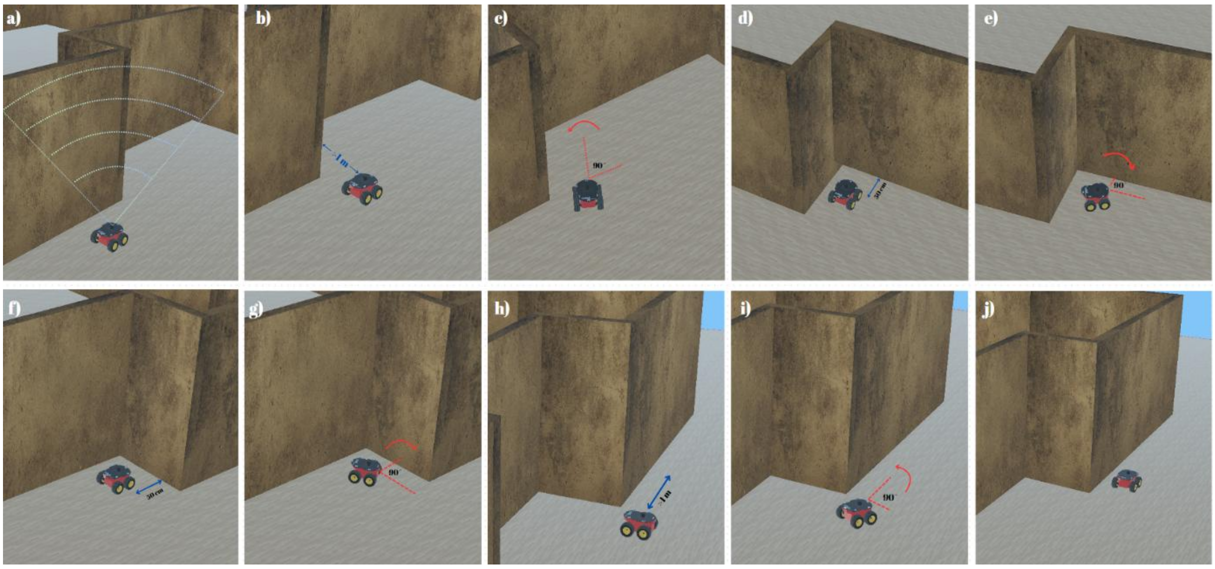

Fig. 8. Simulation outputs of the wall indentation exploration algorithm

4. Results and discussion

As a result of simulation experiments, it was observed that the developed algorithms worked successfully against complex geometries such as recesses and protrusions on the building facade. Thanks to the wall-following algorithm based on the left-hand rule, the vehicle followed a route around the structure at a certain distance and was able to follow the exterior facade line without deviating. The fact that the vehicle continued without deviating from the route at corner points and narrow recesses that required sudden changes of direction, which have the potential to cause complexity, shows that the developed algorithm can correctly analyze the architectural form of the structure.

The vehicle is equipped with various distance sensors and data is collected from these sensors continuously. On the other hand, the algorithm that forms the vehicle's orientation mechanism consists of many "if" loops in order to make the right decisions and ensure continuous progress. When all these are taken into consideration, it is seen that the size of the collected data and the computational complexity of the algorithm allow it to be processed on the Arduino Mega microcontroller card, the memory and processing power of the Arduino Mega are compatible with the selected algorithms and can successfully perform real-time location calculations. This situation shows that the system can be applied with low-cost hardware.

In addition, within the scope of the study, an easy but functional mapping algorithm and a cost-effective tool in terms of hardware were developed by considering the cost. The sensors and routing algorithm used ensured the implementation of environmental mapping with minimum hardware requirements. Simplicity of the algorithm increased the accessibility of the system for both academic studies and field applications.

When all these results are brought together, it was seen that the developed system is sufficient to be used in real applications. The positive evaluations made in terms of simulation tests, sensor performance, hardware compatibility and software stability show the applicability of the system in terms of digital twin production. In this respect, the study contributes to digitalization in the construction sector by developing a low-cost and integrable solution.

5. Conclusions

Traditional methods in today's construction sector take time due to the complexity and difficulty of application and create certain restrictions on efficiency. For such reasons, the need to adapt to digitalization is increasing day by day. At this point, digital twin technology is an important tool in terms of making the design, operation and maintenance processes of buildings more efficient, cost-effective, sustainable and smart. However, data collection, which is one of the basic steps of the digital twin creation process, is a significant challenge in this process due to high hardware costs, manual operations requiring expertise, and time-intensive resource consumption. The maze-based, left-hand rule-based autonomous navigation algorithm developed in this study has automated the data collection process and made it more efficient in terms of both time and cost. Mapping the building geometry through environmental scanning by an autonomous ground vehicle has reduced the workload in the process by minimizing human intervention and enabled the automatic collection of the data needed for the formation of digital twin.

The fact that the developed system can work seamlessly with low-cost hardware has increased the accessibility and applicability of the method. Tests conducted in a simulation environment have shown that the algorithm provides reliable results on building facades with structural recesses and protrusions. However, testing the system on more complex building geometries will provide a clearer understanding of the potential deficiencies and limitations that the algorithm may encounter. In this way, it will be possible to adapt it to more flexible usage scenarios in digital twin formation processes.

Analyzing causal factors of workflow variability in construction projects: An exploratory factor analysis

Rajaa Abuelaish*[1], Ümit Bahadır[1], Vedat Toğan[1]

[1] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. Construction projects are characterized by complexity and high levels of variability, which often lead to reduced performance, cost overruns, and inefficiencies in planning. Recognizing workflow variability as a critical challenge in the construction industry, this study aims to systematically identify and categorize its key causes. A quantitative approach was employed, utilizing a structured questionnaire informed by an extensive literature review, which identified 38 potential causes. The data were analyzed using exploratory factor analysis (EFA), resulting in the retention of 21 causes, grouped into four principal factors: resources, management and planning, material, and prerequisite. The study provides empirical insights into the primary sources of workflow variability in Turkish construction projects, an area with limited prior research. By organizing the causes into clear and actionable categories, the findings offer practical guidance for minimizing variability and enhancing project performance. In particular, the results highlight the critical role of resource management in achieving workflow stability. This research contributes to both academic knowledge and industry practice by presenting a structured framework for understanding and addressing workflow variability in construction.

Keywords: Workflow variability; Turkish construction projects; Factor analysis

1. Introduction

Workflow variability remains a persistent and significant challenge in construction projects, often leading to budget overruns and delays (Han & Park, 2011). The construction industry's inherent complexity arises from the dynamic interaction among multiple variables and activities, resulting in unpredictable workflows and disruptions (Abbasian-Hosseini et al., 2018; Abusalem, 2020). Prior studies emphasize that ineffective variability management significantly impacts project performance, extending durations and increasing costs (Jaśkowski et al., 2021; Salhab et al., 2022).

For example, research by Ballesteros-Pérez et al. (2020) noted variability levels as high as 60% in activity durations, profoundly influencing overall project schedules. Furthermore, reducing variability in critical activities substantially improves project completion probabilities and reduces waiting times (Salhab et al., 2022). Despite this understanding, limited empirical research has investigated the root causes of workflow variability, particularly in developing countries. To address this gap, the present study employs exploratory factor analysis (EFA) through a questionnaire survey to systematically identify and analyze critical factors causing workflow variability in construction projects.

2. Literature review

Workflow variability in production systems primarily results from two interconnected factors: variability sources and delayed flow between upstream and downstream activities (Garcia-Lopez & Fischer, 2024; Wambeke et al., 2011). These factors are interdependent, as variability sources often lead to activity delays, subsequently causing late delivery of downstream workflows (Garcia-Lopez & Fischer, 2024).

Prerequisite work significantly contributes to workflow variability through delayed interactions between upstream and downstream activities (Garrido Martins et al., 2023). Construction processes typically involve interconnected sequences of predecessor (upstream) and successor (downstream) activities, where delays in upstream tasks propagate downstream, creating cumulative disruptions (Su et al., 2024; Wambeke et al., 2011). Consequently, delays in prerequisite activities can trigger rework, extend subsequent task durations, and intensify workflow variability across the project (Salhab et al., 2022; Ye et al., 2015).

Design-related workflow variability mainly results from errors, omissions, and inadequate details in project drawings, causing rework and delays due to frequent changes and incomplete information (Ballesteros-Pérez et

* Corresponding author, E-mail: rabuelaish@hotmail.com

https://doi.org/10.31462/icearc2025_ce_mng_774

al., 2020; Shehab et al., 2023). Resource-related variability, particularly regarding material and equipment availability, critically affects workflow continuity (Umar et al., 2020). Delays or incorrect specifications in material deliveries frequently disrupt tasks, leading to idle time, increased costs, and reduced productivity (Arbulu et al., 2005; Wambeke, 2011; Yap et al., 2018).

Labor-related issues, including absenteeism, skill shortages, low productivity, and inadequate training significantly increase workflow variability (Javanmardi et al., 2016; Lindhard et al., 2019). Unplanned absenteeism and ineffective site management create disruptions, reducing worker morale and performance, particularly in developing countries (Handayani et al., 2021; Radjawane & Darmawan, 2022). Equipment management also plays a vital role, with breakdowns, insufficient availability, or inadequate maintenance practices directly impacting worker efficiency and causing project delays (Ballesteros-Pérez et al., 2020).

Additionally, site congestion and poor workspace layouts lead to overcrowding, safety hazards, and reduced productivity, further exacerbating workflow variability (Salhab et al., 2022; Umar et al., 2020). Finally, ineffective management practices, delayed payments, unclear contract administration, and inadequate communication among project stakeholders significantly intensify workflow disruptions, negatively affecting overall project performance (Ballesteros-Pérez et al., 2020; Peters et al., 2019; Sümer & Arditi, 2022).

The pertinent causes of workflow variability that potentially affect the project performance were explored by conducting a systematic background review. A comprehensive review of 20 relevant studies led to the identification of 61 distinct factors contributing to workflow variability in construction projects. The frequency of each factor, based on its occurrence across the reviewed literature, ranged from one to eight.

3. Methodology

Initially, a literature review was carried out to provide a comprehensive list of common workflow variability causes that could be examined in construction projects. The questionnaire was then designed based on the list of workflow variability causes extracted from the literature review. In the context of construction management studies, a questionnaire survey has been widely used to rank relevant variables (Garrido Martins et al., 2023; Jaśkowski et al., 2021; Shehab et al., 2023). This study employs a quantitative method, as shown in Fig. 1, to explore workflow variability causes and aims to evaluate them by conducting EFA.

Factor analysis is widely recognized as a statistical technique for data reduction and the identification of underlying patterns among interrelated variables (Hair et al., 2019). In this study, 61 causes of workflow variability were initially compiled from the literature and structured into a preliminary questionnaire. The questionnaire was refined through an extensive literature review and expert consultations. Face validity was applied to ensure the clarity and relevance of item wording, while expert feedback was used to modify existing items and suggest new ones (Broder et al., 2007). Based on this assessment, necessary adjustments were made to enhance content accuracy. A pilot study was subsequently conducted to evaluate the questionnaire's structure and usability in preparation for full-scale data collection (Dikko, 2016).

Incorporating feedback from the pilot study, the final version of the questionnaire comprised two sections: Section A collected respondents' general information (3 items), while Section B asked respondents to rate the identified workflow variability causes across 38 items using a five-point Likert scale (1 = not significant; 5 = extremely significant). The survey was distributed both electronically and face-to-face to Turkish construction professionals, including contractors, clients, and consultants. Out of 300 distributed questionnaires, 201 fully completed responses were received, yielding a response rate of 67%, considered high compared to similar studies (Culfik et al., 2014; KV & Bhat, 2019; Umar et al., 2020).

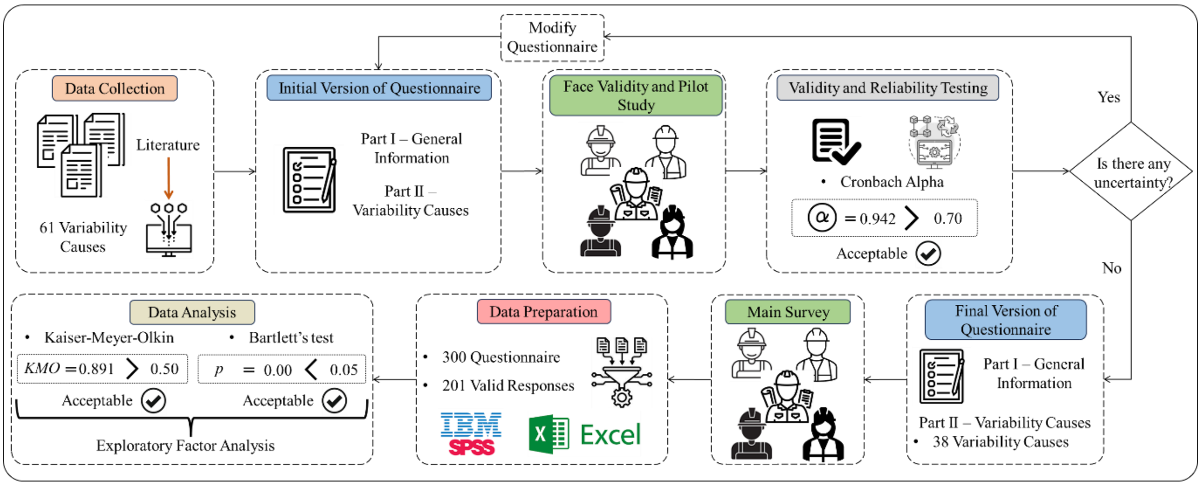

Fig. 1. Research methodology

Table 1 summarizes the professional profiles of survey respondents, highlighting diverse job roles and extensive experience. Approximately half possessed over 10 years of experience in construction, with 79.6% holding administrative positions across various specializations, predominantly within contracting firms. This respondent profile is appropriate and sufficiently representative for conducting exploratory research.

To identify underlying factors causing workflow variability in construction projects, EFA was conducted on the identified variability causes, consistent with established practices in construction management research (Umar et al., 2020; Yap et al., 2018). Prior to analysis, assumptions such as data suitability, correlation adequacy, and rotation effectiveness were verified (Taherdoost et al., 2014). EFA effectively clusters correlated variables into fewer interpretable underlying factors, facilitating a clearer understanding of relationships among variables (Hair et al., 2019; Yap et al., 2018). This analytical approach uncovers hidden data structures and provides reliable constructs useful for subsequent scale development (Jadidoleslami et al., 2018). IBM SPSS Statistics (version 27) was utilized to perform the EFA and categorize workflow variability causes systematically.

4. Results and discussion

Prior to performing EFA, a correlation test was conducted to assess relationships among the workflow variability items. Principal component analysis (PCA) was applied to identify and extract initial factors (Taherdoost et al., 2014). Items with factor loadings lower than 0.50 or those exhibiting significant cross-loadings were excluded (Hooper, 2012). Factors were extracted based on eigenvalues greater than one (Suhr, 2006), and their internal consistency was verified using Cronbach's alpha, with values above 0.70 indicating acceptable reliability (Bolarinwa, 2019). The overall Cronbach's alpha for the 38 items before rotation was 0.942, indicating excellent internal consistency. To achieve clearer and more interpretable factor structures, this study uses PCA varimax rotation, the most commonly applied method for easier interpretation of the extracted factors (Umar et al., 2020; Yap et al., 2018).

EFA examines correlations and variances to uncover the underlying structure of data and identify common factors among variables (Hair et al., 2019). It also assesses item alignment with factors, facilitating the removal of irrelevant or overlapping items to enhance scale clarity and reliability (Ye et al., 2015). Prior to conducting EFA, tests such as the Kaiser-Meyer-Olkin (KMO) measure and Bartlett's test of sphericity are required to assess data suitability. A KMO value above 0.5 indicates adequate sampling and the presence of shared variance (Howard, 2016), while a significant Bartlett's test ($p < 0.05$) confirms that the correlation matrix is appropriate for factor extraction (Ayarkwa et al., 2012). In this study, the KMO value was 0.891, well above the threshold, confirming sampling adequacy. Bartlett's test of sphericity was also significant ($p = 0.000$), supporting the feasibility of factor analysis. These results validate the suitability of the dataset for extracting meaningful underlying factors using EFA.

Factor analysis assesses the proportion of a variable's variance that is shared with other variables, referred to as communality (Field, 2005). Table 2 presents the communalities of each cause, indicating the extent to which their variances are explained by the underlying latent factors. Communality values typically range between 0.4 and 0.7 (Taherdoost et al., 2014). To enhance interpretability, the extracted factors were subjected to varimax rotation (Umar et al., 2020). Items with factor loadings below 0.50 or those exhibiting cross-loadings across multiple components (Costello & Osborne, 2019) were deleted. In each rotation cycle, non-significant or cross-loading items were removed, and the analysis was repeated. Based on these criteria, seventeen items were excluded to ensure the clarity and reliability of the final factor structure.

The rotated component matrix resulted in 21 causes with factor loadings between 0.570 and 0.873, grouped into four factors, as presented in Table 2. These factors collectively explained 60.58% of the total variance, exceeding the 60% threshold considered sufficient for construct validity. The scree plot supported this outcome, showing a clear inflection after the fourth factor. Factor labels were assigned based on dominant factor loadings and conceptual relevance (Yap et al., 2018). The extracted factors were: (1) Resources, (2) Management & Planning, (3) Material, and (4) Prerequisite factors. Items were distributed as follows: seven in factors 1 and 2, four in factor 3, and three in factor 4. Cronbach's alpha values for each factor exceeded 0.70, confirming internal consistency (Bolarinwa, 2019). These validated factors represent the final categorization of key workflow variability causes in construction project.

The extracted EFA factors offer a clear framework for understanding and managing workflow variability in construction projects. By consolidating 21 key causes into four core factors, this classification enables targeted, proactive interventions. High factor loadings underscore the importance of these domains in addressing variability at its source. Categorizing the causes facilitates early identification of potential disruptions, supporting more effective planning and execution. These factors form a robust foundation for developing practical tools to enhance workflow stability and overall project performance. The underlying factors of workflow variability causes, as shown in Fig. 2 are discussed below.

Table 1. Respondent's profile

General information	Categories	Frequency	Percent%
Profession area	Administrative position	160	79.6
	Operational position	41	20.4
Nature of the workplace	Consultant	22	10.9
	Government	49	24.4
	Owner	23	11.4
	Contractor	77	38.3
	Subcontractor	30	14.9
Years of experience	Less than 5 years	44	21.9
	From 5 to less than 10 years	58	28.9
	10 years and more	99	49.3

Table 2. Component labels, factor loadings, criteria, and communality in the final rotation of EFA

Factors	Factor loading	Eigen Value	Variance %	Cronbach's Alpha	Communality
Factor 1: Resources	-	7.70	18.70	0.87	-
Lack of worker/crew skills/experience to perform the task	0.718	-	-	-	0.600
Poor productivity	0.720	-	-	-	0.622
People arriving late and/or leaving early because of illness, injury, family or personal reason	0.702	-	-	-	0.557
Low morale and/or lack of motivation	0.698	-	-	-	0.583
Crew size is inadequate	0.659	-	-	-	0.607
Lack of equipment related technical training	0.628	-	-	-	0.504
Equipment allocation problem	0.640	-	-	-	0.518
Factor 2: Management and planning	-	2.06	18.29	0.86	-
Poor contract management	0.700	-	-	-	0.547
Irregular financing and payment for completed works	0.703	-	-	-	0.654
Cultural resistance to change	0.676	-	-	-	0.503
Coordination between different trades	0.686	-	-	-	0.610
Not flexible or unrealistic work schedule	0.748	-	-	-	0.640
Change in scope of work	0.685	-	-	-	0.514
Poor or miscommunication between project stakeholders (project manager, foreman, workers, etc.)	0.570	-	-	-	0.537
Factor 3: Material	-	1.564	14.409	0.86	-
Excess time of the material procurement	0.646	-	-	-	
Problems in material inventories (Accumulation or damaged material)	0.748	-	-	-	0.703
Error in material size	0.873	-	-	-	0.838
Error in material type	0.852	-	-	-	0.796
Factor 4: Prerequisite	-	1.397	9.176	0.70	-
Obtaining required permits for the work to begin	0.789	-	-	-	0.648
Sequencing of planned activities	0.789	-	-	-	0.644
Inspections for previously completed work (for example: quality test)	0.752	-	-	-	0.595

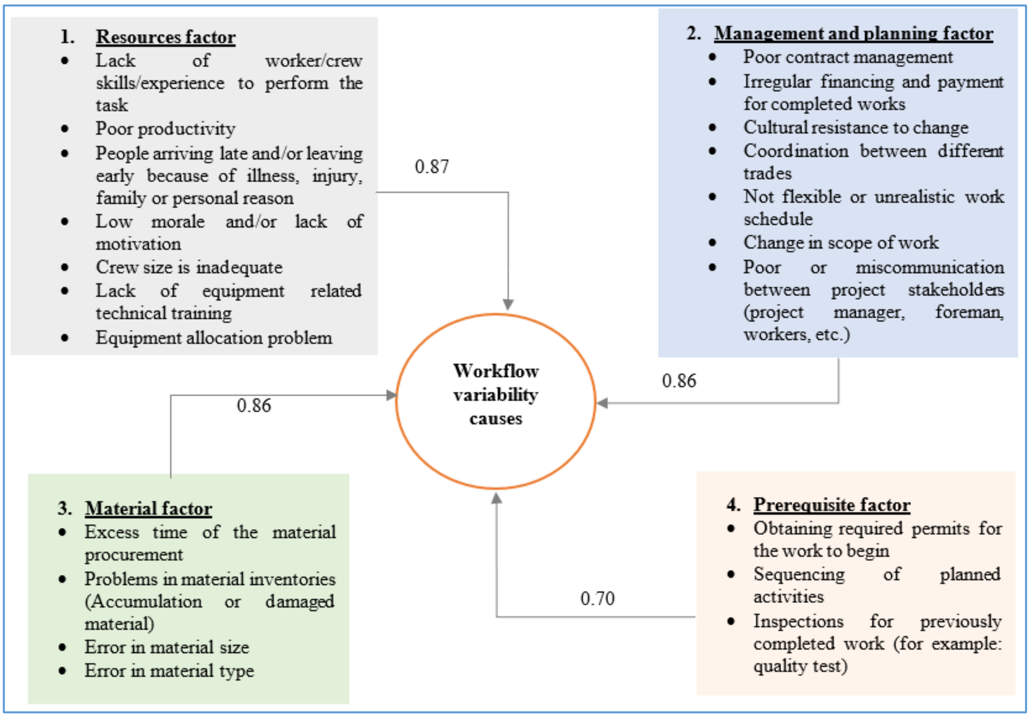

Fig. 2. Components diagram of workflow variability causes

Prior studies have consistently linked poor resource coordination to delays and inefficiencies (Christodoulou, 2017). To mitigate such impacts, it is essential to ensure that labor and equipment are reliably allocated in the right quantities, at the right time and place (Abbasian-Hosseini et al., 2018).

4.2. Management and planning factor

The management and planning factor accounts for 18.3% of the total variance, making it the second most influential factor contributing to workflow variability in construction projects. This factor includes seven key causes, with factor loadings ranging from 0.57 to 0.75, encompassing issues such as contract administration, financing, coordination, communication, workload scheduling, and scope changes. These findings highlight that addressing workflow variability requires a holistic approach to improving planning and managerial practices (Wambeke et al., 2011).

Ineffective communication, poor planning, and cultural resistance to change are widely recognized as internal drivers of variability (Kimpland, 2009). Clear documentation and regular stakeholder communication are essential for preventing misunderstandings and maintaining workflow continuity (Latilo et al., 2024; Sigalov et al., 2021). Disruptions often arise when trades prioritize individual productivity over coordinated progress, leading to delays in downstream activities and misuse of project buffers (Lindhard & Wandahl, 2014).

Contract-related issues, such as delayed payments and lack of transparency, further contribute to workflow instability by disrupting cash flow and lowering productivity (Sigalov et al., 2021). Timely and structured financial management enables efficient resource allocation and supports smoother project execution (Francis et al., 2016). Moreover, unrealistic scheduling and frequent scope changes imposed by clients intensify workflow interruptions, increase error risks, and compromise overall project performance (Assaad et al., 2020; Love & Smith, 2018). Effective planning and contract management are therefore vital to reducing workflow variability and ensuring reliable construction performance.

4.3. Material factor

The material factor, comprising four key factors with loadings between 0.697 and 0.792, accounts for 9.80% of the total variance, making it the third most influential contributor to workflow variability. This factor emphasizes the strategic importance of proper material selection, timely delivery, and maintaining sufficient inventory levels on-site to support uninterrupted workflows. Disruptions related to material issues often result in rework, delays, and inefficiencies (Arbulu et al., 2005; Wambeke et al., 2011; Zhang et al., 2015).

Client-driven changes, incorrect specifications, and late deliveries frequently lead to idle labor and task interruptions, impacting downstream activities (Hwang et al., 2019; Yap et al., 2018). Furthermore, material management is often isolated from production planning, causing misalignments that exacerbate workflow disruptions. Common challenges include shortages, delivery errors, and excessive on-site inventory, all of which contribute to schedule unreliability and are considered forms of waste (Arbulu et al., 2005).

Material-related errors, particularly those unnoticed until installation, can significantly delay progress and reduce productivity. Therefore, implementing integrated and proactive material control strategies is essential for minimizing variability and ensuring reliable, continuous construction workflows (Wang et al., 2019).

4.4. Prerequisite factor

The prerequisite factor accounts for 9.2% of the total variance and includes three critical factors, permits, inspections, and activity sequencing, with factor loadings ranging from 0.75 to 0.79. This factor highlights the essential role of prerequisite conditions in maintaining workflow continuity and minimizing variability in construction projects.

These factors are directly linked to the delayed release of flows between upstream and downstream activities, a primary source of workflow variability (Hamzeh, 2009). Construction processes function as interdependent systems, where disruptions in upstream task completion adversely affect the performance of successor activities, increasing waiting times and variability-related waste (Salhab et al., 2022).

Effective management of prerequisite flows, such as ensuring permits and inspections are completed and that work is properly sequenced, is critical for reducing variability. This involves assessing the readiness of tasks and ensuring constraints are removed before execution (Garcia-Lopez, 2017). Approaches like the make-ready process in the Last Planner System reinforce the importance of executing only work that is free of constraints, thereby improving planning reliability and enhancing workflow stability in complex construction environments (Lindhard & Wandahl, 2014; Montalbán-Domingo et al., 2024).

5. Conclusions

Addressing workflow variability is essential for improving the performance and reliability of construction projects, as it has a direct impact on productivity, scheduling efficiency, and overall project outcomes. Given the persistent nature of workflow variability in the construction industry, this study aimed to investigate its fundamental causes and contribute to a deeper understanding of their origins. Through EFA, the study identified and categorized 21 key causes into four core factors: resources, management and planning, material, and prerequisite factors. These categories offer a structured framework for recognizing and addressing the primary sources of variability. The findings provide valuable insights for project managers during the planning and preparation phases, supporting the development of targeted strategies to minimize variability and enhance project performance.

This study emphasizes the need for improved management of resources, particularly labor and equipment, to ensure workflow reliability. It also highlights the importance of effective material planning and timely delivery in minimizing disruptions and maintaining workflow continuity. Addressing these factors during the planning phase can significantly reduce workflow-related variability and project disruptions. Early attention to workflow issues enhances project clarity and performance. The findings offer a basis for developing a comprehensive framework for managing workflow variability and contribute to improving current practices in construction project management. As this study focuses on identifying the root causes of workflow variability, future research is encouraged to develop and test workflow management strategies tailored to these causes, enabling more targeted and effective approaches for improving construction project performance.

Acknowledgments

The authors would like to thank questionnaire respondents for their remarkable contributions to this study.

Abstract. In highway construction projects, the location selection of site layout is a critical process in terms of project efficiency, cost and time management. This selection is a complex process that requires consideration of many factors. In this study, a survey is conducted for the problem of selecting a suitable construction site location along the route and a multi-criteria evaluation is performed with the AHP (Analytic Hierarchy Process) method. Literature review results and interviews with experts in the field are effective in determining the factors that are effective in site selection. In order to determine the importance levels of the factors, interviews and questionnaires are conducted with experts in the field. In the application phase of the questionnaire; the participants are asked to evaluate the relative importance of the factors under the main and sub-criteria through pairwise comparisons. The collected data are analyzed with the AHP method. AHP is a method that evaluates the criteria numerically by considering complex decision-making processes in a hierarchical structure. With this method, it is aimed to express the priority ranking of the factors related to the selection of construction site locations problem numerically and consequently to support the decision with mathematical data.

Keywords: Site layout; Location selection; AHP; Multi-criteria evaluation; Decision-making

1. Introduction

Highway construction projects are among the high cost investments that spread over large areas. In these projects, the effectiveness of the planning and implementation processes directly affects the success of the project. Determining the appropriate construction site location provides both economic and environmental benefits by ensuring that labor, equipment and material logistics are managed at an optimal level. The decision of the construction site location is one of the strategic and critical decisions that significantly affect both the construction time and costs. This process of selection and evaluation is a complex one that requires many factors to be taken into account. The complex evaluation processes that decision makers often encounter can be made more systematic and objective with multi-criteria decision making (MCDM) techniques. The Analytical Hierarchy Process (AHP) is one of the most widely used approaches among these techniques. AHP is a powerful method in which both quantitative and qualitative criteria can be evaluated together, which can convert the preferences of the Decider into numerical data in a structured manner.

The AHP method used in site selection analyses finds application in a wide range of areas, from the selection of the most suitable location for solid waste warehouses (Siddiqui et al., 1996) to the selection of industrial zones (Eldrandaly et al., 2003). In the literature, there are many studies conducted using AHP.

Kodali and Routroy (2006) studied the location problems of potential facilities in the supply chain using the AHP method. In a study conducted by Başkaya and Akar (2005), they tried to decide which of the fabric alternatives should be produced by using the Analytical Hierarchy Process, which is a decision-making method that takes subjective evaluations into account in the selection of production alternatives. Kalan (2024) determined the importance ranking of the station locations by using the AHP method in the location selection of the stations to be built on the Mersin-Gaziantep HSR (high speed rail)line. Tzeng et al.(2002) used AHP method in restaurant location selection in Taipei. Hwang et al. (2005) evaluated the supplier selection and planning model using AHP, a multi-criteria decision method. Yang and Lee (1997) used AHP to find a solution for location selection. Burdurlu and Ejder (2003) decided on the site location of the furniture sector by using AHP method. In his study, Zahir

* Corresponding author, E-mail: goncakamber@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_mng_795

(1991) eliminated the uncertainties related to the decision of location by ranking them according to their priorities with AHP.

In this study, the AHP method, which is one of the multi-criteria decision-making methods in the selection of construction site locations required for highway construction projects, was used to determine the criteria weights. The criteria needed and to be taken into consideration in the region where the construction site facility will be established are determined and a decision hierarchy is formed according to the weights and importance levels of these criteria. The decider's preference values were determined by making pairwise comparisons of all criteria that make up this hierarchical structure.

2. Materials and methods

When there are two or more quantitative and qualitative criteria and objectives in decision problems, such decision-making situations are considered as Multi-Criteria Decision Making (MCDM) problems. MCDM methods are analytical methods that allow simultaneous evaluation of measurable and immeasurable strategic and operational factors and can involve multiple people in the decision-making process.

In this study, the problem of selecting a suitable site location along the route for highway construction sites is considered as a MCDM problem. In the solution of the problem, the AHP method, which is one of the MCDM methods, is used. As a result of interviews with experts in the field and literature research, criteria that are considered to be effective in site selection are determined. Interviews and surveys are conducted with experts in the field to determine the importance of the criteria. In the application phase of the questionnaire, deciders are asked to determine the importance values of the criteria through pairwise comparisons. The data collected in the evaluation phase of the questionnaire are analyzed with the AHP method.

2.1. Analytical Hierarchy Process

AHP was first proposed by Myers and Alpert in 1968. It is one of the very important decision-making techniques developed by Thomas L. Saaty in 1977 to help decider in the decision-making process (Yaralıoğlu,2001). Since the day it was developed, AHP has found application opportunities in many fields. Some of these application areas are soil analysis (Min, 1994), resource allocation (Cheng & Li, 2001), marketing (Davies, 2001), energy (Kim & Min, 2004), education (Saaty, 1991), risk analysis (Millet & Wedley, 2002), environmental impact assessment (Ramanathan, 2001) and land suitability analysis (BanaiKashani, 1989). The increase in the number of uses of applications over time has enabled the development of the method.

AHP is a multi-criteria decision-making method that can evaluate quantitative and qualitative criteria in decision making, incorporate the preferences, experiences, intuitions, knowledge, judgments and thoughts of the group or individual into the decision process, and solve complex problems in a hierarchical structure. The decision maker can include both objective and subjective considerations in the decision process. Therefore, this situation provides the decision-maker with the opportunity to recognize their own decision-making mechanisms.

In AHP, the hierarchy is organized in at least three levels. At the top level of the hierarchy is the objective. There are main criteria at a lower level, and sub-criteria below the main criteria, if any. For pairwise comparisons to be consistent, the number of criteria should be determined correctly and each criterion should be defined correctly. Criteria should be classified according to their common characteristics. It is a very good method for group decision-making. Thanks to consistency analysis it is possible to analyze the flexibility of the result. Since the construction of the hierarchy and pairwise comparison matrices is subjective, experienced and specialized experts are needed. The algorithmic steps of the AHP method are as follows:

Step 1. Identification of the problem
Step 2. Establishing the Hierarchical Structure
Step 3. Construction of pairwise comparison matrices
Step 4. Normalizing pairwise comparison matrices
Step 5. Calculation of the priority vector
Step 6. Calculation of the consistency ratio
Step 7. Ranking of decision options

AHP is basically based on the comparison of the criteria that are effective in solving the problem according to their degree of importance. After the purpose, factor and sub-factors are determined, pairwise comparison decision matrices are created to determine the importance of factors and sub-factors among themselves. The importance scale of 1-9 proposed by Saaty is used in the creation of these matrices and is given in Table 1. A score of one represents equal importance between two criteria, while a score of nine indicates that one criterion is extremely important compared to the other (Saaty, 2008). If the decision to be made at the end of the study will affect many people, pairwise comparison decision matrices are formed by combining the judgments of different people. In this merging process, many researchers recommend the use of the geometric mean method to obtain consistent pairwise comparison matrices (Saaty, 2000; Tam&Tummala, 2001).

Table 1. Pairwise comparison scale for AHP (Saaty, 2008)

Importance Scale	Definition	Explanation
1	Equal importance	Two activities contribute equally to the objective
3	Moderate importance	Experience and judgement slightly favour one activity over another
5	Strong importance	Experience and judgement strongly favour one activity over another
7	Very strong importance	An activity is favoured very strongly over another
9	Extreme importance	The evidence favouring one activity over another is of the highest possible order of affirmation
2,4,6,8	Intermediate values	Values between two consecutive judgments to be used when compromise is needed

2.1.1. Identification of the problem

The first step in AHP analysis is to define the decision problem. At this stage, the purpose of the problem, that is, the decision to be made, should be determined. The purpose of this study is to be able to choose the most suitable location for highway construction sites along the route.

2.1.2. Establishing the hierarchical structure

In the step of creating the hierarchical structure, the main goal to be achieved is at the top. Once the main objective is set, there are main criteria at a lower level and sub-criteria below the main criteria. The number of stages of the hierarchy depends on the complexity and level of detail of the problem. It is very important to correctly identify the criteria in the hierarchical structure of the decision model. While determining the criteria, surveys, literature review, opinions of experts and practitioners operating in the field related to the decision problem are utilized. As given in Table 2, the criteria affecting the selection of the highway construction site location are listed to consist of the main and sub-criteria. Distance and terrain characteristics are expressed as the main criteria.

Distance criterion consists of sub-criteria of proximity to the center of the work area, residential areas, raw material sources, fuel stations and support construction sites.

The land characteristics criterion consists of three sub-criteria: land structure (land height, slope, ground type), infrastructure supply (drinking water, electricity, telephone, natural gas, sewerage) and land use.

Table 2. Hierarchical structure of criteria

Determination of the most suitable location for highway construction sites	
The Main Criteria	The Sub-Criteria
Distance	Proximity to the center of the work site
	Proximity to the residential areas
	Proximity to raw material sources
	Proximity to fuel stations
	Proximity to support construction sites
Land characteristics	Land structure
	Infrastructure supply
	Land use

2.1.3. Construction of pairwise comparison matrices

The pairwise comparison matrix is created by comparing the criteria at the same level in the hierarchical structure in pairs, and by comparing the sub-criteria within the criteria they are connected to. The comparison matrix is created in accordance with the comparison scale in Table 1 proposed by Thomas L. Saaty. The elements above the diagonal are the “aij” value obtained as a result of the comparison of the i-th criterion with the j-th criterion. The “aji” value obtained by comparing the j-th criterion and the i-th criterion in the matrix is equal to the “1/aij” value due to the correspondence property. The pairwise comparison matrix obtained as a result of the comparison is presented in Table 3. Since the elements on the diagonal of the matrix are self-comparisons of the criteria, the value of these elements is “1”.

Table 3. Pairwise comparison matrices ($A=[a_{ij}]$)

Criteria	Criteria 1	Criteria 2	Criteria 3	…	Criteria n
Criteria 1	1	a_{12}	a_{13}	…	a_{1n}
Criteria 2	$a_{21}=1/a_{12}$	1	a_{23}	…	a_{2n}
Criteria 3	$a_{31}=1/a_{13}$	$a_{32}=1/a_{23}$	1	…	a_{3n}
…	…	…	…	1	…
Criteria n	an1=1/a1n	$a_{n2}=1/a_{2n}$	$a_{n3}=1/a_{3n}$	…	1

2.1.4. Normalizing pairwise comparison matrices
Each element in the matrix is normalized by dividing it by its own column total. The sum of each column value in the normalized matrix is "1". Its formula is given in Equality 1.

$$a'_{ij} = \frac{a_{ij}}{\sum_{i=1}^{n} a_{ij}} \quad (1)$$

2.1.5. Calculation of the priority vector
The formula given in Equation 2 is used to calculate the priority vector. The sum of each row values of the normalized matrix is averaged by dividing by the size of the matrix. Therefore, the weight of the criterion in that row is obtained. These values are the importance weights calculated for each criterion.

$$W_i = \frac{\sum_{j=1}^{n} a'_{ij}}{n} \quad (2)$$

2.1.6. Calculation of the consistency ratio
First, the comparison matrix A is multiplied by the column vector W and the column vector D is obtained in Equality 3. The elements of the column vector X and the column vector W are mutually divided in Equality 4 and the arithmetic average is taken in Equality 5. So λ is calculated.

$$A \times W = |a_{ij}| \times |w_i| = |x_i| \quad (3)$$

$$d_i = \frac{x_i}{w_i} \quad (4)$$

$$\lambda_{max} = \frac{\sum_{i=1}^{n} d_i}{n} \quad (5)$$

After λ is calculated, the Consistency Index (CI) is calculated in Equality 6. CR is obtained by dividing the CI value by the Random Index (RI) value given in Table 4. The CR formula is given in Equality 7.

$$CI = \frac{\lambda_{max} - n}{n-1} \quad (6)$$

$$CR = {}^{CI}/_{RI} \quad (7)$$

Table 4. Random Index (Saaty, 1980)

n	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
RI	0.00	0.00	0.58	0.90	1.12	1.24	1.32	1.41	1.45	1.49	1.51	1.53	1.56	1.57	1.59

If CR ≤ 0.10, the comparisons are consistent. If CR > 0.10 the results obtained are inconsistent.

2.1.7. Ranking of decision options
The decision option with the highest weight is determined as the decision option that should be preferred for the solution of the problem.

3. Results and discussion

In this study, the site selection problem required for highway construction projects is discussed. In the solution of the problem, AHP method is preferred from multi criteria decision making (MCDM) methods. The criteria that may be effective in the construction site location selection process are determined as a result of literature review and interviews with experts in the field. Surveys and interviews with civil engineering experts are conducted to determine the importance of these criteria. The basis of the AHP method is the mutual comparison of criteria according to the importance performance suggested by Saaty. A survey was prepared in accordance with this importance scale and civil engineers who are experts in this field were asked to evaluate the criteria. The results of the surveys conducted with 11 civil engineers are evaluated in the MS Excel program. In the MS Excel program, the geometric mean of the expert opinions is taken and the weights of the criteria are determined by creating pairwise comparison matrices. The obtained criterion weights are given in Table 5.

Table 5. Weights of main and sub-criteria

The Main Criteria		The Sub-Criteria		Common weights	% weights	Consistency ratio
Criteria	Weights	Criteria	Weights			
Distance	0.66667	Proximity to the center of the work site	0.40043	0.267	26.7	λ_{max} =5.26324 CI=0.06581 RI=1.12 CR=0.05876≤ 0.10 The comparisons are consistent.
		Proximity to the residential areas	0.13394	0.089	8.9	
		Proximity to raw material sources	0.12393	0.083	8.3	
		Proximity to fuel stations	0.07173	0.048	4.8	
		Proximity to support construction sites	0.26996	0.180	18	

The table continues below

Land characteristics	0.33333	Land structure	0.62322	0.208	20.8	λ_{max} =3.01834
		Infrastructure supply	0.23949	0.079	7.9	CI=0.00917
						RI=0.58
		Land use	0.13729	0.046	4.6	CR=0.01581≤ 0.10 The comparisons are consistent.
TOTAL	1.00000	TOTAL		1.000	100	

4. Conclusions

Site selection problems are encountered both in the service sector and in the production sector. There are many examples of site loacation problems such as construction sites, factories, warehouses, universities, and airport locations. In this study, the problem of site location is addressed.The AHP method, which evaluates qualitative and quantitative data together, is often used in appropriate site location analyses. In the AHP method, expert opinions are taken to determine the extent to which the criteria affect the site location. Criteria weights are calculated by creating pairwise comparison matrices. The consistency of the transactions is tested by calculating the consistency ratio. In this study, a questionnaire was conducted and 11 opinions of civil engineers who are experts in this field were evaluated in the MS Excel program.

The weights of distance and land characteristics criteria and the sub-criteria of these criteria are calculated and given in Table 5. The importance weights and consistency ratios found for the main and sub-criteria are shown in Table 5.

- When the results are analyzed, it is seen that the consistency ratios of all pairwise comparison decision matrices are less than 0.10.
- Based on this, it is concluded that the pairwise comparison decision matrices are consistent.
- As a result of the analyses conducted, the distance main criterion was determined as the most important criterion in the ranking of criteria with a priority value of 0.6667 for choosing a highway construction site location.
- Land features are the second criterion in the ranking of the main criteria with a priority value of 0.3333.
- As a result of the evaluation of the sub-criteria, the most important of the criteria were determined as proximity to the center of the work site, land structure, proximity to support construction sites, respectively.

The construction site location criteria determined by using expert opinions and literature will form the basis of the following studies.

Prioritization of design risks in construction projects

Aynur Kazaz[1], Gökçen Arslan*[1]

[1] Akdeniz University, Department of Civil Engineering, 07070 Antalya, Türkiye

Abstract. The complex and unique structure of construction projects inherently contains numerous risks that may prevent their successful completion. Multiple studies conducted by various researchers on risk assessment in construction projects have identified design risks, along with financial and construction risks, as the most significant factors affecting construction projects. This study aims to identify and prioritize design risks that may impact construction projects. To this end, 11 design risks potentially affecting construction projects were identified and prioritized according to their likelihood of occurrence and their impact on project success. In prioritizing design risks, expert opinions from designers with a minimum of 20 years of experience in Turkey were solicited, and the obtained data were prioritized using the Fuzzy AHP technique. The study results indicate that the most significant design risks are the client's revision requests, faulty design, and incompatibility between design projects. The findings of this study are expected to contribute to the existing literature on risk and risk management in construction projects. Furthermore, it is anticipated that the results obtained can guide the industry in determining priority areas for developing strategies to mitigate design risks in construction projects.

Keywords: Construction projects; Design risks; Fuzzy AHP; MCDM; Risk management

1. Introduction

Construction projects represent highly intricate systems that necessitate extensive interdisciplinary coordination and are inherently influenced by long-term uncertainties. These projects are dynamic and multifaceted structures where financial, political, legal, technical, design, and environmental risks intersect, posing substantial challenges to cost efficiency, schedule adherence, quality assurance, sustainability objectives, and occupational safety protocols. This study aims to systematically identify and prioritize design-related risks inherent in construction projects. In pursuit of this objective, an extensive literature review was undertaken, and the identified risk factors were meticulously assessed through expert evaluations, and the data obtained from these assessments were processed using the Fuzzy Analytical Hierarchy Process (Fuzzy AHP) methodology to establish a structured prioritization model.

The results of this study are anticipated to refine risk perception in the Turkish construction industry and facilitate the development of structured risk mitigation strategies. Prospective research directions may encompass a more integrative approach by incorporating proactive and reactive risk management strategies, culminating in the formulation of an adaptive and scalable decision-support model tailored to the diverse nature of construction projects, thereby offering substantive contributions to the academic and professional discourse in the field.

2. Literature review

The construction industry is a critical sector on a global scale in terms of its economic contribution to Gross Domestic Product (GDP), employment creation potential and value production (Schoonwinkel & Fourie, 2016; Urbański et al., 2019; Boateng et al., 2022). However, the long-term, financially intensive and multi-stakeholder nature of construction projects causes the projects to be exposed to various risk factors. If risks cannot be managed, failure scenarios such as serious cost overruns, time losses and failure to meet quality standards may occur in projects. The complex, variable and risk-prone nature of construction projects increasingly increases the importance of risk management practices within the sector; In this context, academic research also focuses on sector-specific risk management strategies and offers comprehensive reviews on the subject. A substantial body of research has focused on the identification and prioritization of risks in construction projects. Within this domain, design risks have been widely recognized by scholars as one of the most critical risks influencing construction project outcomes (Table 1).

2022	Shelake et. al.	Geological characteristics, Site Condition, Groundwater, Actual construction, Administration, Design, Management, Faults in contracting, Resource Monitoring, Miscellaneous

Design-related risks are inherently prevalent in construction projects; moreover, inadequate management of these risks can initiate a chain reaction of secondary risks, potentially jeopardizing the project's success throughout the tendering, procurement, and construction phases. Therefore, conducting a comprehensive analysis of potential design-related risks at the early stage of construction projects and implementing necessary precautionary measures are crucial for ensuring the successful completion of the projects.

Although the literature provides extensive coverage of the identification and prioritization of general risks in construction projects, research specifically focusing on the prioritization and management of design-related risks remains remarkably scarce. However, as illustrated in Table 2, the limited existing studies have identified several critical risk factors that may compromise project success. These include requests for design modifications, delays in the employer's approval process, design solutions unsuitable for on-site implementation, communication deficiencies within the design team, and changes in project scope (Liu et.al., 2017; Gashaw and Jilcha 2023; Wuni et.al. , 2023; Erlita et al., 2023).

Table 2. Design risk factors from different studies

Research and its scope	Design Risk Factors
Subramanyan et.al (2012) Research Scope: Investigation of project risk assesment in Indian construction industry	Insufficient data collection and survey before design Complex/nonexecutable design Delay in performing inspection and testing by consultant Unclear and inadequate details in drawings Non use of advanced engineering design software
Liu et.al. (2017) Research Scope: To identify the design risk factors and interrelationships between these factors in design build projects	Inaccurate, missing, vague, or illegal information in employer's requirements Unduly long period of design review required by employer or employer's deferred design review Employer's requirement for design changes A communication gap or misinterpretation on exchange information between employer and designers Delayed information from suppliers Insufficient geological investigation or unknown geological conditions Poor morale among designers Churn among core designers Inadequate communication or coordination between designers Designers' incompetency Designers' unfamiliarity with local requirements of human rights, religion, cultural customs, and lifestyle Difference between designers' work habits and local practice Inadequate checks on design input Inadequate checks on design drawings Unproven design solutions adopted Inadequate design standard/specification adopted Overdesign due to conservatism Employer's excessive right to design review or employer's misuse of right to design review Inaccurate information from suppliers Inaccurate parameters of interfaces between matching equipment Information loss or misconception during design conversion Employer's disagreement on source of main equipment or materials Infringement of design scheme on someone else's intellectual property
Gashaw and Jilcha (2023) Research Scope: Determining design risks in railway projects	Change in scope of work by the client Incomplete design Cost underestimation Design changes Inadequate site investigations Design errors Misunderstanding of client's requirements Contractor's experience Design delay Lack of coordination Schedule pressure Client's lack of experience Poor labor productivity Change in government regulation and law Unsafe project location

Table 2 continued

Research and its scope	Design Risk Factors
Wuni et.al. (2023) Research Scope: To conduct a knowledge-based evaluation and ranking of the design risk factors (DRFs) for modular integrated construction projects.	Inaccurate information, defective design and change order Unable to freeze design early Late involvement of suppliers, fabricators and contractors Lack of bespoke MiC design codes, guidelines and standards Supply chain information gap and inconsistency Design complexity Dimensional and geometric tolerance errors Design information gap between the designer and fabricator Inadequate design planning Inefficiency in design approval Design rework Unsuitability of the design for the MiC method
Erlita et al. (2023) Research Scope: To identify risk factors that cause delays in the preliminary design, design, procurement and construction processes of a factory building project	Building permit data is different from site conditions Lack of open spaces on site Changes in development regulations Issuance of purchase order and late progress payments In-depth feasibility study Incomplete as built drawing Design idea changes Consultant presentation The process of tendering and the implementation of new site Differences in idealism with foreign consultants Design errors The machine plan has not been fixed Delay in production of drawings and tender documents Late progress payment from owner Late of design approval from owner Changes from owner Waiting for owner's decision Coordination meetings between consultants Poor communication and coordination with other parties Drawing information is in PDF format Use of different software Differences between local and foreign regulations Unclear scope of work

The objective of this study is to determine the critical design risk factors that could influence construction projects in Türkiye from the perspective of designers. Using the Fuzzy AHP technique, risks were evaluated and prioritized according to their probability of occurrence and their degree of impact on project success. The anticipated results aim to enrich the existing body of research on design risks. Furthermore, by drawing attention to these risks and suggesting mitigation strategies, the study aspires to support the effective management of design-phase risks, which, if left unaddressed, could lead to project failures in later stages.

3. Methodology

The primary objective of this study is to prioritize design risks in the Turkish construction industry. To achieve this, design risk factors that may influence project success were identified through a comprehensive literature review. The probability of occurrence and impact levels of these risks were assessed based on insights gathered from expert designers via focus group discussions. As a widely recognized qualitative research method, focus groups serve as a validation technique that enables data collection through structured and interactive discussions moderated by an expert, typically involving five to ten participants (Chan et al., 2012; Aladağ & Işık, 2019). In this study, ten experienced designers participated in focus group discussions. The demographic details of the experts who contributed their opinions to this study are summarized in Table 3.

Table 3. Demographic information of participants

Expertise (Profession)	Civil Engineer (2) Mechanical Engineer (2) Electrical/Electronics Engineer (1) Architect (3) Interior Designer (1)
Role	Designer (10)
Annual project budget (USD$/year)	1 - 10 Million (2) 10 - 100 Milyon (8)
Experience in the Construction Industry (years)	10 -20 (2) 20 -30 (4) > 30 (4)
Education Level	Bachelor's degree (7) Master's degree (3)

The Fuzzy Analytic Hierarchy Process technique was subsequently applied to prioritize the data obtained from these discussions. The Fuzzy Analytic Hierarchy Process (FAHP) was developed by incorporating fuzzy logic into the conventional AHP methodology to improve decision-making in environments characterized by uncertainty. This approach employs fuzzy numbers, which are more effective in representing linguistic variables. Various FAHP techniques have been introduced in the academic literature, among which Chang's method (Chang, 1996) is particularly notable. Chang proposed the fuzzy extent analysis technique, which utilizes triangular fuzzy numbers. The following section outlines the key steps involved in the Fuzzy Analytic Hierarchy Process (FAHP) methodology.

Step 1: Model Development and Problem Structuring – Through a comprehensive literature review, 11 design risk factors listed in Table 4, were identified as potentially critical to the success of construction projects.

Table 4. Design risk factors

Risk Code	Design Risk Factors
DR01	Incompatibility between design projects
DR02	Change of regulations and standards
DR03	Faulty design
DR04	Missing details in project drawings
DR05	Design delay
DR06	Failure to analyze the needs and customer demands required for design correctly
DR07	Poor performance of the design team
DR08	Failure to provide optimized design for construction
DR09	Employer's design revision request
DR10	Inadequate site/ geological investigations
DR11	Inefficiency in design approval

Step 2: Construction of Pairwise Comparison Matrices Using Fuzzy Judgments with Triangular Fuzzy Numbers – Experts were asked to perform a pairwise evaluation of the identified indicators. To determine the relative preferences between two components within the fuzzy AHP matrix, the Triangular Fuzzy Scale (Table 5) was utilized.

Table 5. Triangle fuzzy scale (Chang 1996)

Preferences expressed in linguistic variables	Numeric variables	Triangle fuzzy scale	Triangle fuzzy reciprocal scale
Just Equal	1	(1, 1, 1)	(1, 1, 1)
Equally Important/preferred	2	(1/2, 1, 3/2)	(2/3, 1, 2)
Weakly Important/preferred	3	(1, 3/2, 2)	(1/2, 2/3, 1)
Strongly More Important/preferred	4	(3/2, 2, 5/2)	(2/5, 1/2, 2/3)
Very Strongly More Important/preferred	5	(2, 5/2, 3)	(1/3, 2/5, 1/2)
Absolutely More Important/preferred	6	(5/2, 3, 7/2)	(2/7, 1/3, 2/5)

Step 3: Implementation of Chang's Extent Analysis Method – After constructing the pairwise comparison matrix using fuzzy numbers, Chang's Extent Analysis Method was employed to eliminate the uncertainty present. Developed by Chang (1996), this method offers a structured framework for converting fuzzy data into crisp mathematical representations. In this context, let X = (x1, x2, x3, ..., xn) represent the object set, and U = (u1, u2, u3, ..., um) denote the goal set. According to Chang's Extent Analysis Method, each object is individually analyzed for each goal, gi, respectively. Initially, the fuzzy synthetic extent value is calculated using equations (1) to (4):

$$S_i = \sum_{j=1}^{m} M_{gi}^{j} \; x \left[\sum_{j=1}^{n}\sum_{j=1}^{m} M_{gi}^{j}\right]^{-1} \tag{1}$$

$$\sum_{j=1}^{m} \left(\sum_{j}^{m} l_j, \sum_{j=1}^{m} m_j, \sum_{j=1}^{m} u_j\right) \tag{2}$$

$$\left[\sum_{j=1}^{n}\sum_{j=1}^{m} M_{gi}^{j}\right] = \left(\sum_{j}^{m} l_j, \sum_{j=1}^{m} m_j, \sum_{j=1}^{m} u_j\right) \tag{3}$$

$$\left[\sum_{j=1}^{n}\sum_{j=1}^{m} M_{gi}^{j}\right]^{-1} = \left(\frac{1}{\sum_{j=1}^{n} u_i}, \frac{1}{\sum_{j=1}^{n} m_i}, \frac{1}{\sum_{j=1}^{n} l_i}\right) \tag{4}$$

Then, degree of possibility was obtained using the value of fuzzy synthetic extent. Probability values were calculated using using equations (5, 6). Here, the possibility of choosing one criterion out of the other criterion was obtained. The weights vector was then obtained with the help of the possibilities. The normalized weights vector was used to select the best alternative. The degree of possibility of M2=(l2, m2, u2)≥ M2=(l2, m2, u2) is defined as:

$$V\,(M_2 \geq M_1) = sup_{y\geq x}[\min\,(\mu_{M1}(x), \mu_{M2}(y))] \tag{5}$$

The probability degree of triangular fuzzy numbers $M1$=($l1$,$m1$,$u1$) and $M2$=($l2$,$m2$,$u2$) can also be defined as follows;

$$V\,(M_2 \geq M_1) = hgt(M_1 \cap M_2) = \mu_{M2}(d) = \begin{cases} 1 & m_2 \geq m_1 \\ 0 & l_1 \geq u_2 \\ \frac{l_1 - u_2}{(m_2-u_2)-(m_1-l_1)} & otherwise \end{cases} \tag{6}$$

The expression $V(M2 \geq M1)$ here expresses the membership function value of the intersection point of triangular (convex) fuzzy numbers $M1$ and $M2$. Additionally, to compare $M1$ and $M2$, both values of $V(M2 \geq M1)$ and $V(M1 \geq M2)$ must be found. The degree of probability of convex fuzzy number M being greater than k convex fuzzy numbers Mi, i=1,2,…,k can be defined as follows:

$$V(M \geq M_1, M_2, \dots, M_k = V[(M \geq M_1), (M \geq M_2), \dots, (M \geq M_k)] = minV(M \geq M_i), \tag{7}$$

$$i = 1, 2, 3, \dots, k$$

Taking $i \neq k$ for k=1,2,…,n and $d(A$i)= min $V(S$i≥Sk), the weight vector for the criteria can be given as follows:

$$W' = (d'(A_1), d'(A_2), \dots., d'(A_n))^{T} \tag{8}$$

The weight vector obtained in the previous step is normalized to obtain the following vector.

$$W = (d(A_1), d(A_2), \ldots, d(A_n))^T \quad (9)$$

Step 4: Calculation of the Fuzzy Eigenvalue – After constructing the pairwise comparison matrix and applying Chang's Extent Analysis Method to mitigate uncertainty, the Eigenvalue was computed to evaluate the consistency of the matrix. Saaty (1980) introduced the Consistency Index (C.I.) and Consistency Ratio (C.R.) as measures to verify the reliability of comparison matrices. The Consistency Index of a matrix is determined using Equations (10) and (11).

$$CI = \frac{(\lambda_{max} - n)}{(n-1)} \quad (10)$$

$$CR = \frac{CI}{RI} \quad (11)$$

where: λ_{max} is the largest Eigen value of the comparison matrix, n is the dimension of the matrix, and RI(n) is a random index, that depends on n, as shown in Table 6.

Table 6. Consistency index, R.I., of random matrices (Golden and Wang, 1989)

Number of Criteria	1	2	3	4	5	6	7	8	9	10	11
RI	0.00	0.00	0.58	0.90	1.12	1.24	1.32	1.41	1.45	1.49	1.51

In accordance with the scale ranging from zero to one, the overall inconsistency ought to be approximately 10%. However, if the judgments provided by the experts demonstrate inconsistency, as stated by Büyüközkan and Çifçi (2012) and Yasmin et al. (2013), the decision maker is required to undertake the process of repeating the pairwise comparison matrix. To defuzzify a triangular fuzzy number, denoted as M = (l, m, u), and convert it into a crisp number, one can utilize Eqn (12) (Kwong and Bai, 2003).

$$M - Crisp = \frac{4 * m + l + u}{6} \quad (12)$$

In this research, a fuzzy decision support system was developed using Microsoft Excel to solve FAHP matrices. The Excel spreadsheets incorporated Chang's Extent Analysis Method as the primary procedure for processing these matrices. All components of the study, including the initial matrix configuration, problem definition, input matrices, FAHP matrix solutions, consistency ratio calculations, and weighted values (W), were systematically executed within the Microsoft Excel environment.

4. Findings and discussion

The successful completion of construction projects is strongly linked to the effectiveness of risk management strategies. While extensive research has been conducted on risk management in construction projects, studies specifically addressing design-related risks remain relatively scarce. It is believed that implementing effective risk management strategies during the early stages of a project, particularly in the design phase, can significantly enhance the likelihood of project success by mitigating risks that may emerge in later phases. This study aims to prioritize design risk factors relevant to the Turkish construction sector. As a result of the FAHP-based analysis of data obtained from the interview, Table 7 presents key findings, including risk occurrence probabilities, their impact on project success, consistency ratios, and final weightings.

The consistency rates for the pairwise comparison matrices constructed to evaluate the probability of occurrence of the identified risk factors and their impact on project success were 0.024 and 0.025, respectively. Both values fall within the acceptable threshold of 0.10, ensuring the reliability of the comparisons. Based on the probability of occurrence, the top five ranked risk factors are as follows: missing details in project drawings, employer-initiated design revisions, inconsistencies between design projects, delays in the design phase, and inefficiencies in the design approval process. The five most significant risk factors with the potential to jeopardize project success are as follows: design defects, employer-requested design modifications, misinterpretation of design requirements and client expectations, inconsistencies across design projects, and poor performance of the design team. In the final ranking, derived from the arithmetic average of the risk factor weights based on both their probability of occurrence and their impact on project success, the most influential risk factor was identified as the employer's revision request. This factor accounted for approximately 15% of the total weight among the 11 assessed factors. Ranked second was faulty design, with an importance weight of 13%, followed by design project incompatibility in third place, with an approximate weight of 11%. The failure to accurately analyze the employer's requirements and design needs (10.60%) and insufficient field and geological investigations (9.20%) were ranked fourth and fifth, respectively.

Table 7. Design risk factors ranking

Risk Code	Design Risk Factors	Weights regarding the prob. of occur.	Rank regarding the prob. of occur.	Weights regarding the impact on project success	Rank regarding the impact on project success	Final Weight	Final Rank
DR01	Incompatibility between design projects	12.31%	3	9.18%	4	10.75%	3
DR02	Change of regulations and standards	0.11%	11	7.24%	6	3.68%	11
DR03	Faulty design	10.29%	6	16.33%	1	13.31%	2
DR04	Missing details in project drawings	14.85%	1	1.59%	10	8.22%	8
DR05	Design delay	11.79%	4	5.02%	8	8.40%	7
DR06	Failure to analyze the needs and customer demands required for design correctly	9.88%	7	11.32%	3	10.60%	4
DR07	Poor performance of the design team	9.54%	8	8.14%	5	8.84%	6
DR08	Failure to provide optimized design for construction	3.66%	9	6.05%	7	4.86%	10
DR09	Employer's design revision request	14.50%	2	15.69%	2	15.09%	1
DR10	Inadequate site/ geological investigations	2.07%	10	16.33%	1	9.20%	5
DR11	Inefficiency in design approval	11.01%	5	3.11%	9	7.06%	9
CR (Consistency ratio):		0.024		0.025			

The research findings indicate that inadequate analysis of client demands and design requirements, along with employer-initiated revision requests, can significantly hinder project success. Similarly, a separate study conducted to identify critical risks and their impacts in Build-Operate-Transfer (BOT) projects has highlighted that design risks originating from the employer are among the most influential factors contributing to cost overruns and schedule delays (Aladağ & Işık, 2019). In a different study, it was also emphasized by Gashaw and Jilcha (2023) that design changes, scope changes and coordination deficiencies are the most effective design risk factors in construction project time and cost overruns. A study on risk analysis in tunnel construction highlighted that design modifications pose a critical challenge to project success. Extensive research has highlighted that design alterations represent a major impediment to project success. Accordingly, scholars have recommended the implementation of contractual constraints on employer-driven design revisions to minimize their disruptive effects (Subramanyan et al., 2012; Satıcı and Satıcı, 2024). Different research on employer-related risks in the design phase of construction projects has identified scope changes and design defects as critical risk factors, following employer inexperience, poor coordination, and rigid project schedules. Moreover, these risks have been shown to extend project durations by up to 6%. The same study suggests that implementing quality control systems, involving an independent consultant for design review, and establishing a coordination unit are the most effective strategies for mitigating these risks. Notably, the implementation of these strategies has been found to reduce project schedule overruns by 28% (Albogamy and Dawood, 2015). Another empirical study examining critical risk factors in construction projects and their implications for project duration and cost performance identified organizational, construction, financial, design, and political risks as the most influential. The study reported that these risks could extend project timelines by 21% and increase costs by 42%. However, it was highlighted that with the implementation of targeted risk mitigation strategies, these adverse effects could be mitigated by 57% in terms of time delays and 67% in cost overruns. (Kazaz and Arslan, 2024). In addition to cost overruns, Bachayo et al. (2022) emphasized that frequent design changes, last-minute employer demands, and design flaws significantly contribute to the increase in construction waste. Erlita et al. (2023) investigated the primary contributors to time overruns in factory construction projects and found that employer-induced delays in design approval and insufficient coordination among designers exert a substantial influence on project timelines. Their findings highlight the necessity of expediting employer decision-making in both the design and construction phases and mitigating coordination inefficiencies to achieve timely project completion.

Another critical factor influencing project success is the lack of coordination among designers. Given that inadequate communication within the design team can lead to design delays and increase the risk of design flaws, addressing collaboration issues becomes even more essential. Also, Erlita et al. (2023) too highlighted the imperative of streamlining employer decision-making processes during the design and construction phases and strengthening coordination mechanisms within the design team to ensure that construction projects adhere to their intended schedules. Liu et al. (2017) emphasized that establishing a well-structured and proficient design team, along with ensuring team stability, is a crucial strategy for minimizing design-related risks. The adoption of digital technologies, such as Building Information Modeling (BIM), is frequently recommended as a key strategy for mitigating integration challenges among stakeholders throughout both the design and construction phases (Othman and Alamoudy, 2021; Moshtaghian and Noorzai, 2022; Sun et al., 2023; Tabarroki et.al., 2024). A study on the selection of optimal risk strategies in construction projects has also demonstrated that the integration of BIM-based project management and artificial intelligence-supported decision support mechanisms constitutes the most effective risk mitigation measures in project risk management (Kazaz & Arslan, 2023).

In summary, the most critical risks affecting the success of construction projects were identified as employer-driven design modifications, design errors, inconsistencies between design projects, inadequate analysis of design requirements, and insufficient field and geological investigations. To mitigate the impact of employer-initiated design changes, organizing detailed stakeholder meetings and workshops between the employer and the design team during the preliminary and detailed design stages, conducting a comprehensive analysis of needs and requirements, and incorporating change management procedures into contracts—such as legally documenting additional costs and time adjustments related to change requests, limiting revisions, and clearly defining responsibilities arising from design modifications—are proposed as effective solution strategies. To minimize inconsistencies between design teams and design projects, increased adoption of BIM, the preference for integrated project delivery methods, and the utilization of interoperable software tools are recommended. Furthermore, ensuring effective design control through independent design consultants and standardizing design processes are suggested strategies to mitigate the risk of design errors. In addition to comprehensive geotechnical investigations, detailed site exploration before the design phase and the use of design guidelines that consider site-specific and environmental conditions can help mitigate the adverse impacts associated with design risks.

Beyond these measures, technological solutions such as the implementation of smart contracts to regulate employer-driven revision requests, the integration of artificial intelligence-powered quality control systems for design verification, the application of virtual and augmented reality tools along with digital twin technology to minimize revision requests and expedite design approval processes, and the deployment of unmanned aerial vehicles (drones) and robotic systems to gather precise and comprehensive field data to prevent inadequate site and geological assessments are also proposed as effective strategies for the efficient management of design risks.

5. Conclusion

The objective of this research was to identify design risk factors that hold critical importance in the success of construction projects. To achieve this, data obtained from expert designers through interviews were analyzed using the Fuzzy AHP technique. The findings revealed that the most influential risk factors were design revisions, faulty designs, and inconsistencies among design teams and projects. To mitigate these risks, solution strategies such as increasing the adoption of digital tools like BIM, limiting revision requests through contractual provisions, and standardizing design and control processes were proposed.

It is anticipated that the findings of this study will contribute to the existing body of knowledge on design risks in construction projects and that the identified critical risk factors will support the development of effective risk management strategies during both the design and construction phases. However, several limitations should be noted. The study did not conduct a separate impact analysis of design risks in relation to fundamental project goals, including cost, time, quality, sustainability, and safety. Additionally, while risk factors were prioritized, no specific ranking was provided for the suggested mitigation strategies. Moreover, the research was confined to qualitative risk analysis. Future studies should aim to overcome these limitations by broadening the scope of research and validating the findings through case studies.

Abstract. In the last decade, advancements in computer science and Artificial Intelligence (AI), particularly Machine Learning (ML), have significantly impacted energy consumption modeling. ML, with its ability to solve complex, non-linear problems, is widely used in building energy consumption studies. The accuracy of these models depends heavily on the selection of algorithms and input features. This study aims to demonstrate how different algorithms and input features affect the accuracy of building energy consumption predictions. A publicly available dataset, including outdoor air variables, HVAC energy consumption data, time, and occupant-related factors from an office building in California, was used for this study. The HVAC energy consumption was modeled using four ensemble learning algorithms: Random Forest, Adaboost, Bagging, and Gradient Boosting across three scenarios. Scenario (1) used only weather variables; Scenario (2) combined weather and time-related variables; and Scenario (3) included weather, time-related, and occupant-related variables.. Performance metrics were used to evaluate the results, which showed Random Forest performed best in all scenarios. Its accuracy increased from 0.19 in scenario (1) to 0.81 in scenario (3), highlighting the importance of time-related and occupant-related variables in energy consumption. These findings provide valuable insights for building managers aiming to improve energy efficiency in office buildings.

Keywords: Energy consumption modelling; Advanced ensemble algorithms; Machine learning; Office building

1. Introduction

Recently, there has been more focus on energy efficiency in the building sector because of environmental concerns and higher building operation costs. Among the various systems in buildings, Heating, Ventilation, and Air Conditioning (HVAC) systems account for a substantial portion of energy consumption, especially in commercial buildings (Simpeh et al., 2022). Accurate prediction of HVAC energy usage is therefore vital for developing effective energy management and control strategies.

With the rapid advancement of computational power and Artificial Intelligence (AI), particularly Machine Learning (ML), researchers have increasingly turned to data-driven methods to model and predict building energy consumption. ML techniques have shown great promise in handling the complex, non-linear relationships between various factors affecting energy use, such as weather conditions, time patterns, and occupant behavior (Das et al., 2024; Zhou et al., 2024; Hosamo & Mazzetto, 2025; Sharma, 2022). Compared to traditional physics-based models, ML-based approaches offer faster computation, adaptability, and higher accuracy in many scenarios (Wu & He, 2023; Alawi et al., 2024; Liu et al., 2019). Ensemble learning, a subfield of machine learning, combines the predictions of multiple models to improve robustness and accuracy. Algorithms such as Random Forest, Bagging, AdaBoost, and Gradient Boosting have been widely used in various prediction tasks due to their ability to reduce overfitting and capture complex patterns in data.

Despite the increasing adoption of ensemble models in the field, the influence of different input features — such as weather variables, time-related and occupant-related variables — on model performance has not been comprehensively analyzed in a unified framework. This gap becomes more critical when modeling HVAC energy consumption, which is highly sensitive to both external environmental changes and internal occupancy behaviors (Müller, 2021; Mo & Zhao, 2021; Zhang & Wen, 2019).

This study aims to address this gap by evaluating the performance of four ensemble regression algorithms — Random Forest, AdaBoost, Bagging, and Gradient Boosting — in predicting HVAC energy consumption using different combinations of input features. A real-world, open source dataset from an office building in California

was utilized, including outdoor air parameters, HVAC energy use, time attributes, and occupancy-related parameters. The study was structured around three scenarios to examine the incremental impact of input features. Scenario 1 involved using only weather variables as model inputs. In Scenario 2, time-related variables were added to the weather variables to enhance the input set. Finally, Scenario 3 further expanded the input set by incorporating occupant-related variables, resulting in a comprehensive combination of weather, time, and occupancy features.

2. Data and method

In this study, an open dataset from the years 2018-2020 obtained from an office building located in Berkeley, California, was utilized (Luo et al., 2022). The building from which the dataset was obtained is a medium-sized office building located on the Lawrence Berkeley National Laboratory campus in Berkeley, California (Building 59 or Wang Hall).

The building is divided into two wings, north and south, and is segmented into a total of 57 thermal zones. Thermal zones that have exterior walls and windows are classified as exterior zones, while the others are classified as interior zones. Heating and cooling for the offices are provided by a underfloor air distribution system. The system utilizes 4 Roof Top Units (RTUs) located on the roof with water-cooled direct expansion coils to supply cold air to the underfloor plenums. Each RTU, serves the offices on the third and fourth floors between specific vertical lines of the building, although the service areas are not separated by internal wall partitions. Detailed information about the building and the RTU systems can be accessed from (Luo et al., 2022). Due to the fact that each RTU controls different sections of the building and the number of occupants in these sections differs, the historical building automation data values vary. Therefore, in this study, . the focus was on predicting energy consumption of RTU1, which operates 14 thermal zones located in the north wing of the building.

The distributions of 30-minute interval data, collected between February 22, 2018 and February 22, 2020, which include the weather variables — outdoor air temperature, relative humidity, dew point, and solar radiation — as well as the energy consumption of RTU1, are presented in Fig. 1.

The weather variable data mentioned above were preprocessed for use in the study. In this process, if any data point for a given variable was missing at a particular timestamp, the corresponding data points for all other variables at that timestamp were also excluded. Furthermore, due to changes in the operating principles of the HVAC system caused by a wildfire near the building location between 11/12/2018 and 11/20/2018, the data from this period were also removed from the dataset. Subsequently, an outlier analysis was conducted on the remaining data, and identified outliers were eliminated. The boxplots illustrating the results of the outlier analysis for each variable are presented in Fig. 2.

The relationships between the preprocessed weather variables and HVAC energy consumption are illustrated in Fig. 3.

In addition to weather variables, the time-related variables were defined as year, month, day, and hour, while the occupant-related variables were defined based on occupants' working and non-working days and hours in this study. These variables were encoded using the Label Encoding method. The encoded labels are presented in Table 1. As a result, a dataset consisting of 11 columns and 22,136 rows was constructed for predicting RTU energy consumption.

As observed from the relationships in Fig. 3, the association between RTU energy consumption and the variables is non-linear. Therefore, in this study, ensemble learning algorithms were preferred for the prediction of energy load. In this context, four regression algorithms — Random Forest, AdaBoost, Bagging, and Gradient Boosting — from the sklearn.ensemble library in Python were implemented.

Random Forest is an ensemble learning method based on decision trees. It operates by constructing a large number of decision trees during training and outputting the average of their predictions in regression tasks. Each tree is trained on a randomly selected subset of the data with randomly selected features, which increases diversity and reduces overfitting (Zhang & Suganthan, 2014). The model improves prediction accuracy and robustness by aggregating the results of many weak learners (Lin et al., 2017).

Bagging Regression trains multiple instances of a base learner (commonly decision trees) on different bootstrap samples drawn from the training set. Each learner is trained independently, and the final prediction is made by averaging the outputs. This parallel structure helps reduce variance and prevents overfitting (Ghojogh & Crowley, 2019). Bagging is especially effective when the base model is prone to high variance (Grandvalet, 2004).

AdaBoost Regression combines several weak learners in a sequential manner. Initially, all data points are given equal weights. After each iteration, the weights of incorrectly predicted samples are increased, so that the next learner focuses more on these hard-to-predict cases. The final prediction is a weighted sum of the outputs from each model. In regression, AdaBoost minimizes the weighted absolute error, making the model more attentive to difficult samples (Shanmugasunda et al., 2021).

Gradient Boosting Regreesion also builds models sequentially, but unlike AdaBoost, it uses gradient descent to minimize a specific loss function. At each step, a new weak learner is trained to predict the residual errors of the combined previous learners. This process continues until a predefined number of learners is reached or the error no longer improves. Gradient Boosting is known for its high accuracy, but it requires careful tuning to avoid overfitting (Bentéjac et al., 2021).

In this study, the performance of the algorithms was evaluated using Mean Absolute Error (MAE), Root Mean Square Error (RMSE), Coefficient of Variation of the Root Mean Square Error (CV-RMSE), and the coefficient of determination (R^2). The corresponding formulas are presented in Equations 1–4. MAE and RMSE are scale-dependent metrics that reflect the magnitude of errors in relation to the building's energy consumption data. CV-RMSE and R^2 indicate the degree of deviation between predicted and actual values. The closer the R^2 value is to 1, the more similar the trend between predicted and actual values. The CV-RMSE for computer-based prediction models performing hourly-level forecasts should be between 10% and 30% according to ASHRAE Guideline 14–2014.

$$\begin{gathered} MAE = \frac{1}{n}\sum_{i=1}^{n}|(y_i - \hat{y}_i)| \\ RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(\hat{y}_i - y_i)^2} \\ CV - RMSE = \frac{\sqrt{\frac{1}{n}\sum_{i=1}^{n}(\hat{y}_i - y_i)^2}}{\bar{y}} \\ R^2 = \frac{\sum_i(\hat{y}_i - y_i)^2}{\sum_i(\bar{y}_i - y_i)^2} \end{gathered} \qquad (1)$$

where y_i represents the actual value of observation i, , $\hat{y}_i$ denotes the predicted value by the model, $\bar{y}$ is the mean of the observed values, and n refers to the number of samples.

3. Findings and discussion

In the study, the energy consumption prediction model of the RTU was created with four different ensemble learning algorithms using different input features in three different scenarios. The performance metrics of the prediction models in which only weather variables were used as input parameters for Scenario 1 are presented in Fig. 4. It is observed that all algorithms yielded relatively low R^2 values, indicating poor predictive performance. Random Forest achieved the highest R^2 (0.19) among the four algorithms, followed by Gradient Boosting (0.16), Bagging (0.12), and Adaboost (0.12). Similarly, Random Forest exhibited the lowest MAE and RMSE values within this scenario, suggesting a slight edge over the other models when only weather data were available. Nevertheless, the overall predictive accuracy remained limited due to the restricted input features.

The performance metrics of the prediction models in Scenario 2, that is, in which time-related variables are used as input features in addition to weather variables, are presented in Fig. 5. Random Forest again demonstrated superior performance, achieving an R^2 of 0.67, a MAE of 2.35, and a RMSE of 7.02, indicating a notable enhancement compared to Scenario 1. Bagging followed closely behind with an R^2 of 0.65. On the other hand, Adaboost and Gradient Boosting still lagged behind, with relatively lower R^2 values (0.42 and 0.54, respectively) and higher MAE and RMSE values compared to Random Forest and Bagging. The overall results highlight that the inclusion of time-related variables significantly contributes to improving model accuracy, particularly for ensemble-based models like Random Forest and Bagging.

The performance metrics of the prediction models in Scenario 3, that is, where weather, time-related and occupant-related features are all used as input features, are presented in Fig. 6. Random Forest achieved the best results across all metrics, with an R^2 of 0.81, MAE of 1.94, and RMSE of 5.78, outperforming all other algorithms across the three scenarios. Bagging also showed a significant improvement, reaching an R^2 of 0.78. Although Adaboost and Gradient Boosting demonstrated slight enhancements compared to Scenario 2, their performances remained inferior to those of Random Forest and Bagging, reaffirming their relatively lower adaptability to the problem structure. Furthermore, the overall decrease in CV-RMSE values from Scenario 1 to Scenario 3 indicates a progressive enhancement in predictive reliability as additional input features were incorporated.

Considering the results across all scenarios, it is evident that the selection of input features critically influences model performance. Using only weather variables led to limited predictive capabilities, whereas the addition of time-related features notably enhanced model accuracy. The further inclusion of occupant-related variables resulted in the most substantial improvements, suggesting that the operational characteristics of the building, such as occupancy patterns, play a significant role in energy consumption dynamics. This observation aligns with previous research emphasizing that occupant behavior and occupancy schedules are critical factors affecting HVAC system performance and overall building energy use (Hong et al., 2016; Uddin et al., 2021; Li et al., 2021; Ebuy et al., 2023). Among the algorithms, Random Forest consistently demonstrated superior adaptability and predictive performance across different input settings, highlighting its robustness and effectiveness in modeling complex building energy behaviors. This finding is also consistent with previous studies that have similarly reported the strong predictive capability and stability of Random Forest in building energy modeling applications (Liu et al., 2021; Wang et al., 2018; Deng et al., 2018; Pham et al., 2020).

These findings underscore the importance of integrating operational variables, such as occupancy patterns, alongside weather and time-related data when modeling building energy consumption. While weather conditions are undeniably influential, they alone are insufficient to fully capture the variability in HVAC system behavior. The addition of time-related variables improved the models by capturing periodic and seasonal effects, while the incorporation of occupant-related variables further enhanced the models by accounting for human-driven fluctuations in system operation. Particularly, the notable improvements observed in Random Forest and Bagging performances highlight the advantages of ensemble methods in handling complex, multi-dimensional input spaces.

The consistently superior performance of Random Forest, followed closely by Bagging, across all scenarios can be attributed to their inherent characteristics. Random Forest benefits from aggregating multiple decision trees trained on bootstrapped datasets with random feature selection, which enhances its generalization ability and reduces overfitting, particularly when dealing with noisy, multi-variable data such as weather, time, and occupancy patterns (Faisal et al, 2025). Bagging, while similar in leveraging multiple models, lacks the random feature selection step, which may explain why its performance, although strong, remained slightly behind that of Random Forest (Strobl et al., 2009). The robustness of these two ensemble approaches indicates their effectiveness in capturing non-linear relationships and complex interactions among input features, which are prevalent in building energy consumption data.

Furthermore, considering the CV-RMSE values obtained across all scenarios, it can be observed that the predictive models meet acceptable accuracy standards. According to ASHRAE Standard 14–2014, computer-based prediction models performing hourly-level forecasts should exhibit a CV-RMSE between 10% and 30%. In Scenario 1, despite the limited input set, all models achieved CV-RMSE values within this acceptable range, although their R^2 scores indicated weak explanatory power. With the addition of time-related and occupant-related variables in Scenarios 2 and 3, not only did the R^2 values substantially improve, but the CV-RMSE values also decreased, especially for Random Forest and Bagging, reaching approximately 11.6% and 11.8% respectively in Scenario 3. These results confirm that the models are well-calibrated and validate the effectiveness of incorporating richer input sets to enhance predictive accuracy and reliability for practical applications.

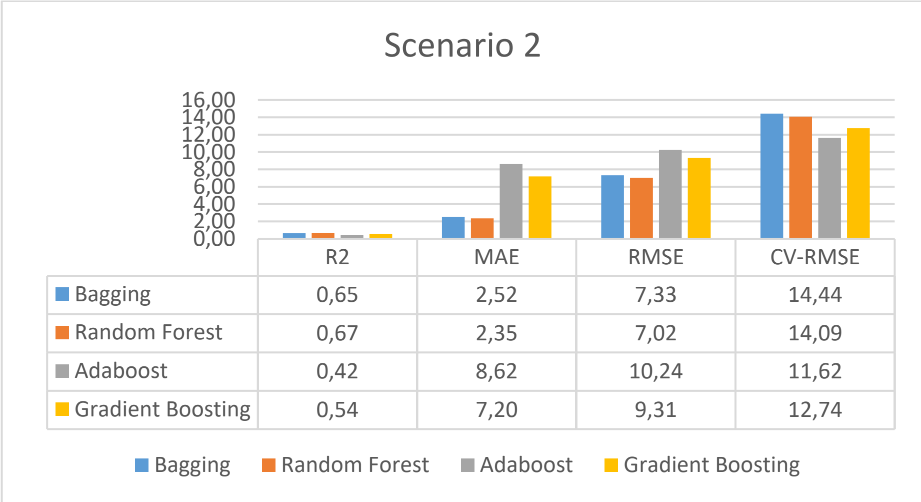

Fig. 5. Performance metrics for Scenario 2

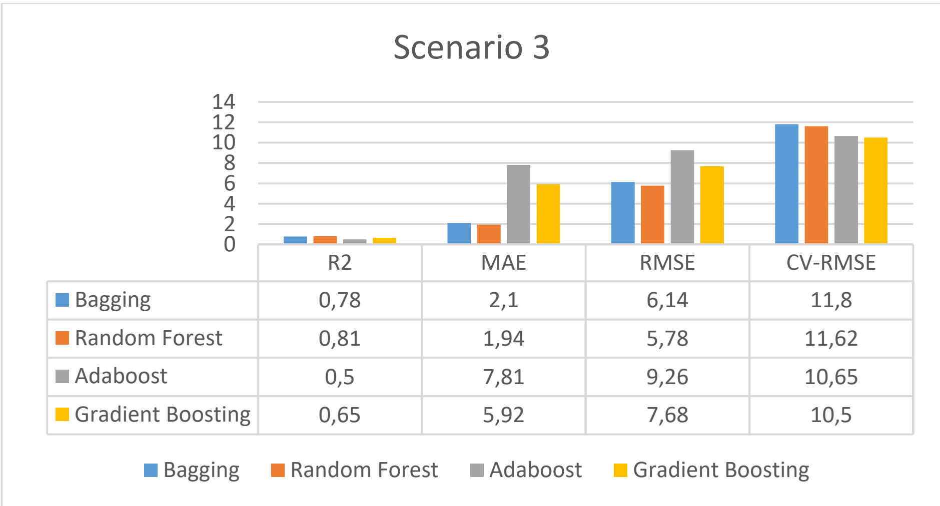

Fig. 6. Performance metrics for Scenario 3

4. Conclusion

This study investigated the modeling of office building energy consumption using various advanced ensemble algorithms under different input faetures scenarios. Specifically, three scenarios were developed based on the inclusion of weather variables alone, the addition of time-related variables, and the further incorporation of occupant-related variables. The predictive performances of Bagging, Random Forest, Adaboost, and Gradient Boosting algorithms were evaluated based on R^2, MAE, RMSE, and CV-RMSE metrics.

The key findings of the study are summarized as follows:

- The selection of input features critically influenced model performance. Using only weather variables resulted in limited predictive accuracy.
- The addition of time-related variables significantly enhanced model performance, capturing periodic and seasonal effects in energy consumption patterns.
- The further inclusion of occupant-related variables led to the most substantial improvements, highlighting the importance of operational characteristics such as workday and working hour status.
- Among the algorithms tested, Random Forest consistently demonstrated superior adaptability and predictive accuracy across all scenarios, followed closely by Bagging.
- The CV-RMSE values obtained for the models across all scenarios were within the acceptable range specified by ASHRAE Guideline 14–2014 (10–30%), with the best-performing models achieving CV-RMSE values close to 11%, indicating strong predictive reliability.

This study provides valuable insights into the importance of careful input feature selection for energy consumption modeling and the effectiveness of ensemble learning approaches, particularly Random Forest and Bagging, in handling complex building energy dynamics. The findings are particularly beneficial for building energy managers, HVAC system designers, and researchers aiming to enhance energy efficiency through data-driven modeling strategies.

For future work, expanding the input feature set to include real-time occupancy detection data, HVAC operational parameters, and indoor environmental quality measurements could further improve model performance. Additionally, exploring deep learning approaches or hybrid ensemble techniques may yield even more robust and accurate prediction models for building energy management applications.

Abstract. Off-site construction (e.g., prefabricated construction and modular construction) is among the most modern industrial techniques for construction. Most recently, the use of technological means in off-site construction processes has attracted considerable attention as it offers many advantages in terms of productivity, health and safety, production quality, and sustainability within the construction industry. This study aims to develop a comprehensive framework to identify technologies and explore their impacts on construction production. In order to achieve the study objective, a systematic literature review was conducted to identify the relevant technologies in the first stage. Then, the identified 46 studies that were published between 2022 and 2025 were analyzed to reveal the benefits and advantages brought by them. The results indicate that building information modeling (BIM), tracking tools, and machine learning methods were the most frequently adopted technological tools/methods. These technologies can facilitate information and data sharing, visualization, and constructability issues in construction projects. Meanwhile, this study focuses on different applications of technologies implemented in various countries. Overall, this study is expected to help project practitioners evaluate the applicability of the proposed technologies in construction projects in many countries. The results would contribute to a better understanding of the potentials of emerging technologies and develop more effective ways of managing, controlling, coordinating, and operating the projects.

Keywords: Modular construction; Digitalization; Prefabricated construction; Literature review; Construction industry

1. Introduction

Off-site construction is an alternative traditional construction method used to minimize project cost and shorten the on-site construction duration (Lei et al., 2023). Prefabricated construction, modular construction, industrialized construction, and assembly construction methods can be indicated as off-site construction practices (Cheng et al., 2023; Junjia et al., 2025; Lei et al., 2023). These construction practices can reduce carbon emissions, waste generation, noise and risks faced, while also playing a significant role in increasing productivity, production quality, and occupational health and safety (Junjia et al., 2025; Y. Wang et al., 2024; Zhan et al., 2024). The off-site construction process consists of project planning, design, manufacturing, transportation, and on-site installation/assembly (Lei et al., 2023).

In this context, integrating advanced technologies within these processes presents better performance outcomes (Cheng et al., 2023). In the literature, various technological tools are used to obtain digital data, achieve automation and ensure digital connectivity in the work environment (Bhatia & Diaz-Elsayed, 2023). Some of the adopted technological tools/methods are: building information modeling (BIM), blockchain, smart contract, machine learning methods, sensors, and digital twin (Chen et al., 2022; Cheng et al., 2023) and each of them offers specific advantages. Although past studies have focused on the integration of technology and off-site construction, there is a gap in the literature in providing a general view on the applicability of technologies.

This study aims to develop a comprehensive framework for identifying the technologies used in off-site construction and analysing their usage purposes and benefits to the construction process. To achieve this objective, a systematic literature review was conducted to address the technologies adopted, and the selected studies were classified based on the construction techniques and technologies. Furthermore, the different methodologies applied in the utilization of these technologies in the off-site construction and countries covered in each research are also assessed. The findings of this study would be beneficial to explore the potential of technological improvements for enhancement construction practices.

2. Methodology

The research methodology applied in this study is shown in Fig. 1. A systematic literature review was conducted to identify technologies/methods adopted for off-site applications by using search engine Scopus. Scopus for this study was preffered because of its wider coverage, broad usage, and fast indexing capability (Kazmi & Sodangi, 2022; Koc & Gurgun, 2021; Rathnayake et al., 2022). The keywords chosen for search strings of Scopus are listed in Fig. 1. In "Title, Abstract, and Keywords" sections, the first search string had keywords that related to off-site construction and its alternatives, the second string comprised of keywords relating to technology, and the third string was related to "construction industry". This search resulted in 730 documents. Then, the search results were limited by the following criteria: (1) the articles written in English, (2) only journal papers, (3) document type chosen as article, and (4) results between 2022-2025. A total of 193 papers were identified and each was investigated on the abstract level. At the end of the abstract and full text screening, 46 research papers were found suitable to this study.

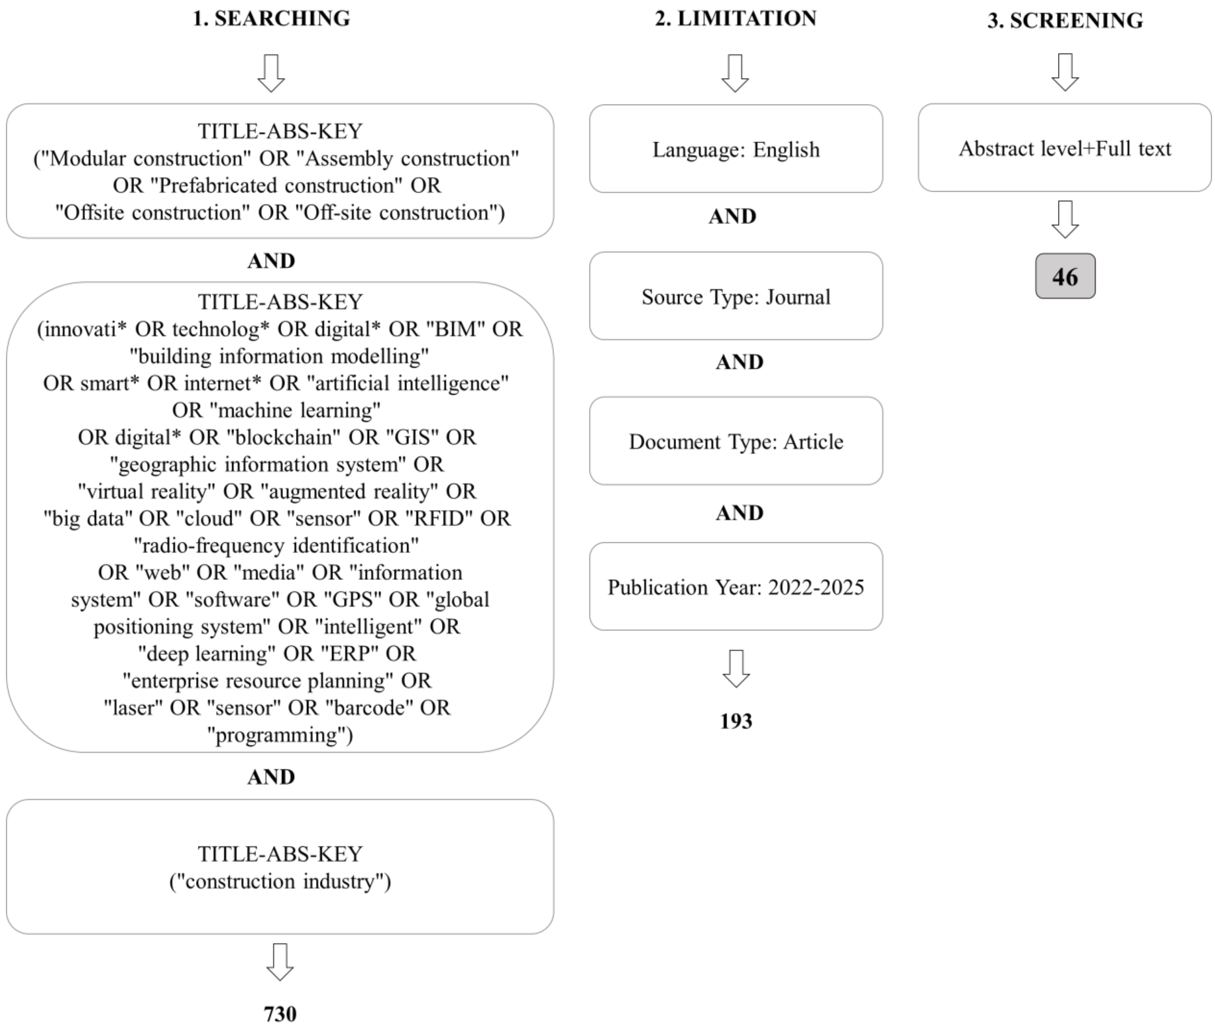

Fig. 1. Research flow

3. Results and discussion

The articles were categorized based on off-site construction techniques. The findings show that 17, 15, and 14 of the studies addressed off-site construction, modular construction, and prefabricated construction contexts, respectively. The yearly distribution of the articles indicated that 12 studies had been published in 2021, 10 studies in 2023, 23 studies in 2024, and 1 study in 2025. The findings illustrate that diverse technological tools and techniques (such as BIM, sensors, and machine learning methods) were implemented in the selected studies. Besides, it was observed that various methodologies were applied in the reviewed articles such as case study, questionnaire study, interviews, and multi-criteria decision making (MCDM) methods, and most of the studies were conducted in the different countries. To identify publications according to the region, the data source country was addressed. When the region was not explicitly mentioned in the studies, the country of the corresponding author was considered (Gurgun et al., 2024). Technologies used, qualitative and/or quantitative analyses, and countries implemented in studies are shown in Figure 2 for modular construction, in Figure 3 for prefabricated construction, and in Figure 4 for off-site construction. The findings show that researchers extensively adopted BIM, machine learning/deep learning tools, and internet-supported tools. Since case study can be regarded as a powerful method that reveal existing gaps between current literature and practice (Zhao et al., 2022), it was found to be the most frequently used method in the selected articles, even adopting in nearly all technology applications. Furthermore, the majority of the selected studies conducted research in China, Australia, and South Korea, while one study included a comparative analysis of off-site construction measurement level in Singapore, United Kingdom, Hong Kong, Malaysia, and China (Im et al., 2024).

In terms of modular construction, most of the articles adopted BIM (8 publications), machine learning/deep learning methods (2 publications), and circular economy (2 publications) (Fig. 2). These tools were mainly related to improvement in scheduling requirements, reducing waste generation and energy consumption, increasing project quality and construction safety, and offering design alternative options (Dewagoda et al., 2024; Liu et al., 2022; Mayouf et al., 2024; Wei et al., 2022).

Fig. 2. Technologies used in modular construction

Regarding prefabricated construction, BIM (9 publications) was the most frequently addressed technology (Fig. 3) with a particular focus on used data formats (such as 2D drawings, 3D model, and 4D BIM model), its practical benefits (such as enhancing management efficiency, shortening construction duration, and promoting quality development), and visual simulation (Xiang et al., 2024; Y. Xiao & Bhola, 2022; Zhang et al., 2024; Zou & Feng, 2023). On the other hand, utilizing for progress/location monitoring, obtaining more details, and providing time and resource efficiency were among the mainly addressed benefits of tracking tools (such as Internet of Things (IoT), sensors, and laser scanning) (Katiyar & Kumar, 2022; M. Wang et al., 2024; Y. Wang et al., 2024).

In terms of off-site construction, most of the selected articles widely adopted BIM (7 publications) as well as machine learning/deep learning algorithms (5 publications) (Fig. 4). At this point, using machine learning algorithms can help management process of projects enhancing the usability of the workflow, reducing constraint violations, and enabling quality inspection systems (Bae et al., 2024; Lee et al., 2022). On the other hand, blockchain applications for off-site construction context were indicated in 2 of the examined studies (Fig. 4). In this context, researchers emphasized that increased visibility and transparency contribute to the decision-making process (Bakhtiarizadeh et al., 2022; Kim et al., 2023).

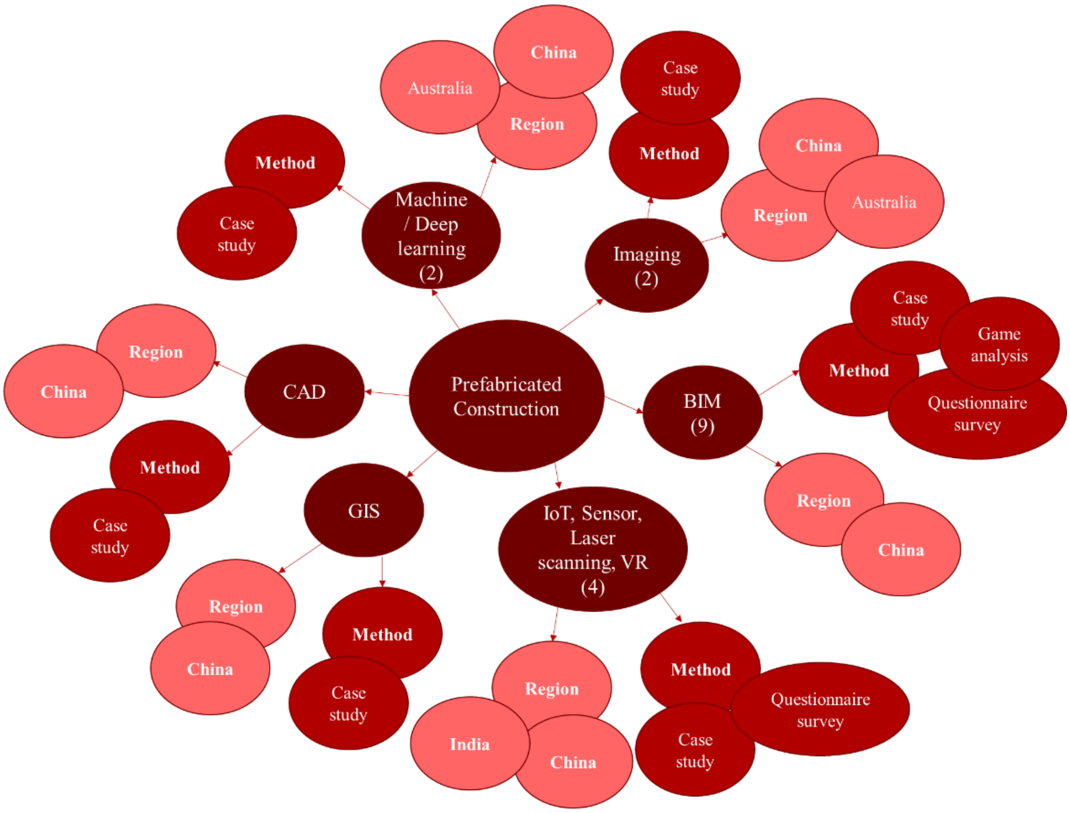

Fig. 3. Technologies used in prefabricated construction

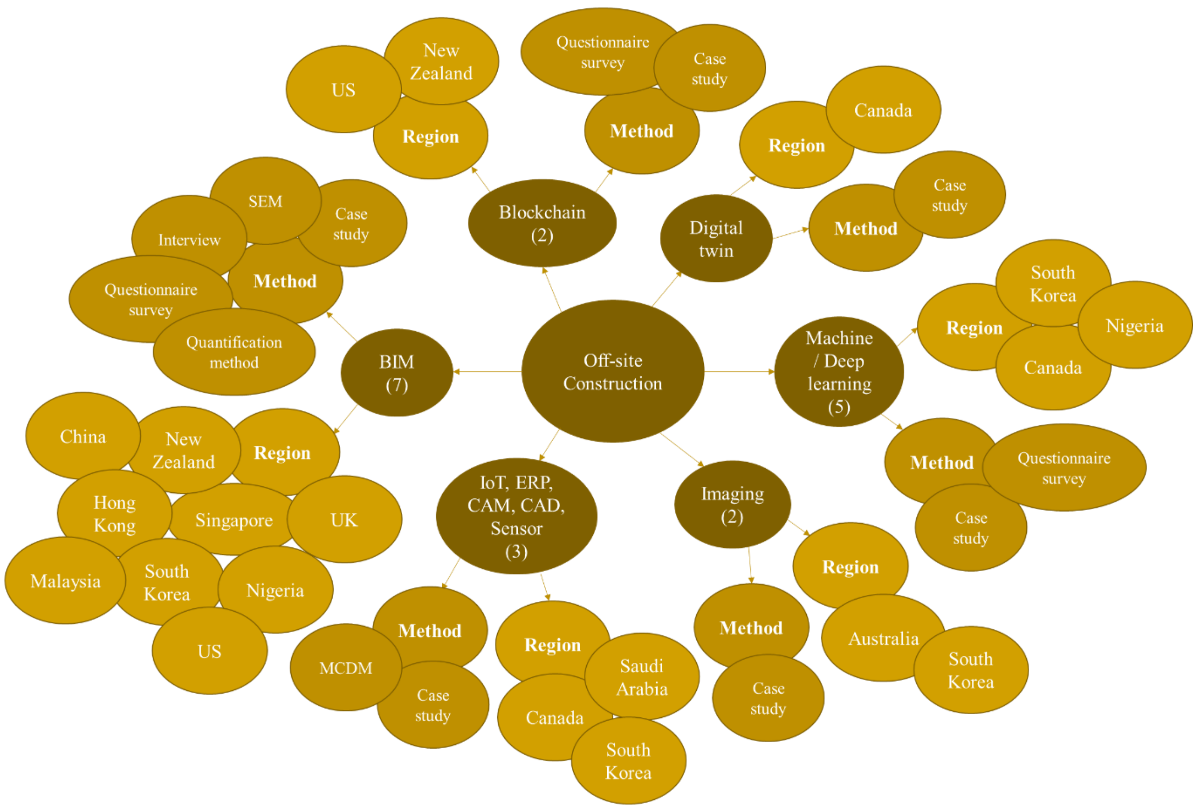

Fig. 4. Technologies used in off-site construction

As explained in Figure 5, technological tools/methods have been used widely for diverse purposes and discovered many benefits and advantages brought by them. It is apparent from the findings that purposes of BIM application in off-site construction are higher compared with other tools. BIM-enabled applications could greatly improve construction process, facilitate information and data flow, reduce constructability issues, and increase communication among different disciplines (Kordestani Ghalenoei et al., 2024; Kordestani et al., 2024). Moreover, a plethora of studies emphasized the benefits of using other technologies (e.g., (Lee et al., 2022; Lei et al., 2023; Xi, 2023; J. Xiao et al., 2024), as shown in Figure 5. On the other hand, hybrid use of some of these tools was also observed in some of the studies. For instance, Katiyar & Kumar (2022) used BIM and IoT to track project stages automatically; Gao et al. (2024) integrated BIM and Geographic Information System (GIS) to quantify greenhouse gas emissions from prefabricated elements; Tan et al. (2024) developed automated quality control approach via BIM and Light Detection and Ranging (LiDAR); and J. Xiao et al. (2024) used digital twin to evaluate virtual and real world concurrently, and the digital twin system was supported by blockchain for efficient data sharing among users. Overall, Figure 5 provides a practical contribution to the technologies to maintain their functions and roles in off-site construction practices.

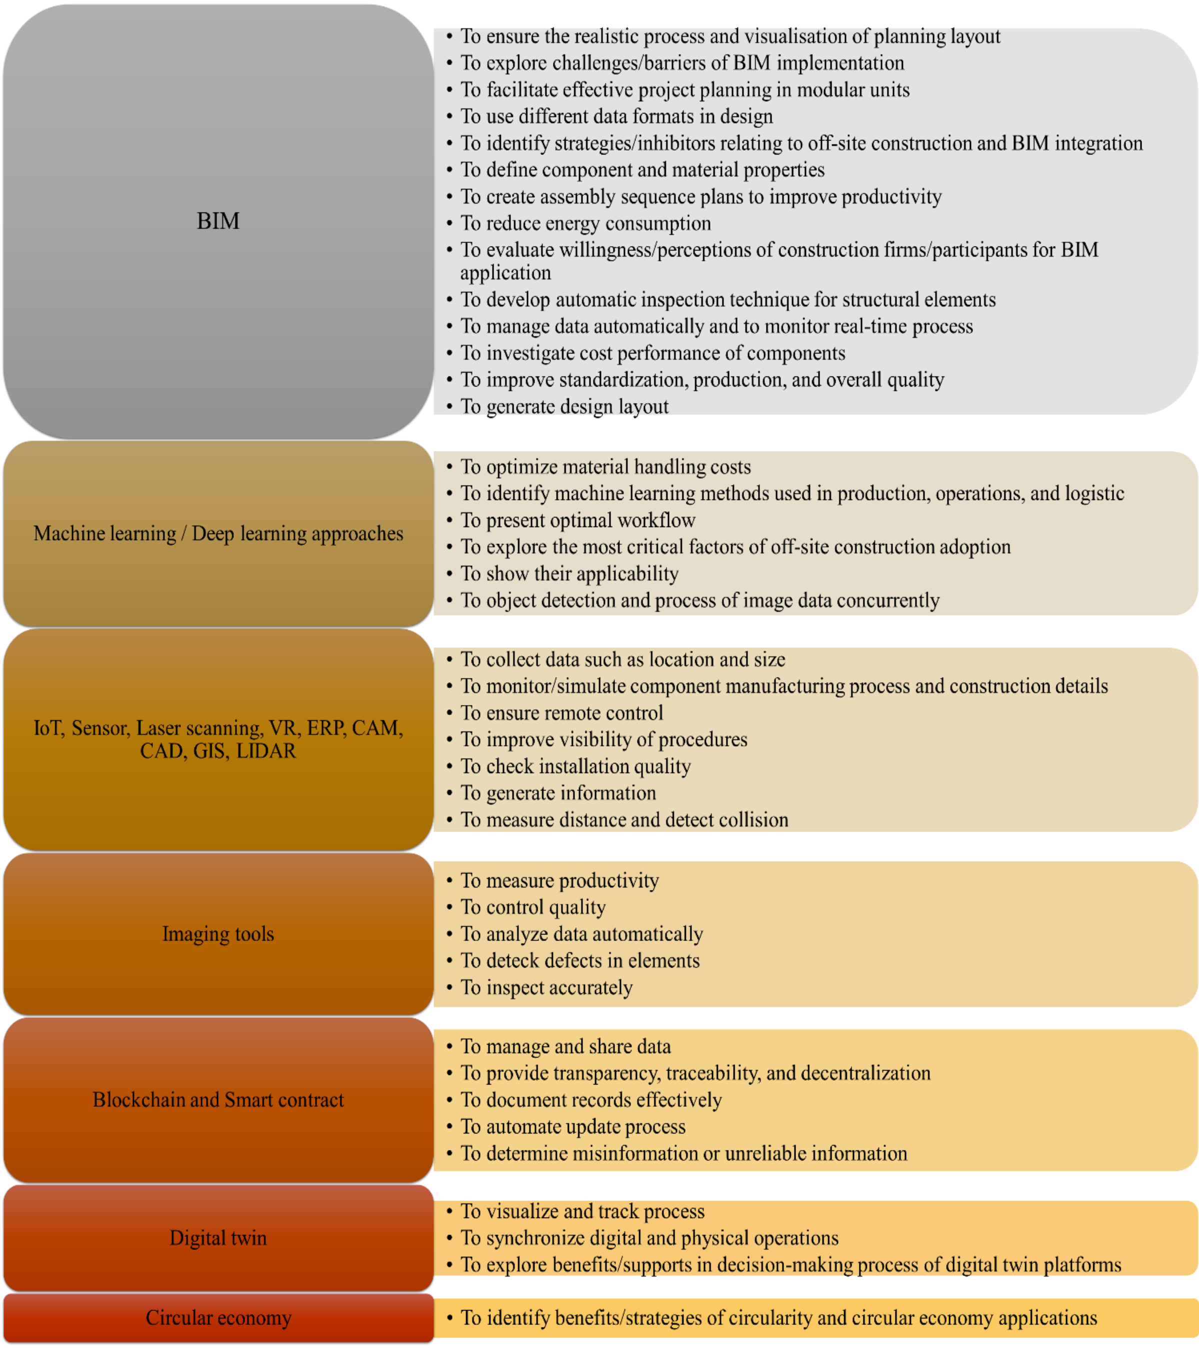

Fig. 5. Usage purposes and benefits of technological tools/methods in the selected articles

4. Conclusions

Off-site construction can be considered as a practical solution that provides high efficiency and low cost ways. In the literature, many studies have promoted to improve traditional construction practices by adopting innovative technologies. For investigating the applicability of technologies, various methodologies have been used in many countries. This study offers a review of the use of technologies in off-site construction techniques by focusing on research articles published between 2022 and 2025. BIM was found to be the most widely used technology to improve and facilitate the process in modular, prefabricated, and off-site construction contexts. In addition, case study and questionnaire survey were also frequently utilized, and studies relating to technology integrated off-site construction were conducted in many countries such as China, Australia, and South Korea. It was also observed that the integration of different technological tools can be an effective option as an innovative construction method.

- This study provides a deep understanding of the technologies adopted in each country for off-site applications and the methods applied to examine these technological applications in the selected studies.
- This study can inform both practitioners and researchers for effective implementation of off-site construction.
- The findings can be used as a guideline to the technology usage in each technique of off-site construction by indicating the potential benefits of technologies for construction practices.

Thermal insulation optimization for energy efficient buildings in Antalya: Multi-criteria decision making approach

Aynur Kazaz[1], Ender Yetim[*1]

[1] Akdeniz University, Department of Civil Engineering, 07058 Antalya, Türkiye

Abstract. The rapid growth of the world's population and increasing demand for housing have significantly increased energy consumption, exacerbating environmental challenges. By ratifying the Paris Climate Agreement in 2021, Türkiye has committed to improving energy efficiency and reducing greenhouse gas emissions. These commitments highlight the need for energy-efficient building design, especially given Türkiye's extensive building stock and high energy consumption in the construction sector. Heating, which accounts for a significant portion of building energy consumption, underscores the critical role of thermal insulation. This study investigates the optimal insulation thicknesses for various building envelope components in Antalya, located in the 1st degree day zone of Türkiye. The analysis includes different building elements (masonry wall-block bims, hollow brick, aerated concrete-, reinforced concrete wall, roof flooring, earth contact flooring), two different fuel types (natural gas, electricity), and four insulation materials (XPS, EPS, glass wool, and rock wool). Using Life Cycle Cost Analysis (LCCA) and Heating Degree Days (HDD) and Cooling Degree Days (CDD) data, the study calculates optimal insulation thicknesses, energy savings, payback periods, and environmental impacts using a static method. The results were evaluated using Multi-Criteria Decision Making (MCDM) methods including Analytical Hierarchy Process (AHP) and Technique for Ranking Preference by Similarity to Ideal Solution (TOPSIS) and a holistic thermal insulation optimization was provided for Antalya. This study differs from other studies by using electrical energy for heating in optimum thermal insulation calculations, performing a holistic optimisation for the building envelope and using MCDM analysis. The study's focus on sustainable energy and its exploration of the relationship between energy efficient design practices and costs are expected to benefit municipalities, academia, and the construction industry.

Keywords: Thermal insulation thickness; Life-cycle cost analysis; AHP; TOPSİS; Multi-criteria decision making

1. Introduction

The rapid growth of the global population has led to increased housing demand, resulting in higher energy consumption and the accelerated depletion of limited natural resources (Arslan & Oral, 2023). This trend has exacerbated climate change and raised energy costs, turning energy efficiency into a critical global issue (Ertürk, 2021; Sloggy et al., 2021). The building sector accounts for approximately 40% of global energy consumption and 35% of greenhouse gas emissions (Zamorano, 2022). In the European Union (EU), 35% of the building stock is over 50 years old and 75% is energy inefficient (Eurostat, 2024). Without effective measures, building energy consumption and associated emissions are projected to double by 2050 (Canbolat & Albak, 2024; Celik et al., 2025; Mohkam et al., 2023). In response, the European Commission's "Fit for 55" package aims to reduce emissions by 55% by 2030 and increase energy efficiency by 32.5% (Wilson, 2021). Similarly, the International Energy Agency projects that $4 trillion in annual clean energy investments will be necessary by 2030 to achieve net-zero emissions by 2050 (IEA, 2021).

Türkiye, as a signatory to the Paris Agreement, has committed to a 21% reduction in greenhouse gas emissions by 2030 and to promoting energy-efficient building practices (Resmi Gazete, 2021). In alignment with these targets, the first and second National Energy Efficiency Action Plans (NEEAP) aim to achieve significant cumulative energy savings and emissions reductions through targeted investments (Ministry of Energy and Natural Resources, 2024). In residential buildings, space heating constitutes a major share of energy consumption: 64% in the EU (Eurostat, 2024) and 65% in Türkiye (TÜİK, 2024), with natural gas being the predominant energy source in both regions.

Building envelope design plays a critical role in improving energy efficiency, offering potential energy savings of up to 50–60% with appropriate interventions (Shehadi, 2018). Specifically, effective thermal insulation can

[*] Corresponding author, E-mail: ender-ytm@hotmail.com

https://doi.org/10.31462/icearc2025_ce_mng_945

reduce fuel consumption by 25–50%, minimizing both heating and cooling loads (Altun et al., 2020; Özturan & Seyhan, 2024). Thus, improving the thermal performance of building envelopes remains a key strategy for reducing energy consumption and supporting climate goals.

In the literature, many studies have determined optimum insulation thickness through Life Cycle Cost Analysis (LCCA) using various building elements, insulation materials, and fuel types across different climatic zones (Akan, 2021; Akan & Akan, 2022; Akbulut, 2024; Aktemur et al., 2021; Kon & Caner, 2023; Uçar, 2024). However, these studies often focus primarily on economic optimization through cost minimization, with limited integration of user preferences and environmental impacts. Addressing this gap, the present study evaluates outputs such as insulation thickness, insulation material cost, fuel cost, total cost, energy savings, payback period, and emission value using the Analytic Hierarchy Process (AHP) and the Technique for Order Preference by Similarity to Ideal Solution (TOPSIS). By incorporating multi-criteria decision-making, this study offers a user-centered and sustainability-oriented framework, contributing to the literature by promoting a holistic evaluation approach that integrates technical, economic, and environmental considerations.

2. Materials and methods

This study analyzes external thermal insulation for residential buildings in Antalya, representing Türkiye's Mediterranean Climate Zone. Three external wall types (three row-hole hollow block, hollow brick, aerated concrete), reinforced concrete wall, roof flooring and earth contact flooring were assessed. Natural gas and electricity were considered as heating sources to evaluate their influence on optimum insulation design. Four common insulation materials (XPS, EPS, glass wool, rock wool) were analyzed. Using the static method and LCCA, optimum insulation thicknesses, annual energy savings, payback periods, and CO_2 emissions were calculated. Results were weighted by the AHP and ranked using the TOPSIS method within a multi-criteria decision-making framework.

2.1.Structure of building envelope

2.1.1. External wall layers

In this study, external insulation was preferred to minimize thermal bridges and effectively reduce heat losses through exterior walls. The wall section configurations are presented in Fig. 1, while the physical properties and cost details of the insulation materials are provided in Table 1.

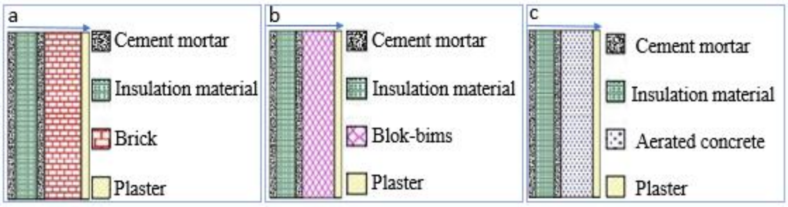

Fig. 1. External wall layers (a) Brick wall, (b) Hollow block wall, (c) Aerated concrete wall

Table 1. Unit price and thermal conductivity value of exterior wall materials

Wall material	Dimension (WxLxH[a])(mm)	Thermal conductivity coefficient (W/m.K)	Total wall thermal conductivity R(m²K/W)	Unit price ($/m³)
Three row-hole hollow block	190x390x180	0.20	1.19	30.21
Hollow brick	250x200x235	0.22	1.38	17.94
Aerated concrete	150x250x600	0.19	1.03	65.09

[a]W:width; L: length; H: height

2.1.2. External reinforced concrete envelope layers

In the study, the insulation material and optimum insulation thickness in the concrete wall (with outdoor air contact), roof flooring and earth contact flooring that make up the facade, ceiling and base surfaces. In the study, the total resistance of thermal conductor R(m²K/W) values of the outer reinforced concrete envelope layers were obtained as 0.34 for concrete wall, 0.32 for roof flooring and 0.44 for earth contact flooring. Section configurations are shown in Figure 2. In this study, four insulation materials were evaluated: Extruded polystyrene (XPS), expanded polystyrene (EPS), glass wool, and rock wool. Their thermal conductivity coefficients were determined as 0.035 W/mK, 0.032 W/mK, 0.031 W/mK, and 0.037 W/mK, respectively. The corresponding unit costs were 66.89 $/m³ for XPS, 43.51 $/m³ for EPS, 71.76 $/m³ for Glass Wool, and 79.72 $/m³ for Rock Wool.

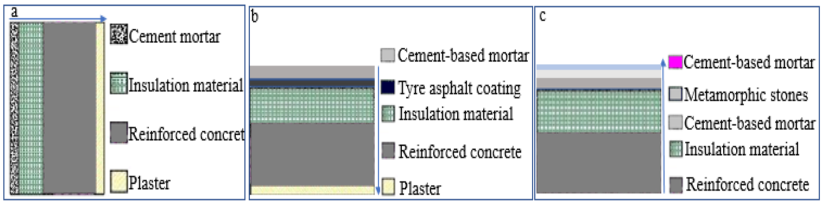

Fig. 2. Building concrete envelope structure (a) Concrete wall, (b) Roof flooring, (c) Earth contact flooring

2.2. Calculation for heating and cooling loads of building envelope

In the calculations, heating degree-days (HDD) were considered for temperatures ≤15°C and cooling degree-days (CDD) for temperatures >22°C, and the corresponding heat losses and energy demands were determined. For Türkiye's 1st climate zone, average HDD and CDD values were calculated as 711 and 751, respectively, based on 2010–2020 data. Heat loss and gain per unit surface of exterior walls were calculated using Eq. 1 (Ucar & Balo, 2010).

$$q = U \cdot \Delta T \tag{1}$$

In these equations, U represents the total heat transfer coefficient and ΔT the temperature difference between the exterior and the constant interior environment. Annual heat loss ($q_{year,h}$) and heat gain ($q_{year,c}$) per unit surface are calculated using Eqs. 2 and 3, based on U, the heating degree-days (HDD), and cooling degree-days (CDD). The U-value for a typical wall is determined using Eq. 4 (Kon, 2018).

$$q_{year,h} = 86400 \cdot HDD \cdot U \tag{2}$$

$$q_{year,c} = 86400 \cdot CDD \cdot U \tag{3}$$

$$U = \frac{1}{R_i + R_{wall} + R_{ins} + R_o} \tag{4}$$

In Eq. 4, R_i and R_o represent the convective heat resistances of the interior and exterior environments, respectively, while R_{wall} denotes the conduction resistance of the uninsulated wall layers. The thermal resistance of the insulation material (R_{ins}) is calculated using Eq. 5, where x is the insulation thickness and k is the thermal conductivity (Rosti et al., 2020). The total resistance of the non-insulated wall ($R_{w,t}$) is determined by Eq. 6 (Alsayed & Tayeh, 2019), and the overall heat transfer coefficient (U) is calculated using Eq. 7 (Vincelas & Ghislain, 2017).

$$\mathrm{R_{ins}} = \frac{\mathrm{x}}{\mathrm{k}} \tag{5}$$

$$\mathrm{R_{w,t}} = \mathrm{R_I} + \mathrm{R_{wall}} + \mathrm{R_o} \tag{6}$$

$$\mathrm{U} = \frac{1}{\mathrm{R_{w,t}} + \mathrm{R_{ins}}} \tag{7}$$

$E_{year,h}$ value is the annual energy need required for heating and $E_{year,c}$ value is the annual energy need required for cooling. They are calculated by Eq. 8 and Eq. 9 (Koru et al., 2022). The fuels used in the study and their properties are presented in Table 3.

$$\mathrm{E_{year,h}} = \frac{86400 \cdot \mathrm{HDD}}{(\mathrm{R_{w,t}} + \mathrm{R_{ins}}) \cdot \eta} \tag{8}$$

$$\mathrm{E_{year,c}} = \frac{86400 \cdot \mathrm{CDD}}{(\mathrm{R_{w,t}} + \mathrm{R_{ins}}) \cdot \mathrm{COP}} \tag{9}$$

Table 3. Properties of fuels used for heating (Çay & Gürel, 2013; Koru et al., 2022)

Fuel	Price	Lower calorific value (Hu)	Efficiency ($\eta_{H,S}$)
Natural gas	0.28 $/m³	34.285x10⁶ J/m³	0.93
Electricity	0.08 $/kWh	3.599x10⁶ j/kWh	0.99

2.3. Cost analysis and determination of optimum thickness for insulation material

Applying insulation to exterior walls can significantly reduce heat losses and gains; however, a cost analysis is necessary to determine the optimum insulation thickness. The annual energy cost per unit surface for heating ($C_{year,h}$) and cooling ($C_{year,c}$) is calculated using Eqs. 10 and 11, respectively (Canbolat et al., 2020).

$$\mathrm{C_{year,h}} = \frac{86400 \cdot \mathrm{U} \cdot \mathrm{HDD} \cdot \mathrm{C_{fuel}}}{\mathrm{Hu} \cdot \eta} \tag{10}$$

$$\mathrm{C_{year,c}} = \frac{86400 \cdot \mathrm{U} \cdot \mathrm{CDD} \cdot \mathrm{C_e}}{\mathrm{COP}} \tag{11}$$

In Eqs. 10 and 11, C_{fuel} denotes the unit price of fuel, Hu the lower calorific value, η the thermal efficiency of the combustion system, Ce the electricity unit price, and COP (assumed as 3) the cooling system efficiency. The life-cycle cost analysis method was used to determine the optimum insulation thickness, with annual energy costs calculated based on the Present Value Factor (PVF) and the defined life cycle. PVF varies depending on inflation (g) and interest (i) rates. The actual interest rate (r) is calculated using Eq. 12 when i > g, Eq. 13 when g > i, and PVF is subsequently computed using Eq. 14. If i = g, PVF is determined through Eq. 15 (Aydın & Bıyıkoğlu, 2020).

$$\mathrm{r} = \frac{\mathrm{i} - \mathrm{g}}{1 + \mathrm{g}} \tag{12}$$

$$\mathrm{r} = \frac{\mathrm{g} - \mathrm{i}}{1 + \mathrm{i}} \tag{13}$$

$$\mathrm{PVF} = \frac{(1 + R)^N - 1}{r \cdot (1 + r)^N} \tag{14}$$

$$\mathrm{PVF} = \frac{N}{1 + i} \tag{15}$$

The Present Value Factor (PVF) was calculated as 7.95 using 2021-January economic data from the Central Bank of the Republic of Turkey (10-year life cycle, 19.60% interest rate, and 14.60% inflation). Insulation cost is determined by Eq. 16, where Cy represents the unit cost of insulation. The total heating and cooling costs for an insulated building are calculated using Eqs. 17 and 18, respectively. For buildings insulated for both heating and cooling, the total cost is calculated using Eq. 19 (Koru et al., 2022).

$$\mathrm{C_{ins}} = \mathrm{C_y} \cdot \mathrm{x} \tag{16}$$

$$\mathrm{C_{ins,t,h}} = \mathrm{C_{year,h}} \cdot \mathrm{PVF} + \mathrm{C_y} \cdot \mathrm{x} \tag{17}$$

$$\mathrm{C_{ins,t,c}} = \mathrm{C_{year,c}} \cdot \mathrm{PVF} + \mathrm{C_y} \cdot \mathrm{x} \tag{18}$$

$$\mathrm{C_{ins,t,h,c}} = \mathrm{C_{year,h}} \cdot \mathrm{PVF} + \mathrm{C_{year,c}} \cdot \mathrm{PVF} + \mathrm{C_y} \cdot \mathrm{x} \tag{19}$$

The optimum insulation thickness minimizing the total heating cost is calculated using Eq. 20, while that minimizing the total cooling cost is determined by Eq. 21 (Bolattürk, 2008). The optimum thickness minimizing both heating and cooling costs is obtained through Eq. 22 (Aydın & Bıyıkoğlu, 2020).

$$\mathrm{X_{opt,h}} = 293{,}94 \cdot \left(\frac{\mathrm{HDD} \cdot \mathrm{C_{fuel}} \cdot \mathrm{PVF} \cdot \mathrm{k}}{\mathrm{Hu} \cdot \mathrm{C_{ins}} \cdot \eta}\right)^{\frac{1}{2}} - \mathrm{k} \cdot \mathrm{R_{w,t}} \tag{20}$$

$$\mathrm{X_{opt,c}} = 293{,}94 \cdot \left(\frac{\mathrm{CDD} \cdot \mathrm{C_e} \cdot \mathrm{PVF} \cdot \mathrm{k}}{\mathrm{C_{ins}} \cdot \mathrm{COP}}\right)^{\frac{1}{2}} - \mathrm{k} \cdot \mathrm{R_{w,t}} \tag{21}$$

$$\mathrm{X_{opt,c}} = 293{,}94 \cdot \left(\frac{\mathrm{CDD} \cdot \mathrm{C_e} \cdot \mathrm{PVF} \cdot \mathrm{k}}{\mathrm{C_{ins}} \cdot \mathrm{COP}}\right)^{\frac{1}{2}} - \mathrm{k} \cdot \mathrm{R_{w,t}} \tag{22}$$

2.4. Payback period method

The total annual net savings for buildings with heating-only insulation are calculated using Eq. 23, while those with both heating and cooling insulation are determined by Eq. 24. In these equations, C_h and $C_{h,c}$ represent the 10-year heating and heating-cooling energy costs of uninsulated buildings. The payback periods of insulation investments are calculated using Eq. 25 and Eq. 26, respectively (Kurekci, 2016).

$$\mathrm{A_{year,h}} = \mathrm{C_h} - \mathrm{C_{ins,t,h}} \tag{23}$$

$$A_{year,h,c} = C_{h,c} - C_{ins,t,h,c} \tag{24}$$

$$PP_h = \frac{C_{ins}}{Ayear,_h} \tag{25}$$

$$PP_{h,c} = \frac{C_{ins}}{A_{year,h,c}} \tag{26}$$

2.5. Environmental analysis

In the study, emission values depending on different insulation materials and thickness of insulation materials were calculated according to the use of natural gas and electrical energy. The amount of CO_2 emission per unit surface according to the annual fuel consumption is calculated by Eq. 27 and Eq. 28 (Çay & Gürel, 2013).

$$\mathrm{M_{CO_2}} = \frac{\mathrm{x} \cdot \mathrm{M_{CO_2}}}{\mathrm{M_{fuel}}}\ (\mathrm{kg\ CO_2/kg\ fuel}) \tag{27}$$

$$\mathrm{M_{CO_2}} = \frac{44\mathrm{x}}{\mathrm{M_{fuel}}}\ \mathrm{E_A}\ (\mathrm{kg\ CO_2\ /m^2 - year}) \tag{28}$$

2.6. Selecting the optimal insulation material

In this study, economic optimization parameters were defined as criteria and insulation materials as alternatives. The Analytic Hierarchy Process (AHP) was used to prioritize the criteria, while the Technique for Order Preference by Similarity to Ideal Solution (TOPSIS) was applied for selecting the optimal insulation material. AHP, developed by Saaty (1977), is based on pairwise comparisons to determine the relative importance of multiple criteria (Kazaz & Arslan, 2023). The method involves three main phases: (i) structuring the decision hierarchy, (ii) collecting expert judgments using a 1–9 scale to construct a pairwise comparison matrix, and (iii) calculating the Consistency Index (CI) and Consistency Ratio (CR) to assess the reliability of the comparisons, which should be below 0.10 (Saaty, 2004; Senan et al., 2023). The equations given below are used to calculate the consistency index and consistency ratio (Eqs. 29-30) (Saaty, 2004).

$$CI = \frac{\lambda_{\max} - n}{\mathrm{n} - 1} \tag{29}$$

$$CI = \frac{CI}{\mathrm{RI}} \tag{30}$$

The most suitable insulation material was selected using the Multi-Criteria Decision Making (MCDM) approach, based on the performance values determined for building envelope alternatives. Given the defined insulation options and evaluation based on seven criteria, the TOPSIS method was deemed appropriate for this study. Developed by Yoon and Hwang (1980), TOPSIS ranks alternatives based on their relative closeness to the ideal solution. The MCDM process involves defining the problem, generating alternatives and criteria, weighting criteria, evaluating options, selecting the appropriate method, and ranking alternatives (Erikci Çelik & Zorer Gedik). The TOPSIS procedure includes six steps: constructing the Decision Matrix (A), Standard Decision Matrix (R), Weighted Standard Decision Matrix (V), determining Ideal (A*) and Negative Ideal (A^-) solutions, calculating Discrimination Measures (Si*, Si^-), and computing the Relative Closeness (Ci*) to the ideal solution. Based on these analyses, the optimal insulation material was identified. In the decision matrix, the rows contain the decision points whose superiority is desired to be listed, and the columns contain the evaluation factors to be used in decision making (Saaty, 2004). In Eq. 31, m gives the number of decision points and n the number of evaluation factors in the Aij matrix. The Standard Decision Matrix is calculated using the elements of matrix A and using Eq. 32 (de Lima Silva & de Almeida Filho, 2020; Wang et al., 2022).

$$\mathrm{A_{ij}} = \begin{bmatrix} \mathrm{a_{11}} & \cdots & \mathrm{a_{1n}} \\ \vdots & \ddots & \vdots \\ \mathrm{a_{m1}} & \cdots & \mathrm{a_{mn}} \end{bmatrix} \tag{31}$$

$$\mathrm{r_{ij}} = \frac{\mathrm{a_{ij}}}{\sqrt{\sum_{k=1}^{m} a_{kj}^2}} \tag{32}$$

After the decision matrix is created, the normalization process (r_{ij}) is performed. In this step, the goal is to convert the criteria numeric values into comparable numeric values between 0 and 1. This transformation is carried out with the help of Eq. 33. Then, the weight values (w_i) of the evaluation factors are determined with the help of Eq. 34 (Li et al., 2022).

$$\mathrm{R_{ij}} = \begin{bmatrix} \mathrm{r_{11}} & \cdots & \mathrm{r_{1n}} \\ \vdots & \ddots & \vdots \\ \mathrm{r_{m1}} & \cdots & \mathrm{r_{mn}} \end{bmatrix} \tag{33}$$

$$\sum_{i=1}^{n} w_i = 1 \tag{34}$$

The elements of each column in the normalized decision matrix (R) are multiplied by their respective criterion weights to form the weighted normalized matrix (V) (Eq. 35) (Chakraborty, 2022). In the V matrix, the maximum and minimum values for each criterion are identified to establish the ideal and negative ideal solutions (Eqs. 36–41) (Abdel-Basset & Mohamed, 2020; Chen, 2021; Rafiei-Sardooi et al., 2021).

$$V_{ij} = \begin{bmatrix} w_1 r_{11} & w_2 r_{12} & w_{13} r_{13} & \dots & w_n r_{1n} \\ w_1 r_{21} & w_2 r_{22} & w_3 r_{23} & \ddots & w_n r_{2n} \\ & & & & \vdots \\ w_1 r_{m1} & w_2 r_{m2} & w_3 r_{3m3} & \cdots & w_n r_{mn} \end{bmatrix} \tag{35}$$

$$A^* = \{(max_i v_{ij} | j \in J), (min_i v_{ij} | j \in J'\} \tag{36}$$

$$A^* = \{(max_i v_{ij}\} \tag{37}$$

$$A^* = \{v_1^*, v_2^*, \dots, v_n^*\} \tag{38}$$

$$A^- = \{(min_i v_{ij} | j \in J), (max_i v_{ij} | j \in J'\} \tag{39}$$

$$A^- = \{(min_i v_{ij}\} \quad (40)$$

$$A^- = \{v_1^-, v_2^-, \ldots, v_n^-\} \quad (41)$$

In both Eq. 36 and Eq. 39, benefit (maximization) and loss (minimization) values are indicated. In the TOPSIS method, the Euclidean Distance Approach is applied to determine the deviations of each decision point from the ideal and negative ideal solution sets (Eqs. 42–43). In Eq. 42, Si* denotes the Ideal Discrimination Measure, where Vij represents the maximum value in the ideal set and vj the corresponding value in the weighted decision matrix (Chen, 2019; Yu & Pan, 2021). Similarly, Si⁻ denotes the Negative Ideal Discrimination Measure, where Vij refers to the minimum value in the negative ideal set. These discrimination measures are subsequently used to calculate the relative closeness (Ci*) of each decision point to the ideal solution (Eq. 44) (Çelikbilek & Tüysüz, 2020; Yu & Pan, 2021).

$$S_i^* = \sqrt{\sum_{j=1}^{n} (v_{ij} - v_i^*)^2} \quad (42)$$

$$S_i^- = \sqrt{\sum_{j=1}^{n} (v_{ij} - v_i^-)^2} \quad (43)$$

$$C_i^* = \frac{S_i^-}{S_i^- + S_i^*} \quad (44)$$

In Eq. 32, the Ci* value ranges between 0 and 1, where Ci* = 1 indicates absolute closeness to the ideal solution, and Ci* = 0 indicates closeness to the negative ideal solution. For each building envelope element, the Decision Matrix (A), Standard Decision Matrix (R), Weighted Standard Decision Matrix (V), Ideal (A*) and Negative Ideal Solutions (A⁻), Discrimination Measures (Si*, Si⁻), and Relative Closeness to Ideal Solution (Ci*) were calculated using the AHP and TOPSIS methods and presented in the tables.

3. Results and discussion

Optimum thickness of insulation materials is calculated on the exterior walls for both heating and cooling energy by using three different wall elements (Three-row-hole hollow block, brick, aerated concrete), two different fuel types (natural gas, electricity) and four different insulation materials (xps, eps, glass wool, rock wool) in buildings located in the Mediterranean Climate Zone. The cost calculation based on the optimum thickness of insulation materials used in buildings has been made by taking two situations as reference, according to the type of energy used. The first situation: In the building, natural gas is used for heating and electrical energy is used for cooling. The second situation: electrical energy is used for both heating and cooling in the building. Optimum insulation material thicknesses depending on different insulation materials in Three-row-hole hollow block, hollow brick, aerated concrete, concrete wall, earth contact flooring and roof flooring are presented in Table 4 and cost calculations are presented in Table 5. The amount of CO_2 emission after energy consumption depending on the optimum insulation thickness is presented in Figures (3-8) respectively. In the figures, a) shows the emission values from heating the building, and (b) shows the emission values from heating and cooling the building.

Table 4. Optimum insulation material thickness

Envelope Element		Fuel Type	Insulation Material			
			XPS	EPS	Glass Wool	Rock Wool
			$X_{opt,h,c}$	$X_{opt,h,c}$	$X_{opt,h,c}$	$X_{opt,h,c}$
Wall	Tree row-hole hollow block	Natural gas	0.040	0.059	0.038	0.033

After the economic optimization, a survey was conducted with experts who have experience in the field of insulation in the construction industry, and the criteria weights of insulation thickness, insulation cost, fuel cost, energy savings, payback period and emission amount were determined by the AHP method. The demographic information of the experts participating in the survey is presented in Table 6, the criteria descriptions in Table 7, and the pairwise comparison scale used to prioritize the criteria in Table 8. Comparison matrix, normalized matrix and criterion weights used for weighting insulation material criteria are shown in Table 9 and Table 10.

Table 6. Profile of respondents

Category		Number
Proficiency	Civil Engineer	3
	Mechanical Engineering	5
	Architecture	2
Role	Designer	10
Experience in construction sector (year)	≤10	6
	10 -20	2
	20 -30	1
	≥ 30	1
Education level	Bachelor	8
	MSc or PhD	2

With the AHP method, criterion weights were obtained with a consistency index (CI) of 0.09 and a consistency ratio (CR) of 0.01. Then, the TOPSIS method is applied to the three-row-hole hollow block, hollow brick, aerated concrete, concrete wall, earth contact flooring, roof flooring elements, which form the entire building envelope, separately, according to the type of energy used in heating, and Decision matrix(A) Standard Decision Matrix(R), Weighted Standard Decision Matrix(V), Ideal(A*) and Negative Ideal Solutions(A-), Discrimination Measures(Si*, Si-) and Relative Closeness to Ideal Solution(Ci*) calculations are made and presented in tables (Table 11-12)

Table 7. Criteria classification and explanations

Classification	Explanations
Insulation Thickness	The thickness of the insulation material to be applied in the envelope element. (m)
Insulation Material Cost	The annual cost of the insulation material to be applied to the envelope element, calculated with the Net Present Value. ($/m²-year)
Cost of Fuel	The cost of the annual energy consumed in the building by the application of the insulation material. ($/m²-year)
Total Cost	The total cost of the energy consumed annually in the building by using the insulation material and the annual cost of the insulation material calculated with the Net Present Value. ($/m²-year)
Energy Saving	Reduced energy consumption cost with the use of insulation material compared to the non-insulated situation. ($/m²-year)
Payback Period	The time it takes for the energy savings provided by the application of the insulation material to cover the cost of the insulation material. (year)
Emission Value	The amount of emission caused by the energy consumed in the building by the use of insulation material. (kg CO_2-eq./m²)

Table 8. Pairwise comparison scale (Saaty, 2004)

Importance level	Value Definitions	Description
1	Description	Each activity contributes equally.
3	Less important	As a result of experience and evaluations, an activity is a little more preferred than the other.
5	Quite important	As a result of experience and evaluations, one activity is much more preferred than the other.
7	Very important	An activity is preferred very strongly compared to the other.
9	Highly important	An activity is preferred as the highest possible degree compared to the other.
2,4,6,8	Intermediate values	If words are insufficient to make an assessment, a value in the middle of numerical values is given.

Table 9. The comparison matrix of the priority of the insulation material criteria

	Insulation Thickness	Insulation Material Cost	Cost of Fuel	Total Cost	Energy Saving	Payback Period	Emission Value
Insulation Thickness	1.00	0.21	0.18	0.17	0.13	0.20	0.20
Insulation Material Cost	4.65	1.00	0.80	0.80	0.20	0.68	0.26
Cost of Fuel	5.53	1.25	1.00	1.25	0.34	1.25	0.40
Total Cost	5.80	1.25	0.80	1.00	0.27	0.76	0.23
Energy Saving	7.67	5.04	2.94	3.74	1.00	3.65	2.69
Payback Period	4.94	1.46	0.80	1.31	0.27	1.00	0.57
Emission Value	5.09	3.84	2.48	0.51	0.37	1.74	1.00

As a result of the AHP and TOPSIS methods, it has been seen that the optimum insulation material is EPS for all the elements that make up the building envelope. In this study, in the process of determining the optimum thermal insulation thickness, the technical and economic outputs obtained based on static life cycle cost analysis were re-evaluated with the AHP-TOPSIS multi-criteria decision making method. Criterion weights were determined with AHP and then the most appropriate insulation strategies were determined by ranking the alternatives with TOPSIS method.

In the AHP analysis carried out by taking expert and user opinions through questionnaires, "Energy Saving" was determined as the criterion with the highest importance among the criteria and this criterion ranked first in the total decision weight. This result reveals that energy efficiency policies and sustainable building targets have gained significant awareness among users and sector professionals. "Emission Value" ranked second, which shows that energy efficient building applications are evaluated not only in terms of economic but also environmental sustainability. The third ranked "Fuel Cost" criterion reflects the short and medium term cost sensitivity of the users. The fact that "Payback Period" ranks fourth and "Total Cost" ranks fifth indicates that users prioritise energy and environmental performance over investment cost. The fact that total cost, which is usually the main decision criterion in traditional approaches, is left behind in this ranking is one of the unique aspects of the study. In this context, it is understood that users tend towards environmental and energy-oriented strategies beyond economic optimisation. The sixth ranked "Insulation Material Cost" and seventh ranked "Insulation Thickness" criteria are considered as secondary priorities for decision makers. This result shows that result-oriented outputs (savings, environmental impact) are valued more than technical design variables.

4. Conclusions

This study comprehensively examined the optimization of thermal insulation thickness for residential buildings located in Antalya, representing Türkiye's Mediterranean climate zone. Various building envelope elements, fuel types, and insulation materials were analyzed through a static Life Cycle Cost Analysis (LCCA), and further evaluated using multi-criteria decision-making (MCDM) methods, namely the Analytical Hierarchy Process (AHP) and the Technique for Order Preference by Similarity to Ideal Solution (TOPSIS). Heating and cooling energy loads were calculated based on Heating Degree Days (HDD) and Cooling Degree Days (CDD), and corresponding optimum insulation thicknesses, energy savings, payback periods, and environmental impacts were determined for multiple scenarios involving both natural gas and electricity as energy sources.

Initially, the optimum insulation thicknesses were determined using the static LCCA method, focusing primarily on economic parameters such as insulation cost, energy savings, and payback period. However, when these outputs were re-evaluated through AHP-TOPSIS methods that incorporated environmental impacts and user preferences, a significant shift in prioritization was observed. While the static LCCA approach generally suggested lower insulation thicknesses favoring quicker payback and lower investment costs, the AHP-TOPSIS evaluations tended to favor slightly thicker insulation, optimizing not only for economic benefits but also for maximum energy savings and reduced CO_2 emissions. This comparison highlights that although traditional static methods are effective for pure cost optimization, multi-criteria approaches offer a more holistic evaluation by balancing economic, environmental, and user-centered factors.

The results further indicated that the optimum insulation thickness varied considerably based on wall type, insulation material, and energy source. Specifically, thicker insulation was required when electricity was used as the heating source compared to natural gas, due to electricity's lower efficiency and higher operational cost. Among the evaluated insulation materials, Expanded Polystyrene (EPS) consistently emerged as the most optimal alternative according to AHP-TOPSIS results. Notably, the prioritization of "Energy Saving" and "Emission Value" criteria over traditional cost metrics such as "Total Cost" reflects a paradigm shift towards sustainability-oriented building practices.

The integration of AHP and TOPSIS methods in the insulation optimization process has enabled a user-centered, multi-dimensional decision-making approach, moving beyond conventional economic analyses. By incorporating expert judgments and user expectations into the weighting of evaluation criteria, this study presents a more realistic and comprehensive framework for insulation material and thickness selection. It demonstrates that while initial investment costs remain important, long-term energy savings, environmental benefits, and user-driven considerations must also be pivotal in designing energy-efficient building envelopes.

In conclusion, the proposed methodology provides valuable insights for policymakers, designers, and construction industry stakeholders aiming to enhance building energy performance, particularly in Mediterranean climates. Furthermore, the approach can be adapted to other climatic regions and extended to broader sustainability assessments. Future studies are recommended to integrate dynamic thermal simulations, account for hourly climatic variations, and incorporate real-time occupancy data to further refine and validate the proposed optimization model.

Investigation of the usage of technology in the civil engineering education with bibliometric analysis

Meryem F. Görhan[1], Gökhan Kürklü[2], Gökhan Görhan[*2]

[1] *Huriye Aşkar Secondary School, ICT Teacher, 03200 Afyonkarahisar, Türkiye*
[2] *Afyon Kocatepe University, Department of Civil Engineering, 03200 Afyonkarahisar, Türkiye*

Abstract. In recent years, it is thought that the use of technology in engineering education will increase student motivation, support learning and personalized learning. In this study, it is aimed to quantitatively address the existing studies on the base of increasing technology use in civil engineering education and to reveal the areas of study needed on the subject. In this direction, the concepts of "civil engineering education" and "technology" in the Web of Science database were analyzed by bibliometric analysis method by considering 134 scientific literatures published between 1991 and 2024. VOSviewer was used for the related technique. Four different analyses were applied using VOSviewer software; (I) country network from co-authorship analysis, (II) country network from citation analysis, (III) keyword network from co-occurrence analysis, and (IV) words in abstract network. According to the results of the analysis, it was seen that the countries where the most studies were conducted were USA, England and the People's Republic of China. According to the data obtained, it was determined that the related keywords were engineering education, virtual reality, civil engineering and building information modeling (BIM). However, in the summary sections of the scientific literature, the terms industry and building information modeling (BIM) were found to be prominent. Therefore, considering the concept of technology in civil engineering education, it was concluded that there are few studies on game-based learning, visualization and augmented reality and there is a need for studies on this subject.

Keywords: Civil engineering education, Technology, Bibliometric analysis, VOSviewer

1. Introduction

The term engineer is defined by the Turkish Language Association as "a person who develops technology or systems with the highest level of efficiency and safety in order to meet the needs of humanity within the framework of basic sciences with good aesthetic design". Civil engineering is the branch of engineering that investigates the construction and demolition conditions of facilities to be created by humans in order for living beings to continue their lives in harmony with nature and to build civilization, makes calculations to ensure that they will last for a certain period of time in harmony with nature and economically, and carries out material selection and scientific research (Birinci, 2016).

The qualities of a good civil engineer should have are shaped by the developing technology and the needs of the companies. These qualities are stated by Ohio University as communication skills, decision-making skills, leadership skills, problem-solving skills and organizational skills (Ohio University, 2025). Similarly, the qualifications required for a good engineer are listed by Harvard Business School as technology and computer science skills, leadership, communication, problem-solving, management, research and critical thinking, business operations (Harvard Business School, 2025). In the study conducted by Ramadhan et al., (2023), the qualities that future civil engineers should have are expressed as communication, professionalism, technical, team work, problem-solving, collaboration and sustainability. In the study conducted by Özbaşaran, et al. (2024), 1374 job advertisements for civil engineers were examined. It has been observed that the qualifications sought in civil engineering job advertisements include the ability to use office programs, computer-aided design and project management programs. These qualifications needed by the business world can be provided with computer-aided education and technology education (Demirtürk ve Tunç, 2021). The types of software used in civil engineering are; computer-aided building operation systems (service management series etc.), computer-aided cost systems (bidworx etc.), computer-aided engineering systems (finite element analysis etc.), computer-aided design and visualization systems (AutoCAD etc.), business and information management systems (sap

[*] Corresponding author, E-mail: ggorhan@aku.edu.tr

https://doi.org/10.31462/icearc2025_ce_mng_948

software etc.), planning and project management systems (Microsoft project etc.) and building information modeling (coordinate-based computer software etc.) (Demirtürk and Tunç, 2021).

In this study, civil engineering education refers to the education provided in the field of civil engineering at universities. In civil engineering education, basic science courses (Chemistry, physics, mathematics, etc.), social and human courses (Occupational safety, foreign language, etc.) and specialized field courses (Building materials, etc.) are given. The use of technology in civil engineering education is grouped under two headings as design and calculation and has a multidisciplinary structure (Bayhan & Karaca, 2020). When current studies are examined, it can be seen that the use of technology in civil engineering education has positive effects.. An experimental study was conducted by Hanna and Barber (2001) examining the effect of technology-aided design programs. It was observed that concept building, visual quality, and presentation techniques skills improved. In the study conducted by Blashki et al. (2007), it was concluded that the use of virtual games and forums in engineering education developed risk-taking attitude and creativity. By using technology in engineering education, the efficiency of education is increased, more senses are included in the learning process, and different learning methods are supported (Hernandez-de-Menendez & Morales-Menendez, 2019).

The purpose of this study is to examine the existing studies published in Web of Science (WOS) on the use of technology in civil engineering education using bibliometric analysis. For this purpose, the following research questions guided this study:

1. How are published articles on the use of technology in engineering education distributed by year?
2. Which countries show more interest in the use of technology in engineering education?
3. Which countries receive more citations on the use of technology in engineering education?
4. Which common words reflect the use of technology in engineering education?

2. Materials and methods

In the bibliometric examination of technology use in civil engineering education, a search was conducted in the Web of Science database using the words "civil engineering education" and "technology". The search results were limited to articles and 134 articles were examined. The following steps were followed in this study:

1. Data collection stage: Relevant search results were obtained from the WOS database.
2. The data analysis phase was performed using the VOSviewer tool.
3. The analysis results were examined according to the research questions.

With bibliometric analysis, existing studies are examined mathematically according to specified criteria. With this analysis, the studies conducted in a subject area are evaluated quantitatively. Data on the network between the author, institution, country, words used, citations, etc. are obtained. It reveals a general picture for a specific subject. With biometric analysis, clues can be obtained for revealing the more or less studied topics and the connections and networks between them (Umut Zan, 2012; Yılmaz, 2021).

In this study, VOSviewer 1.6.20 was used as a bibliometric analysis tool. VOSviewer is a tool for constructing and visualizing bibliometric networks, such as co-authorship networks, citation networks, and co-occurrence networks (VOSviewer, 2025). Co-authorship, Co-occurrence, Citation-countries analyses were performed using this tool in this study.

3. Results and discussion

In the bibliometric examination of technology use in civil engineering education, the concepts of "civil engineering education" and "technology" were searched in the Web of Science database. Accordingly, as seen in Fig. 1, according to the research date range, the oldest publication belongs to 1991. In the following years, there were either no publications or only one. In 1999, there was a jump in the number of publications and although it was not continuous, there was an increase in the number of publications for the years. In 2024, the number of publications reached 18. There were 134 publications and 774 citations in total.

VOSviewer software version 1.6.20 was used to access bibliometric analyses and visualize the data. Fig. 2 shows the countries that published and received citations according to the results obtained in this analysis. Accordingly, a total of 41 countries have published on this subject. When the countries with the most publications are examined, the USA ranks first with 44 publications, the PRC ranks second with 24 publications, and Portugal ranks third with 11 publications. While the first place in the citations is unchanged with 244, Portugal ranks second with 233 and the PRC ranks third with 218. Only 13 of these 41 countries have published three or more publications. Publications in 12 countries were not cited at all.. However, Türkiye has two publications and 33 citations on this subject.

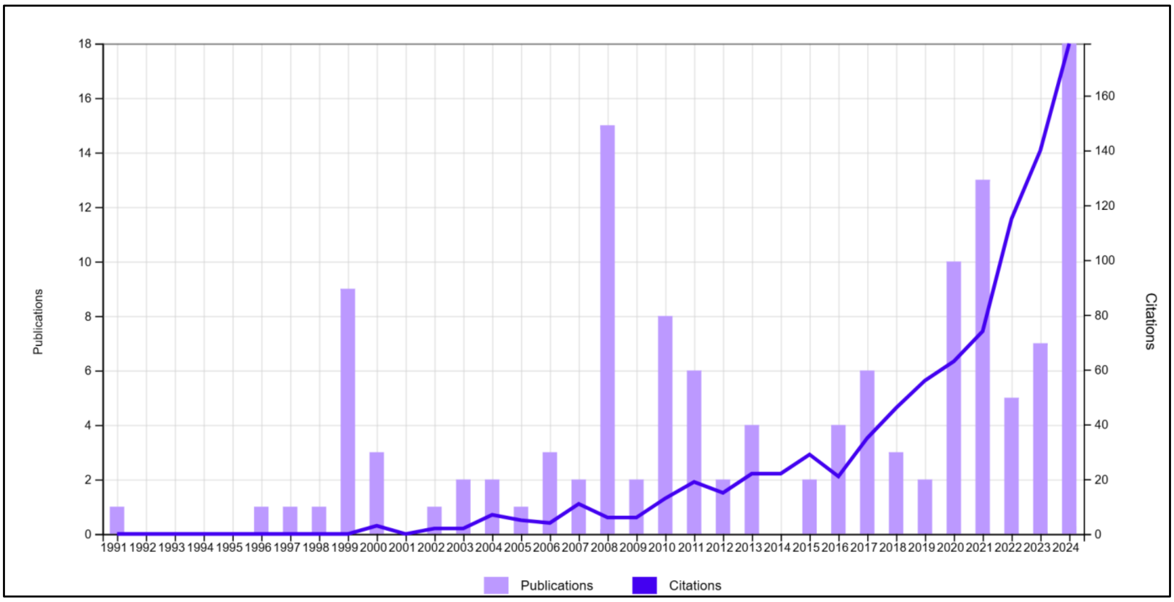

Fig. 1. Distribution of publishing by year

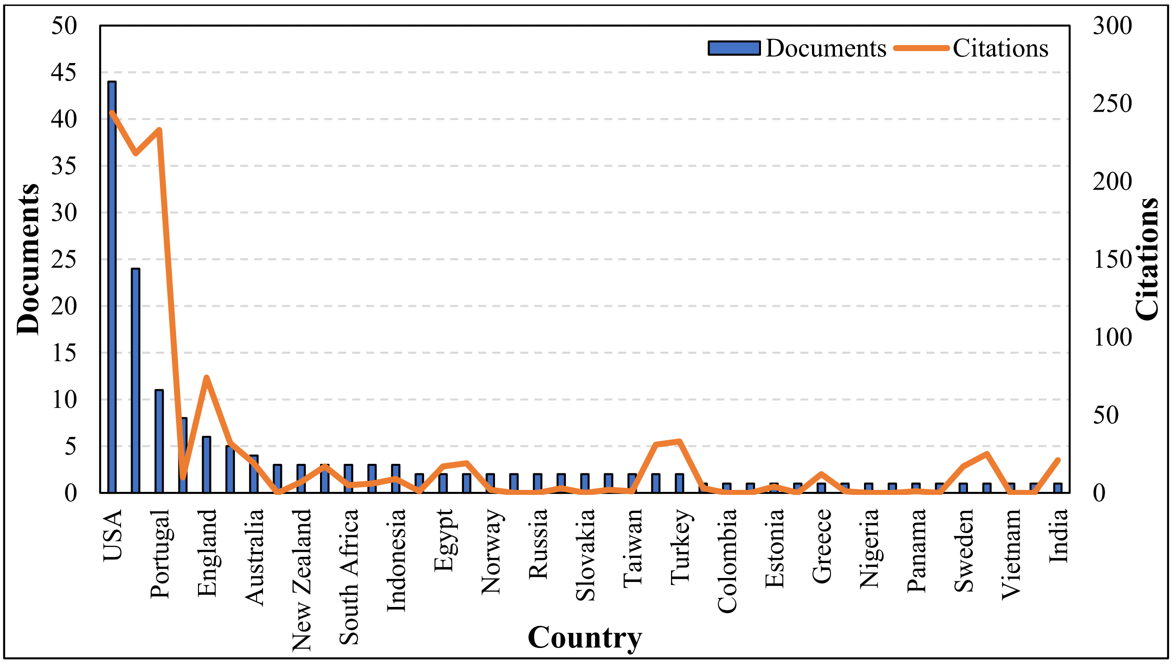

Fig. 2. Documents and citations score of the countries with the most studies

The network visualization map of the studies conducted by these countries through joint authorship is given in Fig. 3 and the density map is given in Fig. 4. Accordingly, a multi-faceted country network is formed in countries with a high number of publications, while a one-sided relationship is observed in countries with a limited number of publications. Although there is no obvious clustering in the density map, the USA stands out. While the number of countries with total link strength of seven and above is 9, the remaining countries are between three and zero and remain local in size.

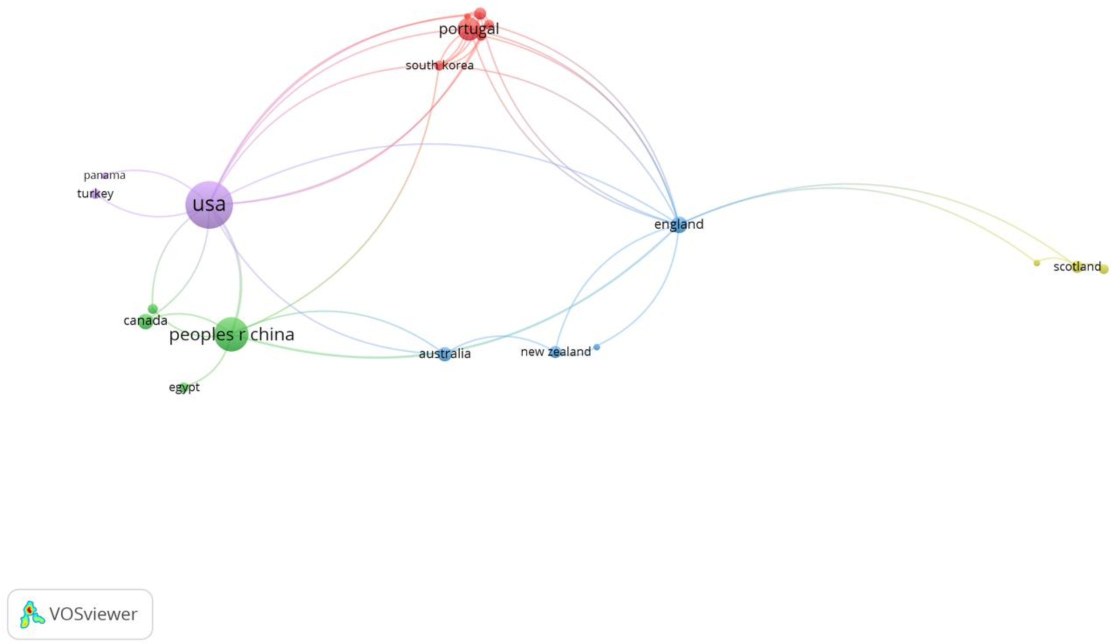

Fig. 3. Co-authorship network of the countries with the most studies

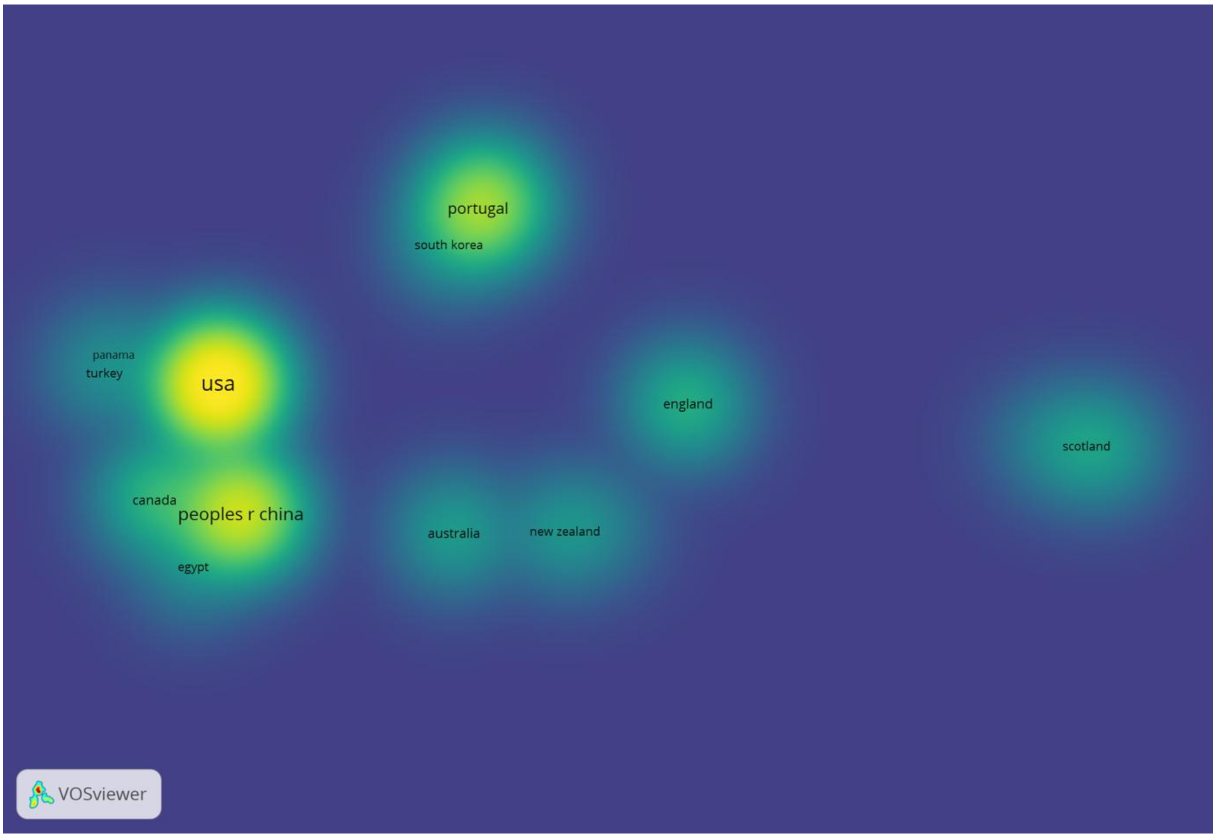

Fig. 4. Co-authorship visualization of the countries with the most studies

Citation was selected as the analysis type, country was selected as the unit, and the results obtained from the analysis without defining a lower limit are given in Figures 5 and 6. Although the USA comes to the fore in citation, when looking at the connection forces, it was seen that the regional ties of the countries also have an effect.

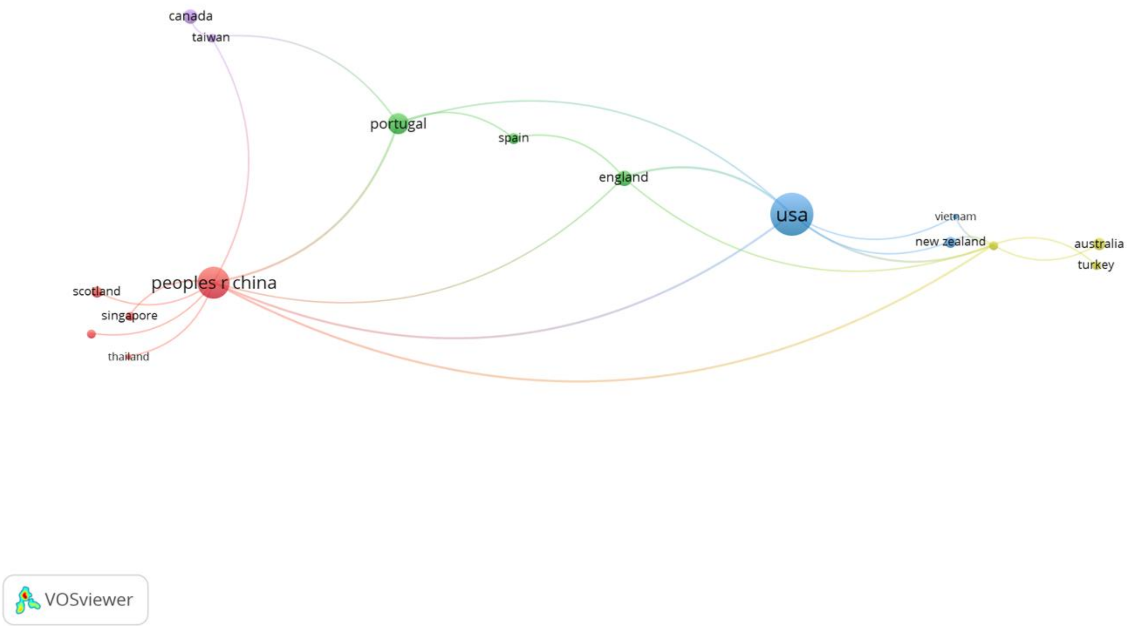

Fig. 5. Citation network of the countries with the most studies

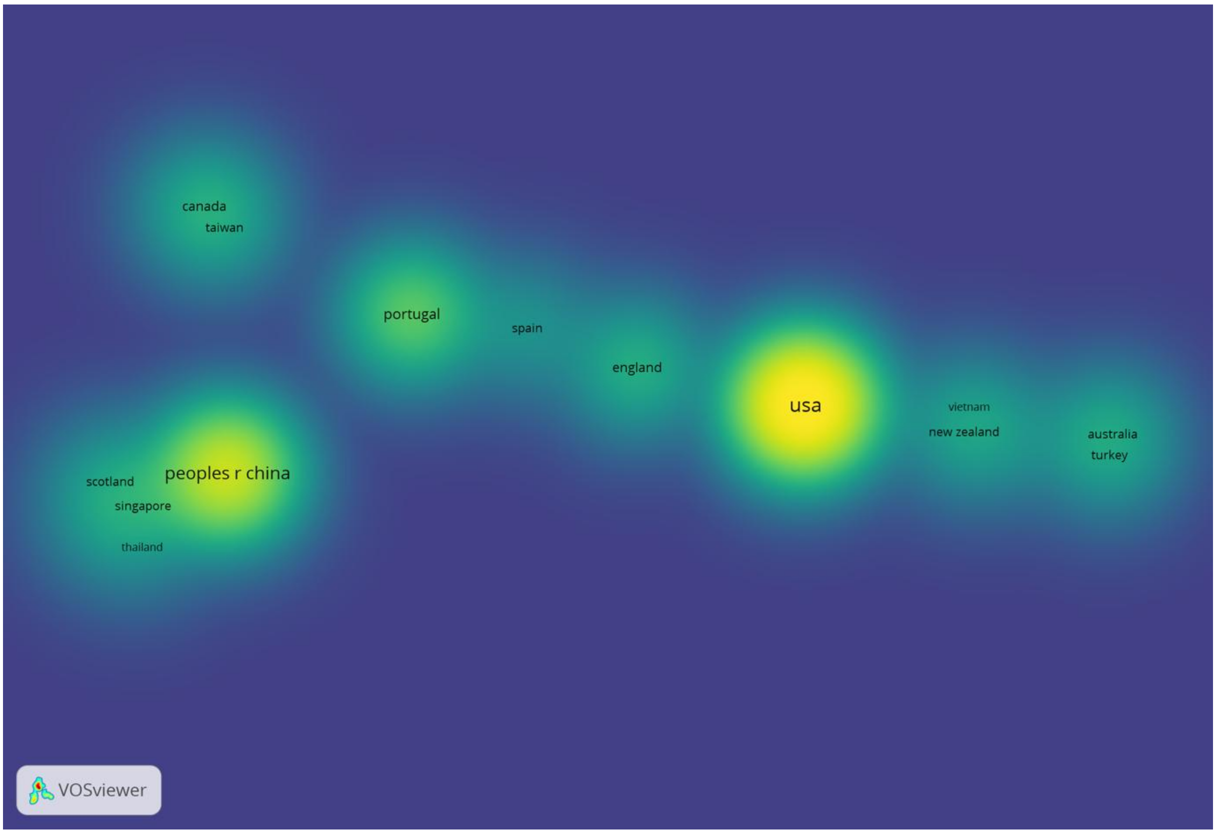

Fig. 6. Citation visualization of the countries with the most studies

In the section where the most frequently used keywords were analyzed in the studies, the selected analysis type was “Co-occurrence” and the unit was “Authors keywords”. Restriction criteria were applied to obtain more meaningful results; in this context, it was required that a keyword be repeated at least three times (Fig. 7).

Accordingly, “engineering education” was used 17 times. If we evaluate the expressions “civil engineering” and “civil engineering education” as close to the expression “engineering education”, it can be said that it was used 41 times in total. Following these, “virtual reality” was used 13 times and “building information modeling (BIM)” was used seven times. The connections between the keywords given in the network map in Fig. 8 are seen. The density distribution is as in Fig. 9. “Virtual reality” is seen densely at the common point of other dense keywords. “Building information modeling (BIM)” is located in a separate position from this word and with less density.

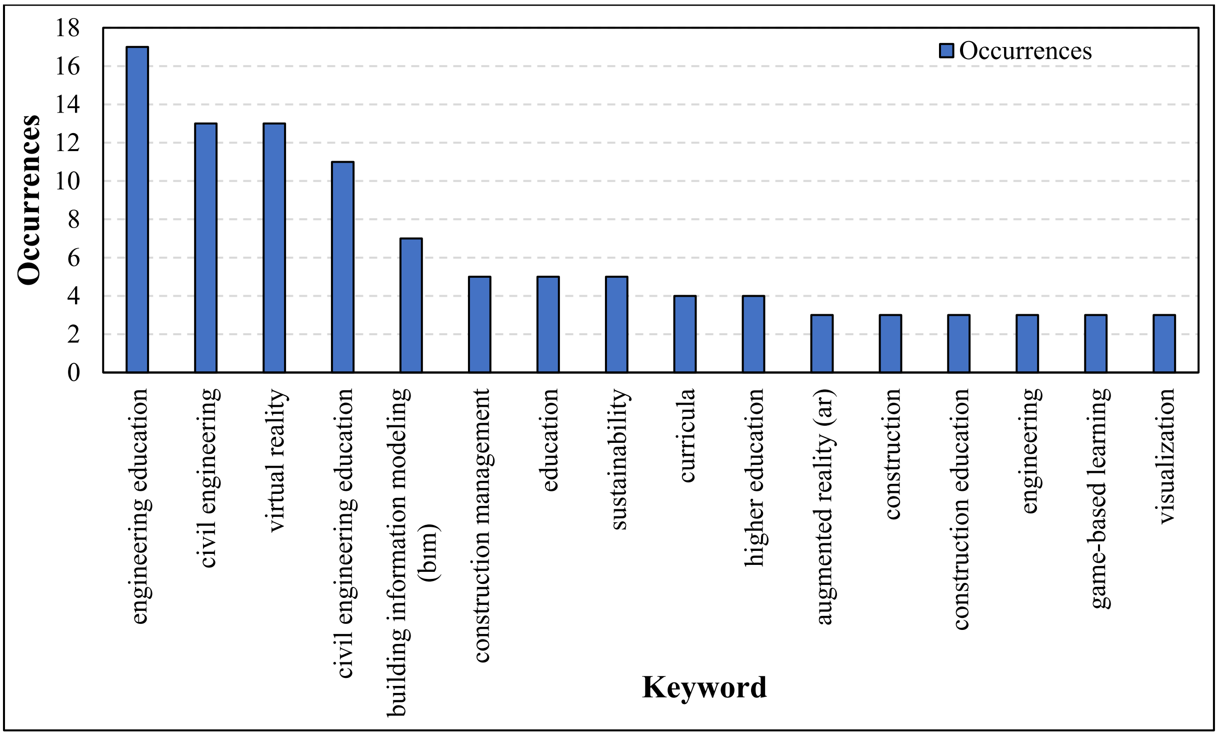

Fig. 7. Occurrence score of most frequently take part keywords

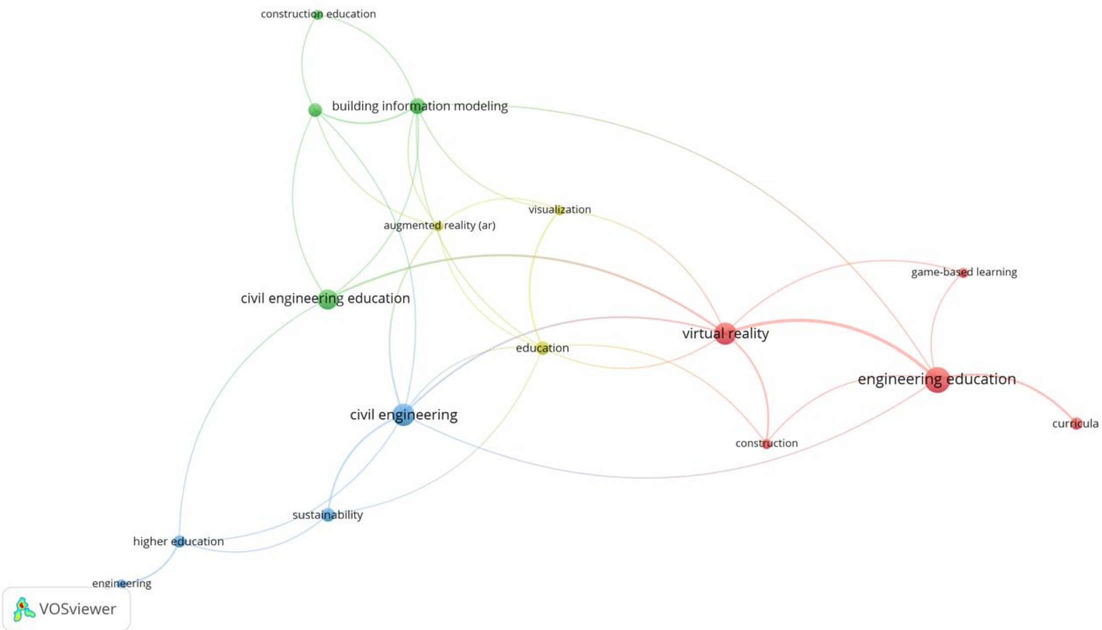

Fig. 8. Co-occurrence network of most frequently take part keywords

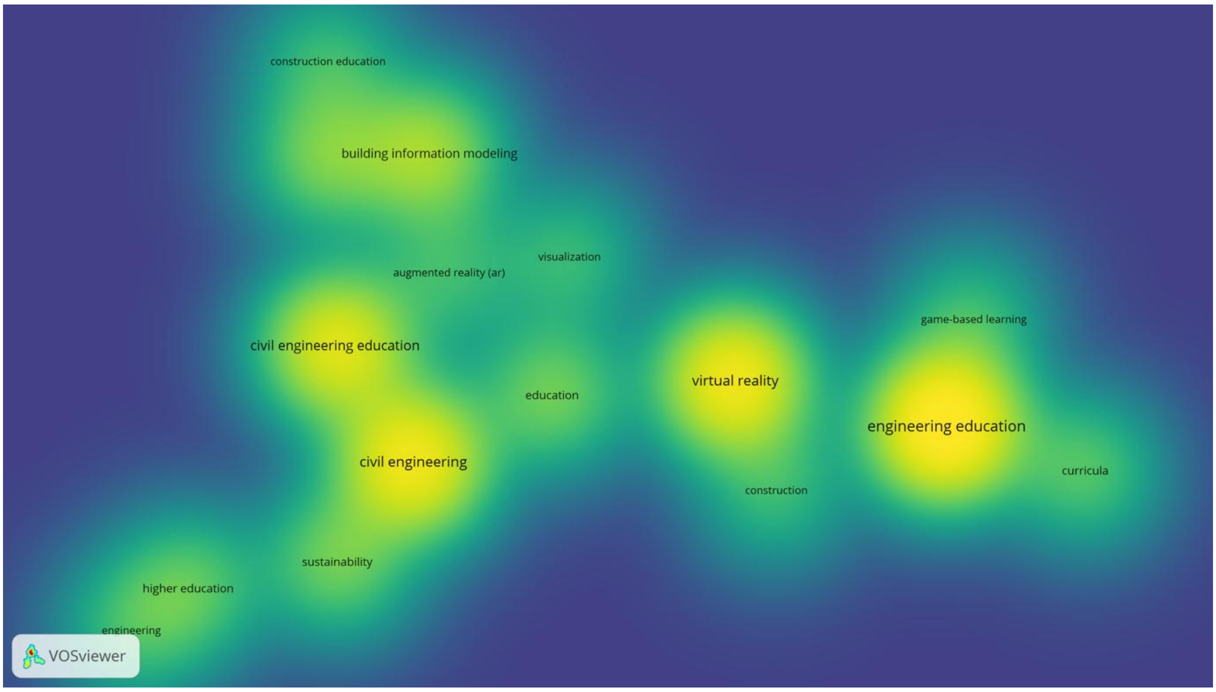

Fig. 9. Visualization of most frequently takes part keywords

By reading the data from the bibliographic database files, a map based on the text data was created and the "Abstract field" of the articles was examined and the minimum occurrence number of a term was considered as five as the boundary condition. Accordingly, the condition of 227 words out of 3550 words was met and 136 words were selected. The occurrence and relevance score values given in Fig. 10 are given. Due to the large number of words in Fig. 10, the graphs in Fig. 11 and Fig. 12 were created by taking into account the words in the first 22. The highest words in occurrences are "industry", "bim" and "work". The most specific word related to the research topic among these three words is seen as "bim". The concepts of "teaching mode" and "fundamental concept" that stand out differently from all other words in relevance score.

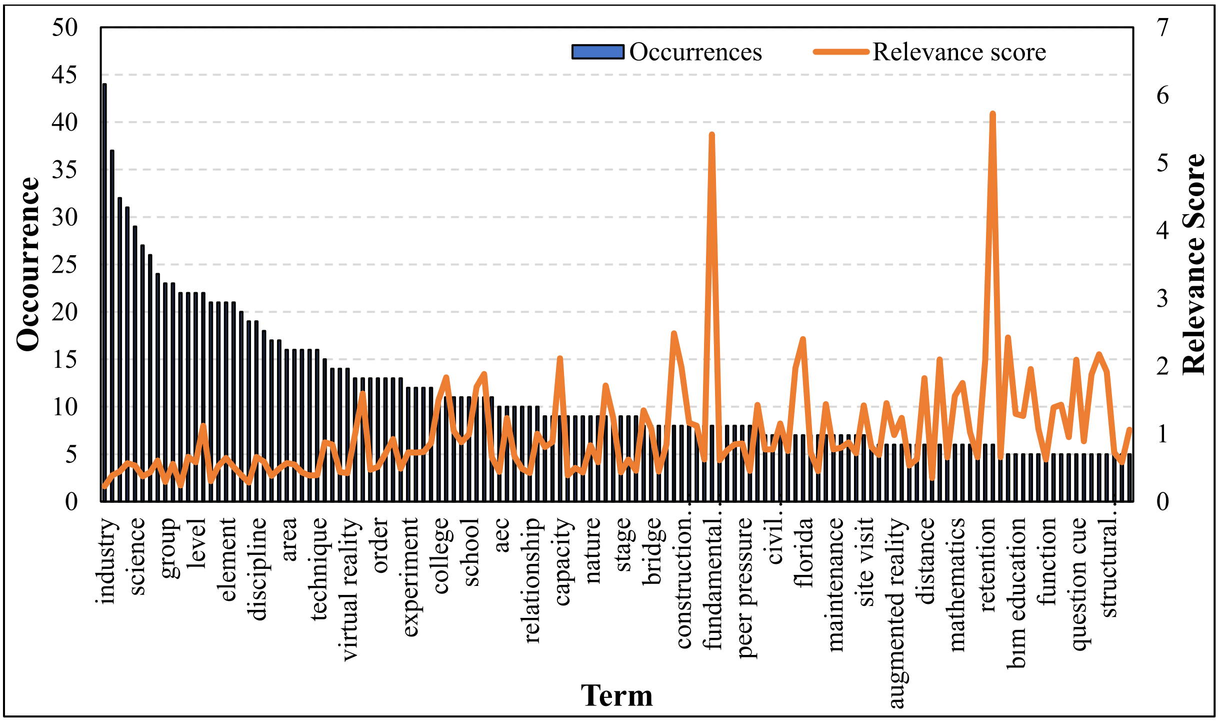

Fig. 10. Occurrence and relevance score of most frequently take part words in the abstract

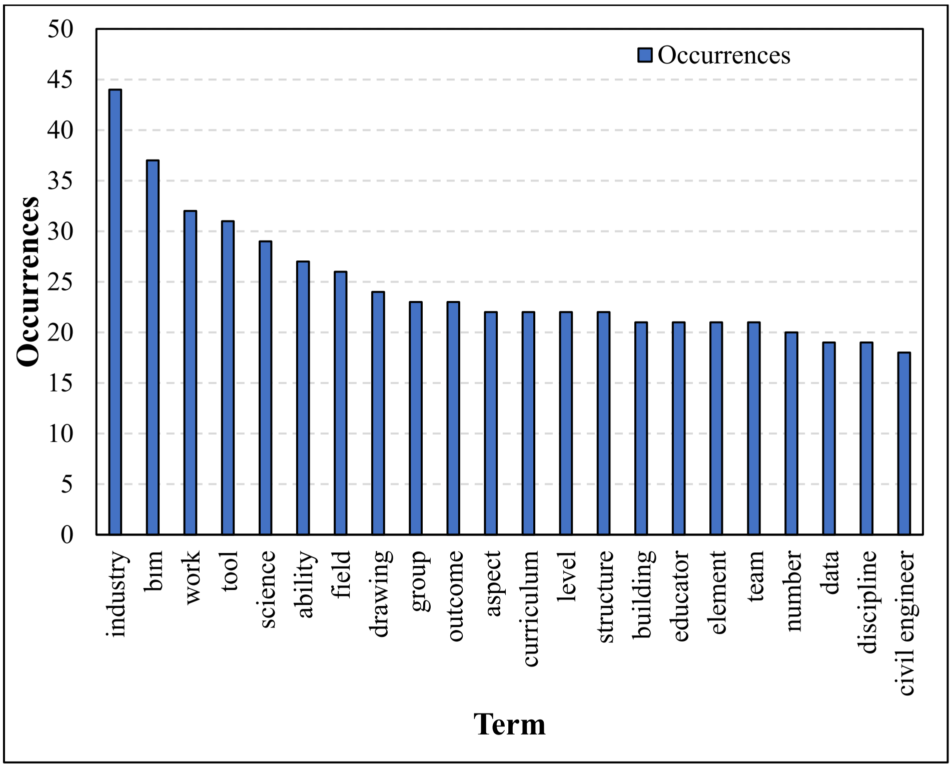

Fig. 11. Occurrences score of most frequently take part words in the abstract

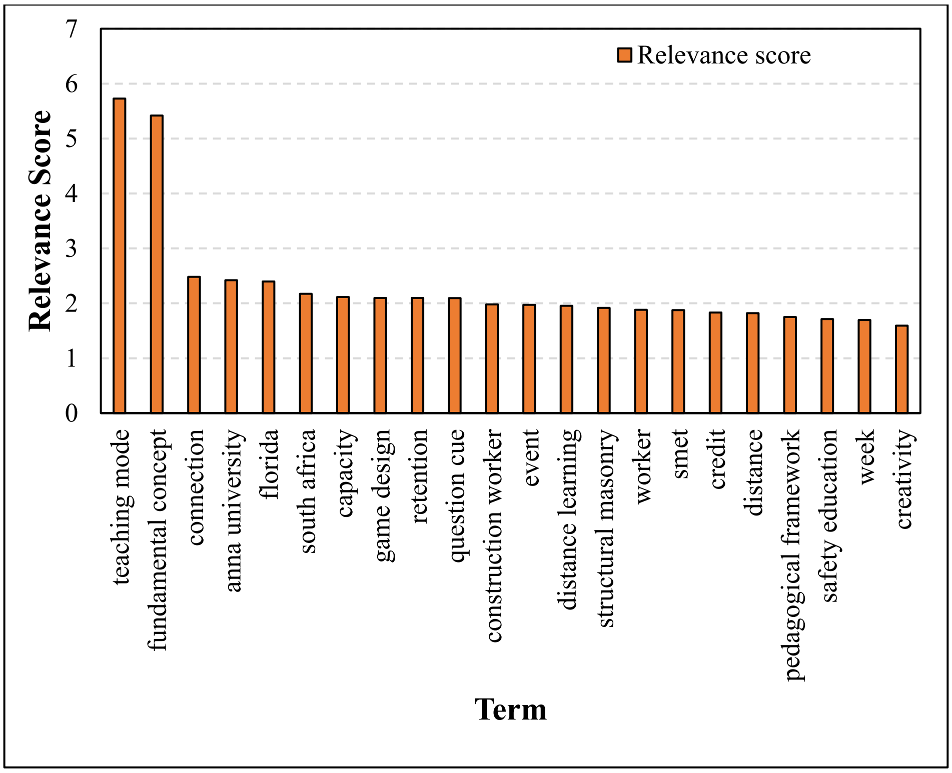

Fig. 12. Relevance score of most frequently take part words in the abstract

Fig. 13 shows the visual mapping of the words used in the “Abstract field” and Fig. 14 shows the density distribution. The connections between the words can be seen through the color distribution. On the density map, the words industry, work, bim, curriculum, strategy, ability, group and tool stand out.

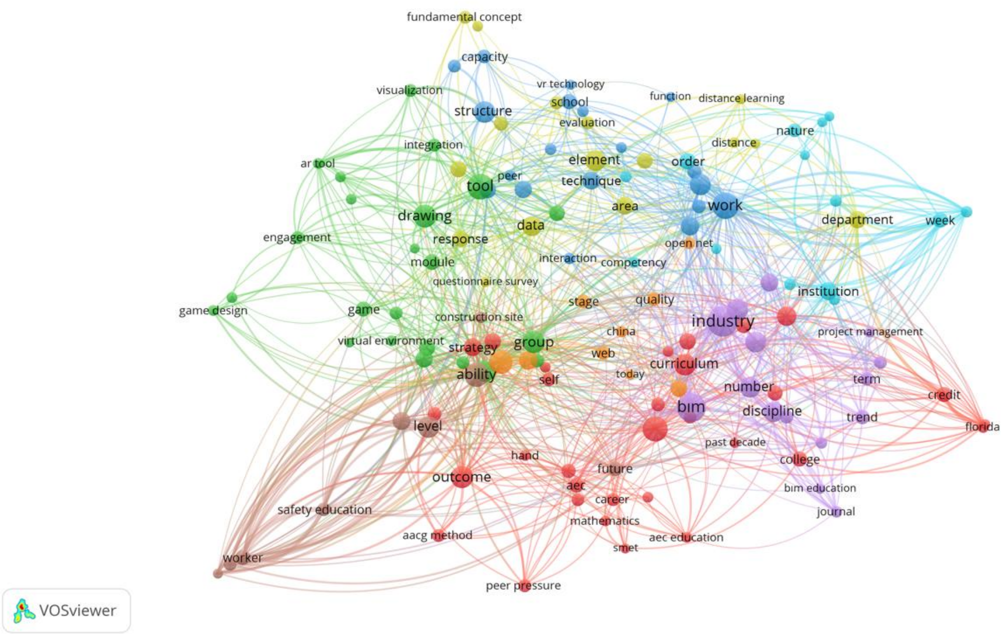

Fig. 13. Network of most frequently take part words in the abstract

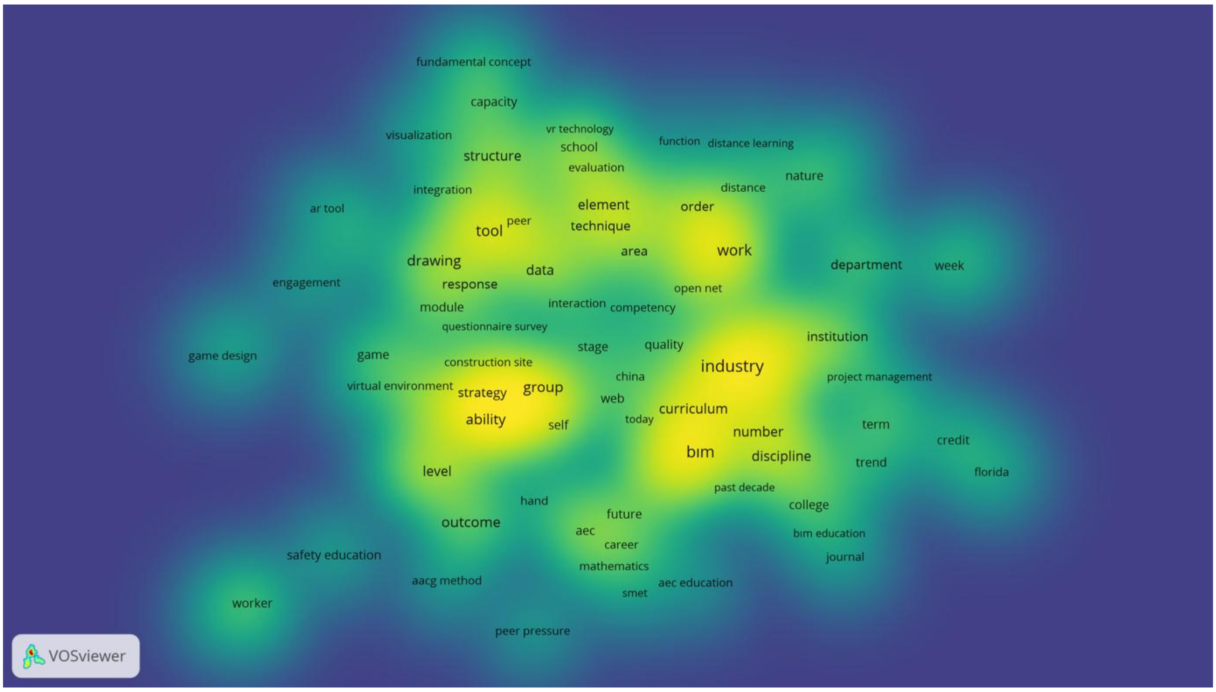

Fig. 14. Visualization of most frequently takes part words in the abstract

4. Conclusions

In this study, studies on the use of technology in engineering education were examined. The results are listed below:

- Current studies begin in 1991.
- When the studies are examined, there is a significant increase in 1999 and 2008. However, there has been an increase in the number of published publications in recent years..
- The countries with the most publications are listed as USA, Portugal and PRC according to the number of citations.
- The most commonly used keywords appear to be civil engineering education, virtual reality and building information modeling (BIM).

- The most frequently used words in the abstract section are industry, work, bim, curriculum, strategy, ability, group and tool.

Enhancing mega-infrastructure project performance in South Africa through critical construction management factors: Insights from confirmatory factor analysis

Dillip Kumar Das*[1], Ayodeji Olatunji Aiyeatn[2]

[1] *University of KwaZulu-Natal, Discipline of Civil Engineering, Howard College Campus, Glenwood, Durban, 4041 South Africa*
[2] *Durban University of Technology, Department of Construction Management and Quantity Surveying, Steve Biko Campus, Durban, 4000, South Africa*

Abstract. Mega-infrastructure projects play a critical role in driving sustainable development in emerging economies like South Africa, fostering inclusive growth, improving service delivery, and promoting regional integration. However, despite their transformative potential, these projects often face significant challenges such as delays, cost overruns, and inefficiencies, particularly during construction. Based on data from a structured stakeholder survey and Confirmatory Factor Analysis (CFA), this study explores the construction-related factors influencing the successful delivery of mega-infrastructure projects in South Africa. The research identifies five interdependent latent constructs that impact project performance: Plant and Technological Resources, Stakeholder Engagement and Communication, Construction Management, Labour and Workforce Organisation, and Material and Logistics Management. Key factors for success include reliable plant and machinery, effective maintenance, strong stakeholder coordination, clear communication, adaptive construction practices, disciplined workforce deployment, and efficient logistics for quality materials. The study suggests several critical strategies to improve project outcomes: (1) ensuring the availability of competent personnel and quality plant for maintenance, (2) adopting transparent stakeholder engagement and advanced communication systems, (3) implementing adaptive construction practices, (4) fostering workforce engagement and discipline, and (5) securing a steady supply of quality materials. Prioritising these strategies is crucial for reducing delays, controlling costs, and achieving project objectives.

Keywords: Communication system; Construction management; Infrastructure; Mega-projects; Supervision and monitoring, Stakeholder engagement

1. Introduction

Sustainable development has emerged as a global imperative, requiring nations to balance economic advancement with social equity and environmental responsibility. In this context, mega-infrastructure projects are seen as critical drivers of long-term transformation—particularly in developing countries such as South Africa—where large-scale public investments are intended to stimulate inclusive economic growth, enhance service delivery, and promote regional integration (Cohen, 2006; Zeybek & Kaynak, 2006; Human Development Report, 2011). These projects span diverse sectors, including transportation, energy, water, communication, health, and education, and typically demand substantial financial investment, institutional coordination, and political commitment (Field & Ofori, 1988; Khan, 2008; Mthalane et al., 2007; Othman, 2012, 2013).

In South Africa, flagship national strategies such as the National Development Plan (NDP) and Strategic Infrastructure Projects (SIPs)—operationalised through the Infrastructure Development Act—reflect the government's ambition to harness megaprojects as engines of sustainable development. Prominent examples include the Gautrain rapid rail system, Kusile and Medupi power stations, Mthombo oil refinery, and the Transnet multiproduct pipeline. Typically valued at over USD 2 billion, these projects are designed to generate employment, stimulate local economies, address historical infrastructure deficits, and enhance national competitiveness.

Despite these aspirational goals, megaproject implementation in South Africa has been marred by chronic underperformance. Approximately 65% of such projects suffer from cost overruns, schedule delays, or failure to meet planned objectives (Deloitte, 2013; Khatleli, 2016; Mashegoana & Khatleli, 2019). These persistent issues highlight deeper systemic problems within the construction delivery phase, where resource limitations, skills

https://doi.org/10.31462/icearc2025_ce_mng_958

shortages, governance deficiencies, and outdated project management practices exacerbate execution complexities. Challenges such as inadequate supervision, fragmented communication, underperforming contractors, and limited technological integration continue to undermine project efficiency.

Globally, recent literature underscores the importance of identifying and understanding Critical Success Factors (CSFs) for megaproject construction, particularly in emerging economies. Key factors contributing to project success include the availability of financial, human, and technological resources; effective stakeholder engagement; robust communication; and adaptive planning mechanisms (Wang et al., 2021, 2022; Malek & Bhatt, 2023). However, the practical realisation of these factors is often hindered by institutional inefficiencies, regulatory bottlenecks, and capacity constraints within implementing agencies. Delays in contractor payments, weak inter-agency coordination, and rigid planning processes frequently result in misalignment between project objectives and actual outcomes.

Mega-infrastructure projects are inherently complex socio-technical systems characterised by uncertainty, diverse stakeholder interests, and intricate interdependencies among resources, personnel, and processes (Flyvbjerg, 2014; Shore & Cross, 2005; Erol et al., 2018). Traditional, linear project management models have proven inadequate in navigating these challenges. Consequently, scholars increasingly advocate for more agile, innovative approaches, such as proactive risk mitigation, stakeholder engagement strategies, digital project management tools, smart construction technologies, and data-informed decision-making (Al Ani, 2024; Caldas & Gupta, 2017; Wu et al., 2018; Zaman et al., 2022).

However, the adoption of advanced construction management systems in South Africa remains limited. Many projects continue to rely on legacy systems and rigid workflows ill-suited to the dynamic nature of megaproject environments. This has resulted in reduced responsiveness to change, poor resource utilisation on construction sites, and an erosion of public trust in large-scale infrastructure initiatives. Additional complications stem from political interference, limited community involvement, and hierarchical organisational structures, all of which further impede project delivery and sustainability (Aiyetan & Das, 2022; Wtaermeyer, 2013).

While macro-level studies have examined financing models, policy frameworks, and institutional arrangements (Ref), there remains a significant gap in empirical research on micro-level construction practices, especially at the site level in Global South contexts. Understanding these granular dynamics—including plant utilisation, labour discipline, stakeholder coordination, material logistics, and on-site supervision—provides valuable insight into the root causes of performance bottlenecks. Moreover, it supports the development of context-sensitive, practically grounded strategies to enhance delivery outcomes. Although existing literature identifies broad success factors such as financial models and governance structures, there is insufficient exploration of micro-level, construction-related factors and their systemic interactions. Given megaprojects' complex, socio-technical nature, a systems-based perspective is essential—one that integrates construction methodologies, stakeholder dynamics, workforce organisation, and logistical management within a coherent performance framework.

This study addresses this gap by examining the factors influencing the successful delivery of megaprojects in South Africa, using empirical analysis from Confirmatory Factor Analysis (CFA). The study focuses on five key latent constructs—Plant and Technological Resources, Stakeholder Engagement and Communication, Construction Management, Labour and Workforce Organisation, and Material and Logistics Management—as core subsystems that underpin construction performance. Accordingly, the objectives of the study are:

- To identify and validate the critical construction-related factors influencing the successful delivery of mega-infrastructure projects in South Africa.
- To examine the role of key subsystems—plant and technological resources, stakeholder engagement and communication, construction management practices, workforce organisation, and material and logistics management—in shaping project outcomes.
- To explore a systems-oriented framework that reflects the interdependence of construction management domains in complex megaproject environments.

For this purpose, the study investigates the following research questions (RQs):

RQ1: What are the key micro-level construction management factors that significantly affect the performance of mega-infrastructure projects in South Africa?

RQ2: How do plant and technological resources, stakeholder engagement, construction management practices, workforce organisation, and material logistics each contribute to project success?

RQ3: How do interactions among technical, organisational, and human subsystems as an integrated system shape megaproject delivery within a systems-oriented framework?

2. Mega infrastructure projects in South Africa

Mega infrastructure projects are large-scale, capital-intensive ventures that span extended durations and require coordination among multiple stakeholders. These include transportation corridors, energy plants, rail systems, and public utilities—all of which are foundational to national development by facilitating economic growth, enhancing regional integration, and improving service delivery. In South Africa, such projects are envisioned as engines of socio-economic transformation, job creation, and industrialisation (Burger & Hawkesworth, 2011).

Despite their strategic significance, many mega projects in South Africa have experienced chronic underperformance. High-profile examples—such as the Gautrain rapid rail link, Eskom's Medupi and Kusile power stations, and the stadiums for the 2010 FIFA World Cup—have been plagued by delays, cost overruns, and quality deficiencies (Fourie, 2008). The Medupi project, for instance, escalated from an initial R69 billion budget to over R150 billion, with completion delayed by nearly a decade (Eberhard & Godinho, 2017).

These challenges are compounded by systemic issues within the South African construction industry, including skills shortages, volatile demand, regulatory hurdles, fragmented value chains, and weak institutional capacity (CIDB, 2016). Moreover, governance inefficiencies, stakeholder misalignment, and corruption exacerbate project risks (Aiyean & Das, 2022; Watermeyer, 2013).

In response, the government has introduced reforms such as the National Infrastructure Plan (NIP) and the establishment of Infrastructure South Africa (ISA) to enhance project readiness and execution capacity (RSA, 2020). Nonetheless, the recurring underperformance of mega infrastructure projects calls for a systematic investigation to identify the factors that influence the success of mega projects and explore strategies from a systems-oriented strategic perspective to improve the success of such projects.

3. Literature review

3.1. Critical factors affecting mega project performance

Mega projects inherently involve high uncertainty, risk, and multiple interfaces, making them susceptible to inefficiencies in key performance metrics. The "iron triangle" of time, cost, and quality remains a foundational framework for evaluating project outcomes, yet achieving an optimal balance is often elusive due to challenges such as regulatory delays, shifting political priorities, financing issues, and complex procurement processes. In South Africa, delays are often attributed to late approvals, contractor underperformance, and coordination failures, while cost overruns are linked to poor planning, inflation, and scope changes (Windapo & Cattell, 2013; Mbachu & Nkado, 2007).

Effective project planning and proactive risk management are consistently identified as critical success factors. However, issues such as optimistic bias and strategic misrepresentation often result in unrealistic estimates and misalignment of scope. In South Africa, the lack of rigorous feasibility assessments and early stakeholder involvement undermines the credibility and efficiency of project execution (Flyvbjerg et al., 2003; CIDB, 2016).

Governance and leadership are also key, with weak accountability and political interference frequently reducing transparency and hindering performance monitoring. South African mega projects often suffer from diffuse accountability, political interference, and institutional weaknesses, which diminish effective oversight and adaptive decision-making (Aiyeatn & Das, 2022; Watermeyer, 2013).

Furthermore, poor stakeholder engagement and communication can lead to community resistance, legal disputes, and project stoppages. Strategic engagement and effective communication frameworks are crucial for aligning diverse interests and minimising risks (Aaltonen & Kujala, 2010; Olander & Landin, 2008).

Resource availability, including skilled labour shortages and logistical delays, continues to disrupt project timelines. South Africa faces critical skilled labour shortages, compounded by industrial disputes and weak safety standards (Holt, 2001; CIDB, 2016). Logistical inefficiencies and fragmented supply chains, especially in rural or underdeveloped regions, are significant barriers to timely project completion (Olawale & Sun, 2015).

3.2. Role of key subsystems in mega project delivery

The performance of mega projects is highly dependent on the coordination of subsystems such as plant and technological resources, stakeholder engagement, construction management, labour and workforce organisation, and material and logistics management. The availability, suitability, and operational efficiency of construction equipment significantly impact project productivity and cost. Technological tools such as Building Information Modelling (BIM), drones, and ICT platforms can enhance planning, monitoring, and execution. However, adoption remains limited in South Africa due to high initial investment, lack of technical capacity, and cultural resistance to innovation (Gamil & Rahman, 2020; Windapo, 2016).

Effective stakeholder engagement frameworks ensure inclusive decision-making, risk-sharing, and dispute minimisation. Miscommunication can derail project timelines, particularly in cross-cultural and politically sensitive contexts. Strategic communication and trust-building are essential for aligning diverse interests (Freeman, 1984; Aaltonen & Kujala, 2010; Olander & Landin, 2008).

Sound construction management practices—such as accurate scheduling, cost control, and project governance—are fundamental to project success. Adopting formal methodologies like PMBOK and PRINCE2 enables systematic monitoring and accountability. In South Africa, poor site management, inconsistent oversight, and leadership gaps have been flagged as recurring issues (PMI, 2017; Windapo & Cattell, 2013).

Labour productivity, skill availability, and organisational cohesion are decisive factors in construction outcomes. South Africa continues to face critical skilled labour shortages, compounded by industrial disputes and weak safety standards. Structured workforce management and improved training programs are necessary to bridge performance gaps (Holt, 2001; CIDB, 2016).

Material availability, procurement efficiency, and logistics planning directly influence construction timelines and budgets. The use of digital tools and just-in-time delivery models can reduce waste and improve responsiveness. In South Africa, logistical inefficiencies and fragmented supply chains remain significant barriers, particularly in rural or underdeveloped regions (Cheng & Kumar, 2014; Olawale & Sun, 2015).

The literature reveals that the successful delivery of mega infrastructure projects depends on an integrated understanding of multiple performance dimensions and subsystem interactions. Traditional project management approaches must be supplemented by frameworks that accommodate complexity, dynamic interdependencies, and contextual realities.

3. Research methodology

This study adopted a quantitative, cross-sectional research design aimed at validating the latent structure of factors influencing the successful delivery of mega infrastructure projects. Confirmatory Factor Analysis (CFA) was employed to assess the factorial validity of a hypothesised five-factor measurement model.

3.1. Data collection

Due to the lack of structured statistical data related to construction site factors, primary data were collected through a structured stakeholder survey. The study targeted professionals directly or indirectly engaged in mega infrastructure projects across three South African provinces—KwaZulu-Natal, Gauteng, and Western Cape—where such projects are most concentrated.

Participants were selected based on professional roles, qualifications, and experience in areas such as project planning, design, management, or site-level decision-making. Out of 225 stakeholders contacted via email, telephone, and in-person invitations, 189 agreed to participate, yielding a strong response rate of 84%, which was considered sufficient for exploratory factor analysis.

The sample included a diverse mix of contractors, project managers, engineers, quantity surveyors, site agents, designers, and academics. A structured questionnaire was developed based on a comprehensive literature review and expert consultations. Respondents were asked to rate the influence of various site-related factors on project performance using a five-point Likert scale (1 = Very Low to 5 = Very High).

The survey was administered both online and face-to-face. To ensure inclusivity and eliminate bias, no restrictions were applied regarding race, gender, age, or nationality. The collected data were cleaned and assessed for missing values, multivariate outliers, normality, and reliability before being analysed using CFA to ensure suitability for statistical examination.

3.2. Data analysis

Confirmatory Factor Analysis (CFA) was used to examine whether observed variables reliably reflect a smaller number of latent constructs. As a theory-driven method based on the common factor model, CFA assumes that the correlations among observed variables can be explained by their loadings on latent constructs and measurement error (Brown, 2015). Fig. 1 presents the CFA model with the factor loadings.

The basic CFA equation is given in Equation 1:

$$X = \Lambda\xi + \delta \tag{1}$$

where x is a vector of observed variables, Λ is the matrix of factor loadings, ξ is the vector of latent variables (factors), δ is the vector of measurement errors

The covariance matrix of observed variables is represented by Equation 2:

$$\Sigma = \Lambda\Phi\Lambda^{T} + \Theta\delta \tag{2}$$

where: Σ is the model-implied covariance matrix, Φ is the covariance matrix of latent variables, $\Theta\delta$ is the diagonal matrix of error variances

3.2.1. Measurement model specification

The hypothesised model consisted of five first-order latent constructs: Plant and Technological Resource, Stakeholder Engagement and Communication, Construction Management, Labour and Workforce Organisation, and Material and Logistics Management.

Each construct was measured using multiple observed indicators derived from empirical literature. Indicators were restricted to load on a single factor, and error terms were assumed to be uncorrelated unless theoretically justified.

3.2.2. CFA estimation and model fit evaluation

CFA was conducted using the Maximum Likelihood Estimation (MLE) approach, which provides robust parameter estimates under the assumption of multivariate normality. The MLE objective function is expressed in Equation 3:

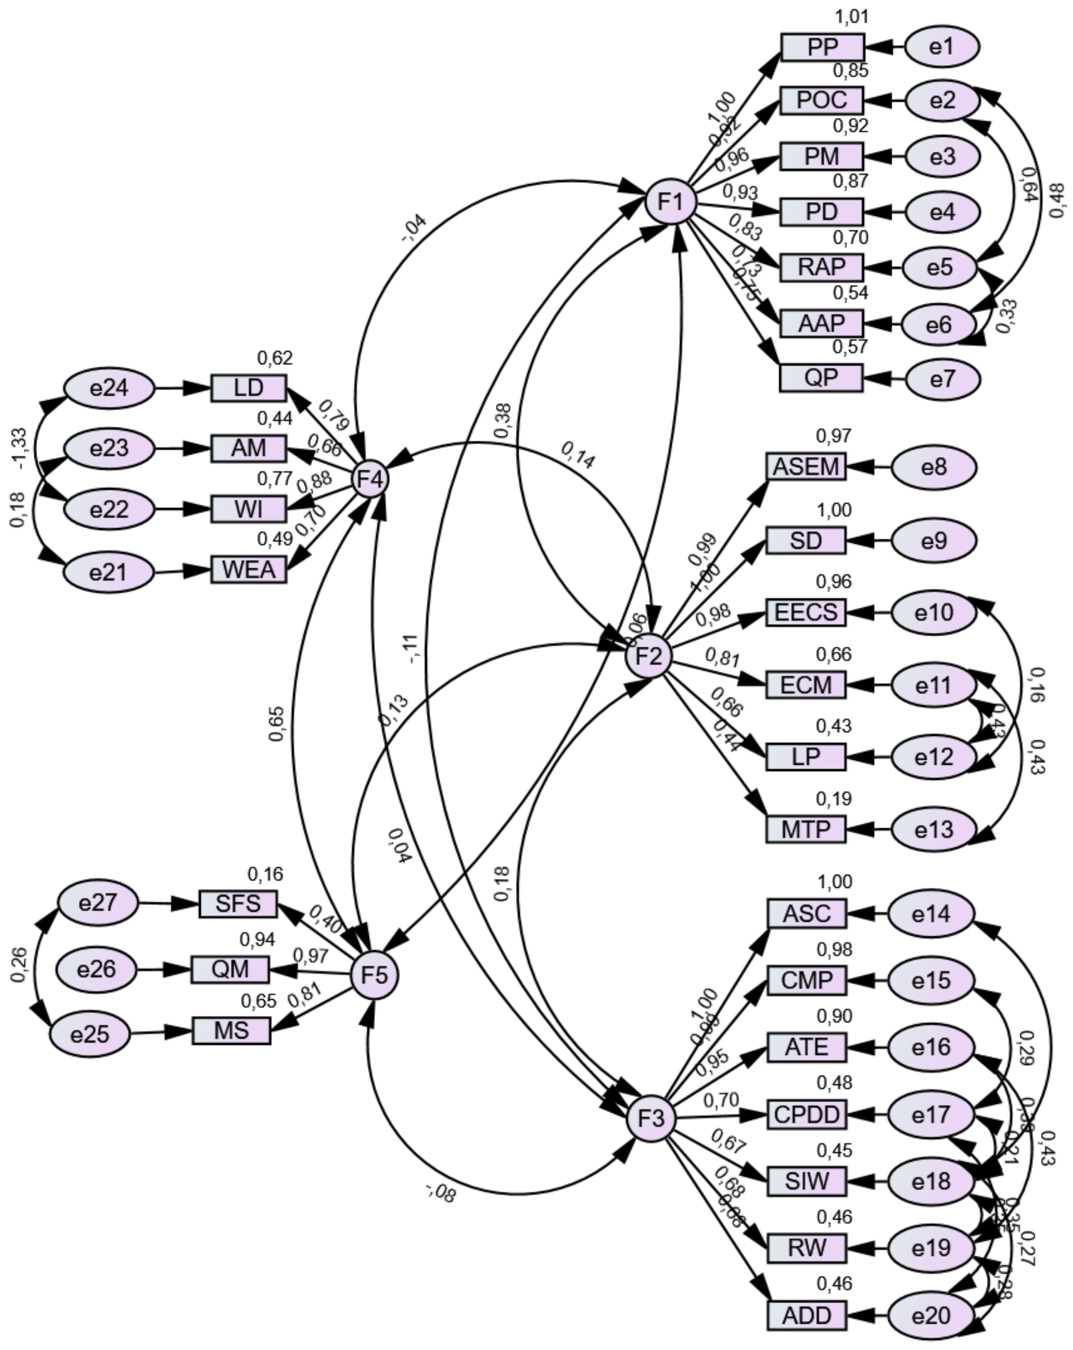

Fig. 1. Confirmatory factor analysis model results (Factor loadings)

$$FML = log|\Sigma| + tr(S\Sigma^{-1}) - log|S| - p \tag{3}$$

where tr is the trace operator, |·| denotes the determinant, S is the sample covariance matrix, p is the number of observed variables

Model fit was evaluated using several indices such as Chi-square (χ^2) and normed chi-square (χ^2/df), with χ^2/df < 3.0 considered acceptable; Comparative Fit Index (CFI) and Tucker-Lewis Index (TLI), with values ≥ 0.90 indicating good fit; Root Mean Square Error of Approximation (RMSEA), with RMSEA < 0.08 deemed acceptable; Standardised Root Mean Square Residual (SRMR), with values < 0.08 reflecting good fit (Kline, 2016).

3.2.3. Assessment of validity and reliability

Convergent validity was assessed through standardised factor loadings (≥ 0.70), and items with slightly lower loadings were retained if theoretically significant (Hair et al., 2019). Average Variance Extracted (AVE) was calculated using Equation 4:

$$AVE = \frac{\sum \lambda i^2}{(\sum \lambda i^2 + \sum \theta_i)} \tag{4}$$

An AVE ≥ 0.50 was considered acceptable. Construct Reliability (CR) was calculated to ensure internal consistency (Equation 5):

$$CR = \frac{(\sum \lambda i)^2}{((\sum \lambda i)^2 + (\sum \theta_i))} \tag{5}$$

A CR ≥ 0.70 was deemed acceptable. Discriminant validity was assessed using the Fornell-Larcker criterion, ensuring that the square root of AVE for each construct exceeded its correlation with other constructs (Fornell & Larcker, 1981).

3.2.4. Model specification and misspecification treatment

The initial CFA model was structured based on theoretical insights and stakeholder input. Each observed variable was specified to load onto only one latent construct with uncorrelated residuals unless empirical diagnostics indicated otherwise.

In cases of model misfit, such as Heywood cases (e.g., loadings > 1.0 or negative error variances), modification indices were examined. Adjustments such as correlating residuals or removing problematic indicators were considered, but only applied when theoretically defensible.

All statistical analyses were performed using IBM SPSS AMOS version 30. The final model integrates theoretical relevance and statistical robustness, offering a valid measurement framework for analysing the interdependencies of construction-related factors in the delivery of mega infrastructure projects.

4. Results and discussion

4.1. Reliability and normality analysis

To ensure the internal consistency of the measurement scale, Cronbach's alpha was calculated. The result yielded a Cronbach's alpha coefficient of 0.88 (Table 1), indicating a high level of internal reliability (George & Mallery, 2003; Nunnally, 1978). To assess the suitability of the data for CFA, skewness and kurtosis statistics were examined to evaluate the assumption of normality. Skewness values ranged between -0.233 and 1.145, indicating that the data distribution is approximately symmetric and within the acceptable range of ±2 (George & Mallery, 2010). Similarly, the kurtosis values ranged between -0.260 and 2.333, also falling within the acceptable limits of ±7 recommended by Byrne (2010), suggesting no significant issues with the peakedness of the distribution (Table 1). These results indicate that the data do not deviate significantly from normality and are therefore considered suitable for CFA and other parametric statistical analyses.

Table 1**.** Summary of reliability and normality statistics

Measure	Value/Range	Acceptable Range	Interpretation
Cronbach's Alpha	0.88	≥ 0.70	High internal consistency-reliable
Skewness (range of values from all items)	-0.233-1.145	±2	Within normal range (acceptable)
Kurtosis (range of values from all items)	-0.260-2.333	±7	Within normal range (acceptable)

4.2. Model fit information

The model fit information of the Confirmatory Factor Analysis (CFA) offers evidence that the five-factor measurement model exhibits an acceptable fit to the observed data. The model fit information is presented in Table 2. The model produced a statistically significant chi-square value (χ^2 = 647.942, df = 298, p < 0.001).

Table 2. The model fit information

Fit Index	Value	Recommended Threshold	Interpretation
Chi-square (χ^2)	647.942	—	Significant (expected in large samples)
Degrees of Freedom (df)	298	—	—
Normed Chi-Square (χ^2/df)	2.174	< 3.0 (acceptable)	Acceptable
Root Mean Square Error of Approximation (RMSEA)	0.078	< 0.08 (acceptable)	Acceptable
Goodness-of-Fit Index (GFI)	0.818	≥ 0.90 (good)	Slightly lower but acceptable
Comparative Fit Index (CFI)	0.945	≥ 0.90 (acceptable)	Excellent
Tucker-Lewis Index (TLI)	0.935	≥ 0.90 (acceptable)	Excellent
Normed Fit Index (NFI)	0.903	≥ 0.90 (acceptable)	Acceptable
Standardised Root Mean Square Residual (SRMR)	0.057	< 0.08 (acceptable)	Acceptable
RMSEA 90% Confidence Interval	0.071–0.087	0.05-0.10	Within an acceptable range

However, given the well-documented sensitivity of the chi-square statistic to sample size, the normed chi-square (χ^2/df) is considered a more appropriate indicator of model fit. The normed chi-square value (χ^2/df = 2.174) is found to be within the acceptable range ($1 \leq \chi^2/\text{df} \leq 3.00$). Also, the Complementary fit indices further support the model's adequacy. The Comparative Fit Index (CFI) was 0.945, and the Tucker-Lewis Index (TLI) was 0.35, exceeding the recommended threshold of 0.90. The Root Mean Square Error of Approximation (RMSEA) was 0.078, with a 90% confidence interval ranging from 0.071 to 0.87, indicating a moderate yet acceptable level of fit. The Standardised Root Mean Square Residual (SRMR) was also 0.057, well below the conventional cut-off value of 0.08, suggesting a good correspondence between the model and the observed data.

Furthermore, most standardised factor loadings were statistically significant ($p < 0.001$) and surpassed the recommended threshold of 0.70 (Table 3), indicating strong relationships between the latent constructs and their observed indicators. Thus, the model demonstrates a good fit and is deemed suitable for subsequent analysis.

4.3. Factors influencing the success of mega projects

The standardised factor loadings from the Confirmatory Factor Analysis (CFA) are presented in Table 3. The results of CFA identified five key latent constructs that significantly influence the successful delivery of mega projects. The latent constructs are (1) Plant and Technological Resources, (2) Stakeholder Engagement and Communication, (3) Construction Management, (4) Labour and Workforce Organisation, and (5) Material and Logistics Management. Each construct is supported by statistically significant factor loadings, affirming both their empirical relevance and theoretical robustness (Table 3).

4.3.1. Plant and technological resources (F1)

This construct emerged as a critical driver of project performance, evidenced by high standardised loadings for indicators such as Plant maintenance (0.957), Plant downtime (0.934), Plant operators and competence (0.924), Robotics and automation of plant (0.835), Quality of plant (0.754) and Availability of advanced plant (0.734). These findings underscore the importance of operational efficiency, equipment reliability, skilled personnel, and advanced automation technologies in maintaining productivity and ensuring continuity in large-scale infrastructure projects.

4.3.2. Stakeholder engagement and communication (F2)

Strong loadings were observed for stakeholder delineation (0.999), ensuring effective communication among stakeholders (0.977), advanced stakeholder engagement methods (0.987), and effective communication methods (0.811), reflecting the centrality of transparent and structured stakeholder interactions. Although leadership (0.656) and monitoring of team performance (0.439) had lower loadings, they remain relevant, indicating that leadership dynamics and performance oversight also contribute to effective stakeholder coordination. Overall, this construct highlights the need for participatory engagement strategies, clear role definitions, and open communication channels to reduce uncertainty and align stakeholder interests.

4.3.3. Construction management (F3)

This dimension is anchored by strong loadings for construction methods and process (0.992), and availability of tools and equipment (0.947), with moderate contributions from change in plan design and drawings (0.696), rework (0.678), availability of detailed drawings(0.676) and supervision and inspection of work (0.670). These results emphasise the importance of systematic planning, adaptive construction methodologies, and robust oversight mechanisms for ensuring quality and timely project execution.

4.3.4. Labour and workforce organisation (F4)

The factor is characterised by high loadings of workforce involvement(0.876) and labour discipline (0.786), as well as moderate loadings of work and equipment allocation (0.698) and availability of manpower (0.663), which contribute meaningfully to the construct. This highlights the role of engaged, disciplined labour forces and strategic human resource allocation in facilitating smooth project implementation.

4.3.5. Material and logistics management (F5)

This construct was validated by strong loadings for quality of material(0.967) and material supply (0.805). However, storage facilities on site (0.397) exhibited a lower loading, possibly reflecting contextual variability. These findings affirm the significance of timely and organised material delivery and stringent quality control processes for effective infrastructure project execution.

Together, the five constructs provide a robust, evidence-based foundation for analysing the complex variables that impact megaproject success. The findings highlight the critical need for cohesive planning that spans technical systems, organisational structures, and stakeholder involvement. Prioritising strategic alignment in areas such as plant readiness, stakeholder collaboration, adaptable construction processes, workforce organisation, and logistical resource planning is crucial for meeting cost, schedule, and quality objectives.

Table 3. Standardised factor loadings

Latent Factor	Observed Variable	Standardised Loading
F1: Plant and Technological Resources	Plant maintenance	0.957
	Plant downtime	0.935
	Plant operators and competence	0.924
	Robotics and automation of the plant	0.835
	Availability of advanced plant	0.734
	Quality of the plant	0.754
	Plant productivity	1.003
F2: Stakeholder Engagement	Stakeholders delineation	0.999
	Advanced stakeholder engagement methods	0.987
	Ensuring effective communication among the stakeholders	0.977
	Effective communication methods	0.811
	Leadership	0.656
	Monitoring of team performance	0.439
F3: Construction Management	Accessibility and site conditions	1.001
	Construction methods and processes	0.992
	Availability of tools and equipment	0.947
	Change in plan design and drawings	0.696
	Supervision and inspection of work	0.670
	Rework	0.678
	Availability of detailed drawings	0.676
F4: Labor and Workforce Organization	Workforce involvement	0.876
	Labour discipline	0.786
	Work and equipment allocation	0.698
	Availability of manpower	0.663
F5: Material and Logistics Management	Quality of material	0.967
	Material supply	0.805
	Storage facilities on site	0.397

5. Discussion and systems framework

5.1. Discussion

Mega-infrastructure projects are increasingly positioned as transformative instruments for sustainable development in emerging economies (Zeybek & Kaynak, 2006; Human Development Report, 2011). South Africa's strategic orientation—reflected in initiatives such as the National Development Plan (NDP) and Strategic Infrastructure Projects (SIPs)—demonstrates an explicit ambition to deploy large-scale investments for economic redress, regional integration, and long-term growth (Field & Ofori, 1988; Khan, 2008; Othman, 2012). However, despite these ambitions, the chronic underperformance of megaprojects—manifesting in cost overruns, schedule slippages, and quality shortfalls—points to deeper systemic inefficiencies (Deloitte, 2013; Mashegoana & Khatleli, 2019).

Critically, the literature attributes many of these failures to the rigid application of traditional project management paradigms in contexts defined by uncertainty, political complexity, and resource asymmetry (Flyvbjerg, 2014; Erol et al., 2018). While the project management "iron triangle"—time, cost, and quality—remains conceptually central (Atkinson, 1999), its practical utility in mega-infrastructure projects is limited without adaptive, context-sensitive approaches (Windapo & Cattell, 2013; Mbachu & Nkado, 2007). For example, governance breakdowns and weak oversight mechanisms in South African projects are symptomatic of deeper institutional fragility (Aiyetan & Das, 2022; Watermeyer, 2013), where fragmented communication and contractor underperformance derail project continuity.

From a systems theory perspective, megaprojects are not merely technical ventures but complex socio-technical systems, requiring the orchestration of interdependent subsystems (Shore & Cross, 2005; Caldas & Gupta, 2017). The study’s identification of five latent constructs through Confirmatory Factor Analysis (CFA)—namely Plant and Technological Resources, Stakeholder Engagement and Communication, Construction Management, Labour and Workforce Organisation, and Material and Logistics Management—resonates with current scholarly emphasis on integrated and multivariate frameworks for infrastructure delivery (Wang et al., 2021; Malek & Bhatt, 2023; Zaman et al., 2022).

Plant and Technological Resources, with strong CFA loadings, highlight the underexplored link between plant efficiency, automation, and project productivity. In contexts such as South Africa, where outdated machinery and poor maintenance are prevalent, this construct aligns with Gamil and Rahman’s (2020) emphasis on Building Information Modelling (BIM) and smart construction technologies as levers for performance optimisation. However, the low adoption of such tools—due to cultural inertia, high upfront costs, and skills deficits—continues to inhibit technological modernisation (Windapo, 2016).

The second construct, Stakeholder Engagement and Communication, affirms the proposition by Freeman (1984) and Aaltonen & Kujala (2010) that stakeholder alignment is central to project resilience. In practice, South African megaprojects often fail to harmonise divergent interests due to top-down governance and exclusionary decision-making, resulting in community resistance and legal entanglements (Olander & Landin, 2008). Here, the empirical validation of stakeholder delineation and communication effectiveness (CFA loadings near 0.999 and 0.977, respectively) reinforces the need for participatory frameworks and trust-building mechanisms.

Construction Management practices, particularly those related to supervision, method choice, and flexibility in responding to design changes, form another cornerstone of successful delivery. While global frameworks such as PMBOK and PRINCE2 advocate for standardised project governance (PMI, 2017), empirical studies in South Africa repeatedly note deficiencies in these areas, often stemming from weak project leadership and inconsistent oversight (Windapo & Cattell, 2013; CIDB, 2016). The CFA findings support this, showing strong loadings for construction methods and tool availability, underscoring the importance of structured yet adaptable execution strategies.

The Labour and Workforce Organisation construct also warrants attention, particularly in light of South Africa’s persistent labour-market challenges. Holt (2001) and Hwang & Ng (2013) have stressed that skilled labour shortages, poor labour discipline, and weak safety regimes are significant sources of inefficiency. The high CFA loading for workforce involvement (0.876) suggests that meaningful engagement and discipline are pivotal to labour productivity. However, systemic issues like inadequate training and politicised union dynamics undermine project execution (CIDB, 2016).

Finally, Material and Logistics Management remains a persistent bottleneck in infrastructure delivery, especially in rural or under-resourced areas. The CFA-confirmed relevance of material quality and supply corroborates findings by Cheng & Kumar (2014) and Olawale & Sun (2015), who argue that fragmented supply chains, poor storage facilities, and last-mile delivery failures often derail otherwise well-conceived projects.

Importantly, the empirical model presented in this study substantiates the need for a systems-oriented performance framework that recognises the interdependence of technical, human, and organisational factors. As Flyvbjerg et al. (2003) argue, optimism bias and strategic misrepresentation often cloud feasibility assessments; thus, integrating micro-level construction practices into performance analysis can ground strategic planning in operational realities. This is particularly vital for the Global South, where systemic risks—such as institutional weakness, socio-political volatility, and regulatory ambiguity—compound project complexity (Ofori, 2015).

Moreover, the CFA-based model supports a paradigm shift away from deterministic, linear planning towards adaptive governance and agile construction management. As suggested by Wu et al. (2018) and Al Ani (2024), digital platforms, proactive risk tools, and dynamic feedback loops are essential in navigating uncertainty and achieving performance resilience.

5.6. Toward a systems-oriented framework for mega project delivery

Collectively, the findings reinforce the conception of mega projects as complex socio-technical systems—an idea advanced in the work of Shore and Cross (2005) and Erol et al. (2018). Each latent construct identified through CFA represents a vital subsystem, whose interactions fundamentally shape project outcomes. This systems perspective complements the emerging literature advocating for non-linear, integrated project management models (Zaman et al., 2022; Al Ani, 2024). The empirical robustness of the five constructs underscores the need for coordinated planning across technical, organisational, and human dimensions, rather than siloed interventions.

From a policy and managerial standpoint, this implies that performance optimisation cannot be achieved through isolated reform (e.g., improving procurement efficiency without addressing labour practices or stakeholder engagement). Instead, systems-based interventions—focusing on synchronising subsystems, reducing interface friction, and embedding continuous feedback loops—are more likely to yield sustained improvements in megaproject outcomes.

6. Conclusion

This study examined the critical construction-related factors that influence the successful delivery of mega infrastructure projects in South Africa, where such initiatives are pivotal to national development yet often plagued by delays, cost overruns, and quality shortfalls. A key challenge addressed was the limited understanding of micro-level operational issues within the construction phase—issues such as inefficient plant utilisation, poor stakeholder coordination, labour unrest, inadequate logistics, and weak construction management practices.

Through a confirmatory factor analysis, the study confirmed five interdependent domains—Plant and Technological Resources, Stakeholder Engagement and Communication, Construction Management, Labour and Workforce Organisation, and Material and Logistics Management—as core contributors to project performance. Among these, technical efficiency, participatory governance, robust management processes, effective human capital utilisation, streamlined logistics, technological readiness, stakeholder collaboration, and effective site-level management emerged as dominant success drivers. The findings highlight that systemic inefficiencies at the construction delivery level—rather than only at the strategic or policy level—often underlie project failures.

This study contributes to the growing body of knowledge on mega infrastructure project performance by empirically identifying and validating five critical subsystems—Plant and Technological Resources, Stakeholder Engagement and Communication, Construction Management, Labour and Workforce Organisation, and Material and Logistics Management—that significantly influence project outcomes in the South African context. Through the application of Confirmatory Factor Analysis (CFA), the findings substantiate project delivery's multidimensional and interdependent nature, underscoring the necessity for a systems-oriented approach in policy and practice.

Thus, successful megaproject delivery demands more than financial resources or high-level policy alignment—it requires a holistic, adaptive, and context-sensitive management paradigm that links systemic thinking with operational excellence. Future research could further explore causal relationships among these subsystems and develop dynamic performance models that account for temporal and contextual variability in project environments across the Global South.

Abstract. In steel–concrete composite beams, shear connectors play a critical role in effectively utilizing the tensile strength of the steel profile and the compressive strength of the concrete. Traditionally, shear connectors are attached to the beam flange. While this method is suitable for heavy steel profiles, it leads to damage concentration in the beam flange rather than the shear connector due to the very thin web in cold-formed steel beams. In this study, for the first time in the literature, an innovative shear connector was designed where the connection element is attached to the web of the beam instead of the flange, and its performance was experimentally evaluated. Additionally, the shear connector was partially isolated from the concrete to allow it to bend freely. The experimental study involved full-scale push-out tests, and the results were compared with commonly used bolted shear connectors in practice. The push-out test results revealed that all the damage was concentrated in the proposed shear connector, and no damage was observed in the cold-formed steel beam.

Keywords: Cold formed steel; Concrete; Composite beam; Shear connector; Push-out test

1. Introduction

In recent years, technological advancements have contributed significantly to time and cost savings in the construction industry while also promoting the development of environmentally friendly solutions. In this context, due to their low weight, high strength-to-weight ratios, and environmental benefits, cold-formed steel structures have emerged as a significant alternative in modern construction practices. Particularly since the 1990s, the use of cold-formed steel components has increased markedly and found widespread application, especially in residential and commercial buildings (Hancock, 2003). Compared to hot-rolled steel sections, cold-formed steel sections reduce structural weight and provide substantial savings in transportation and assembly costs (Zeynalian, 2015). The reduction in structural weight also improves the seismic performance of buildings, making such systems attractive in regions with high seismic risk (Karamanoğlu & Ulay, 2017). These developments have increased the demand for durable and efficient structural systems that combine the advantages of different materials. Accordingly, composite systems integrating steel and concrete have long been used due to their durability, rapid installation, and economic benefits (Pavlović et al., 2013). While these systems initially employed hot-rolled steel sections, there has been a growing trend toward using cold-formed steel sections, particularly in low-rise residential and commercial structures. The use of cold-formed steel sections contributes to sustainable construction by reducing both structural weight and material consumption (Wehbe et al., 2013).

Composite systems formed by combining cold-formed steel beams with concrete slabs significantly enhance load-bearing capacity and stiffness. The combination of concrete's high compressive strength and steel's tensile strength leads to improved structural performance (Jianguo et al., 1999). Moreover, the lateral stability provided by the concrete slab reduces the risk of buckling in cold-formed steel components (Zeynalian et al., 2013). However, existing design standards do not adequately address the specific requirements of cold-formed steel–concrete composite systems, necessitating comprehensive research.

Shear connectors, which ensure the transfer of shear forces between steel and concrete, play a critical role in the performance of these systems (Hosseinpour et al., 2018). While welded headed studs are commonly used in traditional hot-rolled steel–concrete systems, the deformation sensitivity of cold-formed steel profiles has led to the exploration of alternative connection methods (Hanaor, 2000). Consequently, the use of mechanical connectors is recommended in cold-formed steel–concrete composite applications (Alhajri et al., 2016).

Irwan et al. (2009) demonstrated that triangular-shaped bent projections can provide 91% to 135% higher shear capacity. Irwan et al. (2011) reported that triangular connectors increased flexural capacity by 18% and that the

* Corresponding author, E-mail: fatihcebir@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_006

profile thickness significantly influenced the damage modes. Bamaga et al. (2019) investigated the performance of angle and plate-type connectors developed for cold-formed steel–concrete composite beams and found that hot-rolled steel plates offered high strength and ductility. Hosseinpour et al. (2021) examined the performance variation of U-shaped connectors depending on screw diameter and steel thickness, showing that screw diameter can increase load capacity by 25–40%. In another study conducted the same year, push-out tests were used to determine the ultimate load and failure modes of cold-formed steel sections with varying thicknesses. Numerical analyses by Hosseinpour et al. (2022) revealed that the embedment depth of the bolt within the concrete slab had a positive impact on shear capacity.

Findings in the literature indicate that current shear connectors are fully embedded within the concrete slab, which limits their deformation capacity and may lead to damage in both the beam and slab components. This study aims to enhance the performance of cold-formed steel–concrete composite systems by designing and experimentally evaluating a novel mechanical shear connector that is partially isolated from the concrete slab.

2. Partially isolated shear connector

In composite beam systems, various shear connectors have been developed to enable load transfer between the reinforced concrete slab and the steel beam. The primary objectives in these designs have been to improve ease of application and/or enhance structural performance. The literature shows that connectors with different geometric configurations have been developed to increase ductility—thereby reducing or delaying damage—and simultaneously improve load-bearing capacity. However, the complete embedment of shear connectors within the concrete slab restricts their ability to deform freely under loading, preventing the intended structural behavior from being fully achieved during the design phase. To overcome this limitation, a design approach that allows the connector to deform independently by partially isolating it from the concrete slab must be adopted.

In this study, a novel shear connector partially isolated from the reinforced concrete slab has been designed (Fig. 1). The proposed system consists of a continuous steel plate placed between two cold-formed C-shaped steel beams that are connected through their webs. The portion of the connector embedded within the concrete slab consists of steel strips arranged in a grid-like form to promote flexural behavior. To achieve this, trapezoidal gaps are created between the strips, preventing direct contact with the surrounding concrete. Load transfer is achieved via reinforcing bars that pass through holes drilled into the upper sections of the strips. Due to the relative displacements that occur between the concrete slab and the cold-formed steel beam, the partially isolated steel strips are able to bend freely. Furthermore, since the connector is welded to the web of the cold-formed steel beam, shear forces developed at the interface can be transferred directly to the beam web, offering a significant structural advantage over conventional connector systems.

In the structural behavior of the connector, the height and width dimensions of the steel strips embedded within the reinforced concrete slab emerge as two key parameters. Due to the limited thickness of the slab, the free length of the steel strips was set at 30 mm, while the width was determined as 5 mm to enhance displacement ductility.

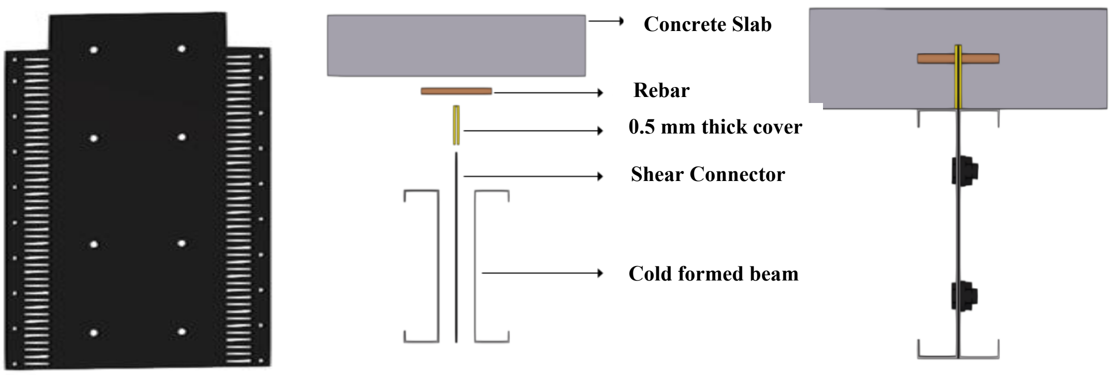

Fig. 1. New shear connector assembly in the composite beam

3. Experimental program

3.1. Test specimens and fabrication

Within the scope of the static push-out tests, a total of five specimens were prepared (Cebir,2024). Three of these specimens were equipped with bolted shear connectors of different diameters, while the remaining two were equipped with the partially isolated shear connectors proposed in this study. Bolted shear connectors, which are commonly used in composite beams, were considered as reference specimens in this study. The specimens labeled PO-B-8, PO-B-10, and PO-B-12 were equipped with M8, M10, and M12 diameter bolted shear connectors, respectively. The longitudinal spacing between the centers of adjacent bolts was set at 200 mm, satisfying both the minimum (six times the bolt diameter) and maximum (914 mm) spacing requirements specified in AISC 360-16. The bolts were arranged in double rows along the beam flanges, with a transverse spacing of 60 mm between the centers of two adjacent bolts. This distance meets the "minimum four times the bolt diameter" requirement stated in AISC 360-16. According to the AISC 360-16 standard, the bolt length must be at least four times the bolt diameter. Accordingly, in the PO-B series specimens, the length of the connectors measured from the top surface of the beam flange was designed as 60 mm (Fig. 2). Additionally, reinforced concrete slabs with a thickness of 80 mm were placed on both flanges of the cold-formed steel beam (Fig. 2), providing a 20 mm concrete cover above the bolted shear connectors (AISC 360-16, 2016).

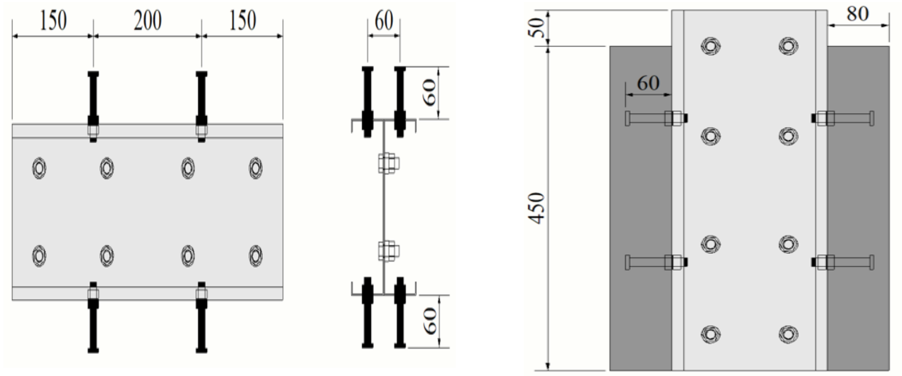

Fig. 2. Bolted shear connector–beam connection detail in PO-B series specimens

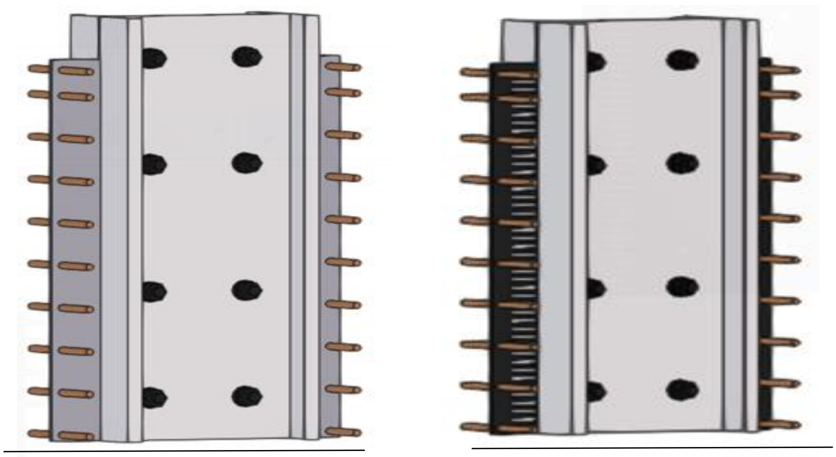
In the PO-PL-ISO and PO-PL specimens, shear connectors formed using 3 mm thick steel plates were placed between cold-formed C-shaped steel profiles joined at their webs and were fixed to the profiles using M10 bolts. The width of the connectors was designed to extend 50 mm beyond both sides of the top and bottom flanges of the C-shaped profile to ensure effective composite action with the reinforced concrete slab (Fig. 3). Additionally, mechanical interaction with the reinforced concrete slab was achieved through reinforcing bars passing through 9 mm diameter holes spaced at 50 mm intervals along the free edges of the connectors. The primary difference between these two specimens lies in the insulation condition of the connector portion embedded within the concrete slab. In the PO-PL-ISO specimen, the 50 mm long section of the connector embedded in the concrete was partially insulated by covering it with a 0.5 mm thick U-shaped steel sheet (Fig. 3(a)), whereas in the PO-PL specimen, the connector was embedded directly into the concrete without any insulation (Fig. 3(b)). This difference between the two specimens was comparatively evaluated in terms of the deformation capacity of the connectors under loading and their interaction behavior with the reinforced concrete slab.



(a) **(b)**

Fig. 3. Beam-to-plate connection detail in PO-PL-ISO and PO-PL test specimens

3.2. Material properties

The steel profile specimens used in the experiments were fabricated from galvanized steel sheets produced by the hot-dip method, classified as S320GD+Z grade according to TS EN 10346 (2015), with a minimum yield strength of 320 MPa and a thickness of 1.5 mm. To determine the mechanical properties of the steel sheets, coupon specimens were prepared according to the dimensions specified in TS EN ISO 6892-1 (2016). Tensile tests were then conducted on these specimens in accordance with the same standard. The average values obtained from the tests are presented in Table 1.

Table 1. Average results obtained from the monotonic tensile test (Öztürk, 2021)

Yield Strength (MPa)	Tensile Strength (MPa)	Elongation at Break (%)	Elastic Modulus (GPa)
334	443	28.7	184.03

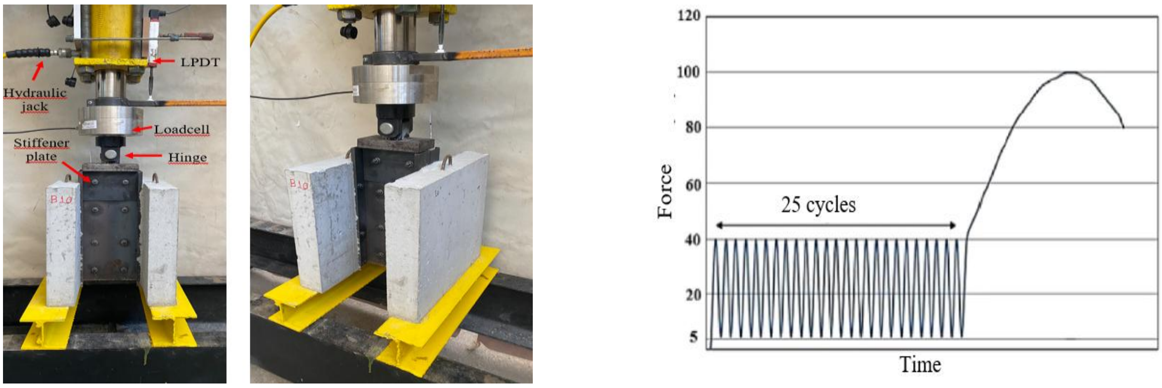
In the experimental studies, two types of connectors were used: bolts and plates. For the bolted connectors, Grade 8.8 bolts with a yield strength of 640 MPa and a tensile strength of 800 MPa were selected. The plates were fabricated from S235JRH (1.0039) grade steel sheets with a minimum yield strength of 235 MPa and a thickness of 3.0 mm, in accordance with the EN 1993-1-1 (2014) standard.

According to the Turkish Building Earthquake Code 2018(67), a minimum concrete class of C30/37 is required for precast reinforced concrete elements. In line with this requirement, the concrete slabs of the test specimens were produced with C30/37 quality concrete. Six cylindrical concrete samples were cast and cured in a standard curing tank for 28 days. At the end of the curing period, compressive strength tests were performed on the specimens (Fig. 4). Based on the results of these tests, the average compressive strength of the concrete material was determined to be 38.8 MPa, confirming that the target values were achieved.

Fig. 4. Uniaxial compression test

3.3. Test setup and loading program

The static push-out tests were conducted using a loading frame. The test specimens were placed freely onto the yellow-colored steel supports, as shown in Fig. 5(a), through the reinforced concrete slabs located at both flanges of the cold-formed C-shaped steel beams. The specimens maintained their vertical stability through the reinforced concrete slabs attached to the flanges. The cold-formed C-shaped steel beam was subjected to a push-out load from its top using a hydraulic jack with a capacity of 1000 kN, inducing relative vertical displacement with respect to the concrete slabs. To prevent potential local damages during load transfer, the upper end of the steel beam, where the load was applied, was clamped from both sides with 8 mm thick steel plates. Similarly, the spacing between the yellow-colored steel supports beneath the reinforced concrete slabs was designed to allow free vertical movement of the beams. During the experiments, a load cell with a capacity of 600 kN was placed at the tip of the hydraulic jack for load measurements, and displacement measurements were taken using a linear potentiometric displacement transducer (LPDT). All data obtained during the tests were transferred and recorded in a computer environment. The loading protocol presented in Fig. 5(b) was applied during the static push-out tests.



(a) **(b)**

Fig. 5. Push-out test setup and loading protocol (Eurocode 4, 2004)

4. Results and discussions

A total of five specimens were tested within the scope of the push-out experiments. The loading protocol shown in Fig. 5(b) was applied; initially, load-controlled cycles were performed, followed by displacement-controlled loading until a 20% reduction from the maximum load was observed. Since reinforced concrete slabs were present on both flanges of the beams, the obtained push-out load values were divided by two for presentation. The push-out load–slip relationships are presented in Fig. 6.

In the PO-B-8, PO-B-10, and PO-B-12 specimens equipped with bolted shear connectors, the maximum push-out loads and the corresponding slip values were found to be relatively close to each other, and only limited differences in load-carrying capacities were observed. However, no direct correlation was identified between the bolt diameter and the load-carrying capacity; the damages were predominantly concentrated in the flanges of the cold-formed steel beams.

In contrast, the PO-PL-ISO and PO-PL specimens with plate-type shear connectors exhibited a distinct yielding plateau, and a ductile behavior was observed in the system response. In the PO-PL specimen, where the steel strips were fully embedded in the concrete, the yield strength was approximately twice that of the PO-PL-ISO specimen, although their ultimate load capacities remained at similar levels. In terms of displacement capacity, the PO-PL-ISO specimen demonstrated superior performance compared to the PO-PL specimen. Overall, the plate-type shear connectors showed a clear superiority over the bolted connectors in both load-carrying and displacement capacities.

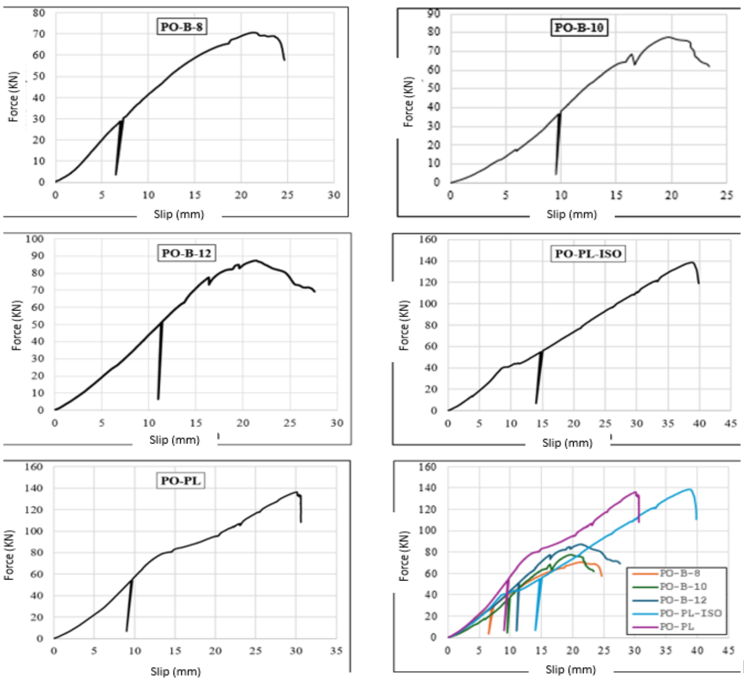


Fig. 6. Load vs. slip displacements curves

4.1. Failure mode

During and after the push-out tests, the types and distributions of damage observed in the specimens were examined. Observations revealed that the damage mechanisms varied significantly depending on the type of shear connector used.

In the PO-B-8 specimen, bending deformations in the bolts and bearing deformations around the bolt holes were observed at the beginning of the test. With increasing load, the bending deformations progressed, leading to bolt failures and tearing in the flange of the cold-formed steel beam. This process resulted in the loss of connection between the bolted connectors and the beam, causing the reinforced concrete slab to separate from the beam flange and terminating the test (Fig. 7(a)). Similarly, in the PO-B-10 specimen, bearing deformations around the bolt holes were observed; however, significant bending deformations in the bolts were not detected. As the load and slip increased, the bearing deformations around the holes progressed, leading to tearing in the beam flange. At the end of the test, damage was observed in both the beam flange and the bolts, along with cracking in the reinforced concrete slab (Fig. 7(b)). In the PO-B-12 specimen, the initial stages of the test showed only bearing deformations at the bolt holes. As the load increased, these bearing deformations intensified, leading to tearing in the beam flange. In this specimen, no significant bending deformation occurred in the bolts during the test; instead, the damage was primarily concentrated in the beam flange. The test was completed when the reinforced concrete slab separated from the beam flange (Fig. 7(c)).

(a) **(b)** **(c)**

Fig. 7. Damages observed during the test on the PO-B-8, PO-B-10 and PO-B-12 specimens

In the PO-PL specimen with a plate-type shear connector, no damage was observed until the yield strength was reached. Due to the full embedment of the steel strips within the concrete, hairline cracks parallel to the shear direction appeared in the reinforced concrete slab immediately after yielding. The size and width of these cracks increased with higher load and slip levels. At the final stage, no damage was observed in the cold-formed steel beam; however, the test was terminated due to the sudden fragmentation of the reinforced concrete slab (Fig. 8(a)). Similarly, in the PO-PL-ISO specimen, which had a partially isolated shear connector, no damage occurred until the yield strength was reached. As the maximum load capacity was approached, cracks formed in the reinforced concrete slab and propagated with increasing load. At the end of the test, no damage was observed in the cold-formed steel beam; the test concluded with the sudden collapse of the reinforced concrete slab (Fig. 8(b)). In both specimens, the connection plate was subjected to bending until the complete failure of the concrete slab. However, in the PO-PL-ISO specimen, the partial isolation of the steel strips from the concrete effectively delayed significant damage in the slab up to the maximum load capacity. Additionally, in both specimens, since the shear connectors were mounted to the web of the cold-formed steel beams instead of the flange, no damage was observed in the beams themselves.

(a) **(b)**

Fig. 8. Damages observed during the test on the PO-PL and PO-PL-ISO specimens

5. Conclusion

In this study, a novel mechanical shear connector was designed for cold-formed steel–concrete composite beam systems, and its performance was experimentally evaluated. The behavior of the developed connector was comparatively assessed against bolted shear connectors commonly used in practice. The main findings obtained from the study are summarized below:

- In specimens with 8 mm diameter bolted shear connectors, initial damage occurred as bending deformation in the connectors. In later stages, bearing deformations and tearing around the bolt holes in the flanges of the cold-formed steel beams were observed, and the test was ultimately terminated by the collapse of the beam flange.
- In specimens with bolted shear connectors larger than 8 mm in diameter, damage was concentrated directly in the flanges of the cold-formed steel beams, and no significant damage was detected in the connectors themselves. Since the flange plates governed the structural behavior, no substantial differences were observed among specimens with different bolt diameters in terms of push-out load, slip, and stiffness values. Therefore, no direct relationship could be established between bolt diameter and load-carrying capacity.
- The proposed shear connector significantly increased both the push-out load capacity and the ductility of the system compared to the bolted shear connectors.
- Mounting the connector directly to the web of the cold-formed steel beam instead of the flanges prevented damage to the steel beam during the push-out tests, concentrating all damage within the connector itself.
- The load–slip curves of the specimens with the proposed shear connector exhibited a distinct yielding plateau, indicating a ductile system behavior.
- The partial isolation of the connector from the reinforced concrete slab delayed crack formation and enhanced the system's ductility; however, it did not result in a significant increase in the push-out load capacity.
- In specimens with bolted connectors, load-carrying capacity was reached through tearing of the beam flanges, whereas in specimens with the proposed shear connectors, it was reached through the fragmentation of the reinforced concrete slab.

[1] *Bayburt University, Department of Civil Engineering, 69000 Bayburt, Türkiye*

Abstract. Functionally graded (FG) materials have been developed to meet the material requirements of engineering fields due to their various superior properties, such as durability, lightness, and sound insulation. Due to their superior properties, FG materials are widely used in modelling structural elements in the field of Civil and Mechanical Engineering. Therefore, the behaviour of structural elements made of FG materials must be thoroughly analysed. This study proposes a higher-order finite element for the buckling analysis of FG sandwich beams. The proposed finite element has 16 degrees of freedom. The finite element analysis considers two types of FG sandwich beams. In addition to the finite element solution, studies were performed using the Ansys Mechanical APDL program. This problem is modelled using the SHELL 281 element in the Ansys Mechanical APDL program. Critical buckling loads of two different types of FG sandwich beams are obtained by considering different boundary conditions. The results obtained are presented in a dimensionless form and compared with those of the literature. Upon examining the results, it is observed that the data agree well with the literature, confirming the accuracy of the finite element.

Keywords: FG sandwich beam; Buckling analysis; A higher-order finite element; Ansys Mechanical APDL

1. Introduction

With the rapid advancement of technology, materials science has continuously evolved. Technological developments in various fields such as engineering, medicine, and aerospace have led to the demand for materials that simultaneously exhibit multiple superior properties, such as high thermal resistance and strength. In response to these demands, researchers have developed laminated composites to meet high temperature and strength performance requirements. Laminated composites are produced by stacking or layering at least two different materials. However, due to the abrupt changes in material properties between the layers, stress concentrations may occur at the interfaces, forming stress cracks. Researchers have developed functionally graded (FG) materials to overcome this disadvantage of laminated composites, in which the material properties vary gradually according to a specific function.

In civil engineering, structural elements have increasingly been designed using functionally graded (FG) materials to withstand mechanical and thermal loads simultaneously. Accurate prediction of the mechanical behavior of FG material-based structural components is essential before their application. For this reason, numerous studies in the literature have focused on the static, free vibration, and buckling analyses of structural elements such as FG shells, plates, and beams.

A new finite element has been proposed for the free vibration and buckling analysis of sandwich functionally graded (FG) beams based on the Higher-Order Shear Deformation Theory (HSDT) (Vo et al., 2014). A finite element has been proposed for the free vibration and buckling analyses of functionally graded (FG) sandwich beams. The equations of motion for the FG beam were derived using Hamilton's principle(Vo et al., 2015). The effects of porosity on the free vibration, buckling, and static behavior of porous functionally graded (FG) beams have been investigated using the Euler-Bernoulli beam theory (Fouda et al., 2017). A finite element model has been proposed for the free vibration and buckling analyses of functionally graded (FG) beams based on the First-Order Shear Deformation Theory (FSDT). The developed finite element has five nodes and ten degrees of freedom. The equations of motion for the FG beam were derived using the Lagrangian formulation (Kahya & Turan, 2017). Using the First-Order Shear Deformation Theory (FSDT), a finite element has been proposed for the static, buckling, and free vibration analyses of laminated composite and functionally graded (FG) beams. The accuracy of the proposed finite element was validated by comparing the obtained results with those available in the literature (Turan, 2018).

golden light publishing

The free vibration and buckling analyses of sandwich beams and laminated composites have been conducted using a finite element model with 9N+7 degrees of freedom (Kahya & Turan, 2018). The buckling behavior of sandwich functionally graded (FG) beams has been investigated using the finite element method in Ansys software. The Taguchi orthogonal array technique was employed to examine and optimize the layer positions and levels of the FG beams (Evran, 2019). Using the finite element method, a new semi-analytical solution has been proposed for the buckling analysis of sandwich functionally graded (FG) beams (Liu et al., 2021). A new finite element has been proposed for the static, free vibration, and buckling analyses of nano functionally graded (FG) beams. The displacement field was obtained using Hermite interpolation. In addition to the proposed finite element solution, a comparison was made by solving the problem using the differential quadrature method (Bian et al., 2022). A finite element has been proposed for the buckling and free vibration analyses of bidirectional functionally graded (FG) porous beams based on the Higher-Order Shear Deformation Theory (HSDT). The proposed finite element has twelve degrees of freedom. Three different types of porosity and various boundary conditions were considered in the study (Turan & Adiyaman, 2023).

This study analyzes the buckling behavior of functionally graded (FG) sandwich beams using a high-order finite element that accounts for shear deformation effects. The finite element has five nodes and sixteen degrees of freedom. The FG material properties vary according to a power law through the beam thickness. The equilibrium equations were derived using the Lagrangian formulation. The analyses considered different boundary conditions, power law index, and slenderness. The results were compared with the results of the literature and the Ansys Apdl package program. It was demonstrated that the results are in excellent agreement.

2. Material method

2.1. Material properties

In this study, two different types of sandwich beams are considered, referred to as Type-1 and Type-2. The material properties of the beams vary in the thickness direction according to Hooke's law, as given in equation (1).

$$P(z) = (P_c - P_m)V_c(z) + P_m \tag{1}$$

P_m and P_s represent the properties of metal and ceramic, respectively. The volumetric fraction function of the ceramic material, V_c, is provided separately for Type-1 and Type-2.

The core of the Type-1 FG sandwich beam is made of homogeneous ceramic material, while the upper and lower layers are composed of FG material, as shown in Fig. 1. The volumetric fraction function of the ceramic material for the Type-1 FG beam is given in equation (2).

The core of the Type-2 FG sandwich beam consists of an FG material layer, with the lower layer made of homogeneous metal material and the upper layer made of homogeneous ceramic material. The volumetric fraction function of the Type-2 FG sandwich beam, V_c, is given in equation (3).

$$\begin{aligned} V_c^{(1)}(z) &= \left(\frac{z-h_0}{h_1-h_2}\right)^p, & h_0 \le z \le h_1 \ (\textit{FG bottom surface}) \\ V_c^{(2)}(z) &= 1, & h_1 \le z \le h_2 \ (\textit{Ceramic core}) \\ V_c^{(3)}(z) &= \left(\frac{z-h_3}{h_2-h_3}\right)^p, & h_2 \le z \le h_3 \ (\textit{FG top surface}) \end{aligned} \tag{2}$$

$$\begin{aligned} V_c^{(1)}(z) &= 0, & h_0 \le z \le h_1 \ (\textit{Metal bottom surface}) \\ V_c^{(2)}(z) &= \left(\frac{z-h_3}{h_2-h_3}\right)^p, & h_1 \le z \le h_2 \ (\textit{FG core}) \\ V_c^{(3)}(z) &= 1, & h_2 \le z \le h_3 \ (\textit{Ceramic top surface}) \end{aligned} \tag{3}$$

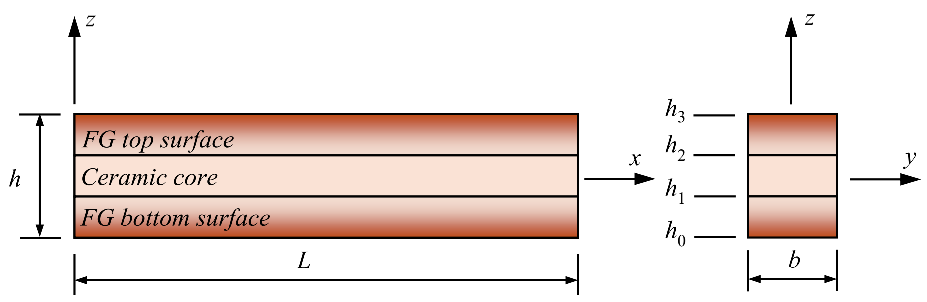

Fig. 1. Type-1 FG sandwich beam

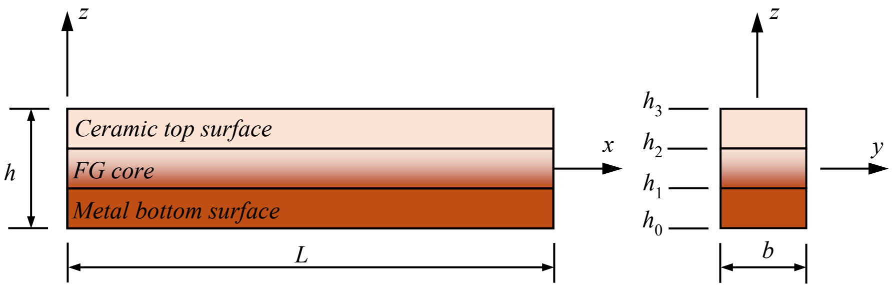

Fig. 2. Type-2 FG sandwich beam

2.2. Solution using the finite element method

In this study, a high-order finite element that accounts for shear deformation effects has been proposed. The finite element has five nodes and sixteen degrees of freedom, as shown in Fig. 3. The displacement vector of the finite element nodes is given in equation (4). The horizontal and vertical displacements, respectively, u and w while the rotations are expressed by ϕ. β_{1i} and β_{2i} the terms represent the higher-order terms derived from the Taylor series expansion.

$$\mathbf{u} = \left(u_i \quad w_j \quad \phi_i \quad \beta_{1i} \quad \beta_{2i} \right), \qquad i=1,2,3 \qquad j=1,2,3,4 \tag{4}$$

The displacement expressions at any point of the FG beam according to the high-order shear deformation theory (HSDT) are given by U and W in equation (5).

$$\begin{aligned} U(x,z,t) &= u(x,t) - z\,\phi(x,t) - z^2 \beta_1(x,t) - z^3 \beta_2(x,t), \\ W(x,z,t) &= w(x,t) \end{aligned} \tag{5}$$

Here, t represents time. The unit shape and displacement expressions of the FG beam are given in equation (6).

$$\varepsilon_{xx} = \frac{\partial U}{\partial x} = u_{,x} - z\phi_{,x} - z^2 \beta_{1,x} - z^3 \beta_{2,x} \quad , \quad \gamma_{xz} = \frac{\partial U}{\partial z} + \frac{\partial W}{\partial x} = w_{,x} - \phi - 2z\beta_1 - 3z^2 \beta_2 \tag{6}$$

Here, $\square_{,x}$ It represents the derivative with respect to x. The normal and shear stresses of the FG beam are given in equation (7). Here, E and G represent the Young's modulus and the shear modulus, respectively.

$$\sigma_{xx} = E(z)\,\varepsilon_{xx} \quad , \quad \tau_{xz} = G(z)\,\gamma_{xz} \tag{7}$$

The expressions used in the solution of the problem, u, w, ϕ, β_1 and β_2 are clearly given in equation (8).

$$\begin{aligned} &u(x,t) = \sum_{i=1}^{3} \varphi_i(x)\, u_i(t) \;, \quad w(x,t) = \sum_{j=1}^{4} \psi_j(x)\, w_j(t) \;, \quad \phi(x,t) = \sum_{i=1}^{3} \varphi_i(x)\, \phi_i(t) \;, \\ &\beta_1(x,t) = \sum_{i=1}^{3} \varphi_i(x)\, \beta_{1i}(t) \;, \quad \beta_2(x,t) = \sum_{i=1}^{3} \varphi_i(x)\, \beta_{2i}(t) \end{aligned} \tag{8}$$

Here, $u_i(t)$, $\phi_i(t)$, $\beta_{1i}(t)$ and $\beta_{2i}(t)$ the terms represent the generalized displacements. $\varphi_i(x)$ and $\psi_i(x)$ the terms represent the shape functions. The equations of motion for the FG beam were derived using the Lagrangian formulation and are given in equation (9).

$$\frac{d}{dt}\left(\frac{\partial \Pi}{\partial \dot{q}_i} \right) - \frac{\partial \Pi}{\partial q_i} = 0 \tag{9}$$

Here, $\dot{q}_i$ and qi represents the independent variables. The Lagrangian equation is expressed in equation

$$\Pi = T - (U^* + V) \tag{10}$$

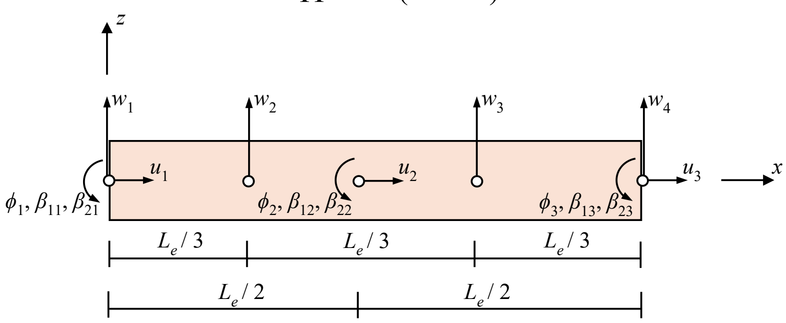

Fig. 3. Proposed finite element

The strain energy of the FG beam is explicitly given in equation (11).

$$
\begin{aligned}
U^{*} &= \frac{1}{2}\int_0^{L_e}\int_A (\sigma_{xx}\varepsilon_{xx}+\tau_{xz}\gamma_{xz})dAdx \\
&= \frac{1}{2}\int_0^{L_e}\Big\{X_0(u_{,x})^2-2X_1u_{,x}\phi_{,x}+X_2\left((\phi_{,x})^2-2u_{,x}\beta_{1,x}\right)+2X_3\left(\phi_{,x}\beta_{1,x}-u_{,x}\beta_{2,x}\right)+ \\
&\quad X_4\left(\beta_{1,x}^2+2\phi_{,x}\beta_{2,x}\right)+2X_5\beta_{1,x}\beta_{2,x}+X_6\beta_{2,x}^2+Y_0\left((\phi)^2-2\phi w_{,x}+\left(w_{,x}\right)^2\right)+ \\
&\quad 4Y_1\beta_1\left(\phi-w_{,x}\right)+2Y_2\left(2\beta_1^2+3\phi\beta_2-3\beta_2w_{,x}\right)+12Y_3\beta_1\beta_2+9Y_4\beta_2^2\Big\}dx
\end{aligned}
\tag{11}
$$

Here, X_a and Y_b express the material coefficients, which are explicitly stated in (12).

$$
X_a=\int_A E(z)z^a dA \ , \ Y_b=G(z)z^b dA \ , \ (a=0,1,...,6; \quad b=0,1,...,4) \tag{12}
$$

The kinetic energy expression of the FG beam is given in equation (13).

$$
\begin{aligned}
T &= \int_0^{L_e}\int_A \rho(z)\left(\dot{U}^2+\dot{W}^2\right)dAdx \\
&= \frac{1}{2}\int_0^{L_e}\Big\{I_0(\dot{u})^2-2I_1\dot{u}\dot{\phi}+I_2\left((\dot{\phi})^2-2\dot{u}\dot{\beta}_1\right)+2I_3\left(\dot{\phi}\dot{\beta}_1-\dot{u}\dot{\beta}_2\right) \\
&\quad +I_4\left(\dot{\beta}_1^2+2\dot{\phi}\dot{\beta}_2\right)+2I_5\dot{\beta}_1\dot{\beta}_2+I_6\dot{\beta}_2^2+I_0(\dot{w})^2\Big\}dx
\end{aligned}
\tag{13}
$$

In this expression, I_c is a coefficient dependent on the material constants, and it is given in equation (14).

$$
I_c=\int_A \rho(z)z^c dA \ , \ (c=0,1,...,6) \tag{14}
$$

For the buckling analysis of the FG beam, a compressive force P_0 is applied at the beam's endpoints. The work done by this force is expressed in equation (15).

$$
V=\frac{1}{2}\int_0^{L_e} P_0\left(w_{,x}\right)^2 dx \tag{15}
$$

By substituting the solutions from equation (8) and considering equations (11), (13), and (15), and taking the derivatives in the Lagrangian expression from equation (10), the equation of motion for the FG beam is obtained as shown in equation (16).

$$
\mathbf{m}\ddot{\mathbf{u}}+\left(\mathbf{k_e}-P_0\mathbf{k_g}\right)\mathbf{u}=\mathbf{f} \tag{16}
$$

Here, $\mathbf{f}$ represents the external force vector. $\mathbf{m}$, $\mathbf{k_e}$ and $\mathbf{k_g}$ represent the element mass, element stiffness, and element geometric matrices, respectively. In the buckling analysis of sandwich FG beams with length L considered in this study, the equation of motion used is derived using the finite element method, as shown in equation (17).

$$
\mathbf{M}\ddot{\mathbf{X}}+\left(\mathbf{K}-P_0\mathbf{K}_g\right)\mathbf{X}=\mathbf{F} \tag{17}
$$

Here, **M**, **K** and $\mathbf{K_g}$ represent the global mass, global stiffness, and global geometric stiffness matrices, respectively. The critical buckling load is denoted by $P_0=(P_0)_{cr}$, and if **M**=0 and **F**=0 are assumed, the equation of motion is obtained as shown in equation (18).

$$
\left(\mathbf{K}-P_0\mathbf{K}_g\right)\mathbf{u}=0 \tag{18}
$$

The obtained equation of motion is an eigenvalue problem, and the values of P_0 that make the coefficient matrices of this equation zero represent the critical buckling loads of the FG beam.

2.3. Solution with ansys mechanical apdl

In this section, the buckling analyses of Type-1 and Type-2 FG sandwich beams are conducted using the Ansys Mechanical APDL software, considering different boundary conditions, slenderness ratios (L/h), and material exponential variation coefficients. The Shell 281 element available in the program is selected for the analyses. After selecting the element, the elastic modulus and density (ρ) values of the FG material are obtained using the MATLAB program and defined in the Ansys software. After defining the material properties, the geometric properties of the FG sandwich beams are specified, with a beam length L and a rectangular cross-section of $b\times h$. After the modeling of the FG sandwich beams was completed, separate convergence studies were conducted for each beam type to determine the sufficient number of finite elements. In the convergence study, for the Type-1 sandwich beam, the homogeneous ceramic layer was not divided, and only the FG surface layers were divided into 20 layers each, resulting in a total of 41 layers. For the Type-2 sandwich FG beam, the FG core was divided into 40 layers, resulting in a total of 42 layers. The mesh generation was performed, and the sandwich FG beams were discretized into finite elements. For the buckling analysis, an axial load of 1 N was applied at the beam ends, and separate analyses were conducted for different boundary conditions, slenderness ratios, and FG material variation coefficients. The obtained results were presented in a dimensionless form in the next section.

3. Results and discussion

In this section, buckling analyses of the sandwich FG beams have been conducted using the proposed finite element method and the Ansys APDL package program, utilizing the material properties provided in Table 1.

The obtained results have been nondimensionalized using equation (19). The nondimensional results are presented in comparison with the literature data.

$$\bar{\lambda} = \frac{12\left(P_0\right)_{cr} L^2}{E_m h^3} \tag{19}$$

3.1. The critical buckling loads of the Type-1 sandwich FG beam

The nondimensional critical buckling loads of the Type-1 FG sandwich beams, obtained through the convergence study using the proposed finite element method and Ansys APDL, are presented in Tables 2 and 3, respectively. Upon examining the data in the tables, the sufficient number of layers for the finite element method was determined to be 14, and for Ansys APDL, it was determined to be 41.

In Table 4, the variation of non-dimensional critical buckling loads with respect to p for different boundary conditions and layer thicknesses is presented, considering L/h=5. The results are compared with literature data. When examining the table, it can be observed that increasing the thickness of the homogeneous ceramic core layer increases the stiffness of the FG beam. As a result, the non-dimensional critical buckling loads increase. The highest non-dimensional critical buckling load was obtained under the clamped boundary condition with a layer thickness of 1-8-1. Furthermore, as the value of p increases, the material property of the FG beam tends to resemble that of metal, leading to a decrease in the non-dimensional critical buckling loads.

In Figure 4, the variation of non-dimensional critical buckling loads with slenderness ratios is comparatively presented for different boundary conditions and various p values, using both the proposed finite element and Ansys APDL, for the case where the layer thicknesses are (1-1-1). Upon examining the obtained results, it is observed that the non-dimensional critical buckling loads increase up to a certain slenderness ratio and then converge. Furthermore, due to the reduction in the stiffness of the FG beam with increasing p values, a decrease in the non-dimensional critical buckling loads is observed.

[(1)] Finite element solution according to FSDT, [(2)] Finite element solution according to HSDT

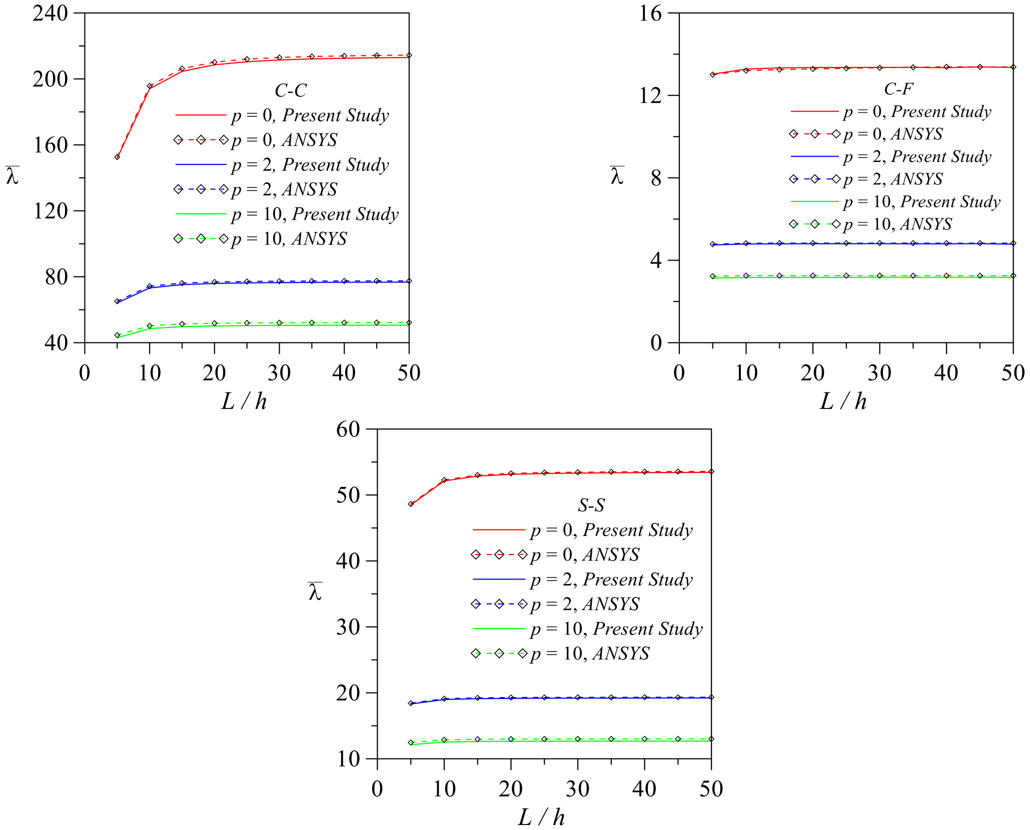

Fig. 4. The variation of dimensionless critical buckling loads of Type-2 sandwich FD beams, calculated using the proposed finite element method and Ansys, depending on the *L*/*h* ratio.

3.2. Critical buckling loads of the Type-2 sandwich FG beam

The data from the convergence studies conducted to determine the sufficient number of layers required for the dimensionless buckling analysis of the Type-2 sandwich FG beam are presented in Table 5 for the proposed finite element and in Table 6 for Ansys. Upon examining the tables, the sufficient number of layers was determined to be 14 for the proposed finite element and 42 for Ansys.

Table 7 presents the dimensionless critical buckling loads obtained using the proposed finite element for *L*/*h*=5, considering different layer thicknesses, boundary conditions, and values of the power-law index *p*. Upon examining the table, it is observed that the dimensionless critical buckling loads decrease with increasing values of *p*. The highest dimensionless critical buckling load is obtained under clamped–clamped boundary conditions with a layer thickness configuration of 1-8-1.

(1) Finite element solution according to FSDT, (2) Analytics solution according to FSDT

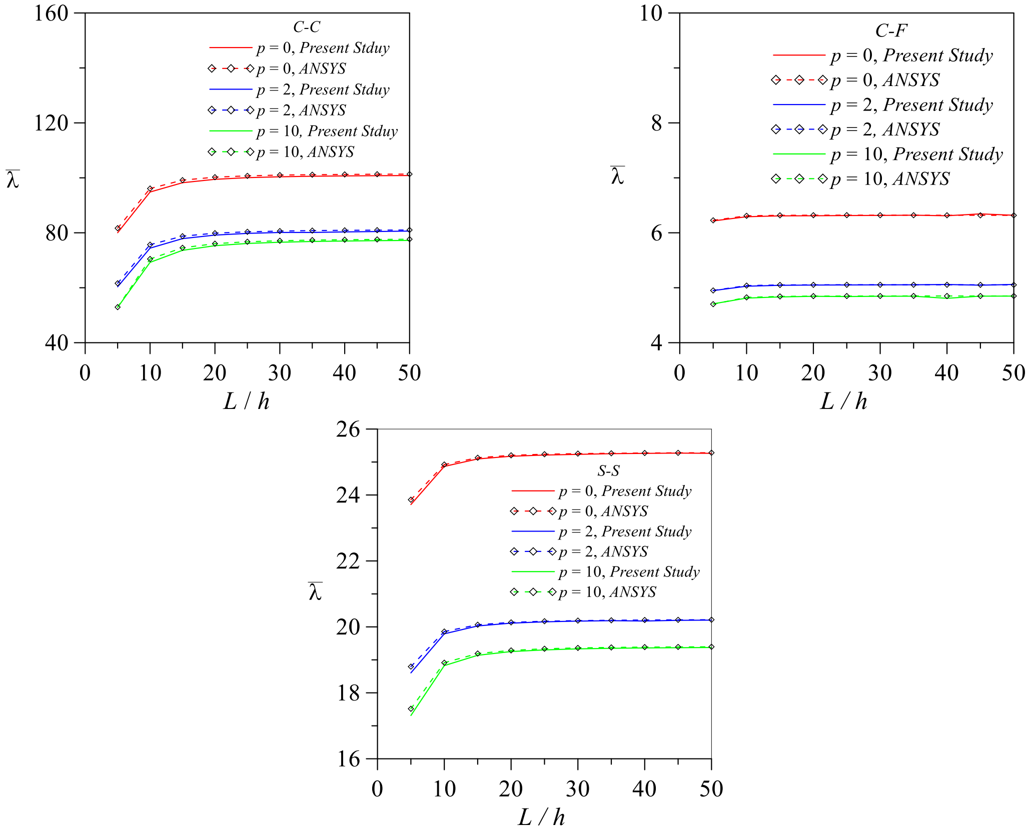

Figure 5. The variation of dimensionless critical buckling loads of Type-2 sandwich FD beams, calculated using the proposed finite element method and Ansys, depending on the L/h ratio.

4. Conclusions

This study proposes a finite element with sixteen degrees of freedom, accounting for higher-order shear deformation effects, for the buckling analysis of sandwich FG beams. The same analyses were solved with the Ansys APDL software to validate the accuracy of the results obtained from the buckling analysis of FG sandwich beams using the proposed finite element. The analyses considered different slenderness ratios, boundary conditions, and FG material variation coefficients. The results obtained by both methods are presented, and the comparisons between them are made with the literature data, showing that the results are highly consistent.

Based on the results obtained from the analyses, the following conclusions can be drawn:

- As the slenderness ratio increases, the dimensionless critical buckling loads decrease.
- For the Type-1 sandwich FG beam, the dimensionless critical buckling loads increase as the core thickness increases.
- When the material property of the Type-2 sandwich FG beam is more metal-dominant, the dimensionless critical buckling loads decrease.

Abstract. The composite materials have created their own importance in all areas of technology with special attention to design materials for civil engineering applications like GRP bars. Spicily, glass fibers are being used as reinforcement of polymeric composite in many industries.To meet the challenges in overcoming the difficulties in mechanical properties, erosion behavior, instant cracking, and thermal resistance, composite materials are developed to solve these difficulties. The present article reveals the effects of degradation conditions like seawater and distilled water in applications of composite materials in the areas related to civil engineering. The article explains the effects of these marine environments on the damage of polyester/glass composites. The idea of composite materials in various applications may explore a new window in modern civil engineering. An investigation was carried out to compare the energy absorption capability of glass/polyester composites in 2 months in salt water and distilled water. The injection molding techniques were used to fabricate the specimens with a 60% glass fiber weight fraction. The Charpy impact test was performed on composite specimens, and the results showed that the glass/polyester composite in distilled water after 1 month and 2 months has the highest energy absorption, compared with the composite degrading in seawater, but it's not that big of a difference, so it's pretty close. In addition, the scanning electron microscopy was assessed to demonstrate the different failure in fracture surfaces. It was found that the glass/polyester composite after aging in marine condition failed by fiber fracture and fracture through the matrix.

Keywords: Mechanical properties; Fibre glass; GRP bars; Seawater; Distilled water

1.Introduction

Glass fiber reinforced polymer composites are used in many marine and water transport industries(Deniz & Karakuzu, 2012; Liao, Gu, Liu, et al., 2024; Liao, Gu, Yan, et al., 2024; Sebaey, 2022), construction of bridges(Jiang, Kolstein, & Bijlaard, 2013) and GFRP bars(Hosen, Johnson Alengaram, Jumaat, Ramli Sulong, & Darain, 2017; Pan & Yan, 2021; Xian, Bai, et al., 2024; Xian, Zhou, et al., 2024)**,** It replaces ordinary steel bars with bars made of composite materials such as Fig. 1, which have corrosion-resistant properties in various aquatic environments and are cheaper in import and manufacturing costs, and the first choice in various applications; it has good mechanical properties and improves the hardness of offshore structures. In this case, composite materials are subjected to mechanical loads and harsh environmental conditions which lead to damage and corrosion over time.

However a decrease in the mechanical properties of polymer matrix composites occurs upon exposure to moisture in distille-water and seawater environments due to the plasticization, hydrolysis of polymer resin and the effect of salts in the water on its properties(Cabral-Fonseca, Correia, Rodrigues, & Branco, 2012; Cerbu, 2010; Fang et al., 2017; Heshmati, Haghani, & Al-Emrani, 2017; Mansouri, Djebbar, Khatir, & Abdel Wahab, 2019),Researches focused on the performance of FRP materials at elevated temperatures (Hawileh & Rasheed, 2017), Because most important factor in the progression and hastening of the degradation on the mechanical characteristics in composite materials is the rise and fall of temperature.More recently, the integration of fiber-reinforced polymer laminates is recognised as an expanded material for the bridge structures owing to its higher

golden light publishing

strength rating(Heshmati, Haghani, & Al-Emrani, 2016; Jiang, Kolstein, Bijlaard, & Qiang, 2014; Jiang et al., 2013), therefore, bars made of composite materials are used as an alternative to steel due to their excellent properties, or they are used as an addition to steel and are called hybrid bars, or repairing steel bridges as they give additions to the properties of steel and give more durability and resistance over time. (G. Feng et al., 2024; Li et al., 2022; Xu, Du, Guo, Pan, & Zhu, 2025)studied the decrease in the mechanical properties of BFRP bars embedding inside the SSC concrete after the exposure in seawater; the maritime environment diminishes dynamic tensile strength and failure strain, while exerting a negligible influence on the elastic modulus(Li et al., 2022) .
Therefore from the literature, it is evident that the FRP composite has been widely used for the beams in construction marine, so, the main goal of the current study is to investigate the structural strength, focusing on the ability to maintain mechanical properties, energy absorption capacities of the specimens and damage characteristics of GFRP composites reinforced with E glass, after exposed to accelerate environmental aging in seawater & distille water.

Fig. 1. GFRP bars(Hosen et al., 2017)

2. Experimental

2.1. Materials and preparations of composites
A standard unsaturated polyester resin and woven fiberglass (mats & toils) and gel cota resin; the materials was provided by local company. An Infusion molding method was used in the fabrication of the composites laminates.

The matrix material was prepared from the unsaturated polyester resin and the catalyst. The catalyst was added to the polyester and the batch was stirred before pour into a mold. Fiber glasses were arranged inside the mold. Four fiberglass's (mats) and four (toils) with nominal size 1m^2 used in each layer plus layer of gel cota, Composite maritime constructions have been protected by a terminal layer of gel coat that shields them from water. Then, the polyester matrix was pour onto the fiberglass in a mold.

The size of the mold was the 1 m^2. And was swept by the wax and covered with the steel frame for easy removal and good surface finishing of the laminates specimen. The specimen preparation process was shown in Fig. 2 Finally, the specimen was removed from the mold and cured for 24 hours at room temperature to ensure the specimen was hard and dry enough for the cutting process.

Fig. 2. Preparation of fiberglass reinforced polyester (Infusion molding).

2.2. Immersion process

The composite laminate samples were immersed in distilled water and seawaters solutions in sealed containers at laboratory conditions (23°C) for 2 month. During the environmental ageing process, the samples were taken out every week and weighed to analyses the weight change of the specimens, the absorption of the composites after different solutions immersion was determined by the weight gain relative to the oven dry weight. For the analysis of weight gain, 5 samples were weighed for each composite type.

2.3.Absorption testing

The absorption in weight percentage (W %) was calculated from Eq. below:

$$w(\%) = \frac{w_t - w_0}{w_t} \times 100 \quad (1)$$

where W_t and W_0 denotes weight of wet composite at time t and the weight of dry specimen, respectively , the process was shown in Fig .3**,** All the coupons were weighed dry and measured with±0.1 mm accuracy. And subdivided into 3 groups according the type of marine environments (dry, seawater, distille water)

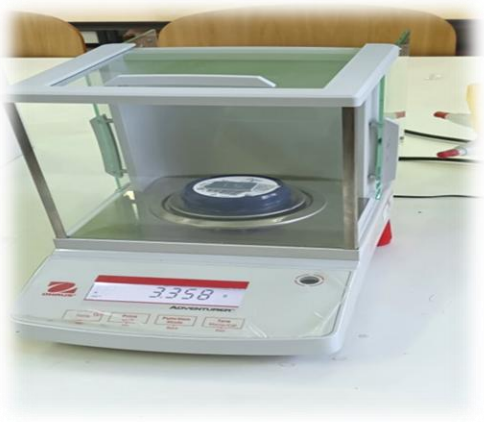

Fig. 3. Weight of specimens

2.4. Charpy testing

Fifths specimens of composite were fabricated for each condition marine, Standard ISO 179 Charpy notched specimens (ISO, 2010), 78 mm × 10 mm × 5,5 mm was cut from the composite plate and tested with energy 50 Joule , Utilizing a cutting machine, the specimens were meticulously cut and refined from the composite to the precise dimensions. The notches were created with a radius of curvature using a motorized notch Vis in the center, in accordance with the norm. The charpy impact tests were conducted by using a universal testing machine Zwick-Roell, the figure 4 shows the specimens before & after breaking.

Fig. 4. Specimen of charpy impact.

3. Result and Discussion

3.1.Absorption Properties

Fig. 5 illustrates the weight gain behavior of the composite as a function of immersion duration in two different aqueous environments: seawater and distilled water. The weight gain, expressed as a percentage, increases progressively with time for both media, indicating the absorption by this material. At initially, especially in the first 14 days, a fast uptake is seen, which might be ascribed to capillary action and surface diffusion into micro-voids and fiber-matrix interfaces. We also saw that salt water absorbed more slowly than distilled water.

These findings support earlier studies (Mansouri et al., 2019), which indicated that the glass/polyester lost less weight under saltwater exposure than under distilled water exposure. and this is due to the ratio of salts in both solutions and the overlap of salts in the voids, so the percentage of salt water absorbed decreases.Subsequently, the absorption rate then decreases and eventually reaches a plateau when balance is neared. However, the glass/polyester composite submerged in distilled water exhibits a little higher weight gain compared to seawater, especially after 35 days. The variation may be attributed to the lower ionic concentration in distilled water and the absence of large amounts of salts, which may enhance the diffusion gradient and make water faster .Conversely, the presence of salts in seawater probably causes osmotic effects and might lower the rate of water diffusion because of interactions with the composite matrix or partial pore blockage.

And these findings imply that the environmental medium greatly affects the moisture absorption properties of the composite, which can affect its mechanical propritie and durability performance under maritime service settings, (Mansouri et al., 2019) Noted that mixed short and woven fibre glass reinforced polyester composite exhibited quick moisture absorption at first, then 20 days stabilised thus Consequently, over prolonged peeriods of periods , the composites will stabilise or slightly decrease in distille water and saltwater.

Fig. 6 shows the weight gain (%) of the composite after 1 and 2 months of immersion in two different environments At 1 Month in Distilled water and seawater the composite show similar absorption (~0,65–0,7% weight gain) ,distilled water appears slightly higher, but within error margins — so the difference might not be statistically significant. and At 2 Months Both groups show a decrease in weight gain compared to 1 month ,so the samples in Distilled-water retain slightly more weight gain (~0,45–0,5%) compared to Seawater (~0,4%). In the initial phases, water ions rapidly penetrate the polyester matrix, filling micro-voids by diffusion-driven mechanisms, Subsequent to the initial saturation; the material may experience structural relaxation. Certain tiny molecules such as those from polyester may be leached out into the solution, resulting in a net weight loss that counteracts additional water absorption.

The polymer chains may reorganize, reducing the free volume and impeding more water absorption our Salts in seawater can reduce the chemical potential of water molecules, slowing their diffusion into the composite, Furthermore, salt ions might create a surface barrier restricting water entrance—a process known as salting-out effect.

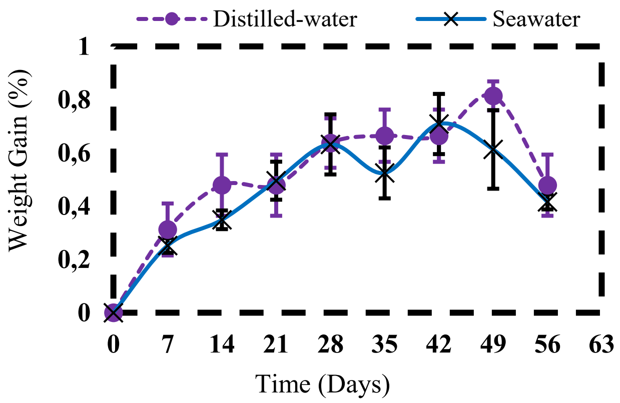

Fig. 5. Weight gain as a function of duration of immersion per day of composite

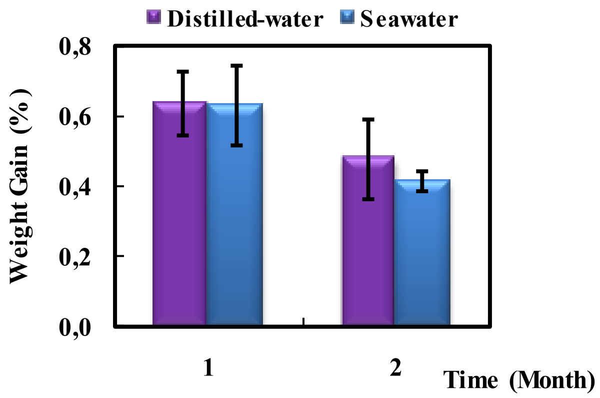

Fig. 6. Weight gain of glass/polyester composite after 1& 2 months of immersion in environments

3.2 Charpy Properties

Fig. 7 shows first State of the Both samples before immersion have a great ability for energy absorption, 195,89 (kJ/m2), this is the baseline impact strength of the virgin composite material. After one month immertion in solutions, there is a notable reduction in the energy absorbed by the glass/polyester composite in both settings; in distille water the value decreases to around 156,54 (kJ/m2), and in seawater the value decreases little to around 150,78 (kJ/m2), this signifies a decrease of around 18-23% from the original value, reflecting a deterioration in toughness or impact resistance during one month of immersion.the decline is slightly more pronounced in the marine environment.

The main cause of the notable decline in impact energy after one month is the negative consequences of water in polyester Matrix Plasticization; the sea and distille waters serve as plasticizers, thereby lowering energy absorption before fracture under impact. Two months later Curiously, the energy absorption capacity for both environments shows a little rise over the one month mark In distilled water, it recovers to around 168 (kJ/m2); in saltwater it recovers to about 162 (kJ/m2); Although there is some recovery, the numbers are still much lower by 13-16% than the first impact strength recorded at firste time.

The sample in distilled water exhibits somewhat greater re covery than the one in saltwater, the little rise in impact energy noted between 1 and 2 months is less common than the early deterioration but may occur under specific situations, such as Saturation Effect, Stress Relaxation/Redistribution, or Plasticization Dominance. Although interfacial weakening and hydrolysis diminish toughness, the plasticization effect may marginally enhance the material's ductility in some instances.

The persistent plasticization enables the compromised material to absorb slightly more energy prior to total failure compared to its condition after one month. This impact is often subordinate to the general deterioration or the experimental variability.

The data presented in Fig. 8 shows the comparative Impact strength of samples exposed to distilled water and seawater environments over 1 and 2 months. At 1 month, composite immersed in distilled water and seawater energy absorption are close, but the composite after distilled water aging is slightly higher and At 2 months, both composite show slightly increased of Impact strength compared to 1 month, with distilled water again a bit higher.When composites are submerged in water (either distilled or seawater), water molecules infiltrate the matrix via diffusion, therefore functioning as a plasticizer inside the polymer matrix.

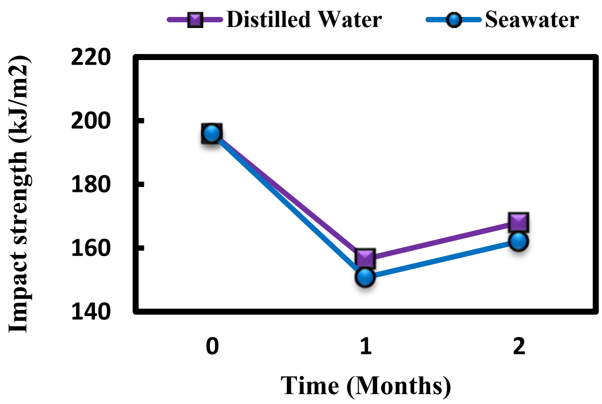

Fig. 7. The energy absorbed by Glass/polyester composite in each environment.

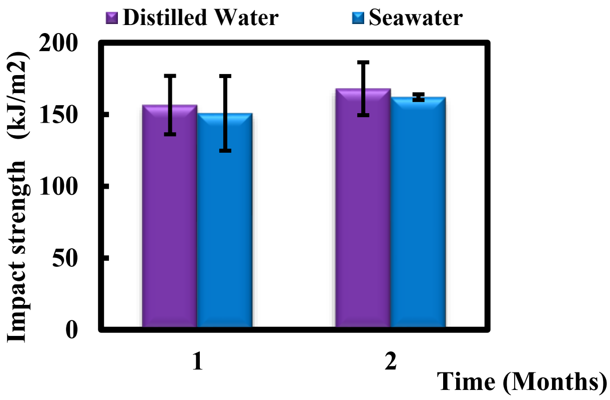

Fig. 8. The Impact strength of Glass/polyester composite in each environment.

This process lowers internal stresses and may temporarily augment impact strength by increasing the ductility of the matrix. Distilled water facilitates pure plasticization without the introduction of salts or ions, whereas saltwater contributes salt ions that can induce micro-cracks and expedite matrix breakdown.Due to the absence of salts, distilled water primarily causes plasticization without significant chemical degradation in the polyester.

Thus, a slight increase in toughness is observed and for the Seawater introduces additional factors like ionic attack and salt crystallization, which can initiate micro-cracks within the matrix of polyester. This reduces impact resistance compared to distilled water.Initially, water ingress improves the ductility. However, if the immersion continued much longer (beyond 2 months), we would expect a decline in impact strength due to long-term hydrolytic degradation.but clearly, the mechanical properties like tensile and flexural strength of aged glass/polyester composite specimens after every time fall in comparison to virgin specimens.

The variations in this mechanical feature, however, seem to lack any obvious pattern. Similar behavior was seen by (Fang et al., 2017; P. Feng, Wang, Wang, Loughery, & Niu, 2014)

3.3 SEM micrographs

Fig. 9 represent the micrograph on the surface befour the immersion, The morphology of the control glass/polyester composite specimen exhibits a robust adhesion between the fiber and the matrix.in Fig. 10 and Fig. 11 represent the SEM micrographs on the surfaces of polyester/glass composite after 4th months of sewater and distille water immersion. humidity aging is Widely recognized as a main cause of the long-term deterioration of an polymers matrix exposed to the environment or in contact with watery solutions like distille water our seawater, Seawater penetration to the surface of the composite coupons and absorption by the resin of polyester over the course of four months led to created voids in the polyester resin and produced a direct effect on mechanical properties. The mechanism of this effects needs deeper analysis and research.

However, in the context of distille water and the effect on the microscopic properties of composite materials, we observe almost the same effect as for seawater.Based on the morphology achieved, composite immersion in seawater and distille water faileds by :dilamination between the layape of composite,change in the surface of polyester matrix with crack propagations through the matrix , and debonding occurs between the fiber and matrix these modes of failure correspond rather well to the measured impact damage by (Fang et al., 2017), Clearly, moisture induces resin hydrolysis and debonding at the interface, which are the main deteriorating factors.

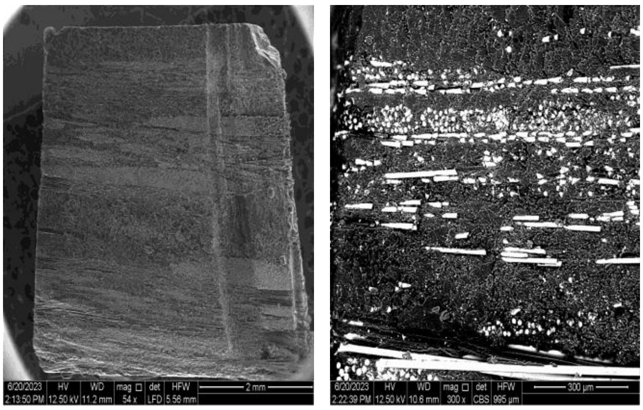

Fig.9. SEM micrograph of polyester/glass composite before immersion

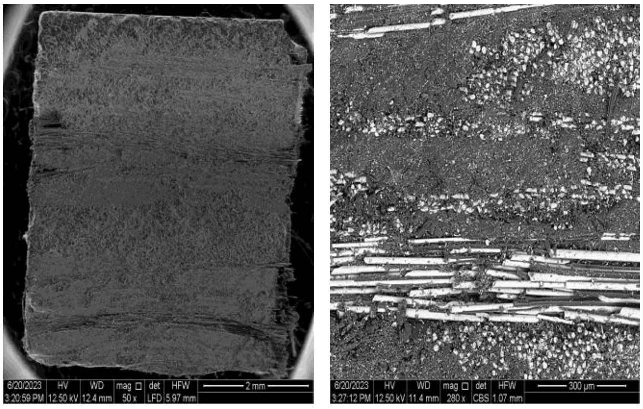

Fig.10. SEM micrograph of polyester/glass composite after 4 months of immersion in seawater

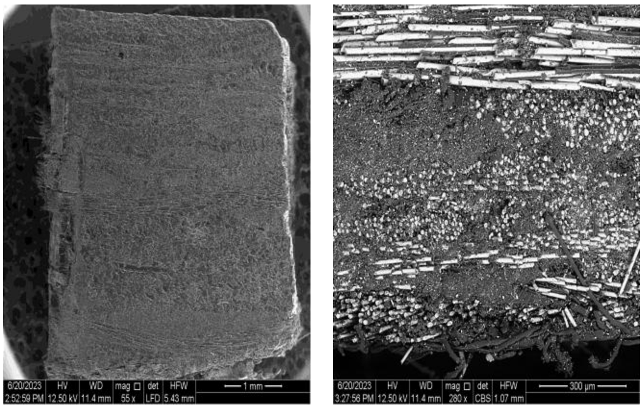

Fig.11**.** SEM micrograph of polyester/glass composite after 4 months of immersion in distille water

4.Conclusion

Current investigation focuses on the influence of seawater & distille water absorptions on glass fiber reinforcement polyester composites and effects of ageing process in impact strength and the absorbed energy values,the following inferences are drawn.

- The glass/polyester composites absorbed more moisture initially, which reduced after 2 months and Distilled water caused slightly higher moisture uptake than seawater.
- Short-term immersion (1–2 months) generally improves impact strength due to plasticization, and Distilled water effect is almoste same aggressive compared to seawater, leading to better preservation of impact properties.
- Almost the same between effects of distile water and seawater in The microscopic properties of glass/polyester surface
- The findings of the research indicate the importance of Change in salt ratio in environmental degradation of impact properties and energy absorption of composite materials in the marine environment, The main goal of this research remains the development of a reliable predictive numerical model of the charpy impacts behavior of glass/polyester materials exposed to real marine environment, which would represent a basic tool to assess the durability of composite marine structures during their exploitation.

FEM and X-FEM analyses of a reinforced concrete flat slab under sudden dynamic impact loading

Ibrahim N. Yahya*[1], Berat F. Soysal[2]

[1]Master student, Çankaya University, Department of Civil Engineering, Ankara, Türkiye
[2]Asst. Prof. Dr., Çankaya University, Department of Civil Engineering, Ankara, Türkiye

Abstract
Civil engineering structures are usually designed to withstand static and earthquake loads. However, the structural elements also need to resist dynamic impact loading as they could be affected by falling objects, causing shock loads. Slabs, in particular, play a vital role in buildings since they transfer loads to other structural elements. This study investigates the nonlinear behavior of a reinforced concrete flat slab under sudden dynamic impact loading. The slab was previously tested in a laboratory using a cylindrical drop hammer, and the experiment was also simulated numerically using the finite element method. In this study, the nonlinear behavior of the reinforced concrete flat slab subjected to impact loading was investigated using both the finite element method (FEM) and the extended finite element method (XFEM). To the best of the author's knowledge, there is no previous research on studying the effect of sudden impact loading on reinforced concrete flat slabs using X-FEM. To this end, a parametric study, together with a mesh sensitivity study, was conducted using both methods. The effect of material properties on the maximum displacement, and failure behavior of the slab was determined. The effect of finite element size was also investigated to address the reliability of numerical models. The FEM and X-FEM results were compared in terms of damage indices and failure modes.

Keywords: Impact Loading; Finite element method; Reinforced concrete flat slab; Extended finite element method

---

1. Introduction
Recently, there has been an increase in interest in designing reinforced concrete structures under the influence of various dynamic loads such as earthquake loads, explosions and shock loads. There has been an increased focus on the impact of shock load on reinforced concrete structures, especially the load resulting from accidental shocks, which can occur due to intentional or unintentional human errors which can lead to a disaster in the targeted structure. Reinforced concrete slabs represent an important part of concrete structures. They are the largest part directly exposed to dead, live and other load types, and one of their main functions is to transfer these loads to other structural elements. Although slabs are among the largest components of a concrete structure in terms of area, they generally have a relatively small thickness; thus, they are considered thinner concrete elements in comparison to columns and beams. Hence, these features make slabs vulnerable to flexural and shear loads, or both, if they are exposed to accidental impact loads directly. Many methods are used to study the effect of shock load on reinforced concrete slabs, some of which are impractical and others very expensive because they require laboratories equipped with multi-purpose measuring devices. The great development in the last three decades, especially in simulation software, has made numerical techniques play a significant role in studying the effect of dynamic loads on the elements of reinforced concrete structures. There has been great interest by researchers in conducting numerical studies of reinforced concrete slabs under the influence of impact loads, mainly using the finite element method, such as Zineddin (2002), Anil et al. (2015), Kumar et al. (2018) and Trivedi & Singh (2013). However, estimating the nonlinear behavior of reinforced concrete slabs under the effect of shock loads is challenging. This study utilizes numerical methods to predict the structural response of reinforced concrete slabs that were tested by Zineddin & Krauthhammer (2007) in a laboratory using a cylindrical drop hammer, when they are subjected to impact loads by using two different approaches; first of the two uses the dynamic/explicit finite element method (FEM) simulation to predict the behavior of the reinforced concrete slabs under the effect of impact load, and the second uses the dynamic/implicit extended finite element method (XFEM) to do the same mission.

2. Theoretical backround

This section discusses fundamental concepts related to impact loading that were adopted in this study. It includes the use of the Finite Element Method (FEM) and the Extended Finite Element Method (XFEM) to simulate reinforced concrete slabs under the effect of impact loads, as well as the Constitutive Model of Concrete.

2.1. Finite element method

Impact analysis on reinforced concrete slabs can be performed using a variety of numerical methodologies. The finite element method (FEM) is one of the most widely used numerical approaches for analyzing engineering problems. Its advancement has enabled the modeling and analysis of a wide range of problems across numerous engineering disciplines. In this study, the FEM program ABAQUS is used. The dynamic equilibrium equations are solved with the ABAQUS/Explicit Solver, which is computationally efficient for studying large models with dynamic responses, as well as for investigating highly discontinuous events or processes. Although the explicit integration rule is simple to solve, it does not provide the same computing efficiency as the implicit dynamics technique (ABAQUS, 2016). In this investigation, the FEM ABAQUS/Explicit code is used to simulate impact loading on reinforced concrete slabs. From the single degree of freedom system shown in Fig. 1, a fundamental dynamics equation can be established. The mass is m, the spring stiffness constant is k, and the damping is denoted by c_v.

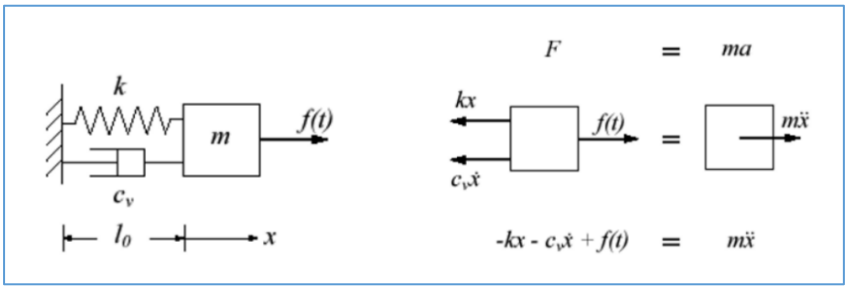

Fig. 1. Single degree of freedom system under dynamic loading (Rehman, 2017)

The equation of motion for this system can be described in Equation (1) by employing the equilibrium of forces and Newton's second law of motion:

$$m\ddot{x}(t) + c_v\dot{x}(t) + kx(t) = f(t) \tag{1}$$

The displacement is expressed as $x = x(t)$. The general governing equation for structural dynamics uses a three-dimensional example to illustrate the same concept. The governing equation for a three-dimensional problem can be derived using the following principle: for any virtual displacement (any small motion that meets the compatibility and essential boundary conditions), the external work done by the applied loads equals the work absorbed by inertial, dissipative, and internal forces. The work balance for an element with volume V and surface area S can be expressed as in Equation (2) (Rehman, 2017):

$$\int_V \delta u^T F dV + \int_V \delta u^T \Phi dS + \sum_{i=1}^{np} \delta u_i^T p_i = \int_V (\delta u^T \rho \ddot{u} + \delta u^T c\dot{u} + \delta\varepsilon^T \sigma)\, dV \tag{2}$$

where F and Φ refer to the surface traction and body forces, respectively, p_i and δu_i represent the concentrated forces and their virtual displacement at np number of points. ρ is the mass density and c is the damping parameter. $\delta\varepsilon$ represents the corresponding strains and δu represents the virtual displacement. This second order differential equation can be solved in ABAQUS using two different methods: the explicit and the implicit procedures. The impact phenomena includes massive deformations, nonlinear material response, and contact boundary conditions, making the implicit approach unattractive and expensive due to the costly inversion of the stiffness matrix, especially in large models, despite its accuracy in dynamic impact loading problem's solutions. However, identical events can be handled more successfully by the explicit technique, which uses the explicit central-difference time integration algorithm in addition to mass matrices with lumped parts. The explicit technique eliminates the requirement for iterations and inversion of tangent stiffness matrix (Rehman, 2017).

2.2. Extended finite element method

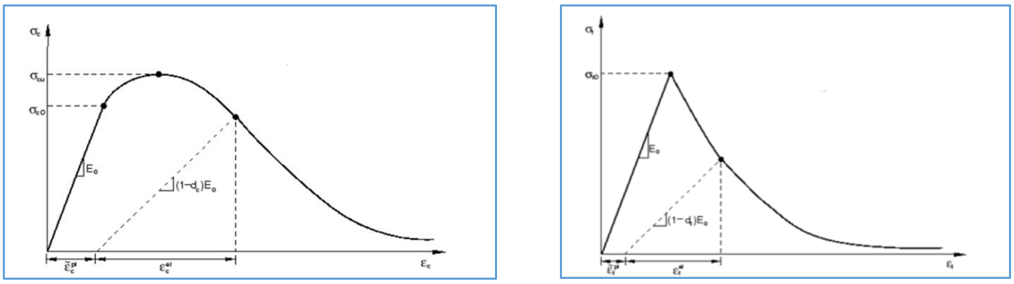
The extended finite element method (XFEM) is an expansion of the traditional finite element method that considers discontinuities like cracks as enriched features. It is based on the partition of unity notion. It enables the presence of discontinuities in an element by extending degrees of freedom using particular displacement functions. It does not need the mesh to match the geometry of the discontinuities. It is a very appealing and successful method for simulating the start and propagation of a discrete fracture along an arbitrary, solution-dependent route without the need for remeshing in bulk materials (ABAQUS, 2016). Belytschko et al. (2009) were the first to introduce the extended finite element approach. Based on Melenk & Babuska's (1996) idea of unit partitioning, it is an expansion of the traditional finite element method that makes it simple to include local enrichment functions in the finite element approximation (Belytschko et al., 2009). The extended finite element technique (XFEM) addresses the issues involved with meshing crack surfaces. The presence of discontinuities is ensured by unique enriched functions combined with additional degrees of freedom. However, the finite element framework and its features, such as sparsity and symmetry, are preserved. It allows for the interaction of contact between cracked element surfaces with a small-sliding formulation, facilitates the application of distributed pressure loads to those surfaces, provides outputs for certain surface variables on cracked elements, and incorporates both material and geometric nonlinearity. The XFEM is applicable to first-order stress/displacement solid continuum elements, first-order displacement/pore pressure solid continuum elements, and second-order stress/displacement tetrahedral elements (ABAQUS, 2016).

2.3. Concrete constitutive model

Reinforced concrete is recognized for its non-linear behavior, which originates from the non-linear stress-strain relationship of ordinary concrete. Concrete numerical modeling is classified into two categories: elasticity and plasticity-based models. Elasticity-based models assume that total stress varies with total strain or with loading or reloading stress histories. Plasticity theory was developed to explain the behavior of ductile materials such as metals. A conventional plasticity model has three basic conditions: a yield surface, a hardening rule, and a flow rule (Tahmasebinia, 2011). In ABAQUS software, three forms of cracking models exist to account for nonlinear behavior of concrete. Smeared Crack Concrete Model is the first of them. This technique is intended for use in circumstances where small confinement pressures cause concrete to undergo mostly monotonic strain. It has a distinct crack detection method in addition to an isotropic hardening yield surface. The second model is the Brittle Crack Concrete Model. Although concrete is quasi-brittle, it is frequently classified as brittle for simplicity. The brittle crack concrete model is a theoretical and computational framework for investigating concrete structures under stress, with a focus on fracture generation and propagation. The third model is Concrete Damage Plasticity Model, CDP. It is the most widely used and precise criterion for studying nonlinear behavior of concrete. This model assumes two basic failure mechanisms: tensile cracking and compressive crushing (ABAQUS, 2016). In this study, Concrete Damage Plasticity model is employed.

2.3.1 Concrete damage plasticity model (CDP)

The concrete damage plasticity material model (CDP) is a constitutive model that is based on both plasticity theory and damage mechanics theory. CDP is developed at the VTT Technical Research Center of Finland (Rehman, 2017). This material model is frequently used to solve geotechnical problems because it precisely describes the mechanical behavior of concrete (Rakić et al., 2021). Concrete damage plasticity (CDP) provides a fundamental technique to describe concrete in various kinds of structural elements, including slabs, beams, shells, and trusses. It is a continuum damage model for concrete that employs plasticity to represent the inelastic behavior of concrete. It use isotropic damaged elasticity alongside with isotropic tensile and compressive plasticity. It considers concrete failures in two ways: tension-based cracking and compression-based crushing. Although it can be used for plain concrete analysis, its major function is to analyze reinforced concrete structures. When modeling concrete, it can be used to simulate dynamic, cyclic, and/or monotonic loads with low confining pressure (Esfahani et al., 2017). As shown in Fig. 2(a), under uniaxial compression, the material is linearly elastic until it hits the initial yielding point, σ_{c0}. After then, the material undergoes strain hardening until it reaches its ultimate limit σ_{cu}, where strain softening occurs. The damage variable, d_c, is a function of plastic stresses and includes the deterioration of the material's stiffness in the stress softening zone. If the material is unloaded in the stress softening zone, the unloading slope decreases as it exceeds the maximum stress since the damage variable d_c rises up from zero (undamaged material) to a maximum value of one (fully damaged material). ε_c^{el} and $\tilde{\varepsilon}_c^{pl}$ represent equivalent elastic and plastic strain in compression, respectively. In uniaxial tension (Fig. 2b), the stress-strain relationship is linear elastic until it reaches the maximum stress σ_{t0}. This failure stress indicates the beginning of cracking in the material. After this point, the material softens, resulting in the production of microcracks. The damage variable, d_t, represents deterioration in tensile stiffness. ε_t^{el} and $\tilde{\varepsilon}_t^{pl}$ are elastic and equivalent plastic strains in tension, respectively (ABAQUS, 2016).



(a) (b)

Fig. 2. Concrete Response in uniaxial loading in compression (a) and tension (b) (ABAQUS, 2016)

The CDP model is defined in ABAQUS by specifying three material parameters and characterizing the inelastic compressive and tensile behavior as a collection of point pairs. Inelastic compressive behavior is characterized by a stress-strain pair of points. However, tensile behavior can also be characterized as a stress-fracture energy or stress-cracking displacement relationship in the form of point data. These parameters are presented briefly in the next section.

2.3.1.1 Concrete damage plasticity parameters

A set of required parameters are specified in order to use the Concrete Damage Plasticity (CDP) Model in ABAQUS. The CDP parameters include three main parameters. First of them are plasticity flow parameters which include: dilation angle, eccentricity, ratio of initial equi-biaxial compressive yield stress to initial uni-axial compressive yield stress and ratio of the second stress invariant on the tensile meridian. Compressive behavior parameters include compressive yield stress, compressive inelastic strain, and compressive damage parameter. Tensile behavior parameters are tensile yield stress, tensile cracking strain, and tensile damage parameter (ABAQUS, 2016).

Plasticity flow parameters are typically determined and calibrated experimentally. The dilation angle, ψ, is defined as the ratio of volume strain to shear strain. The dilation angle for concrete is typically 20 to 40 (Esfahani et al., 2017) or 30 to 40 (Sledziewski, 2017), affecting its ductility. It has been determined that the ideal dilation angle for characterizing concrete behavior in both compression and tension situations is ψ = 31° (ABAQUS, 2016). The eccentricity parameter, ε, is defined as the ratio of tensile strength to compressive strength. The recommended value for the CDP model is ε = 0.1 (Sledziewski, 2017). fb_0/fc_0 parameter is the initial equi-biaxial compressive yield stress, fb_0, divided by the initial uniaxial compressive yield stress, fc_0. The default value equals 1.16 (ABAQUS, 2016). K_c is the ratio of the second stress invariant on the tensile meridian. This parameter is generally set between 0.667 and 1, with some academics suggesting a maximum value of 0.8. The default value in ABAQUS is 0.667 (ABAQUS, 2016). In ABAQUS/Standard and Explicit analyses, the viscosity parameter is employed to regularize the concrete constitutive equations using visco-plasticity. This parameter is ignored in ABAQUS/Explicit. Hence, the default value is zero (ABAQUS, 2016). The inelastic hardening strain in compression is calculated as follows (Equation 3):

$$\varepsilon_{ic} = \varepsilon_c - \frac{\sigma_c}{E_c} \tag{3}$$

where ε_{ic} is inelastic concrete compressive strain, ε_c is nominal concrete compressive strain, σ_c is nominal concrete compressive strength, and E_c is the elasticity modulus of concrete.

The cracking strain is expressed by Equation (4).

$$\varepsilon_{it} = \varepsilon_t - \frac{\sigma_t}{E_c} \tag{4}$$

where ε_{it} is concrete cracking strain, ε_t is nominal concrete tensile strain, σ_t is nominal concrete tensile strength, and E_c is the elasticity modulus of concrete.

The unloading curve slope in the compressive region (Fig. 1a) is determined by the inelastic hardening strain during compression (d_c) (Esfahani et al., 2017). The compressive damage parameter is expressed by the following equation (Equation 5):

$$d_c = 1 - \frac{\sigma_c}{f_c'} \tag{5}$$

where d_c is compressive damage parameter, σ_c is nominal concrete compressive strength, and f_c' is compressive strength of concrete.

The tensile damage parameter (d_t) is expressed by Equation (6):

$$d_t = 1 - \frac{\sigma_t}{f_t} \tag{6}$$

where d_t is tensile damage parameter, σ_t is nominal concrete tensile strength and f_t is concrete tensile strength.

Table 1 shows computed concrete damaged plasticity parameters of the concrete material of compressive strength equals to 35 MPa.

Table 1. CDP Parameters for concrete with 35 MPa compressive strength

3. Nonlinear behavior of reinforced concrete slab under impact loading

This section presents the numerical investigation of the nonlinear behavior of reinforced concrete slabs under the effect of impact loadings. The experimental study conducted by Zineddin & Krauthammer (2007) was simulated using both the FEM-Explicit and XFEM-Implicit codes available in ABAQUS software. The simulation results were compared to the experimental results by means of the displacement of the midpoint of the slab bottom, as well as identifying the failure modes.

3.1 Reinforced concrete slab and impact system description

Zineddin & Krauthammer (2007) used a drop hammer with a weight of 2608kg and a diameter of 250mm to strike RC slabs measuring 3.353m by 1.524m and 90mm thick. The hammer was dropped at predetermined heights of 152mm, 305mm, and 610mm in the center of the slab. Reinforcing bars with a diameter of 10mm were placed 152mm apart throughout both spans. The position of the reinforcement mesh within the slab varied. In the experiment, three slabs were reinforced with two steel meshes located 25mm from both faces, whereas the remaining three had a single steel mesh located in the slab center, 45mm from both faces. Fig. 3 depicts the slab's reinforcing system.

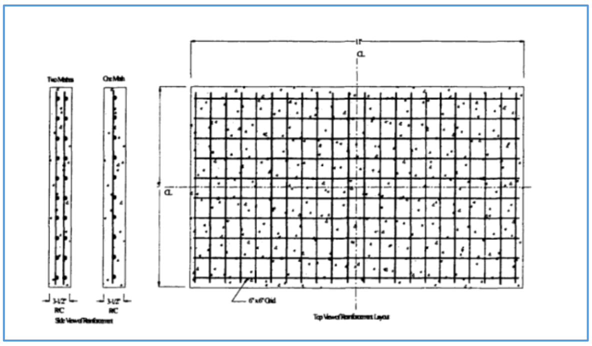

Fig. 3. Reinforcement Arrangement (Zineddin, 2002)

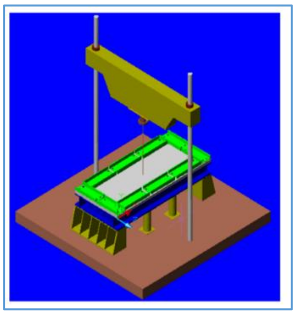
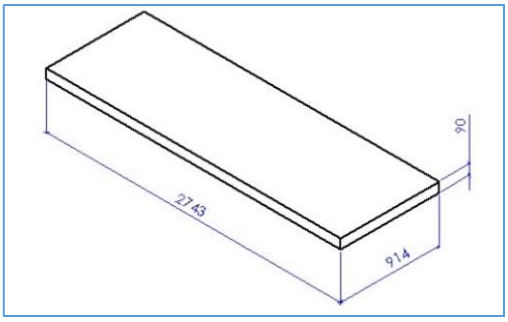
Zineddin & Krauthammer (2007) mentioned that the slab support can best be described as somewhere between simple and fixed support. The slab was connected on all four sides with two rows of 25 mm bolts through steel channels and a strong test frame supported by steel stands as shown in Fig. 4(a). Therefore, the unsupported slab area measured 914 x 2,743mm (**Hata! Başvuru kaynağı bulunamadı.**b).



(a)



(b)

Fig. 4. (a) Experimental impact systems (Zineddin & Krauthammer 2007), (b) the unsupported slab area

3.2 Numerical impact loading setup in ABAQUS

The numerical impact loading system consists of three main components. First, a 3D deformable extruded solid is created to represent the concrete slab, which has dimensions of 2743 mm x 914 mm x 90 mm. Second, two reinforcing steel meshes, each with a square pattern of 152 mm x 152 mm, are included. These meshes contain both long and short reinforcing steel elements with a diameter of 10 mm, and each mesh is positioned beneath a concrete cover of 25 mm on both sides of the slab. The steel reinforcement elements are modeled in ABAQUS as 3D deformable wire structures. Finally, a rigid hemispherical shell with a diameter of 250 mm is used to simulate the falling body, positioned at the midpoint of the slab. **Hata! Başvuru kaynağı bulunamadı.** shows the assembled impact loading system.

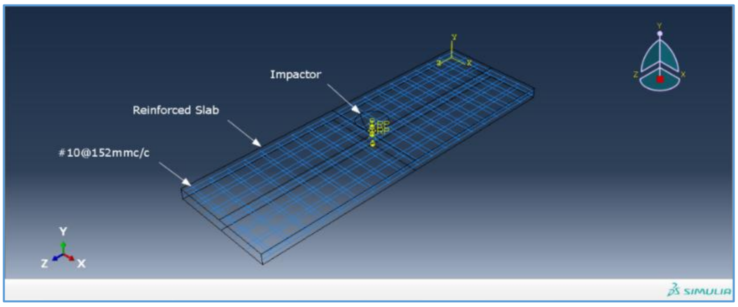


Fig. 5. Numerical impact loading setup

The elastic material properties of concrete and steel employed in the experimental investigation of Zineddin & Krauthammer (2007), as cited by Trivedi & Singh (2013), are as follows: concrete Poisson's ratio (v) equals to 0.17, concrete density equals to 2400 kg/m³, concrete cracking strain equals to 0.002, steel Poisson's ratio (v) equals to 0.33, steel density equals to 7850 kg/m³, steel modulus of elasticity equals to 200 GPa and steel yield strength equals to 500 MPa. As will be explained later, the concrete compressive strength was assumed as 35, 45, 55, and 65MPa. Accordingly, the elasticity modulus and tensile strength were calculated based on the assumed concrete compressive strength using the relationships per ACI318M-14 building design code. Accordingly, the parameters in the CDP model were modified based on the assumed concrete compressive strength.

The slab is assumed to be a fixed supported slab, as can be seen in **Hata! Başvuru kaynağı bulunamadı.**. The impactor considered striking the slab vertically at the slab's upper mid-point as a free-falling body of 2608 kg from a vertical distance of 152mm.

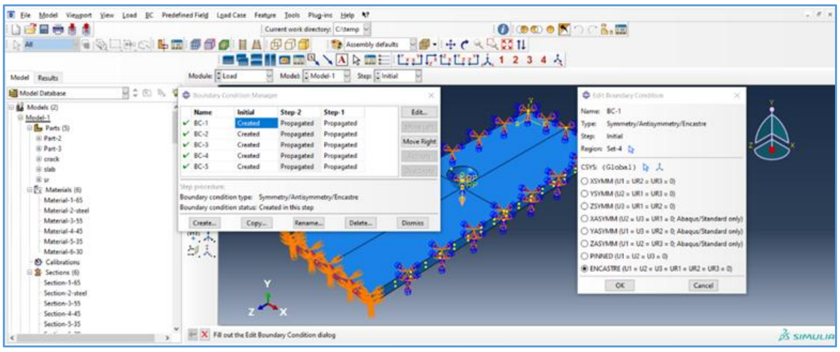

Fig. 6. Fixed supported RC slab

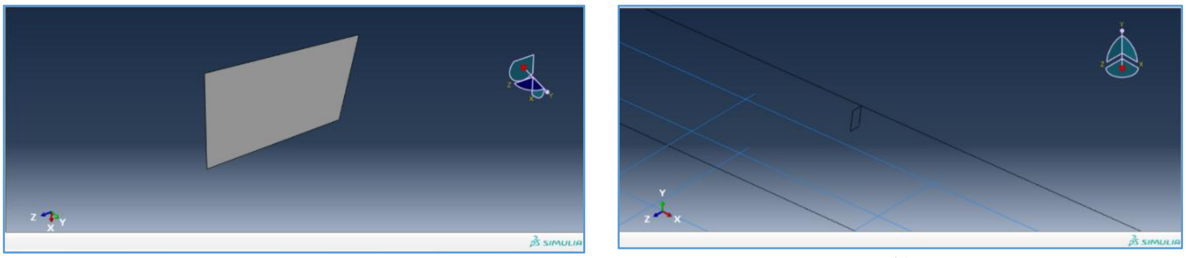
The interaction between the embedded reinforcement and the concrete slab is defined using embedded region constraint property available in ABAQUS. This characteristic enables the steel mesh to behave as reinforcement for the concrete slab. The slab element type is defined as an 8-node linear brick, reduced integration with hourglass control C3D8R available in ABAQUS element library. Steel reinforcement is specified as T3D2, a 2-node linear 3-D truss element type employed for defining rebar. For the rigid impactor, the element type is R3D4, which is a 4-node 3-D bilinear rigid quadrilateral.

To simulate the reinforced concrete slab under the effect of impact loading using the XFEM, the dynamic/implicit code, which is available in ABAQUS/STANDARD, has been used. The same reinforced concrete slab that was used in the FEM-Dynamic/Explicit simulation is utilized. The Dynamic/Implicit-XFEM simulation was implemented by creating an extruded deformable shell part with dimension of 50x25mm, as shown in **Hata! Başvuru kaynağı bulunamadı.**(a)**Hata! Başvuru kaynağı bulunamadı.** below. This part represents the crack that will propagate through the targeted reinforced concrete slab. The crack is embedded in the upper concrete cover of the reinforced concrete slab near the support, as shown in Fig. 7(b).



(a) (b)

Fig. 7. (a) Crack model, (b) Crack location inside the slab

After identifying the cracks, parametric and mesh sensitivity studies utilizing XFEM were conducted, similar to the parametric and mesh sensitivity studies of FEM. The displacement results obtained from these studies were compared with both the experimental data and the FEM results.

3.3 Parametric and mesh sensitivity studies using fEM

The concrete compressive strength used in the experimental study of Zineddin & Krauthammer (2007) was not known because they could not accurately determine the compressive strength of the concrete. However, they mentioned that it was either 28MPa or 41MPa. In contrast, the value of compressive strength adopted by Trivedi & Singh (2013) was 37.5MPa. Due to the range of reported compressive strengths, a parametric study has been conducted, assuming concrete compressive strengths of 35, 45, 55, and 65MPa. Accordingly, the elasticity modulus, tensile strengths and the parameters in the CDP model were modified based on the assumed concrete compressive strength.

As is well known in the finite element analysis approach, the mesh sizes play a vital role in the simulation results. Therefore, a mesh sensitivity study was also conducted to study the influence of changes in mesh sizes on the displacement values. To this end, three different models with mesh sizes of 15x15x15mm, 18x18x18mm and 22.5x22.5x22.5mm were created. For each model, concrete compressive strengths varied from 35MPa to 65MPa, as mentioned above. Hence, in total, 12 nonlinear dynamic simulations were conducted. All simulations were run up to 30 milliseconds, which is the impact test time period adopted by Zineddin (2002) in his numerical study.

The results of the slab displacement at the center are shown in Table 2. The table also includes the relative percent difference ($\frac{Disp_{Exp}-Disp_{FEM}}{Disp_{Exp}} \times 100$) compared to the experimental value of 42 mm. Therefore, the negative values in the table indicate that the displacements are overestimated, and vice versa. It is noted from the table that the displacement values ranged from 41.6 mm to 42.5 mm, indicating that FEM simulations estimated the results within 1% of the experimental results. The displacement results obtained using concrete with a compressive strength of 45MPa were closer to the experimental displacement results than those obtained using concrete with compressive strengths of 35,55 and 65MPa. The relative difference across the mesh sizes was low. For the coarsest mesh, the displacements were overestimated, and with the decrease in the element size, displacements were estimated closer to the experimental value. Therefore, it can be deduced that the chosen mesh sizes are appropriate for simulation and the results are not dependent on the element size. It can be concluded from the parametric and mesh sensitivity studies that the FEM simulations can be used for obtaining the displacement values, as they estimated the values within -0.24 to 0.71% of the experimental results for $f_c' = 45\ MPa$.

Table 2. Displacement results of parametric and mesh sensitivity studies of FEM simulations

Concrete f_c'*	Mesh Size (mm)	Displacement (mm)	Relative Difference (%)
	15x15x15	41.6	0.95
$f_c' = 35\ MPa$	18x18x18	41.8	0.48
	22.5x22.5x22.5	42.3	-0.71
	15x15x15	41.7	0.71
$f_c' = 45\ MPa$	18x18x18	41.8	0.48
	22.5x22.5x22.5	42.1	-0.24
	15x15x15	41.8	0.48
$f_c' = 55\ MPa$	18x18x18	41.7	0.71
	22.5x22.5x22.5	42.3	-0.71
	15x15x15	41.8	0.48
$f_c' = 65\ MPa$	18x18x18	41.9	0.24
	22.5x22.5x22.5	42.5	-1.19

*f_c': Concrete Compressive Strength

Fig. 8 shows the maximum displacement time histories resulting from the impact test of the slab with a compressive strength of 45MPa for the three mesh sizes. It clearly shows how varying mesh sizes affect displacement results. The displacement time history curves of the slab with all three mesh sizes are almost the same until 30 milliseconds, which represents the maximum time period of the impact test adopted by Zineddin (2002). After this time, it is clear that the displacements increased with time for all mesh sizes, until the displacement curve remained constant over a certain time. For example, for the slab with a mesh size of 22.5x22.5x22.5 mm, the displacement curve began to remain constant at 0.3 second, but the displacement curves began to remain constant at 0.34 and 0.4 seconds for the slabs with mesh sizes of 18x18x18 and 15x15x15 mm, respectively.

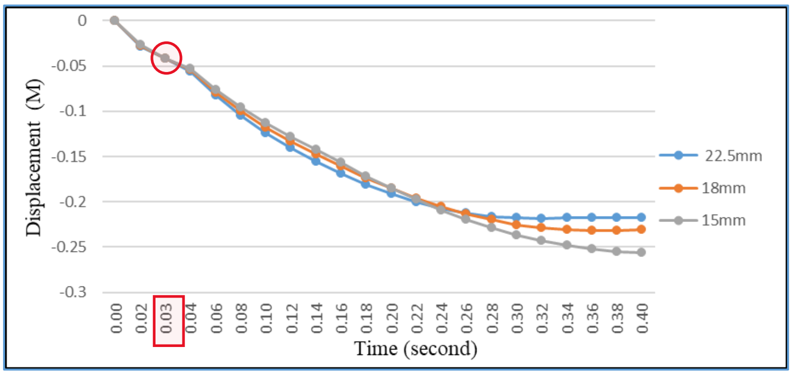


Fig. 8. Maximum displacement time history of the slab with fc'= 45MPa

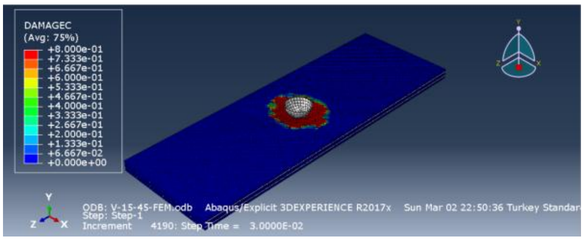
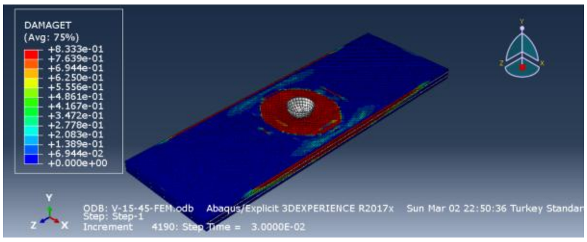
Hata! Başvuru kaynağı bulunamadı.(a) and (b) represent the compression and tension damage, respectively, resulted from the impact loading to the RC slab with a 15mm element size and a compressive strength of 45 MPa. Accordingly, localized compression damage was observed at the center of the slab (**Hata! Başvuru kaynağı bulunamadı.**a). In contrast, damage in tension was distributed, with additional damage observed at the supports (**Hata! Başvuru kaynağı bulunamadı.**b).



(a) Compression damage



(b) Tension damage

Fig. 9. Compression and tension damage of the RC slab

The punching shear failure mode, resulting from the numerical impact loading simulation of the slab with a 15 mm mesh size and a compressive strength of 45 MPa, is illustrated in **Hata! Başvuru kaynağı bulunamadı.**(b). **Hata! Başvuru kaynağı bulunamadı.**(c) presents the results for the 22.5 mm mesh size. When these are compared to **Hata! Başvuru kaynağı bulunamadı.**(a), which shows the punching failure of the reinforced concrete slab from the experiment conducted by Zineddin & Krauthammer (2007), similarities can be observed in the punching shear failure across these scenarios. Notably, it appears that a smaller mesh size in the reinforced concrete slab leads to a closer resemblance in the shape of the punching failure. Additionally, scabbing of the reinforced concrete slab is evident in **Hata! Başvuru kaynağı bulunamadı.**(b) and 10(c). **Hata! Başvuru kaynağı bulunamadı.**(d) highlights that steel yielding occurred in the impact zone beneath the center of the reinforced concrete slab. This steel yielding shows similarities when compared to the experimental results depicted in Fig. 10(a). Thus, it can be concluded that the finite element method (FEM) simulation effectively captured the punching shear failure mode, scabbing, and steel yielding of the reinforced concrete slab.

(d) Steel yielding, 15mm mesh size

Fig. 10. Experimental result, punching, scabbing and steel yielding failure mode

3.4 Parametric and mesh sensitivity studies using XFEM

For parametric and mesh sensitivity studies using XFEM, three different mesh sizes were employed for the reinforced concrete slab: 15x15x15mm, 18x18x18mm and 22.5x22.5x22.5mm. The compressive strengths of the concrete were assumed to be 35,45,55 and 65 MPa, for the parametric simulations. In total, 12 nonlinear dynamic simulations were carried out, and the displacement results were compared with the experimental displacement result, which was equal to 42mm, to validate the effectiveness of XFEM for the impact simulation (Table 3). Additionally, the XFEM results were compared to the FEM results in the same table. The relative percent differences with respect to the experiment and FEM were computed with $\frac{Disp_{Exp}-Disp_{XFEM}}{Disp_{Exp}} \times 100$ and $\frac{Disp_{FEM}-Disp_{XFEM}}{Disp_{FEM}} \times 100$, respectively. Hence, the negative values in the table indicate that the displacements are overestimated, and vice versa.

The data presented in the table shows that displacement values ranged from 41.3 mm to 43 mm. This indicates that the XFEM simulations estimated results within a range of 1.67% to -2.38% compared to the experimental results. In alignment with the FEM solution, the displacement results from concrete with a compressive strength of 45 MPa were closer to the experimental values than those derived from concrete with compressive strengths of 35, 55, and 65 MPa. In this case, for the finest mesh, the relative difference compared to the experiment was only 0.24%. In general, as the element size decreased, the estimated displacements were more aligned with the experimental observation. Coarse meshes tended to overestimate the displacements, while finer meshes provided estimates much closer to the experimental result. Overall, the XFEM results were conservative, showing higher displacements than those obtained through FEM, with a greater deviation in XFEM compared to FEM. Nonetheless, the parametric and mesh sensitivity studies indicate that XFEM effectively simulated the experimental results, particularly for concrete with a compressive strength of 45 MPa.

Table 3. Displacement results of parametric and mesh sensitivity studies of XFEM simulations

Concrete f_c'*	Mesh Size (mm)	Displacement (mm)	Relative Difference (%)	Relative Difference Wrt FEM(%)
$f_c' = 35\ MPa$	15x15x15	41.3	1.67	0.72
	18x18x18	41.7	0.71	0.24
	22.5x22.5x22.5	42.9	-2.14	-1.42
$f_c' = 45\ MPa$	15x15x15	41.9	0.24	-0.48
	18x18x18	42.3	-0.71	-1.20
	22.5x22.5x22.5	42.6	-1.43	-1.19
$f_c' = 55\ MPa$	15x15x15	42.6	-1.43	-1.91
	18x18x18	42.7	-1.67	-2.40
	22.5x22.5x22.5	42.7	-1.67	-.095
$f_c' = 65\ MPa$	15x15x15	42.8	-1.9	-2.39
	18x18x18	43	-2.38	-2.63
	22.5x22.5x22.5	42.8	-1.9	-0.71

Fig. 11 shows the maximum displacement time history resulting from the impact test of the slab with a compressive strength of 45 MPa. Similar to the FEM results, the impact of varying mesh sizes on the displacement results up to 30 miliseconds was minimal.

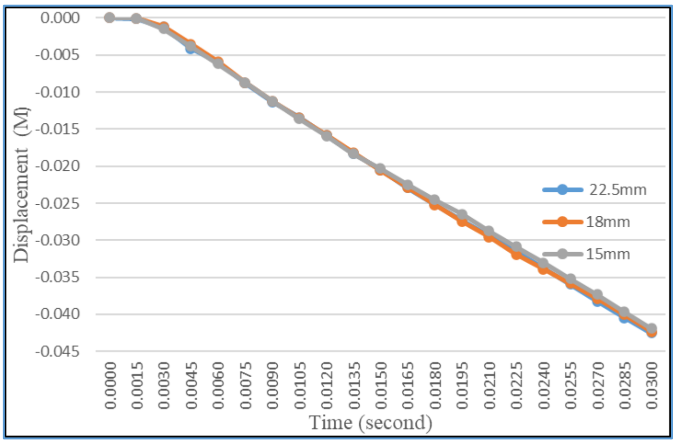

Fig. 11. Maximum displacement time history of a slab with fc'= 45MPa and a mesh size of 15x15x15mm

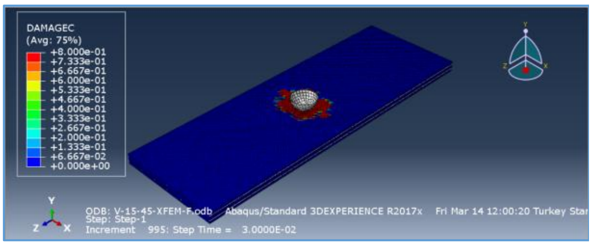
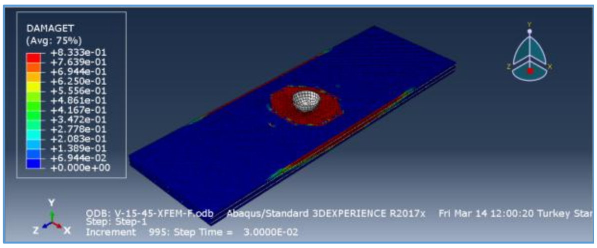
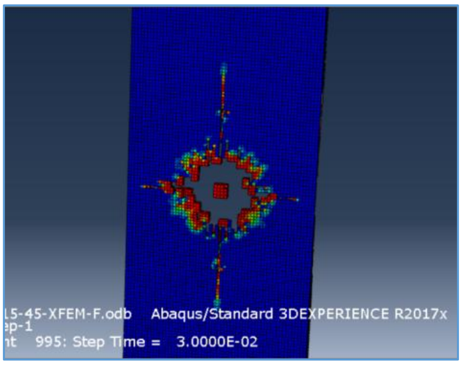
Fig. 12. Failure modes of XFEM simulation
shows the compression and tension damages, perforation and steel yielding modes resulted from conducting XFEM impact loading simulation on the reinforced concrete slab with a 15x15x15mm mesh size and a compressive strength of 45MPa.



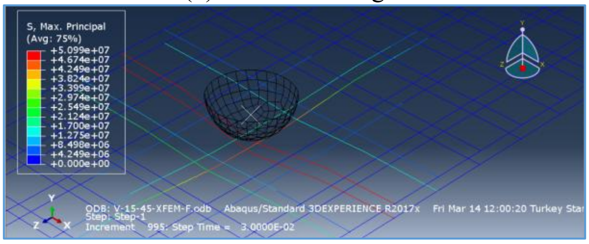
(a) Compression damage



(b) Tension damage



(c) Perforation failure mode



(d) Steel yielding mode

Fig. 12. Failure modes of XFEM simulation

Comparing Figs. 9(a) and 12(a), it is clear that there is no significant difference between the compression damage failure modes resulting from FEM and XFEM simulations. However, the comparison between **Hata! Başvuru kaynağı bulunamadı.**(b) and 12(b) reveal a noticeable difference in the tensile damage mode observed in the targeted area, as well as the damage at the supports. The XFEM results provided a more realistic depiction of the tensile damage mode; on the other hand, in the FEM simulation, the tensile damage was smeared. From Fig. 12. Failure modes of XFEM simulation
(c), it can be noticed that the perforation failure mode obtained by implementing dynamic implicit XFEM impact loading is somewhat similar to the perforation failure obtained by performing dynamic explicit FEM shown in Fig. 10(b), except for the slight difference in the scabbed concrete. The steel yielding modes were similar for FEM (**Hata! Başvuru kaynağı bulunamadı.**d) and XFEM simulations (Fig. 12. Failure modes of XFEM simulation
d).

5. Conclusion

The nonlinear behavior of reinforced concrete slabs under impact loading was investigated by modeling the reinforced concrete slab from the experimental study conducted by Zineddin & Krauthammer (2007) using ABAQUS/CAE 2017. Three different mesh sizes (15x15x15 mm, 18x18x18 mm, and 22.5x22.5x22.5 mm) and four different concrete compressive strengths of 35, 45, 55, and 65 MPa were employed to conduct mesh sensitivity and parametric studies, respectively. This was achieved using both the Dynamic/Explicit-FEM and Dynamic/Implicit-XFEM codes available in ABAQUS. The results were evaluated in terms of maximum displacement, compression, tension, perforation failure modes, and steel yielding.

The following conclusions were drawn from this study:

- The simulation results indicated that the Dynamic/Explicit FEM approximated the displacement obtained experimentally with an error of 0.71%. In contrast, the displacement value estimated using Dynamic/Implicit-XFEM showed an error of only 0.24%. Therefore, the XFEM solution provided results that were closer to the experimental measurements.
- The perforation failure mode and steel yielding modes were approximately similar for Dynamic/Explicit-FEM and the Dynamic/Implicit-XFEM. Furthermore, the deformation and punching failure modes of the reinforced concrete slab in both numerical methods were similar to the punching failure mode obtained

from the experimental study. The compression damage was identical in both FEM and XFEM. However, while the tensile damage was smeared in the FEM simulation, the XFEM result provided a more realistic representation of tensile damage.

- Close agreements were found in the failure modes when comparing the results of the two numerical studies with the experimental study. Additionally, the displacement results differed by less than 1% from the experimental observations, indicating a strong alignment between the numerical and experimental studies. When examining the tensile damage modes, the XFEM model demonstrated an advantage by producing less smeared tensile damage compared to the results from the FEM model.

Abstract. The civil industry is using many types of alternative Polymer materials in the manufacture of bulding structure.However,during application polyester are exposed to marine environments In various constructions used in rivers and lakes Which leads to a change in mechanical properties. Here, the mechanical properties of polyester in composite materials and the changes in distillid water absorption over time due to exposure to this environments were studied This exposure is simulated by diving under controlled laboratory conditions in ambient temperatures. The organization of this paper is as follows: Firstly, the phenomenon of water ageings and absorption ,this section discussed how the marine environment affects the polymers and the absorption phenomenon in composites, Secondly, the effect of water conditions on the mechanical properties of different types of polymers is discussed .Two types of resin, polyester and c-orthocryl, were exposed to water (distilled water) in this study. Specimens were immersed in this environment at room temperature for one month in order to perform an absorption test. Two polymers' absorption of water was recorded and contrasted.Although the polyester's weight gain from absorption was minimal, it differed from that of the other C-orthocryl The mechanical properties of the composites were reduced by the absorption of simulated water.Because of the notable differences in absorption between the polyester and C-orthocryl resins, it may not be feasible to use C-orthocryl as a replacement for polyester in the naval structure sector.

Keywords: distelled water; Absorption ; Composites ; civil structure ; Polymer.

1.Introduction

The utilisation of resin-based polymers in structural contexts has markedly increased owing to their lightweight characteristics, superior strength-to-weight ratios, and corrosion resistance. Thermosetting resins, including c-orthocryl and unsaturated polyester, are often utilised in the production of structural components throughout aerospace, marine, and civil engineering sectors. Nonetheless, a pivotal aspect influencing the long-term efficacy and resilience of these polymers is their interaction with moisture, namely through the absorption of distilled water in humid or submerged environments (Cabral-Fonseca, Correia, Rodrigues, & Branco, 2012; Cerbu, 2010; Fang et al., 2017; Heshmati, Haghani, & Al-Emrani, 2017; Mansouri, Djebbar, Khatir, & Abdel Wahab, 2019).

Water absorption in polymeric materials can result in plasticization, hydrolysis, and microcracking, eventually undermining mechanical and dimensional stability (Sarkar & Young, 2001). The degree and manner of water absorption are affected by the resin's chemical composition, crosslink density, and level of hydrophilicity (Ghasemi et al., 2012). Epoxy resins, recognised for their superior adhesive and mechanical qualities, can absorb greater moisture than polyester resins owing to the presence of polar hydroxyl and ether groups (Wang et al., 2006).

Several research have looked at how these resins absorb moisture. Though variations can happen during extended exposures or at higher temperatures, Kinloch et al. (1983) found that at early stages water diffusion into epoxy systems is usually Fickian. By contrast, while less hydrophilic, polyester resins show hydrolytic breakdown during long-term immersion, especially when not well cured (Djazeb et al., 2017).

Environmental durability is crucial in structural applications; hence, knowing the distilled water absorption behaviour of resin systems is vital for guaranteeing material dependability. This work compares the water

absorption properties of two commonly used resins—epoxy and polyester—when submerged in distilled water, examining the rate, saturation point, and consequent material deterioration.

2. Experimental

2.1. Materials and Preparations of composites

A standard unsaturated polyester and c-orthocryl resins; the materials was provided by local company. An Infusion molding method was used in the fabrication of the polymers laminates. The material was prepared from the unsaturated polyester resin and c-orthocryl resin. The catalyst was added to the polymer and the batch was stirred before pour into a mold with nominal size 1m^2 used . Then, the polymers matrix was pour onto the mold.the specimen was removed from the mold and cured for 24 hours at room temperature to ensure the specimen was hard and dry enough for the cutting process.

2.2. Immersion process

The polyester and c-orthocryl laminates samples were immersed in distilled water in sealed containers at tempirature 23°C for 1 month. During the environmental ageing process, the samples were taken out every week and weighed to analyses the weight change of the specimens, the absorption of the polyester and c-orthocryl after immersion was determined by the weight gain relative to the oven dry weight For the analysis of weight gain, 5 samples were weighed.

3. Result and discussion

Absorption Properties

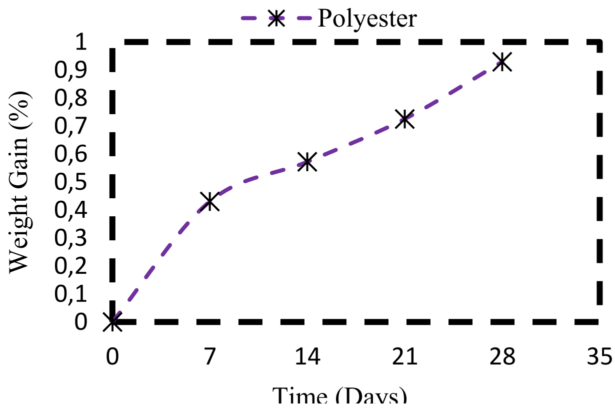

Fig. 1. Weight gain as a function of duration of immersion per day of polyester in distille water.

The graph illustrates the percentage of weight gain in polyester over a period of days, presumably attributable to moisture absorption or chemical interactions with its surroundings. From Day 0 to Day 7, there is an initial rapid uptake. Polyester, as a semi-crystalline polymer, may absorb a limited quantity of water or chemicals, particularly through its amorphous regions.The rapid increase initially indicates that the surface or near-surface absorption sites reach saturation swiftly.Hydrophobic polymers exhibit characteristic behaviour by absorbing a restricted quantity of moisture, predominantly during the initial phase.

From Day 7 to Day 28, there is a gradual long-term absorption.Following initial saturation, the diffusion process decelerates as deeper layers require more time to absorb moisture.The configuration of polyester, characterised by the dense arrangement of polymer chains and little polarity, inhibits extensive infiltration of water or chemicals.The plateauing effect is prevalent in diffusion-controlled systems. and Minimal Final Gain (~0.9%) This corresponds with polyester's established low moisture absorption.The gradual, persistent rise over time may suggest continuous, sluggish diffusion into less accessible areas or chemical interactions resulting in bound water formation.

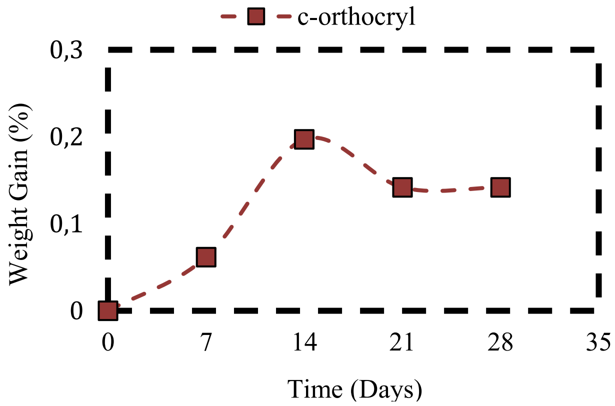

Fig. 2. Weight gain as a function of duration of immersion per day of c-orthocryl in distille water.

The graph depicts the weight gain percentage of a substance designated as "c-orthocryl" over a span of 35 days. During the first phase from Day 0 to Day 7, there is a marginal rise in weight gain, rising from roughly 0% to about 0.07%. This indicates that c-orthocryl commences moisture or substance absorption shortly after exposure, albeit at a gradual pace initially. Initial absorption may be superficial.

During this Mid Phase from Day 7 to Day 14 A more pronounced increase is noted, with weight gain reaching a maximum of around 0.2%. This phase presumably signifies the onset of the material's saturation curve, which begins to ascend rapidly as internal absorption commences. The diffusion into the material matrix may be most vigorous during this phase.

Stabilisation Phase from Day 14 to Day 35 Post Day 14, the curve stabilises, with weight increase maintaining a range of 0.13%–0.15%, indicating a quasi-equilibrium condition of the material. It no longer absorbs a substantial amount of moisture, perhaps due to having achieved its absorption capacity or the stabilisation of environmental variables, such as humidity.

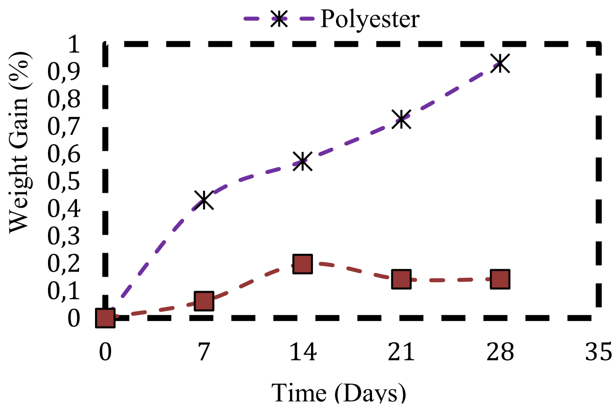

Fig. 3. Weight gain as a function of duration of immersion per day of c-orthocryl & polyester in distille water.

Starting at about 0.05% at Day 0, polyester shows a constant weight rise over time, rising quickly to about 0.4% by Day 7 and then steadily increasing to about 0.9% by Day 28. This implies polyester is reacting with the environment or absorbing moisture over time, therefore generating a noticeable weight increase.
C-orthocryl Starts low too, at ~0.05% at Day 0, Shows a little rise, peaking at about Day 14 with ~0.2% weight growth, Plateaus or slightly declines after that (~0.15% by Day 28), Suggests far less and more constrained contact with the surroundings than polyester.

The significant disparity in weight increase indicates that polyester possesses a greater propensity for absorbing the surrounding medium, possibly attributable to its hydrophilic functional groups (such as ester groups that may interact with water) or its amorphous areas that facilitate molecular diffusion.The alternative material is perhaps more hydrophobic or chemically resistant, maybe a polymer such as polypropylene or polyethylene, recognised for their little moisture absorption.

4. Conclusion

The current investigation focuses on the influence of distille water absorptions on glass polyester & c-orthocryl and effects of ageing process,the following inferences are drawn.

- Polyester shows significantly higher weight gain over time, indicating higher moisture absorption or chemical interaction.
- c-orthocryl material is more resistant, making it more suitable for applications where dimensional stability and moisture resistance are critical.
- Therefore, material choice should depend on the intended environmental exposure ,Use polyester where absorption or permeability is needed (e.g., filtration, controlled-release).
- Use c-orthocryl material (likely a hydrophobic polymer) where durability and moisture resistance are key (e.g., outdoor, packaging, electronics).

Abstract. Fiber-reinforced polymer (FRP) systems are widely used in modern structural engineering for strengthening and rehabilitating structures, owing to advantages such as high strength, low weight, corrosion resistance, and ease of application. However, the structural contribution of FRP systems—comprising various fiber types embedded in polymer matrices—can be significantly diminished when exposed to environmental conditions such as high temperature. In particular, as the polymer matrix approaches its glass transition temperature (T_g), structural integrity begins to deteriorate, leading to reduced load-carrying capacity. This study aims to evaluate the high-temperature performance of FRP systems and examine the influence of thermal effects on their structural contribution. A comprehensive experimental program was designed considering four key parameters: fiber type, number of wrapping layers, temperature level, and exposure duration. Wrapped and unwrapped standard cylindrical concrete specimens were subjected to designated thermal scenarios, followed by compressive strength testing. FRP system performance was assessed based on numerical data (surface temperature and compressive strength) and visual indicators (color changes, resin degradation, and failure modes). The findings show that FRP effectiveness depends not only on composite type and wrapping configuration but also on the level and duration of temperature exposure. As the epoxy matrix approached its T_g, reductions in bonding capacity were initiated, leading to weakened fiber–matrix interactions and a gradual shift in failure behavior with increasing temperature. These results emphasize the necessity of incorporating thermal considerations into the design process and supporting FRP systems with appropriate insulation strategies for reliable performance under high temperature.

Keywords: Concrete; Strengthening; FRP; High temperature; Glass transition

1. Introduction

Fiber-reinforced polymer (FRP) composites have become increasingly preferred materials in the field of civil engineering due to their advantages such as high strength-to-weight ratio, corrosion resistance, design flexibility, and rapid applicability. Particularly in applications such as the strengthening of reinforced concrete structural elements, enhancement of load-carrying capacity, improvement of seismic performance, and repair of damaged regions, FRP systems offer effective and economical solutions. Their lightweight nature, which prevents additional loading on the structural system, their ability to reduce labor time, and their ease of application to different geometries distinguish these systems among modern strengthening techniques. FRP reinforcements are applied by external wrapping or surface bonding to reinforced concrete elements, thereby increasing both the load-bearing capacity and ductility of the structural members.

Nevertheless, despite all these advantages, the sensitivity of FRP systems to high temperature is considered a significant drawback in terms of structural safety. Engineering structures are exposed not only to static and dynamic loads but also to various environmental and thermal effects. Structures may be subjected to different levels of thermal influence in scenarios such as fires, secondary fires following earthquakes, high-temperature accidents in industrial facilities, vehicle fires, or heat accumulation around heat-emitting equipment such as electrical panels, exhaust ducts, and generators. In such cases, the thermal sensitivity of FRP components can lead to a reduction in the load-carrying contribution of the system and cause unexpected performance losses in the strengthened structural elements.

In particular, as the resin matrix approaches its glass transition temperature (T_g), the material undergoes a phase change from a rigid–brittle state to a viscous–soft phase. This transformation weakens the fiber–matrix interaction and leads to a loss of adhesion between the FRP and the concrete surface. Such bond degradation can severely

* Corresponding author, E-mail: emrahan@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_041

limit the load-carrying function of the system and cause unexpected reductions in structural performance. The influence of temperature is not limited to the resin alone; the fiber reinforcements used in the system may also experience structural degradation, such as microscopic separation, embrittlement, oxidation, and reductions in mechanical capacity within specific temperature ranges.

These types of thermal degradation processes lead to the development of critical damage modes in FRP-strengthened structural members, such as delamination, fiber separation, bond failure, and brittle fracture. In particular, under fire scenarios that produce extreme temperatures, preserving structural integrity becomes highly challenging. Therefore, understanding the behavior of FRP systems under high temperature conditions is of great importance for ensuring their safe and durable use in load-bearing structural elements.

In the literature, the behavior of FRP-strengthened reinforced concrete elements under high temperatures is largely attributed to the thermomechanical degradation process that begins as the resin matrix approaches its T_g. Saafi (2002) defined this process in two stages: in the first stage, a significant reduction in stress transfer occurs due to resin softening around T_g; in the second stage, when the fibers reach their decomposition temperature, the load-bearing function is entirely lost. Firmo et al. (2015) reported that the T_g of resin matrices generally ranges between 50–120 °C and emphasized that mechanical degradation begins even before reaching Tg. Furthermore, it was noted that complete degradation of the resin matrix and loss of fiber–matrix interaction occur at temperatures above 300–400 °C. It has also been stated that at 500–700 °C, the load-bearing capacity provided by FRP materials is almost entirely lost. Bazli and Abolfazli (2020) indicated that the T_g typically ranges between 65–120 °C, and that complete thermal degradation (T_d) of the resin occurs between 300–500 °C, resulting in the breakdown of fiber–resin bonds and the near-total loss of structural contribution. The same study defined a critical temperature (T_c) as the temperature at which the FRP material loses 50% of its load-carrying capacity. This threshold was reported to be between 250–330 °C for carbon fiber-based FRP (CFRP) and between 300–350 °C for glass fiber-based FRP (GFRP). Overall, while GFRP systems demonstrated better thermal resistance than CFRP, the latter exhibited superior mechanical strength. Ahmed and Kodur (2011) observed that in uninsulated reinforced concrete beams, the bond between CFRP and concrete weakened at around $T_g \approx 82$ °C, and sudden increases in deflection were recorded beyond this point. Their findings revealed that exceeding T_g does not necessarily result in structural failure and that insulation efficiency is a determining factor in maintaining the performance of FRP. Al-Salloum et al. (2011) reported that such performance losses became more pronounced when T_g (≈88 °C) was exceeded and that CFRP-wrapped specimens were more sensitive to high-temperature effects compared to GFRP-wrapped ones. Gamage et al. (2005) experimentally showed that when epoxy temperatures exceeded 60 °C, there was a sharp decline in bond strength at the FRP–concrete interface and peel-off type failures occurred.

Cleary et al. (2003) reported that increasing temperature also leads to a shift in failure modes; while hoop-splitting mechanisms were predominant at lower temperatures, the failure behavior transformed into seam debonding at higher temperatures. The same study emphasized that T_g should not be considered as a singular failure threshold, noting that permanent bond deterioration and changes in failure modes began at temperatures approximately 30 °C above the matrix's T_g (121 °C). El-Gamal et al. (2015) evaluated the color changes observed in FRP layers as an indicator of thermal degradation, and sudden fiber rupture as a sign of embrittlement behavior in FRP systems. Li et al. (2017) demonstrated that with increasing temperature, both the FRP and adhesive materials exhibited gradual reductions in mechanical properties, accompanied by the formation of micro-cracks at the interface. Moreover, they found that fracture energy was more sensitive to changes in temperature than to the duration of exposure. Lau et al. (2016) stated that epoxy resins begin to soften between 65 °C and 150 °C, and undergo thermal decomposition at temperatures exceeding 400 °C. This degradation, driven by evaporation and dissociation mechanisms, resulted in the complete loss of the load-carrying capacity of the FRP systems. Maraveas et al. (2012) reported that especially for epoxy-based adhesives, bond strength decreased by an average of 40% in the 100–200 °C temperature range, and dropped below 20% above 200 °C. In terms of tensile strength, FRP materials were shown to suffer 60–80% strength losses between 200–400 °C, and almost complete loss of structural capacity above 400 °C. Elsanadedy et al. (2017) observed that even under exposures up to 300 °C, FRP reinforcement continued to enhance the axial load-carrying capacity of reinforced concrete columns. However, this benefit decreased significantly at approximately 345 °C, the decomposition temperature of the epoxy matrix. Green et al. (2006) stated that FRP systems rapidly reached T_g during fire tests, and in the absence of fire insulation, they ignited and became ineffective within minutes. Sobia et al. (2022) emphasized the critical role of insulation applications in maintaining the matrix temperature below T_g in CFRP-strengthened concrete members exposed to fire. They concluded that the duration for which insulation effectively prevents the matrix from exceeding T_g plays a key role in ensuring the residual performance of the system.

As evidenced by the detailed literature review, a wide range of studies have examined the thermal performance of FRP-strengthened concrete members, particularly focusing on the degradation of mechanical properties with increasing temperature and the critical role of the matrix's T_g. However, many of these investigations were limited in scope, either by isolating a narrow set of experimental parameters or by evaluating only specific material configurations under thermal exposure. In contrast, the present study aims to comprehensively assess the behavior of FRP systems under high temperatures by simultaneously considering multiple critical parameters—including fiber type, number of wrapping layers, temperature level, and exposure duration—within a single experimental framework. By integrating both quantitative and qualitative evaluation methods, this research provides a broader understanding of the load-bearing efficiency and failure characteristics of FRP-strengthened concrete elements exposed to high-temperature conditions. The findings are expected to contribute significantly to the development of more robust design strategies that ensure structural safety and long-term performance under thermal effects.

2. Material and methods

In this experimental study, a comprehensive dataset was developed by systematically considering four key parameters: composite fabric type (carbon and glass fiber), number of wrapping layers (1, 2, and 3 layers), temperature level (80 °C, 150 °C, and 250 °C), and exposure duration (90 and 180 minutes). The experimental program commenced with the casting of standard cylindrical concrete specimens (150 × 300 mm). Following curing, the specimens were grouped in accordance with the planned testing matrix (Figure 1). Specimens assigned to the strengthening group were externally wrapped with FRP composites based on predefined configurations of fabric type and number of layers.

Subsequently, to evaluate the extent to which FRP systems retained their functionality under high temperature exposure, the specimens were subjected sequentially to thermal exposure followed by compressive strength testing. The effects of the considered parameters on the performance of the FRP composites were assessed in an integrated manner. This evaluation was based on three primary sources of data: (1) surface temperature measurements conducted during the thermal exposure stage, (2) compressive strength values obtained from mechanical tests, and (3) visual inspections performed throughout both testing phases, including observations of color changes in the composite layers and the identification of fracture mechanisms.

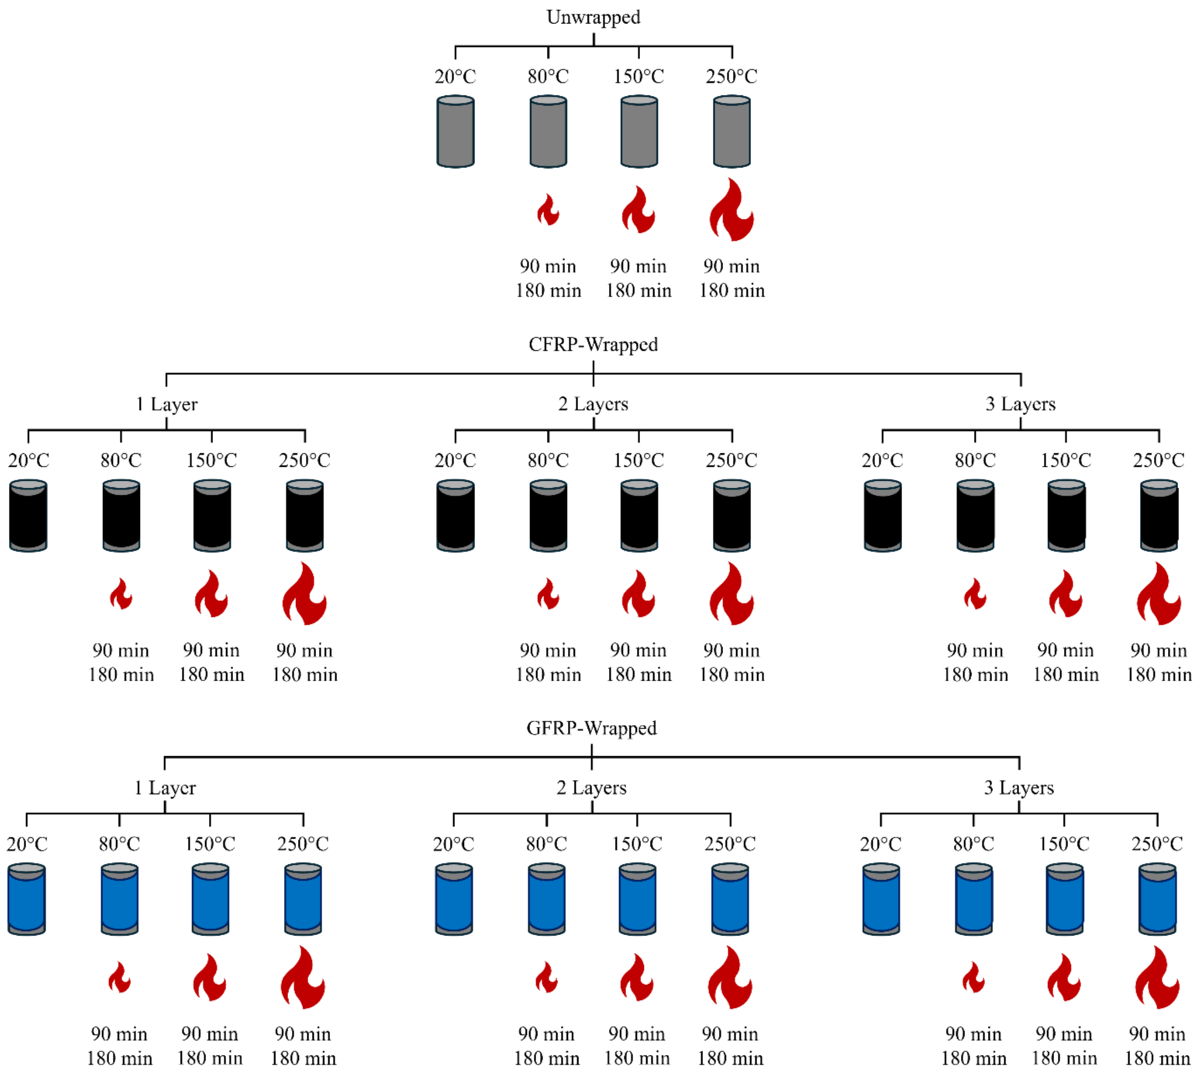

Fig. 1. Test matrix

2.1. Specimen preparation

As shown in Fig. 1, a total of 49 different cases were identified based on variations in the parameters considered within the scope of this study. To increase the reliability of the results and ensure more accurate evaluations through meaningful data, two specimens were prepared for each case, resulting in a total of 98 concrete specimens.

A concrete mixer with an effective mixing capacity of up to 45 liters was used during the production process. The mixed concrete was transferred to a wheelbarrow using shovels and then poured into plastic cylindrical molds placed on a vibrating table. The molds were filled in two stages: the first vibration was applied after filling the molds halfway, and the second vibration was applied once they were completely filled. The exposed top surfaces of the specimens were leveled using a trowel. After a 24-hour resting period, the specimens were demolded and placed in a curing tank. Following a 28-day curing period, they were removed from the tank. This production procedure was repeated 14 times to meet the required number of specimens (Fig. 2). Each concrete mix (for 45 liters) included 46.41 kg of coarse aggregate, 37.65 kg of fine aggregate, 15.75 kg of CEM I 42.5R cement, 7.09 kg of water, 0.4 kg of saturated surface dry water, and approximately 130 g of chemical admixture. The water-to-cement ratio was 0.45.

Fig. 2. Specimen production process

2.2. Strengthening applications

Following the completion of specimen production, preparations for the strengthening applications were initiated. FRP fabrics and epoxy-based adhesives were used for strengthening. Prior to application, both carbon and glass fiber fabrics were cut to appropriate dimensions to ensure a standard overlap length of 20 cm for each of the 1, 2, and 3-layer configurations. It was aimed to achieve an approximate balance between the weight of the fabric and the amount of epoxy adhesive used during wrapping. To this end, the weight of each cut fabric piece was measured using a high-precision electronic scale. The carbon fiber fabrics used in this study had a tensile modulus of 230 GPa, a tensile strength of 4900 MPa, and an elongation at break of 2.1%. For the glass fiber fabrics, these values were 65 GPa, 1300 MPa, and 2.5%, respectively. While the carbon fabrics were unidirectional, the glass fiber fabrics featured a bidirectional open-weave structure, commonly used with cementitious matrices to enhance the compressive strength and ductility of concrete and masonry elements (Trapko, 2013; Ameli et al., 2022).

The strengthening procedure began with the cleaning of the specimen surfaces to remove dust and other contaminants, followed by the application of a primer epoxy layer to the lateral surfaces where wrapping would occur. After a 24-hour waiting period, the wrapping process was carried out using the prepared FRP fabrics and an epoxy adhesive mixture. Both the primer and the adhesive mixture were prepared according to manufacturer specifications by mixing the components in a metal container with a mechanical mixer. The amount of adhesive used during wrapping was monitored by measuring the reduction in the epoxy's weight in the container. The epoxy adhesive used had a T_g of 71 °C, with flash points of its components at 93 °C and 110 °C. During CFRP applications, the amount of epoxy used for 1, 2, and 3 layers was 67.9 g, 104 g, and 140.8 g, respectively. For GFRP, the corresponding amounts were 60.4 g, 80.3 g, and 110.2 g. The specimens were then left to cure under laboratory conditions for 7 days to ensure complete hardening of the epoxy adhesive. Illustrative images of the strengthening process are presented in Fig. 3.

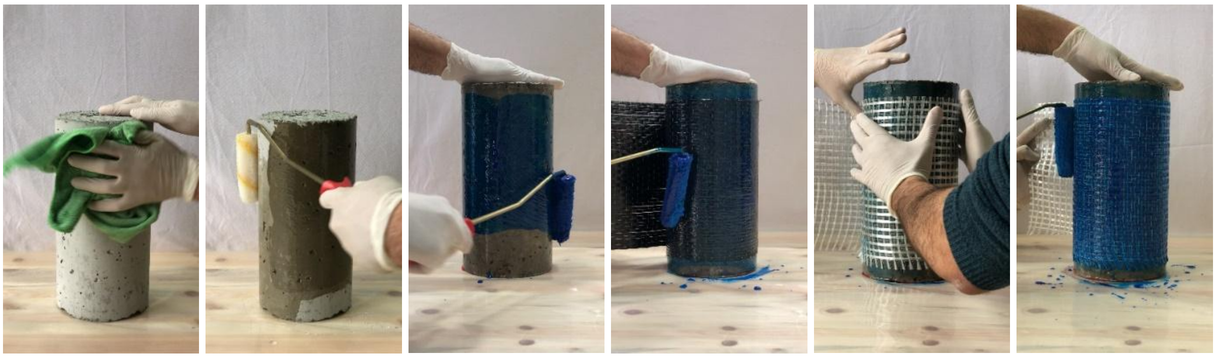

Fig. 3. Strengthening applications on specimens

2.3. Thermal exposure tests

After the completion of the curing process of the strengthened specimens, thermal exposure tests were conducted. For these tests, a trolley-based electric furnace was used. The furnace, powered by electricity and offering a usable volume of 6 m³ (2.0 × 1.5 × 2.0 m), was capable of reaching temperatures up to 1120 °C. Additionally, K-type thermocouples integrated into the system allowed for continuous monitoring of the internal furnace temperature during testing.

Throughout the tests, a constant heating rate of 5 °C/min was applied until the furnace reached the target temperatures defined in the experimental program (80 °C, 150 °C, and 250 °C). Once the target temperature was reached, the specimens were held at that temperature for either 90 or 180 minutes, depending on the designated exposure duration in each scenario. A total of six different thermal exposure tests were carried out based on the combinations of temperature level and exposure time considered in the study (Fig. 4).

Fig. 4. Temperature tests conducted under different heating regimes

Immediately after the completion of each thermal exposure, the furnace door was opened and the surface temperatures of the specimens were measured using an AST TI 1500 model dual-laser portable pyrometer. Subsequently, the furnace trolley was rolled out to extract the specimens, which were visually inspected for any changes in their FRP components and then allowed to cool under laboratory conditions.

2.4. Compressive strength tests

Following the thermal exposure phase and subsequent cooling of the specimens under ambient laboratory conditions, compressive strength tests were conducted in accordance with the BS EN 12390-3 (2019) standard. These tests were performed using a hydraulic compression testing machine with a maximum capacity of 3000 kN. All specimens were loaded under a constant rate of 0.6 MPa/s until failure.

The compressive strength results obtained from each specimen were used as the primary numerical data for assessing the mechanical performance of the FRP systems under high temperature conditions. In addition, immediately after the completion of each test, the failure modes of the specimens were visually inspected and documented to evaluate the influence of temperature on the structural behavior and damage characteristics of the FRP-reinforced concrete elements.

Representative post-test images of specimens strengthened with CFRP and GFRP systems are presented in Fig. 5. These visual observations provided supplementary insights into failure patterns such as delamination, fiber rupture, surface peeling, and debonding, which are critical indicators of thermally induced degradation in FRP composites.

Fig. 5. Post-compression failure mechanisms of FRP-strengthened specimens

3. Results and discussion

This section presents the data obtained from the temperature and compression tests, along with visual inspections conducted after testing, and discusses the findings in detail.

Surface temperature data collected before and after the thermal tests using a pyrometer are presented in Table 1. Visual inspections following the temperature exposure indicated no observable deterioration in the epoxy resin of the strengthened specimens used in Tests 1 and 2. In contrast, specimens used in Tests 3 and 4 showed significant softening in the resin due to exceeding T_g. In the tests conducted at the target temperature of 80 °C, the epoxy surface largely retained its gloss, whereas a matte appearance became noticeable after the 150 °C exposure. For the tests conducted at 250 °C, particularly after the 90-minute exposure in Test 6, partial burning and charring marks were observed on the resin surface, and in some areas, the fibers were fully exposed due to thermal degradation of the matrix.

Table 1. Surface temperature measurements

Test no	Target temperature (°C)	Exposure duration (min)	Surface temperature (°C)		
			Pre-test	Post-test	
				FRP	Concrete
1	80	60	26.2	53.5	69.8
2	80	90	27.1	63.1	77.1
3	150	60	27.0	97.1	130.2
4	150	90	27.1	109.2	134.7
5	250	60	26.8	154.1	211.1
6	250	90	29.3	179.7	229.5

Although average compressive strength results are summarized in Table 2, the general behavioral trends can be outlined as follows: Unwrapped concrete specimens tested at 80 °C exhibited a 6–8% increase in strength compared to ambient conditions; at 150 °C, a short-duration exposure led to a 2% increase, whereas longer exposure resulted in up to a 4% loss. At 250 °C, strength reductions of 6–7% were recorded. CFRP wrapping enhanced compressive strength by 55%, 109%, and 168% for one, two, and three layers, respectively, while GFRP contributed improvements ranging between 14% and 31% for the same configurations. In the 80 °C tests where the T_g was not exceeded, CFRP specimens retained 92–107% of their initial strength, while GFRP specimens retained 85–116%, with values exceeding 100% reflecting temporary strength gains from drying and partial hardening of the concrete core. These results indicate that strength loss begins as FRP–concrete bond degradation starts approaching T_g. At 150 °C, within the epoxy's viscoelastic softening region, residual strength ratios decreased to 88–98% for CFRP and 73–94% for GFRP, indicating a faster deterioration of the glass fiber–epoxy bond compared to the carbon fiber–epoxy bond. At 250 °C, where pyrolytic degradation initiates, GFRP specimens dropped to 67–81%, whereas CFRP specimens maintained 50–100% higher strength than unwrapped concrete even with one or two layers. Extending the exposure duration from 90 to 180 minutes caused an additional 2–11% strength loss at 80 °C and 150 °C, with time sensitivity more pronounced in GFRP systems, while some specimens showed slight strength gains (approximately 5–15%) at 250 °C. These findings confirm that early strength increases due to drying and hardening of the concrete may mask the percentage contribution of FRP, yet softening above T_g and degradation at high temperatures progressively reduce the confinement effectiveness of FRP systems with increasing temperature and exposure time.

Table 2. Average compressive strength values (MPa) obtained from the compression tests

Target temperature (°C)	Exposure duration (min)	Unwrapped	Number of FRP wrapping layers					
			CFRP			GFRP		
			1	2	3	1	2	3
20	---	28.65	44.28	59.84	76.65	32.58	35.22	37.67
80	90	30.97	47.51	60.09	79.09	33.14	40.88	33.27
	180	30.51	46.66	59.26	70.63	31.58	32.21	32.07
150	90	29.24	43.20	56.83	68.50	30.51	30.47	30.36
	180	27.35	41.28	52.88	68.43	28.05	27.56	27.32
250	90	26.53	40.46	52.25	61.38	26.24	23.44	27.31
	180	26.96	42.74	54.84	59.11	25.54	26.85	27.48

4. Conclusions

The findings obtained in this study reveal that the strengthening contribution provided by FRP systems primarily depends on the type of composite material used and the number of wrapping layers. However, the performance of these systems was also found to be sensitive to temperature level and exposure duration. Based on the experimental findings that reveal the behavior of FRP systems under high temperature conditions, the key conclusions are presented below:

- Regardless of temperature effects, FRP strengthening systems provided a significant increase in compressive strength to the concrete specimens. This contribution increased with the number of applied wraps. CFRP systems offered a higher strength gain compared to GFRP systems. Even under thermal exposure, CFRP systems maintained their confinement effectiveness more efficiently. Although GFRP systems provided strength enhancement at low and moderate temperatures, their effectiveness remained limited compared to CFRP. These outcomes are directly associated with the mechanical and thermal properties of the fiber fabrics used in strengthening applications, as well as their compatibility with the resin matrix.
- The strength increase observed in unwrapped concrete specimens at 80 °C and 150 °C was attributed to a temporary drying–stiffening effect due to moisture loss. In some cases, this phenomenon may lead to an overestimation of the actual contribution of FRP systems. Therefore, when evaluating the performance of FRP systems, it is essential to consider the influence of such temporary strength increases and isolate their effects in the analysis.
- Epoxy softening and pyrolytic degradation processes, which became more pronounced above T_g, gradually reduced the confinement effectiveness of the FRP systems with increasing temperature and exposure duration. These reductions initiated as the matrix approached its T_g and became more evident once T_g was exceeded, leading to softening of the epoxy and a decline in bond strength. The findings suggest that bond losses at the FRP–concrete interface begin not only after T_g is exceeded but already as it is approached.
- It was also observed that the failure mechanisms of FRP systems varied significantly depending on temperature and exposure time. While the fiber–matrix integrity was maintained at low temperatures,

increasing temperature led to matrix softening, resulting in delamination, fiber–matrix separation, debonding, and interlayer peeling. At 250 °C, decomposition of the epoxy matrix exposed the fibers, causing brittle fractures and fiber ruptures in these regions. This clearly indicates a substantial reduction in the structural contribution of FRP systems with increasing thermal exposure. After the 250 °C tests, the strength contribution of GFRP systems was entirely lost, whereas CFRP systems, despite a significant reduction, retained some structural functionality.

- These findings clearly demonstrate the vulnerability of FRP composite materials to high temperature. Therefore, the use of such systems must be considered in conjunction with appropriate insulation and fire protection measures to ensure safety and long-term performance.

Abstract. Conventional design methodologies for wind loads frequently depend on static analyses, which may inadequately represent the dynamic behavior of certain structures, such as tall buildings or wind turbines.In such instances, time-domain analysis is more suitable for accurately capturing the wind-induced effects.Time-dependent wind loads for design purposes are typically derived from wind tunnel tests. However, conducting such tests during the preliminary design stages is often impractical due to cost constraints and the potential for iterative design changes. This study proposes a methodology for generating multivariate wind speed fields to be used in the calculation of time-dependent wind loads on structures and in applications such as energy production.The proposed methodology is based on the modeling of the spectrum of atmospheric surface-layer turbulence according to basic wind velocities. It enables the simulation of one-, two-, or three-dimensional fields with one, two, or three components of wind velocity fluctuations (u, v, w). The simulation of these velocity fields is conducted with the models characterized as gaussian random processes dependent on the parameters t and $\mathbf{x}$ position within a finite spatial domain. As a demonstrative application, this study presents a regular 2D vertical grid oriented perpendicularly to the flow, incorporating the longitudinal mean wind velocity and the longitudinal, lateral, and vertical atmospheric turbulence components. This approach can offer a cost-effective and versatile solution for wind analysis, enhancing preliminary design processes and broadening applications in structural and energy-related fields.

Keywords: Mean wind velocity; Velocity of turbulence components; Time domain; Random process

1. Introduction

One of the most critical design considerations for many special structures is their response to wind. On the other hand, A proper selection and design of a building's structural system depend on the accurate identification of the loads acting on the structure and the selection of appropriate analysis methods. Although building codes specify the minimum forces that a structure must withstand, they typically do not impose requirements related to other specific performance criteria. For instance, in the case of tall buildings, inter-story shear forces and occupant comfort are often key design constraints from a serviceability perspective. However, the minimum wind forces prescribed in most codes do not adequately account for the potential dynamic response of tall structures, and therefore may significantly underestimate the actual demand levels. Therefore, wind tunnel studies are often suitable for better characterizing the wind response of the special structures. Very few countries or local authorities have established guidelines for when such testing is required, and the decision is typically left to the discretion of the design professional. Another method for estimating the loads acting on a structure is Computational Fluid Dynamics (CFD) analysis. The results from both methods are commonly translated into an equivalent static load, incorporating an approximation of the structure's dynamic response. In the case of wind tunnel testing, the equivalent static load is calculated by considering the fundamental period of the structure, while contributions from higher modes are typically neglected. This simplification is also inherent in most national standards and building codes. However, such an approach may, in some cases, fail to capture the actual dynamic behavior of the structure. Time-domain analyses methods offer a more appropriate method to incorporate the effects of higher modes, which cannot be accounted for in equivalent static load procedures. However; unlike earthquakes, wind lacks a well-defined time history database, and the temporal variation of wind effects depends on a wide range of factors such as structural geometry, regional characteristics, wind profile, and building height. Consequently, wind represents a highly complex and variable load, and no design code currently prescribes time-domain dynamic load procedures for wind.

Many wind design codes guide towards strength-based design and allow only elastic behavior in the design. However, wind loads acting on special structures such as tall buildings may exceed seismic demands in some cases and have the potential to induce nonlinear structural responses. In recent years, researchers have become increasingly aware of these limitations in both design practices and building codes. As a result, the concept of Performance-Based Wind Design (PBWD)—which allows inelastic behavior under strong wind loading—has been introduced specifically for the design of such structures. Unlike Performance-Based Seismic Design (PBSD), there is a notable lack of guidelines and research addressing inelastic wind design. In PBWD, time-history wind loads are typically derived from surface pressure data obtained through wind tunnel testing. However, for preliminary design phases, conducting wind tunnel experiments is often impractical due to design modifications, the need to evaluate multiple performance levels, and associated costs.

In this context, there is a need to develop a procedure for the generation of synthetic data as a more practical means of determining time-dependent wind loads. This need has served as the primary motivation for this study. To achieve this, it is necessary to obtain either time-dependent pressure coefficients or wind velocity records at the specific location on the structure. In this context, this study proposes a methodology for generating multivariate wind speed fields to be used in the calculation of time-dependent wind loads on structures and in applications such as energy production.The proposed methodology is based on the modeling of the spectrum of atmospheric surface-layer turbulence according to basic wind velocities. For the simulation, a software was developed in the MATLAB language, which can offer different design spectrum options and enables the calculation of height- and time-dependent wind speeds using the conventional spectrum-based method. It enables the simulation of one-, two-, or three-dimensional fields with one, two, or three components of wind velocity fluctuations (*u, v, w*). The simulation of these velocity fields is conducted with the model characterized as gaussian random processes dependent on the parameters t and $\mathbf{x}$ position within a finite spatial domain. A sample application has been provided to demonstrate the methodology developed in the scope of this study.

2. Materials and methods

Studies focusing on the simulation of atmospheric wind velocities are notably limited in number. Moreover, existing research often restricts the user's flexibility in selecting different spectra and parameters, or allows for the generation of wind records at only a single spatial point (e.g., Kwon et al., 2011; Branlard, 2017; Wang et. al., 2018; Cheynet, 2020). Although limited in number, these studies have emphasized the necessity of addressing the gap in the literature and have thus provided both a conceptual basis and a source of motivation for the present study.

Before describing the framework used for wind velocity generation, it is beneficial to first understand the concept of time-dependent data generation. This generation can fundamentally be examnied to two parts: the first involves generating a vector-valued synthetic record at a single coordinate point, while the second involves producing specially distributed data for multiple coordinate points and various vector components.

The first part is particularly useful for understanding the fundamental principles of random data generation. Some of the methods commonly used for this purpose include the Complex Amplitude of White Noise Spectrum (CAWS) Method (Goto and Toki, 1969), the Weighted Amplitude Wave Superposition (WAWS) Method (Shinozuka, 1985), and the Auto-Regressive (AR) Filtering Approach.

In the second part, the process becomes more complex in terms of both methodology and computation. This complexity arises from the fact that the locations within the data set to be generated may lie in one-, two-, or three-dimensional spatial coordinate systems, and each location may possess between one and three vector components. Consequently, the generation of multivariate random data requires the definition of correlation both among different vector components at the same location and among identical vector components across different locations. To characterize these correlations, it is necessary to employ either cross power spectral density functions incorporating coherence functions or covariance functions. Furthermore, spatial (three-dimensional) matrix formulations and solutions are required. In the second part, some of the simulation schemes can used for this purpose include Discrete Frequency Function with FFT (Wittig and Sinha, 1975), Schur Decomposition Approach with AR (Di Paola 1998, Di Paola and Gullo, 2001), Ergodic Spectral Representation Method (Deodatis, 1996; Ding et al. 2006), Conventional Spectral Representation Method (Shinozuka and Deodatis,1991). In this study, the Conventional Spectral Representation Method was adopted for the simulation of three-dimensional (3D) multivariate Gaussian wind velocity fields.

2.1. Theoretical backgrounds

Simulated wind velocity fields are generated depending on time t and of the position $\mathbf{x}= [x, y, z]^T$ in a finite spatial domain. The orthogonal reference system *(x, y, z)* has origin on the ground and the axis z is vertical and directed upwards.

The wind velocity is idealized as the sum of two terms: (1) the mean wind velocity $\overline{U}(\mathbf{x})$ or $U_{mean}(\mathbf{x})$, function of the position $\mathbf{x}$, and oriented in the whole domain along the positive direction of the axis *x*; (2) the random function **u**(**x**, t), function of space and time, whose Cartesian components *u, v, w* along *x, y,* and *z,* respectively, represent the longitudinal, lateral and vertical atmospheric turbulence components.

2.1.1. Design mean wind speed profile models
The mean wind speed profile in each standard is defined either by a Power Law or a Logarithmic Law. The AS/NZ, EU, and ISO standards adopt the Logarithmic Law, while the others primarily use the Power Law. If the basic wind speed at 10 meters height is not known, but the mean wind speed measured at a reference point is available, it is still possible to determine the mean wind speed at the desired height by applying either the logarithmic law or the power law. In the developed software, the calculation of the mean wind speed profile has been made possible through three different options.

The Power Law is defined as follows:

$$\bar{U}(z) = b\left(\frac{z}{10}\right)^{\alpha} U_b \tag{1}$$

Here, α (the exponent of the mean wind speed profile) and *b* are terrain-dependent parameters, z is the height of interest, and U_b is the basic wind speed.

The Logarithmic Law is defined as follows:

$$\begin{aligned} \bar{U}(z) &= \frac{u*}{\kappa} In\left(\frac{z}{z_0}\right) U_b \qquad & z > z_{min} \\ \bar{U}(z) &= \bar{U}(z_{min}) \qquad & z \le z_{min} \end{aligned} \tag{2}$$

u∗ is the friction velocity (also referred to as the shear velocity), z_0 is the surface roughness length, and κ is the von Kármán constant.

Calculation according to the mean wind speed measured at a reference point:

$$\bar{U}(z) = \bar{U}(z_{ref}) \frac{In\left(\frac{z}{z_0}\right)}{In\left(\frac{z}{z_{ref}}\right)} \tag{3}$$

$$\bar{U}(z) = \bar{U}(z_{ref}) \left(\frac{z}{z_{ref}}\right)^{\alpha} \quad eksponent : \alpha = \left(\frac{1}{In(z_{ref} / z_0)}\right) \tag{4}$$

2.1.2. Models for turbulence components
The fluctuating components of the wind velocity are modelled as a Gaussian random process.

Power Spectral Density (PSD) function:

Kailmal Power Spectral Density (PSD) function of the turbulence component ε = *u, v, w* in the point **x** of the finite spatial domain is defined as follows:

$$\frac{fS_u(\mathbf{x}, f)}{u_*^2} = \frac{200 f_{mc}}{[1 + 50 f_{mc}]^{5/3}} \tag{5}$$

$$\frac{fS_v(\mathbf{x}, f)}{u_*^2} = \frac{17 f_{mc}}{[1 + 9.5 f_{mc}]^{5/3}} \tag{6}$$

$$\frac{fS_w(\mathbf{x}, f)}{u_*^2} = \frac{2 f_{mc}}{[1 + 5.3 f_{mc}]^{5/3}} \tag{7}$$

$$f_{mc} = \frac{f.z}{\bar{U}(z)} \tag{8}$$

f: frequency,f_{mc}: Monin coordinate,$S_\varepsilon(\mathbf{x},f)$: represents the power spectral density of the turbulence velocity component in the point **x** of finite spatial domain

Computation of Coherence and Cross Power Spectral Density

Coherence is a function that characterizes the degree of correlation between signals (records) at different spatial locations. In this study, the coherence between two different points for the same vector component is modeled using the function proposed by Davenport (1967). In future developments, alternative coherence models and computational methods may be incorporated into the software to enhance its flexibility and applicability.

$$Coh_{\varepsilon\varepsilon}(\mathbf{x}_j,\mathbf{x}_k;f)=\exp\left(-\frac{2f\sqrt{C_{x\varepsilon}^2\left|x_j-x_k\right|^2+C_{y\varepsilon}^2\left|y_j-y_k\right|^2+C_{z\varepsilon}^2\left|z_j-z_k\right|^2}}{\bar{U}(z_j)+\bar{U}(z_k)}\right) \tag{9}$$

Here, the values of $C_{\mathbf{x}\varepsilon}$ represent exponential decay coefficients, which are determined empirically. Depending on whether the coherence function is defined in a one-, two-, or three-dimensional coordinate system, both the exponential decay coefficients and the spatial location parameters can be simplified. As a result, the formulation allows for one-dimensional, two-dimensional, and three-dimensional solution options.

The exponential decay coefficients have been determined as the average of numerous experiments, as reported by Solari and Piccardo (2001). In their study, the values of $C_{\mathbf{x}\varepsilon}$ were established based on data collected from approximately 40 different researches.

$$\begin{array}{lll} C_{xu}=3.0 & C_{xv}=3.0 & C_{xw}=0.5 \\ C_{yu}=10.0 & C_{yv}=6.5 & C_{yw}=6.5 \\ C_{zu}=10.0 & C_{zv}=6.5 & C_{zw}=3.0 \end{array}$$

The cross power spectral density (CPSD) of two continuous turbulence records is a measure of the degree of correlation between the two signals. In the developed program, CPSD is computed using the following equations:

$$S_{\varepsilon\varepsilon}(\mathbf{x}_j,\mathbf{x}_k;f)=\sqrt{S_{\varepsilon\varepsilon}(\mathbf{x}_j,f)S_{\varepsilon\varepsilon}(\mathbf{x}_k,f)}coh_{\varepsilon\varepsilon}(\mathbf{x}_j,\mathbf{x}_k;f) \tag{10}$$

$$S_{\varepsilon\eta}(\mathbf{x}_j,\mathbf{x}_k;f)=\sqrt{S_{\varepsilon}(\mathbf{x}_j,f)S_{\eta}(\mathbf{x}_k,f)}coh_{\varepsilon\eta}(\mathbf{x}_j,\mathbf{x}_k;f) \qquad \varepsilon,\eta=u,v,w \tag{11}$$

2.1.3. Simulation algorithm

The simulation of the turbulence field is carried out by the spectral-representation algorithm. The procedure is organized as follows:

1- The PSD matrix **S** of the turbulence component ε selected for the simulation is obtained evaluating Eqs. (12) for every pair of simulation points $\mathbf{x}_j$ and $\mathbf{x}_k$ ($j,k=1,\ldots,N_m$) in the simulation domain (Fig. 1).

$$\left[\mathbf{S}(f)\right]_{jk}=S_{\varepsilon\varepsilon}(\mathbf{x}_j,\mathbf{x}_k;f)\ \ (j,k=1,..,N_m) \tag{12}$$

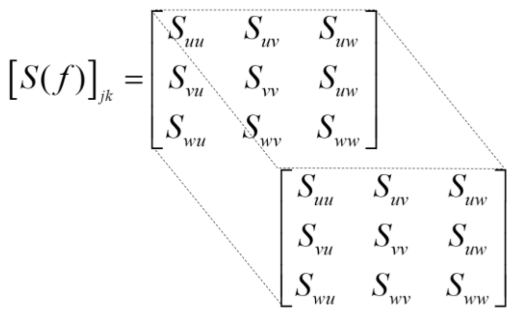

Fig. 1. Solution main matrix

2- Frequency can be discretized using either a linear or logarithmic scale. In this study, the computation is carried out based on a linear frequency scale. Before performing the frequency discretization, it is essential to define the sampling vector parameters used in the analysis. Specifically, the sampling frequency (f_s) and the number of samples (N) should be specified as user-defined input parameters, which would enhance the flexibility and applicability of the analysis process.

Time step, *dt (s):*

$$dt=1/\ f_s \tag{13}$$

Maximum simulation time, T_{max} *(s):*

$$t_{mak}=dt*N \tag{14}$$

Time vector, *t (s)*:

$$t = (0 : N - 1) * dt \tag{15}$$

Minimum resolvable frequency, f_0 (Hz):

$$f_0 = 1 / t_{mak} \tag{16}$$

Nyquist frequency, f_c *(Hz):*

$$f_c = f_s / 2 \tag{17}$$

Frequency vector, f *(Hz):*

$$f = \left[f_0 : f_0 : f_c \right] \tag{18}$$

Therefore, if the frequency vector is to be expressed on a linear scale, it is defined as f_h *(Hz)::*

$$f_h = h\Delta f \qquad (h=1,...,N_{freq}) \tag{19}$$

Here, $\Delta f=f_0$ represents the frequency resolution, and $N_{freq}=N/2$ corresponds to the number of frequency components considered in the simulation.

3- The CPSD matrix, denoted as **S**, is factorized into its eigenvalues and eigenvectors for each frequency value defined by either a logarithmic or linear frequency scale. For this decomposition, either the Cholesky decomposition or the LDL^T decomposition method can be employed. In this study, the LDL^T decomposition technique has been utilized.

$$\mathbf{S}(f_h) = \mathbf{\Theta}(f_h)^T \mathbf{\Gamma}(f_h) \mathbf{\Theta}(f_h) \qquad (h = 1, ..., N_{freq}) \tag{20}$$

Here, $\mathbf{\Gamma}$ and $\mathbf{\Theta}$ denote the matrices containing the eigenvalues and eigenvectors of the CPSD matrix **S**, respectively. The decomposition process defined in the above equation is repeated N_{freq} times ($h = 1{:}N_{freq}$). Subsequently, the core spectral matrix **A** is computed using the eigenvalues, eigenvectors, and uniformly distributed random phase angles**.**

4- The spectral core matrix **A**, composed of a combination of real and complex-valued components, is used to construct the matrix U, which is then transformed using the Inverse Fast Fourier Transform (*IFFT*) algorithm. As a result of this procedure, the time-domain turbulence wind velocities at specified locations are obtained. These data can subsequently be used for the computation of wind-induced forces in the transverse direction or for evaluating base moments.

5- *Power Spectral Density Estimation and Comparison:* To assess the spectral consistency of the generated turbulence velocity records, the generated velocities were converted back to frequency-based power spectral density (PSD) using either the Welch Method (Welch, 1967) or the Multitaper Spectral Estimation Method (Thomson, 1982; Percival and Walden, 1993). The resulting PSD estimates were then compared with the original PSD functions used during the generation of the records. This approach allowed for evaluating the spectral compatibility of the simulated data with the target spectra.

2.2. Case study information

The mesh grid specifications of the example for wind velocity computation and the selected parameters for time-dependent wind velocity calculation, are presented in Table 1. Eurocode (2010) standard was referenced for the parameter values. According to the standard, Terrain Category III represents suburban terrain. The basic wind speed is the velocity calculated from recordings taken over 10-minute averages in the region.

Table 1. Case study information

Wind-exposed a regular 2D vertical mesh grid	Terrain category (Eurocode-2010)	Surface roughness length (z_0)	Friction velocity (u*)	Basic wind speed (U_b)	Sampling frequency (f_s)	Number of samples (N)	Time step *(dt)*	Total time
H=200 m (20 location) B=30 m (4 location)	III	0.3	0.086	30 m/s	20 Hz	16384	0.05 s	820 s

3. Results and discussion

The simulation results of the selected example are summarized under this section. The coordinates of the points where the atmospheric wind velocities are to be computed are presented as a regular 2D vertical grid oriented perpendicularly to the flow in Fig. 2. The Power Spectral Density (PSD) of the turbulence wind velocity component $\varepsilon = u, v, w$ graph computed for a selected point is presented in Figure 3.

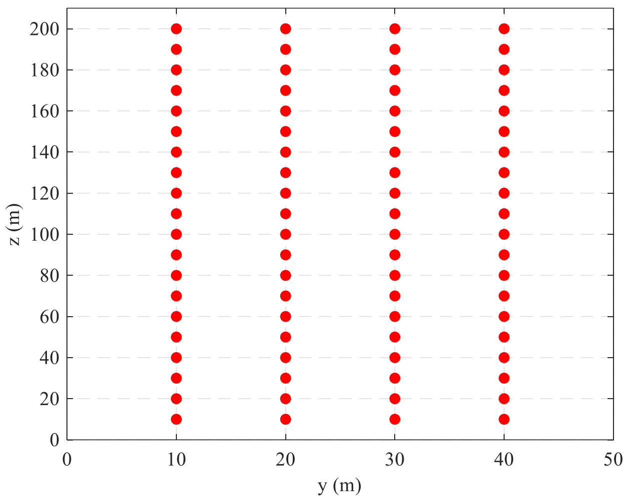

Fig. 2. The spatial coordinates of the points used for the example

As seen in Fig. 3, the PSD characteristics of the turbulence components differ from one another. While the PSD values of the three components are similar in the frequency range between 0.1 Hz and 10 Hz, the longitudinal component becomes significantly dominant at frequencies below 0.1 Hz

It can be stated that the frequencies corresponding to the maximum PSD values obtained for the selected reference wind speed and height are generally far from the fundamental frequency of the structures. Therefore, it can be concluded that the along-wind forces generated by the maximum wind speed data obtained for this example will not have a significant effect on the dynamic response of the structure.

The mean wind velocity in the prevailing wind direction; the time-dependent longitudinal, lateral and vertical atmospheric turbulence velocity components and longitudinal total velocity were calculated for 80 points with specified coordinates (Figs. 4-5). As observed in Fig. 4, the maximum turbulence velocity components (u, v, w) generated are consistent with the PSD used, indicating coherent results. Accordingly, the absolute maximum velocity components $|(u, v, w)|_{max}$ are 35.11, 18.67, and 13.47 m/s, respectively.

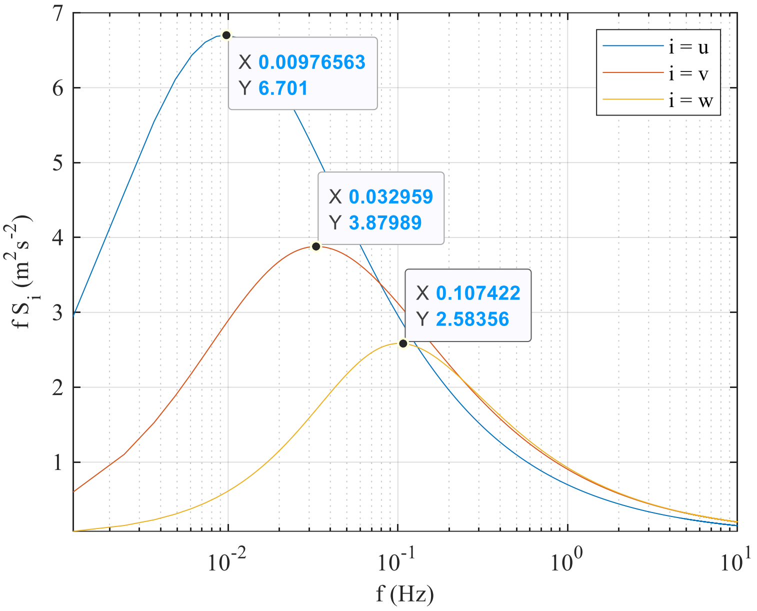

Fig. 3. A sample Kaimal PSD used for the generation of turbulence velocity components
(Heigt of the point=200 m)

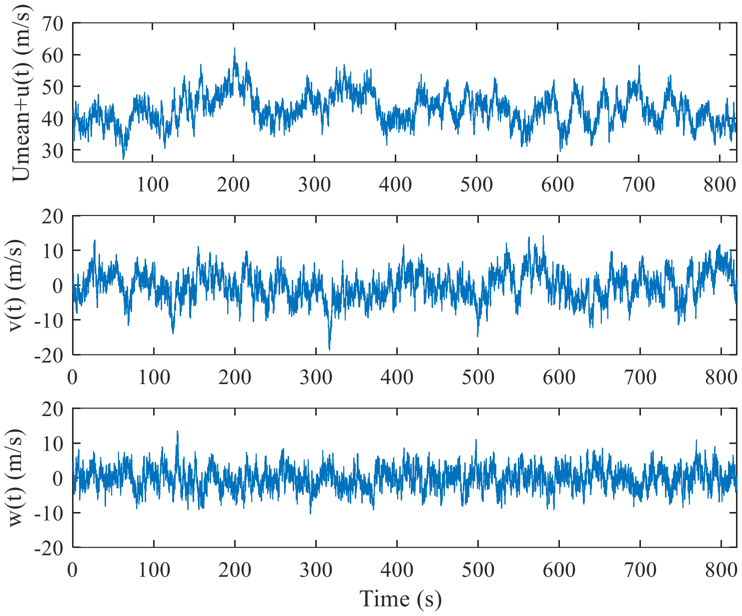

Fig. 4. Wind velocity–time series computed at a point (Height 200 m)

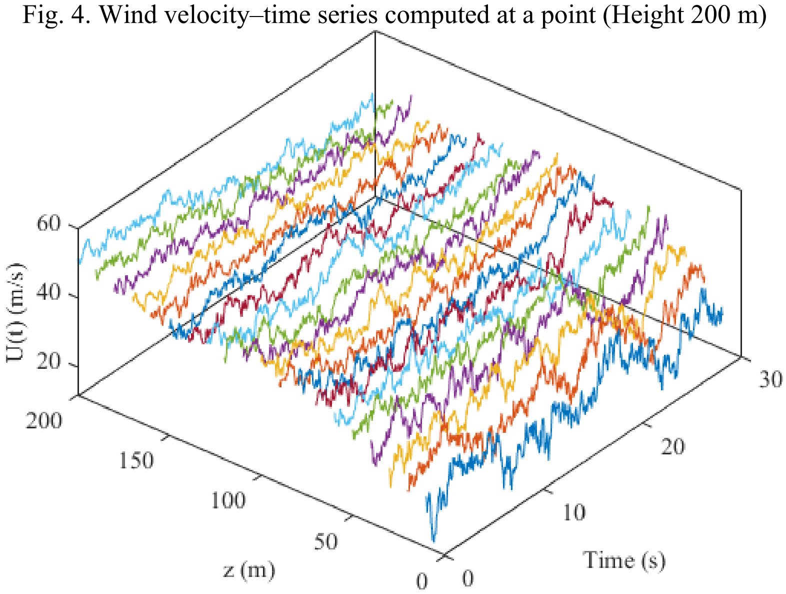

Fig. 5. Longitudinal total velocity, *U(t)*–time series calculated at various elevations

In the subsequent part of the study, the agreement between the mean values calculated from the longitudinal wind velocity time series obtained and the initial mean wind speed was examined at different heights ;and the maximum and minimum wind speeds were compared (Fig. 6). It was observed that the calculated mean wind speeds are very close to the target mean values. Accordingly, it can be stated that the resulting turbulence components have approximately zero-mean, which is generally a desirable condition in turbulence modelling.

It has been observed that the maximum wind speed generally increases with height, and the shape of the resulting maximum wind speed profile is consistent with the mean wind velocity in Figure 6. This is a desirable behavior for the generated wind records. On the other hand, deviations from this trend have been observed at certain points. These deviations are attributed to the influence of the coherence function and the random process (Serhatoğlu, 2025). This behavior closely resembles real atmospheric wind characteristic.

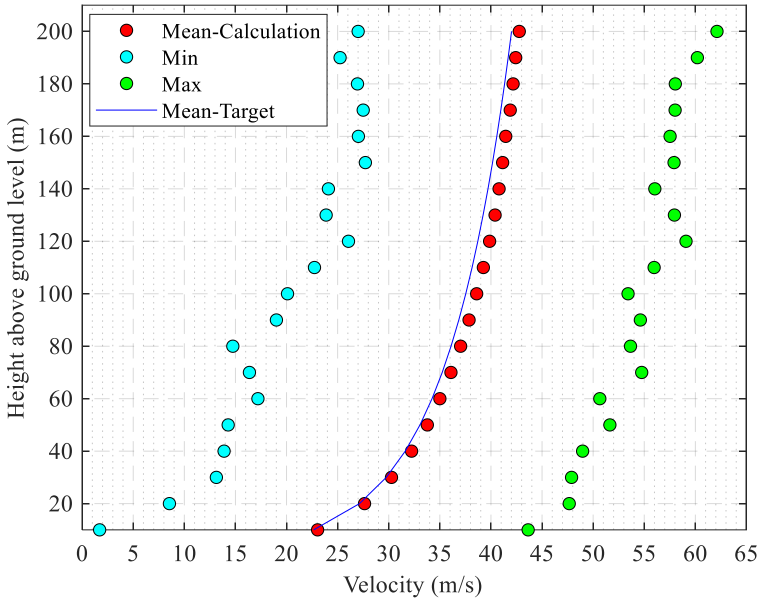

Fig. 6. Mean and maximum/minimum wind velocities calculated from longitudinal velocity *U(t)*–time series at different heights

In the final part of the study, the estimated PSD derived from the generated wind velocity data was evaluated for its consistency with the reference PSD used in the calculations (Fig. 7). Based on the comparison results, it can be stated that the generated records exhibit an acceptable level of agreement with the reference PSD.

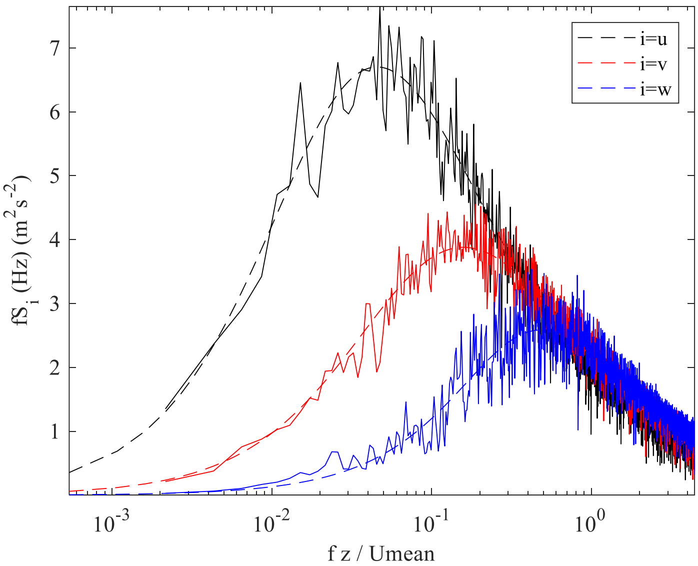

Fig. 7. Comparison of the PSD estimates obtained from generated wind velocities with the reference Spectrum for a sample point (Height 200 m)

4. Conclusions

This study proposes a methodology for generating multivariate wind speed fields to be used in the calculation of time-dependent wind loads on structures and in applications such as energy production. Therefore, a specialized software was developed using the MATLAB language to enable the practical simulation of time-dependent wind velocity components.

To verify whether the developed software produces realistic results, a simulation was conducted on the multi-point example. The results were observed to resemble real atmospheric wind velocity behavior.

Based on the obtained time-dependent wind velocity components, it is possible to compute the corresponding pressure and force distributions over a specific area or all of the structure surfaces. The software is intended to be further enhanced by incorporating various turbulence parameters, PSD and coherence functions and new methodologies to establish a more comprehensive simulation framework.

This approach can offer a cost-effective and versatile solution for wind analysis, enhancing preliminary design processes and broadening applications in structural and energy-related fields.

Dynamic characterization of polycarbonate: A constitutive model capturing temperature and strain rate effects

Cem İ. Kapcı*[1], Merve Z. Tekin[1], Aiman Tarıq[1], Babür Deliktas[1], Mustafa Ö. Yaylı[1]

[1] *Bursa Uludag University, Faculty of Engineering, Department of Civil Engineering, Artificial Intelligence and Computational Mechanics Laboratory, 16059, Bursa, Turkey*

Abstract. Polycarbonate (PC) is a widely used material known for its impact resistance, transparency and thermal properties. However, there are challenges in capturing its behavior under different temperatures and strain rates. The stress drop after yielding and subsequent plastic flow behavior are examples of the major challenges that classical hardening models cannot represent. In this work, a robust constitutive model is developed to accurately describe the mechanical response of PC. The model is based on experimental data from tensile and compression tests performed at various temperatures and strain rates. First, a validation study was carried out for the use of the developed model in a finite element program. The developed model was then implemented in Abaqus/Explicit for impact simulations, allowing realistic predictions of failure modes, crack propagation and fracture behavior. The simulation results were confirmed to show improved accuracy in capturing the temperature and strain rate dependent response of the PC. This research advances predictive modeling for PC, making it highly valuable for applications in protective structures in civil engineering, automotive crashworthiness and impact resistant materials.

Keywords: Polycarbonate (PC); Constitutive model; Strain rate; Temperature dependence; Impact simulation

1. Introduction

Engineering thermoplastics are widely used in the automotive, aerospace and defense industries due to their high impact strength, light weight and ease of production. Plastic components in these industries need to withstand external factors structurally and aesthetically. Especially exterior automotive parts play a crucial role in terms of functionality and safety. Polycarbonate (PC), known for its high impact resistance, optical transparency and thermal stability, is widely used in applications such as headlight covers and protective elements.

The mechanical behavior of PC under impact loading is complex due to its sensitivity to temperature and strain rate. Wei et al. (2024) modeled the deformation behavior of PC under varying temperatures and loading rates using experimental and numerical methods. Husain et al. (2024) evaluated post-impact deformations through Dynamic Enhancement Factor (DEF) obtained from quasi-static and dynamic tests. Mullaoglu et al. (2024) investigated the impact response of PC panels under high velocity steel projectile impacts and analyzed the effects of impact angle and position.

Ma et al. (2024) investigated the effect of fabric weave patterns on the energy absorption of PC-based composites. Ćwiklak et al. (2024) demonstrated the importance of accurate material parameter definitions for PC-based glass and panel systems under bird impact simulations. Kholoosi and Nia (2024) compared glass, PC and TPU layer systems and showed that PC significantly increases impact resistance.

Bozkurt (2025) analyzed how curvature and core thickness affect ballistic performance in honeycomb structures. Long et al. (2025) emphasized that combining shear thickening fluids (STF) with PC increases energy absorption under impact. Li, Nie, and Wu (2025) developed a hybrid model combining SPH and FEM to analyze damage in transparent armor systems composed of sapphire, glass and PC layers.

Lance et al. (2025) studied the high strain rate behavior of polymers, emphasizing viscoelastic and shock absorbing properties. Aziukovskyi et al. (2024) proposed a nonlinear modeling approach for external ballistic problems. Li et al. (2024) established a mathematical correlation between ballistic resistance and mechanical properties of armor steel based on the Johnson-Cook model. Ongaro et al. (2024) investigated computational and lumped parameter models for internal ballistic processes and evaluated their strengths and limitations.

An et al. (2024) applied machine learning techniques to model the relationships between mechanical properties and ballistic performance and identified key optimization strategies.

The existing literature is predominantly simulation studies, which are limited for temperature and strain rate sensitive materials. In this study, the effects of temperature and strain rate dependent variations in material parameters for PC impact analysis are comprehensively investigated for a polycarbonate lens.

2. Material model used for PC

Finite element method (FEM) modeling of amorphous thermoplastic polymers such as polycarbonate presents significant challenges due to the complex mechanical properties of the material. In addition to exhibiting viscoelastic and viscoplastic behavior, this material is notable for its sensitivity to temperature and strain rate. Therefore, advanced material models are required to accurately represent the nonlinear, time-dependent and temperature-dependent behavior. In this context, it is inevitable to develop parametrically optimized material models calibrated with experimental data in order to obtain reliable results in multi-axis loading situations. Furthermore, in dynamic analyses under high strain rate, the integration of appropriate constitutive (relative) relations is required for the material model to adequately reflect time-dependent effects.

In this study, to overcome these problems, the Modified Liu-Subhash model is preferred to characterize the nonlinear mechanical behavior of PC (Wei, 2024). The expression is as follows:

$$\sigma(\varepsilon_p,\ \dot{\varepsilon}\,, T) = \ (1 - m_1 T^{*m_2})[A(e^{\alpha\varepsilon_p + \eta_1} - 1) + \mu e^{B}(e^{\gamma\varepsilon_p + \eta_2} - 1)](1 + C(ln\,\dot{\varepsilon}\,^{*})^{p}\,) \quad (1)$$

Here, A, B, α, β and γ are undetermined parameters and ε is the total strain of the specimen. A is associated with the yield stress and governs the stress level of the flow platform. The variables α and β determine the modulus of the elastic phase and the transition phase of the curve, respectively. Parameters β and γ primarily govern the plastic phase of the curve and changing their values can change the starting point and upward slope of the material strengthening phase. Here ε_p is the plastic strain, η_1 is the product of α and ε_p, and η_2 is the product of γ and ε_p . Moreover, the fluctuation of the ambient temperature and the loaded strain rate has a significant influence on the yield stress of the PC specimen, and its law is the same as the development trend of the temperature function and strain rate function of the J-C model. m_1 and m_2 are unspecified parameters. T^* represents the dimensionless temperature and is defined as $T^*= (T-T_r) / (T_g - T_r)$. T represents the ambient temperature in the experiment. T_r represents the room temperature, which is 298K. The glass transition temperature (T_g) of PC is 413K. Since the strain rate strengthening effect of PC at high strain rates is more significant than at low strain rates, p is used as a correction factor. $\dot{\varepsilon}^* = \dot{\varepsilon} / \dot{\varepsilon}_0$ .where $\dot{\varepsilon}_0$ represents the reference strain rate, typically ranging from 0.001 s^{-1} to 1 s^{-1}

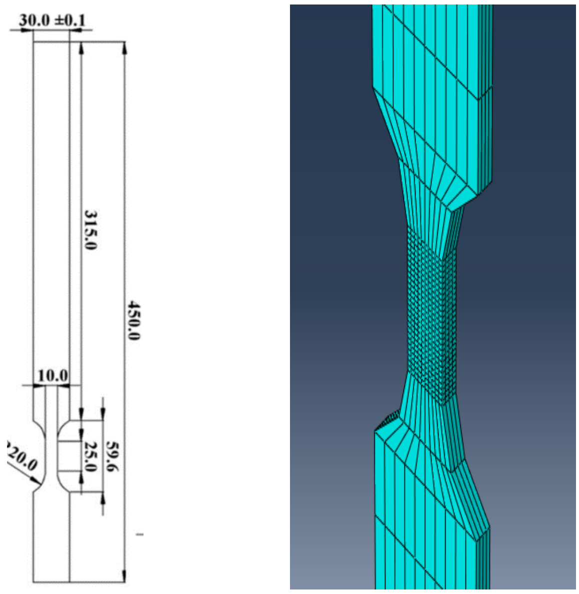
2.1. VUHARD implementation in abaqus

In order to integrate this unique material model into finite element analysis, the user-defined hardening subroutine VUHARD, which is compatible with the Abaqus Explicit solver, was used. VUHARD allows to describe the complex hardening behavior of the material during plasticization, especially in cases where standard material definitions are insufficient. In this study, the evolution of the yield stress in the developed material model depending on variables such as equivalent plastic strain and temperature was integrated into the Abaqus environment through the VUHARD subroutine written in Fortran. Thus, the accuracy of the developed model in numerical analyses could be tested and compared with experimental findings.

3. **Validation of constitutive model**

The Liu-Subhash constitutive model parameters suitable for the stress-strain relationship of polycarbonate (PC) are given in Table 1. With these parameters, a three-dimensional, quasi-static tensile specimen model was created in ABAQUS software. The dimensions of the model are taken from Wang et al. (2019) and the experimental data are taken from Wei et al. (2024). The length of the specimen is 450 mm, the gauge is 25 mm and the thickness is 4 mm. Other values are given in Fig. 1(a). A fine mesh was used in the center of the neck region of the specimen, with element dimensions of 0.8 mm × 0.8 mm × 0.8 mm × 0.8 mm × 0.8 mm (Fig. 1(b)). As we proceeded along the length of the specimen, the mesh size was gradually increased. The element type used is C3D8R.

The results of the tests performed at various speeds and temperatures were repeated exactly and which tests were performed at which speeds and temperatures are given in Table 2.



a) Abaqus model b) Meshing of tensile test

4	4	298
5	20	298

4. Finite element analysis

In the finite element model in this study, a ballistic impact simulation is performed to evaluate the accuracy of the modified Liu-Subhash model in the field of impact dynamics.

4.1 Finite Element Model Description

In this study, the outer lens of a car headlight, which is known to be made of polycarbonate material, was used for representation. It is shown in Fig. 2. The width of the lens, modeled as the outer lens of an average car headlight, is 570 mm at its widest point. Fig. 3 shows how it was modeled in Abaqus

The projectile is described as cylindrical with a diameter of 12.9 mm and a length of 25 mm. The projectile was created as a solid object with no defined material. The mass of the projectile is 25 grams. The projectile is defined as 60 m/s. The contact between the projectile and the target plate is set to surface-to-surface contact. The contact property option set a sliding friction coefficient of 0.1 for the contact surface of the projectile with the target plate and defined the usual contact behavior as hard contact

Fig. 2 Car headlight and exterior lens

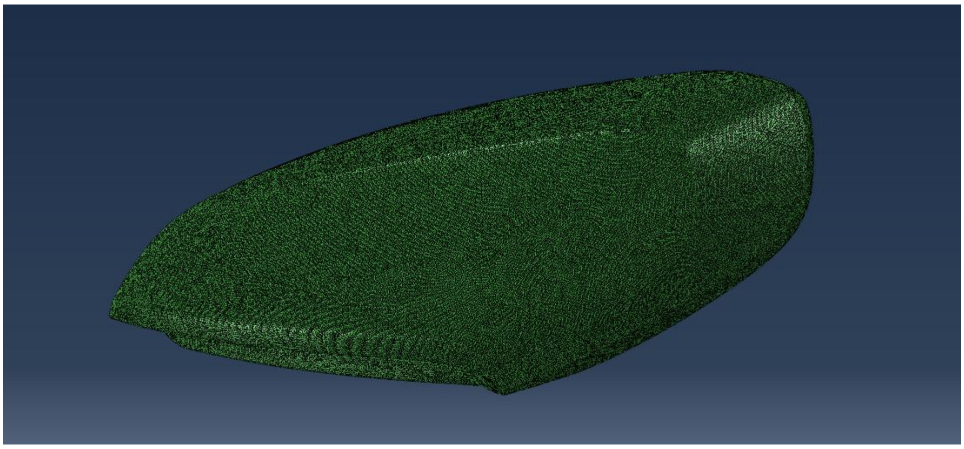

Fig. 3 Abaqus model

4.2 Finite element model result

At the end of the simulation, the behavior of the lens against impact is modeled and compared with the results of the simulation with the Johnson-Cook model. The two models were given an inlet velocity of 60 m/s and their behavior as residual velocity was compared. Both models gave similar results. Graphs for the 2 models are shown in Fig. 4.

5.Conclusions

Although the modified Liu-Subhash model gave comparable results to the Johnson-Cook model, it showed significant differences in behaviour under impact loading of the polycarbonate lens. These differences were particularly evident in the post-yield regime and at varying strain rates, with the Liu-Subhash model more accurately representing the viscoplastic properties of the material. This indicates that although both models produce numerically similar results in some scenarios, their predictive capacities differ in reflecting the actual mechanical response of the polycarbonate lens under dynamic loading.

Therefore, diversification of experimental data and evaluation of multiple shots in model validation studies will make important contributions to increase the reliability of simulation results and to compare the performance of material models more accurately.

Post-earthquake damage status and numerical analysis of a historical masonry building

Kağan Çanakçı*[1], Muhammet Karaton[1]

[1] Fırat University, Department of Civil Engineering, 23119 Elazığ, Türkiye

Abstract. Turkey, due to its geographical location, possesses a rich stock of historical structures inherited from the Roman, Byzantine, Seljuk, and Ottoman periods. These historical buildings have a variety of sizes, shapes and materials that reflect the technical and aesthetic features of their periods. While preserving and strengthening these structures and passing them on to future generations makes an important contribution to preserving our cultural heritage, the fact that most of these historical structures are masonry structures and are generally designed to carry vertical loads makes them of special importance in strengthening works. Because the resistance of historical masonry structures to dynamic lateral loads such as earthquakes is quite low. In particular, the Kahramanmaraş earthquakes that occurred in 2023 have once again revealed the requirement of evaluating the dynamic performance of historical artifacts. For this reason, determining the performance of historical structures under external loads and increasing the resistance of structures with inadequate performance with appropriate retrofitting methods emerges as a critical engineering problem. In this study, the damage status of a historical masonry building after the 2023 Elbistan-Kahramanmaraş earthquake was examined and the causes of damage were examined in detail. In this context, the finite element model of the structure was created with the macro modeling technique and dynamic analyzes were performed. The analyzes were performed with the nonlinear analysis method in the time history using the SAP2000 finite element software. As a result of the numerical analyzes performed using the Malatya records of the 2023 Elbistan-Kahramanmaraş earthquake (Mw = 7.7), the post-earthquake damage status of the building was compared with the numerical model.

Keywords: Masonry building; Macro modelling; Dynamic analysis; Time history analysis

1. Introduction

Turkey is a country with high seismic activity and hosts numerous historical structures that bear the traces of different civilizations throughout history. A significant portion of these historical structures were constructed using the masonry construction technique. In masonry structures, the majority of static and dynamic loads are carried by the walls. Earthquakes are among the external factors that cause the most damage to these walls. Earthquake forces create tensile and shear stresses in the walls, causing cracks to form, wall elements to separate, and ultimately, structures to partially or completely collapse. Therefore, determining the performance of historical structures under external loads and increasing the resistance levels of structures that are found to be inadequate in terms of performance with appropriate reinforcement methods emerge as an important engineering problem.

In this context, there are many studies in the literature. In a study conducted in 2021 [1] (Nochebuena-Mora et al., 2021), a macro-model of a 49 meter high historic masonry bell tower was developed, and performance analyses under different loading conditions were carried out. The static and dynamic effects of the bell mass were incorporated into the model. To evaluate the tower's performance, modal analysis, nonlinear static pushover analysis, and nonlinear time-history dynamic analysis were performed and compared. Seismic forces were applied in both directions to determine the possible crack patterns in the structure, and it was calculated that the crack widths ranged between 1 and 5 mm under the maximum displacement scenario.

It was observed that the structure remained within linear behavior limits in all three methods. Despite the high computational demand and long analysis times, the nonlinear dynamic analysis was identified as the most accurate method. In another study, four different finite element models were developed for a U-shaped masonry prototype composed of stone units, and nonlinear dynamic analyses were conducted (Maccarini et al., 2018). Three of these models were created using a macro-modeling approach, while one was developed using a simplified micro-modeling technique. It was determined that the macro-modeling approach reduced the number of degrees of freedom and computation times by 90%. In the next step, analyses were carried out on a rectangular-shaped

* Corresponding author, E-mail: canakcikagan@gmail.com

https://doi.org/10.31462/icearc2025_ce_sme_085

structure, and the results were compared with those from the first stage. Through this comparison, the influence of building geometry on strength and ductility was evaluated. In order to the seismic performance of the historic masonry structure known as Arge-Tabriz, a numerical model was developed using a macro-modeling approach (Hoveidae et al., 2021). Nonlinear time-history dynamic analysis and static pushover analysis were performed on this model. For the dynamic analysis, four different earthquake records with magnitudes ranging from 6.5 to 7.7 were utilized. Field surveys were conducted to identify existing crack patterns in the structure, and these were compared with the cracks obtained from the analysis results. The comparisons revealed that the finite element model showed a high level of agreement with the actual condition of the structure. It was concluded that, due to the inherently low seismic resistance of masonry structures, the primary cause of the observed damage over the years has been the occurrence of earthquakes. A finite element model was developed to investigate the structural behavior, assess the seismic performance, and identify potential damage mechanisms of a section of the Tabriz Bazaar, recognized as the world's oldest bazaar (Aghabeigi & Farahmand-Tabar, 2021). The finite element model was developed using a macro-modeling approach. Mechanical tests were conducted to determine the material properties of the structure. Static analysis, modal analysis, and nonlinear time-history dynamic analysis were performed to evaluate the structural performance. Despite the structure demonstrated adequate strength under its self-weight, certain sections became unsafe under seismic loading when yield criteria were considered. The results indicated that the most critical part of the structure was the main dome, which necessitated strengthening interventions. Carbon fiber reinforcement was proposed for the dome and the walls. After the strengthening, performance analyses showed that the lateral load-bearing capacity of the walls increased by approximately 575%.

A three-dimensional finite element model was created using macro elements to determine the performance of a historical masonry building that experienced large displacements on its front facade as a result of the earthquakes that occurred in Italy (Barbieri et al., 2013). Nonlinear time-history dynamic analyses were conducted on the model. The building has a rectangular plan with dimensions of 67 × 16 meters and a height of 22 meters. A total of 465,490 solid finite elements were generated for the model. Consistent with the observed damage, dynamic analysis results indicated that the façade walls experienced significant damage within the first seconds of seismic loading. It was concluded that the building's seismic performance was insufficient, and necessary retrofitting measures were recommended. The study revealed that numerical simulations are very important for evaluating the seismic performance of historical structures.

A finite element model was created using the macro modeling method to determine the seismic performance of a masonry educational building damaged in the earthquake that occurred in Croatia in 2020 after reinforcement (Moreti et al., 2022). Three different numerical models were created by selecting three different reinforcement methods. The first of these models was strengthened with carbon fiber, the second with reinforced concrete, and the third with both carbon fiber and reinforced concrete. Nonlinear pushover analysis was applied to the models and the performance analyses of the strengthened buildings were compared. The strengthening methods were compared in terms of earthquake performance capacity, cost and environmental impact. It was concluded that the reinforced concrete strengthening method was the best method in terms of capacity, but the carbon fiber method was a better method in terms of environmental impact. In their study, Jasieńko et al. (2021) aimed to identify the causes of structural damage in a historic masonry structure resulting from various loading combinations. The building consists of a dome, drum, buttresses, arches, and columns. To model this complex structural system, plastic material models were employed within the finite element method. The connection between the dome and the buttresses was modeled using three-dimensional solid elements, and a diameter-to-thickness ratio was proposed for the dome geometry. Nonlinear pushover analyses were performed on the building model to assess its performance, and crack patterns consistent with the historically observed damages were obtained, thus validating the accuracy of the numerical model.

2.Historical house

In this study, a historical building located in Malatya province was studied. The historical building was located in Malatya, Turkiye, at coordinates 38.2817° North, 38.2606° East. The location of the building on the Turkish Earthquake Hazard Map is shown in Fig. 1. The masonry walls on the ground floor of the building are built entirely of rubble stone, but the first floor consists of different masonry material properties called stone and adobe. The average floor height is 3.15 meters, and the total construction area is 252 m^2. The façade view of the building is given in Fig. 2. The plans and façade views of the building are given in Fig. 3. The building was determined to be heavily damaged as a result of the February 6 Kahramanmaraş earthquakes.

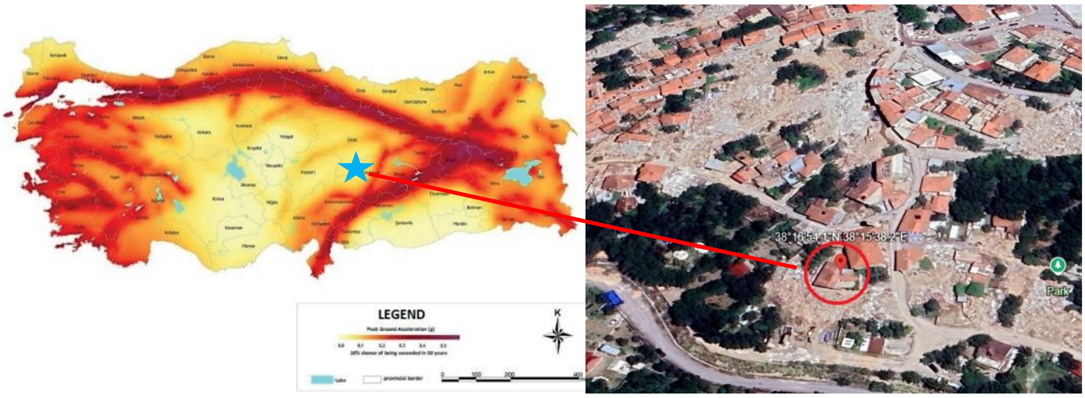

Fig. 1. The location of the building on the Turkish Seismic Hazard Map (TSHM, 2018)

Fig. 2. Façade of the building

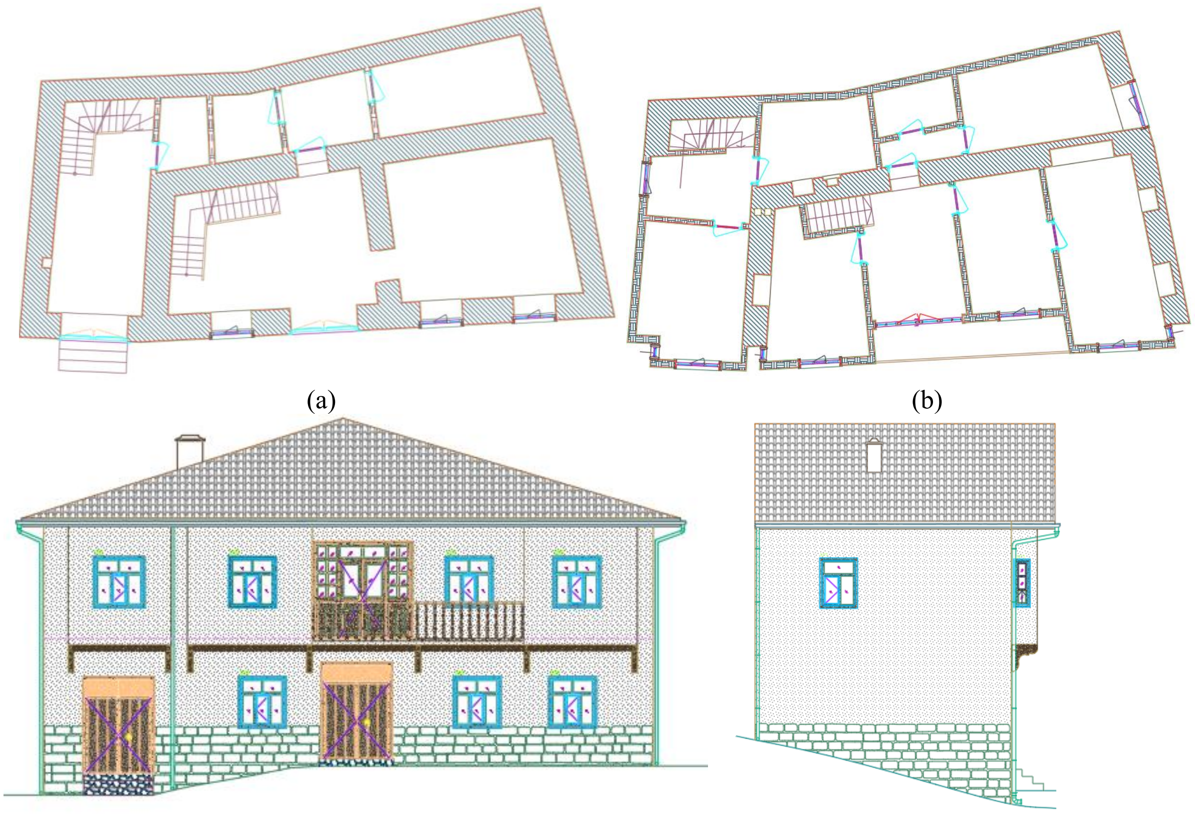

Fig. 3. Building (a) Ground floor plan, (b) 1st floor plan, (c) front façade, (d) side façade

3. Damage status of the structure

After the 2023 Elbistan-Kahramanmaraş earthquakes, the damage status of the structure was examined in order to compare it with the numerical analyzes of the structure. In the examinations, it was determined that the masonry walls on the ground floor of the structure were constructed as rubble stone, but the first floor was composed of different masonry material properties called stone and adobe. It was observed that the adobe and stone materials on the first floor of the structure had different strengths. For this reason, separations were observed at the wall joints. It is thought that the significant damages in the structure occurred due to the different strengths of these materials. Due to the materials used in the structure inadequate compressive and tensile strength, shear cracks was observed on the edges of the windows as a result of seismic loading. The areas where the most damages occurred are shown in Fig. 5, and sample photographs of the damages in the structure are shown in Fig. 6. In addition, there was shedding in the materials and plasters of all walls.

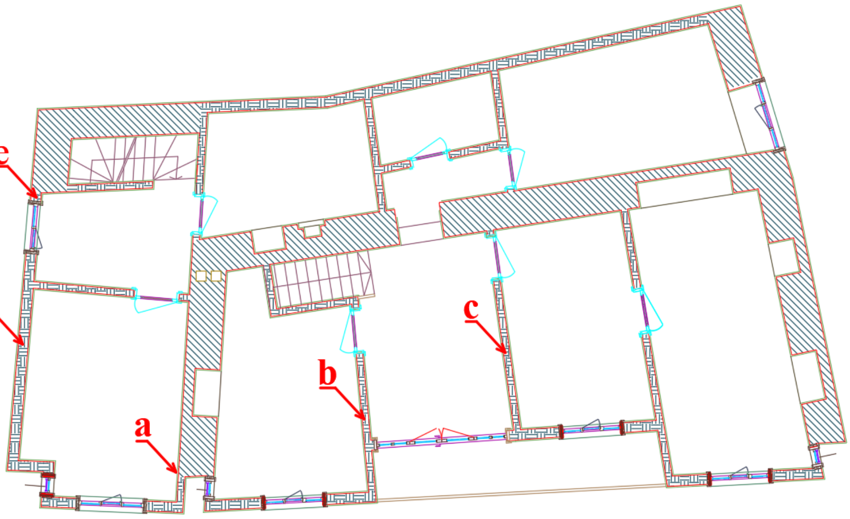

Fig. 5. The regions where most damage occurs.

(a) (b) (c)

(d) (e)

Fig. 6. Example photos of the damages.

4. Numerical solution

In this section, the stability analyzes of the current status of the structure under static and dynamic loads are examined. The finite element method was used to perform these analyses, with solutions obtained using the SAP2000 finite element software. The finite element model, created using the macro-modeling approach, consists of a total of 5.934 nodes and 3.046 solid elements. The finite element model of the historical structure is shown in Fig. 7. The foundation-soil interaction of the structure is defined as fixed support. Two different materials, stone and adobe, were defined for the masonry walls. The material properties of the stone and adobe walls are given in Table 1 and the this material properties were obtained according to the composite material theory. The linear analysis method in the time history was applied to the building using the records of the 2023 Pazarcık-Kahramanmaraş earthquake (Mw = 7.7) (Fig. 8). The dynamic response of the building was evaluated.

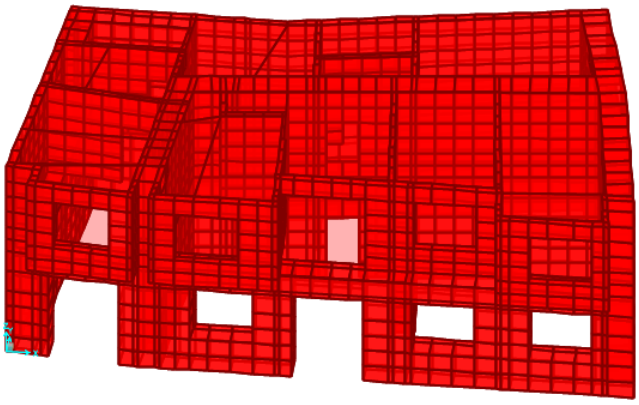

Fig. 7. Finite element model of historical structure.

Table 1. Masonry wall material properties (Mpa)

Wall	Young Modulus	Compressive strength	Tensile strength	Poisson ratio
Stone	21276	15.95	1.69	0.28
Adobe	136.5	1.4	0.14	0.25

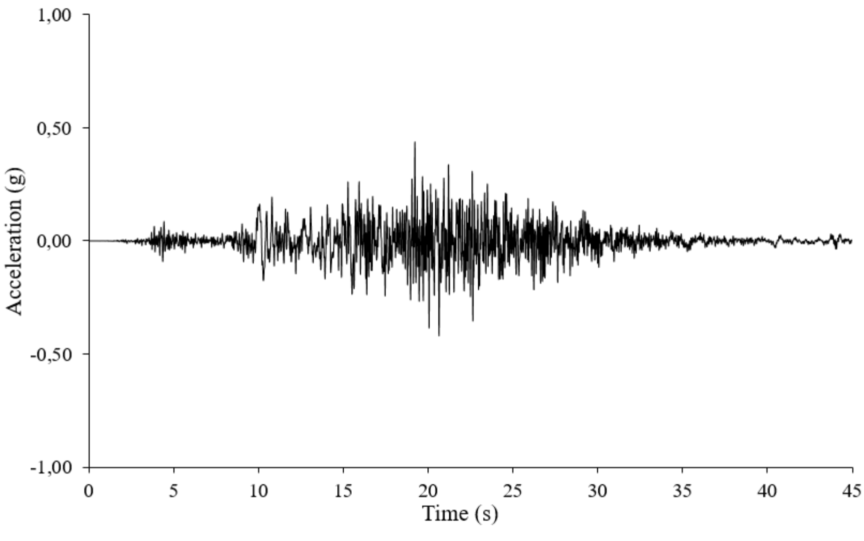

Fig. 8. 2023 Acceleration record of the Elbistan-Kahramanmaraş earthquake

The time history graph of the displacement values in the x direction for node 5056, which is the top point of the structure, under the combined effect of static and seismic loads, is shown in Fig. 9. It can be observed that the maximum displacement occurs at 10.31 seconds. As seen in Fig. 9, the maximum and minimum displacement values were recorded as -0.555 mm at 10.31 seconds and 0.513 mm at 9.87 seconds, respectively. The corresponding maximum and minimum principal stress-strain curves for these moments are presented in Fig. 10. A detailed examination of the obtained results revealed that the maximum principal stress, minimum principal stress, and shear stress were found to be 0.266 N/mm², -0.321 N/mm², and 0.299 N/mm², respectively.

4. Conclusions

In this study, the damage status of a historical masonry building after the 2023 Elbistan-Kahramanmaraş earthquake was examined and the causes of damage were examined in detail. In this context, the finite element model of the structure was created with the macro modeling technique and dynamic analyzes were performed. The analyzes were performed with the nonlinear analysis method in the time history using the SAP2000 finite element software. As a result of the numerical analyzes performed using the Malatya records of the 2023 Elbistan-

Kahramanmaraş earthquake (Mw = 7.7), the post-earthquake damage status of the building was compared with the numerical model.

According to the study results:

- It was observed that the adobe and stone materials on the first floor of the structure had different strengths. For this reason, separations were observed at the wall joints.
- Shear cracks was observed on the edges of the windows as a result of seismic loading.
- Since the materials used in the structure inadequate compressive and tensile strength, damage occurred to the structure due to the effects of earthquake loads.
- As a result of numerical analysis, the maximum and minimum displacement values were obtained as -0.555 mm at 10.31 s and 0.0513 mm at 9.87 s, respectively.
- As a result of numerical analysis, maximum, minimum principal stress and shear stresses were found to be 0.266, -0.321 and 0.299 N/mm2, respectively. The stress values obtained from the numerical results exceeded the stress values of the existing material.
- Due to the low resistance of masonry structures to seismic forces, it is recommended that retrofitting measures be implemented for masonry buildings.

Free vibration analysis of FG-CNTRCs with arbitrary CNT distribution based on higher-order shear deformation theory

Serhan Koç*[1], Gökhan Adıyaman[1]

[1] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. This paper introduces a finite element (FE) model, featuring three nodes and four degrees of freedom per node, to conduct free vibration analysis of carbon nanotube reinforced composite (CNTRC) beams. The free vibration behaviour of single-walled carbon nanotube (SWCNT) reinforced nanocomposite beams under various boundary conditions is investigated using the higher-order shear deformation theory (HSDT). CNTRC beams featuring arbitrary distributions of CNTs are examined. The consideration of arbitrary CNT distribution, representing potential defects or specific design configurations, ensures a realistic depiction of composite beam behaviour during free vibration analysis. For diverse end supports, including simply supported, clamped, and free conditions, the energy formulas, with varying coefficients, are solved by employing Hamilton equations to derive the governing differential equations. The material properties of functionally graded CNTRC (FG-CNTRC) beams are assumed to vary gradually along the thickness direction and are predicted using the extended rule of mixture. The free vibration analysis is conducted for the CNTRC beam in order to interpret the influence of different CNT volume fractions, distribution profiles, boundary conditions, and beam-slenderness ratios. The numerical values obtained are subsequently compared with those associated with a normal CNT distribution.

Keywords: Free vibration; Arbitrary distribution; Frequency; HSDT

1. Introduction

Mankind consistently pursues engineering materials that offer reliability, economic advantages, and environmental sustainability. Among these promising materials, carbon nanotubes (CNTs), initially introduced by Iijima in 1991 (Iijima,1991), have emerged prominently due to their remarkable physical and mechanical properties. Extensive research efforts utilizing analytical, experimental, and numerical methods have demonstrated that CNTs possess superior strength-to-weight ratios and multifunctional attributes such as electrical conductivity, making them highly favorable as reinforcing elements within polymer composites (Shirazi et al.,2011).

Composite materials reinforced with CNTs have gained widespread popularity due to their distinct advantages compared to traditional engineering materials. Notably stronger and harder than steel, CNTs also have significantly lower densities, positioning these composites ideally for advanced applications in aerospace, automotive, and electronics sectors. Additionally, their impressive corrosion resistance and extended fatigue life make CNT-reinforced composites particularly suited for challenging operational environments.

In CNTRC beams, the introduction of CNTs modifies the dynamic response, producing measurable shifts in natural frequencies and alterations in mode shapes. These effects are governed by the overall CNT volume fraction, the chosen gradation profile, and the imposed boundary conditions, underscoring the need for comprehensive numerical modeling to capture the resulting vibrational behavior.

Numerous studies have advanced the understanding of free vibration characteristics in CNTRC beams. Shen et al. (2017) compared various higher-order shear deformation theories to predict dynamic responses of CNTRC beams, highlighting the critical impact theory selection has on vibration analysis accuracy. Ansari et al. (2020) comprehensively investigated the vibration responses of functionally graded CNTRC beams, emphasizing the effects of different boundary conditions, CNT distributions, and volume fractions on the beams' dynamic characteristics. More recently, El-Ashmawy and Xu (2021) developed a finite element model based on Timoshenko beam theory, thoroughly exploring the combined impacts of CNT orientation and functional gradation on both static and free vibration behaviors of CNTRC beams. Their findings underscore the potential to tailor mechanical properties effectively by manipulating CNT orientations and grading indices without increasing structural mass.Investigation into the free vibration characteristics of CNT-reinforced beams remains ongoing

https://doi.org/10.31462/icearc2025_ce_sme_092

however, the notable advancements achieved in recent years have facilitated the design of novel and optimized CNT-reinforced beam configurations with a broad spectrum of potential applications.

This study investigates the free-vibration response of CNT-reinforced beams utilizing a three-node finite element formulated within the context of Higher-Order Shear Deformation Theory (HSDT), featuring twelve degrees of freedom per element. To enable the examination of responses within specific regions of the beam's cross-section, an arbitrary cross-sectional geometry was considered. For the numerical implementation along the beam's length, the beam was divided into equal segments along the z-axis. The fundamental governing relations were derived from HSDT principles. Effective material properties were determined using the extended rule of mixtures. Hamilton's principles were employed to derive the equations of motion, which were subsequently solved numerically to obtain dimensionless natural frequency values. The results, covering various support conditions, CNT volume fractions, and slenderness ratios, are presented.

2. Materials and methods for modeling cntrc beams

The uniform distribution (UD) and three functionally graded distributions (FGA, FGX) for a CNTRC beam of thickness h are illustrated in Fig. 1. The beam's length, width, and height are denoted by L_t, b, and h, respectively.

Fig. 2 illustrates the beam's geometric properties and coordinate system, with displacement in the y-direction assumed zero. The carbon nanotube volume fractions are then defined as functions of the thickness coordinate as follows:

The distribution of CNTs as a function of the z coordinate is given as follows:

UD-CNT $$V_{cnt}(z) = V_{tcnt} \quad (\frac{-h}{2} \le z \le \frac{h}{2}) \tag{1a}$$

FGA-CNT $$V_{cnt}(z) = (1 - \frac{2z}{h})V_{tcnt} \quad (\frac{-h}{2} \le z \le \frac{h}{2}) \tag{1b}$$

FGX-CNT $$V_{cnt}(z) = \frac{4z}{h}V_{tcnt} \quad (0 \le z \le \frac{h}{2}),\ V_{cnt}(z) = -\frac{4z}{h}V_{cnt} \ (-\frac{h}{2} \le z \le 0) \tag{1c}$$

The parameters V_{cnt} and V_{tcnt} denote the volume fraction of carbon nanotubes and the total volume fraction, respectively. Composite mechanical properties are governed by the relative proportions of reinforcement and matrix. Effective Young's and shear moduli for CNT-reinforced beams are obtained by calibrating molecular dynamics simulation outcomes to the extended rule of mixtures (Ashmawy and Xu,2021).

The elastic behavior of the CNT-reinforced composite is described by its longitudinal and transverse Young's moduli, E_{11} and E_{22}, and by its shear moduli, G_{12}, G_{13}, and G_{23}. These composite moduli are obtained from the constituent phase properties: E_{11}^{cnt},E_{22}^{cnt}, and G_{12}^{cnt} for the nanotube phase, E^m and G^m for the polymer matrix. Load-transfer efficiency between phases is characterized by the parameters η_1, η_2, and η_3. Poisson's ratio of the composite, $\nu(z)$, is similarly phase-specific, with values ν_{12}^{cnt} and ν^m for the nanotubes and matrix, respectively. Finally, the mass densities of the two phases are denoted ρ^{cnt} and ρ^m.

$$E_{11}(z) = \eta_1 V_{cnt}(z)E_{11}^{cnt} + V_m(z)E^m \tag{2a}$$

$$\frac{\eta_2}{E_{22}(z)} = \frac{V_{cnt}(z)}{E_{22}^{cnt}} + \frac{V_m(z)}{E^m} \tag{2b}$$

$$\frac{\eta_3}{G_{12}(z)} = \frac{V_{cnt}(z)}{G_{12}^{cnt}} + \frac{V_m(z)}{G^m} \tag{2c}$$

$$\nu(z) = V_{cnt}(z)\nu_{12}^{cnt} + V_m(z)\nu^m \tag{2d}$$

$$\rho(z) = V_{cnt}(z)\rho^{cnt} + V_m(z)\rho^m \tag{2e}$$

$$V_m(z) = 1 - V_{cnt}(z) \tag{2f}$$

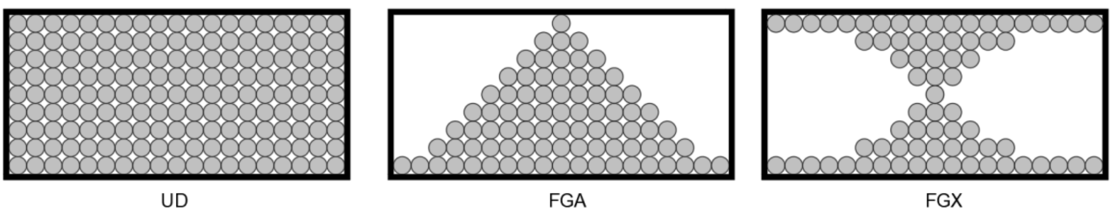

Fig. 1. SWCNT patterns in a CNTRC beams UD, FGA and FGX

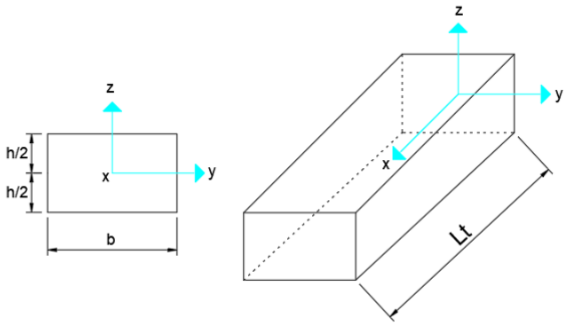

Fig. 2. Geometric properties and coordinate system of the beam

The associated nodal displacement vector for this element is defined as follows:

$$u_0 = N_1 u_1 + N_2 u_2 + N_3 u_3 \tag{3a}$$

$$w_0 = M_1 w_1 + M_2 w_2 + M_3 w_3 + M_4 \phi_1 + M_5 \phi_2 + M_6 \phi_3 \tag{3b}$$

$$\beta_0 = N_1 \beta_1 + N_2 \beta_2 + N_3 \beta_3 \tag{3c}$$

$$\phi_0 = \frac{\partial w_0}{\partial x} \tag{3d}$$

According to the HSDT, the axial displacement of the bar is given by:

$$u = u_0(x) - z\phi(x) + f(z)\beta(x) \tag{4a}$$

$$w = w_0(x) \tag{4b}$$

In this formulation, u and w denote transverse and axial displacement components (along the x- and z-axes) at any beam point. The mid-plane displacements along the x and z-axes are represented by u_0 and w_0, respectively, while ϕ corresponds to the section's rotation. The shear deformation shape function f(z) is adopted from Reddy's higher-order theory (Reddy,2003).

$$f(z) = z - \frac{4z^3}{3h^2} \tag{5}$$

According to the theory of elasticity, the shape-displacement relations are given as follows.

$$\varepsilon_{xx} = \frac{\partial u}{\partial x} = \frac{\partial u_0}{\partial x} - z\frac{\partial \phi_x}{\partial x} + f(z)\frac{\partial \beta_x}{\partial x} \tag{6a}$$

$$\varepsilon_{xz} = \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} = -\phi(x) + f(z)\beta_x + \frac{\partial w_0}{\partial x} \tag{6b}$$

Fig. 3 depicts the finite-element model comprising three nodes and twelve degrees of freedom. Under plane stress assumptions, the transverse normal stress component was set to zero, and the associated stiffness contribution was omitted from the analysis.

$$\begin{Bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_4 \\ \sigma_5 \\ \sigma_6 \end{Bmatrix} = \begin{bmatrix} Q_{11} & Q_{12} & Q_{13} & 0 & 0 & 0 \\ Q_{12} & Q_{22} & Q_{23} & 0 & 0 & 0 \\ Q_{13} & Q_{23} & Q_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & Q_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & Q_{55} & 0 \\ Q_{16} & Q_{26} & Q_{36} & 0 & 0 & Q_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \\ \varepsilon_6 \end{Bmatrix} \tag{7}$$

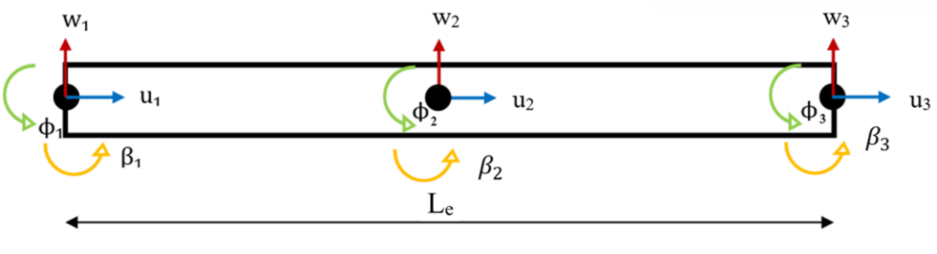

Fig 3. Finite Element Model

Here, σ and ε denote the stress and strain tensors, respectively, whose components define the mechanical behavior of the CNT-reinforced beams

$$Q_{11} = \frac{E_{11}(z)}{1-\nu^2}, Q_{12} = \frac{\nu_{12}(z)E_{22}(z)}{1-\nu^2}, \mathrm{Q}_{22} = \frac{E_{22}(z)}{1-\nu^2} \tag{8a}$$

$$Q_{44} = G_{23}(z), Q_{55} = G_{13}(z), Q_{66} = G_{12}(z) \tag{8b}$$

By accounting for the CNT orientation, the constitutive stress–strain relations are mapped from the principal material axes (1, 2, and 3) to the global Cartesian coordinate system (x, y, and z), yielding

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{yz} \\ \sigma_{xz} \\ \sigma_{xy} \end{Bmatrix} = \begin{bmatrix} \bar{Q}_{11} & \bar{Q}_{12} & 0 & 0 & \bar{Q}_{16} \\ \bar{Q}_{12} & \bar{Q}_{22} & 0 & 0 & \bar{Q}_{26} \\ 0 & 0 & \bar{Q}_{44} & \bar{Q}_{45} & 0 \\ 0 & 0 & \bar{Q}_{45} & \bar{Q}_{55} & 0 \\ \bar{Q}_{16} & \bar{Q}_{26} & 0 & 0 & \bar{Q}_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{yy} \\ \varepsilon_{yz} \\ \varepsilon_{xz} \\ \varepsilon_{xy} \end{Bmatrix} \tag{9}$$

Under the plane-strain hypothesis, the out-of-plane strain component is taken as zero. Consequently, the following stress and shear-strain components vanish: [$\sigma_{yy} = \sigma_{yz} = \sigma_{yy} = \varepsilon_{yz} = \varepsilon_{xy} = 0$ ve $\varepsilon_{yy} \neq 0$]

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{xz} \end{Bmatrix} = \begin{bmatrix} \tilde{Q}_{11} & 0 \\ 0 & \tilde{Q}_{55} \end{bmatrix} \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{xz} \end{Bmatrix} \tag{10a}$$

$$\tilde{Q}_{11} = \bar{Q}_{11} - \frac{(\bar{Q}_{12})^2}{\bar{Q}_{22}}, \tilde{Q}_{55} = \bar{Q}_{55} \tag{10b}$$

The governing equations of motion are obtained using Hamilton's Principle, stated as (Nejati,2016)

$$\delta\Pi \;=\; \delta(U-T) \;=\; 0 \tag{11}$$

where δU represents the variation of the potential energy and δT is the variation of the kinetic energy. The relevant integrals defining U and T for the element are given by

$$U = \frac{1}{2}\int_0^{L_e}\int_A [\sigma_x \frac{\partial \delta u}{\partial x} + \sigma_{xz}(\frac{\partial \delta u}{\partial z} + \frac{\partial \delta w}{\partial x})] \tag{12a}$$

$$T = \frac{1}{2}\int_0^{L_e}\int_A \left\{\rho[(\frac{\partial \delta u}{\partial t})^2 + (\frac{\partial \delta w}{\partial t})^2]\right\} \tag{12b}$$

Since b=1, the width does not affect the area integral, so a one-dimensional through-thickness integration is performed instead of a full two-dimensional procedure. The total height h is divided into N horizontal layers of thickness (see Fig. 4).

$$\Delta z = h/h_n \tag{13}$$

Within the i_{th} layer, the sampling points for the CNT distribution function g(z) are defined as

$$z_i^- \;= -\frac{h}{2} + (i-1)\Delta z \tag{14a}$$

$$z_i^0 \;= z_i^- + \frac{\Delta z}{2} \tag{14b}$$

$$z_i^+ = z_i^- + \Delta z \tag{14c}$$

The integral of g(z) over the layer is then approximated by Simpson’s one-third rule

$$\int_{z_i^-}^{z_i^+} g\,(z)dz \;\approx\; \frac{\Delta z}{6}[g(z_i^-) \;+\; 4g(z_i^0) \;+\; g(z_i^+)]. \tag{14d}$$

All expressions (Eqs. 14a–14d) are evaluated in succession for each layer to construct the overall through-thickness integral.

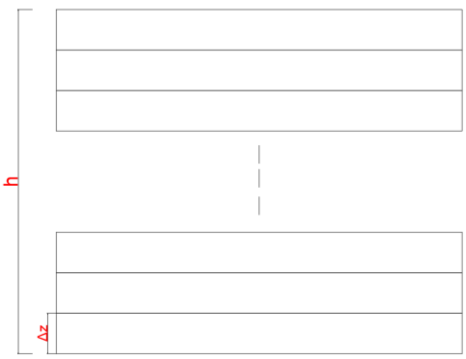

Fig 4. Illustration of the beam cross-section discretized arbitrarily into uniform layers of thickness Δz

The layer-wise contributions are cumulatively summed from the beam's base to any specified elevation z, yielding a highly accurate estimate of the CNT influence at that height. Comparison with a reference analytical profile shows that the composite Simpson's rule implementation reproduces the known results with negligible error.

Finally, by using the variation approach, the governing equations of the FGCNT beam are obtained.

$$\delta u = 0 \;\Rightarrow\; \frac{\partial \sigma_x}{\partial x} + \frac{\partial \sigma_{xz}}{\partial z} = \rho \frac{\partial^2 u}{\partial t^2} \tag{15a}$$

$$\delta w = 0 \;\Rightarrow\; \frac{\partial \sigma_z}{\partial z} + \frac{\partial \sigma_{xz}}{\partial x} = \rho \frac{\partial^2 w}{\partial t^2} \tag{15b}$$

Neglecting the inertial forces in Eqs. (14a) and (14b), the governing equations for free-vibration analysis of the FG-CNT beam are derived, enabling the determination of its natural frequencies.

3. Numerical results

In numerical analyses (10,10) a matrix called PMMA reinforced with seat type single-walled CNTs is used. Assuming a room temperature of 300 K, the material properties of the poly methyl methacrylate matrix called PMMA are ν^m=0.3, ρ^m=1190 kg/m^3, E^m=2.5 GPa. Material properties of armchair type CNTRC reinforcement;ν_{12}^{cnt}=0.19, G_{12}^{cnt}=17.2 GPa, E_{11}^{cnt}=600 GPa, E_{22}^{cnt}=10 GPa and ρ^{cnt}=1400kg/m^3. Table 1 presents the total CNT volume fractions together with their corresponding efficiency parameters.

Table 1. Total volume fractions and efficiency parameters of CNTs

V_{tcnt}	$\boldsymbol{\eta_1}$	$\boldsymbol{\eta_2}$	$\boldsymbol{\eta_3}$
0.12	1.2833	1.0556	1.0556
0.17	1.3414	1.7101	1.7101
0.28	1.3238	1.7380	1.7380

The following section presents an investigation of the dimensionless free-vibration characteristics of a finite-element beam configured with a variety of boundary conditions (clamped–clamped, clamped–simply supported, simply supported–simply supported, and clamped–free) using the classical beam theory. A convergence study was conducted, and h_n=25 was used to verify calculation accuracy. For the two-distribution combinations, h_n=20 was adopted. The resulting dimensionless natural frequency, ϖ, for each boundary case is determined from the relation

$$\varpi = \omega L_t \sqrt{\frac{I_0^m}{A_{11}^m}} \tag{16}$$

I_0^m and A_{11}^m are given below

$$I_0^m = \int_{-h}^{h} \rho^m (1 - (\upsilon^m)^2) dz \;\text{ and }\; A_{11}^m = \int_{-h}^{h} E^m dz \tag{17}$$

Fig. 5 shows that ϖ decreases as L_t/h increases for all distribution types and V_{tcnt}, reflecting the lower natural frequencies of more slender beams in free vibration. At a given slenderness ratio, FGX produces the highest ϖ, FGA yields intermediate values, and UD the lowest, demonstrating how gradation enhances vibrational performance.

Table 2 presents the first three dimensionless natural frequencies ϖ of CNTRC beams under simply supported conditions for various CNT distribution types and V_{tcnt}. Results are compared with Yas and Samadi (2012), who used Hamilton's principle and Timoshenko beam theory for free-vibration analysis, confirming the accuracy and convergence of the arbitrary cross-section model. The FGX distribution yields the highest ϖ, FGA is intermediate, and UD the lowest. The maximum relative deviation for FGX at V_{tcnt}=0.28.

Table 3 and Table 4 present the first dimensionless natural frequency ϖ of CNTRC beams for all pairwise mixtures of two CNT distribution types at slenderness ratios of 5 and 20 (θ=0), under various boundary conditions and volume fractions V_{tcnt}.

The data demonstrate that exchanging the order of two distributions (UD & FGX) produces identical ϖ values. Mixtures involving the surface-graded FGX distribution consistently deliver higher natural frequencies than those employing FGA or UD, with the largest gains observed under the most constrained boundary (C–C). Increasing V_{tcnt} from 0.12 to 0.28 raises ϖ in all cases, reflecting the stiffening effect of greater CNT content.

The UD & FGA mixture yields a lower natural frequency than the UD distribution alone. In contrast, the FGA & UD combination produces higher frequencies than either UD or FGA individually. The UD & FGX pairing gives an intermediate result exceeding UD but falling short of FGX. Likewise, the FGA & FGX mixture elevates frequencies above both single distributions, whereas the FGX & FGA arrangement reduces the frequency relative to either FGX or FGA alone.

Table 4 shows that the UD & FGA combination consistently underperforms both UD and FGA alone, while FGA & UD exceed each single-distribution case. The UD & FGX pairing improves the response relative to UD but remains below the single FGX distribution, and although FGA & FGX raises the frequency above both individual distributions, the FGX & FGA sequence yields lower results than either FGX or FGA by itself.

4. Conclusions

The finite-element framework, which employs layered through-thickness discretization and Simpson's rule, reproduces reference free-vibration frequencies of CNTRC beams with negligible error. The dimensionless fundamental frequency decreases as the slenderness ratio increases and increases with higher CNT volume fraction. Among single-distribution configurations, the surface-concentrated FGX pattern yields the highest frequencies, the FGA pattern produces intermediate values, and the uniform UD distribution gives the lowest.
In mixed-distribution cases, the sequence of gradation dictates the outcome:

- UD & FGA reduces the frequency below either UD or FGA alone.
- FGA & UD raises the frequency above both single distributions.
- UD & FGX yields a value between UD and FGX.
- FGA & FGX elevate the frequency beyond both parent patterns.
- FGX & FGA produces a lower frequency than either FGX or FGA alone.
- These sequence-dependent effects persist across slenderness ratios of 5 and 20, zero angular orientation, all boundary conditions, and various volume fractions.
- The findings provide clear guidance for optimizing CNTRC beam vibrational performance through informed selection of CNT gradation pattern, volume fraction, and mixture order.

Abstract. An earthquake is a natural disaster that critically tests the resilience of structures. The 2023 Kahramanmaraş earthquakes, with their significant magnitude and destructiveness, have once again raised concerns about the seismic performance of the building stock in our country. Accurately modeling the loads caused by earthquakes and predicting the behavior of structures are crucial in engineering practices. Nonlinear analysis methods are frequently used to assess structural performance. The pushover analysis determines the capacity curve of a structure, revealing its general resilience level, while time history analysis provides a detailed evaluation of seismic behavior. Both methods offer valuable insights for earthquake engineering, but their results may differ in interpretation. In this study, nonlinear analysis methods, namely pushover and time history analysis, were applied on a 6-storey multi-storey building model. In the time history analysis, the ground motion record obtained from 4406 station during the February 6, 2023 Elbistan earthquake (M_w: 7.6) was used. The results of both methods were compared and the differences they provided in terms of evaluating the seismic behavior of the structures were examined.

Keywords: Reinforced concrete structure; Time history analysis; Pushover analysis

1. Introduction

Earthquakes are natural disasters that causing loss of life and property with their devastating effects. Many countries in the world are affected by this disaster; earthquakes are an inevitable fact of daily life and construction in countries located on active fault zones. Türkiye has active fault zones (North Anatolian Fault, East Anatolian Fault and West Anatolian Fault zones) that cause devastating earthquakes. The 2023 Kahramanmaraş earthquakes (Pazarcık Mw: 7.7 and Elbistan Mw: 7.6) that occurred on the Eastern Anatolian fault line showed the destructive effects of earthquakes (Dema, 2023). In the literature studies conducted after the earthquake, the deficiencies in the existing building stock and the causes of damage to the buildings were given in detail (Avcıl, 2024; Işık, 2024; İnce, 2024; Yetkin, 2024).

For earthquake-resistant design, engineering approaches and methods have a big importance. The behavior of buildings under earthquake effects should be accurately modeled and analyzed. There are different methods for modelling the nonlinear behaviour of buildings. Among these methods, pushover analysis and time history analysis are widely used, especially in the performance evaluation of existing structures. Some studies in the literature have questioned the effectiveness of these two methods. In the study conducted by Korkmaz and Düzgün (2006), four reinforced concrete frame structures (3, 5, 8 and 15 floors) were considered and nonlinear static pushover analyses were performed for these frame structures under rectangular, triangular and parabolic load effects. Static pushover analyses were compared with the results of time history dynamic analyses performed with 50 different earthquake data. In the study conducted by Çapa (2020), linear and nonlinear calculation methods were applied on three, five and seven-story buildings according to TBDY 2018. In order to evaluate the earthquake performance with the static pushover method and the nonlinear analysis method in the time history, parameters such as maximum plastic rotation values of the plasticized sections, base shear forces, peak displacement values and damage amounts in the structural system were analyzed and compared. In the study conducted by Toplu and Kırtel (2021), three different seismic base isolated structure models were designed and comparisons were made with different analysis methods in these models. Nonlinear behaviors and collapse mechanisms of structures were analyzed using static pushover analysis with time history analysis method based on real earthquake records. As a result of the study, it was observed that the data obtained in the time history were compatible with the pushover analysis results.

In this study, it is aimed to compare two nonlinear analysis methods used in reinforced concrete buildings. For this purpose, a reinforced concrete building with a 6-storey frame system was designed. Nonlinear time history analyses of the designed building were performed using an acceleration record of the 2023 Elbistan earthquake. The damage to the building as a result of these two methods was compared. TBEC-2018 was taken into consideration in the analyses and evaluations made within the scope of the study.

2. Material and metod

TBEC-2018 was taken into consideration in the analyses and evaluations made within the scope of the study. In numerical analysis, SAP2000 finite element program was used. The fiber element method was used for consider the nonlinear behavior of reinforced concrete elements. It is a widely used method for nonlinear behaviour of reinforced concrete structures and provides successful results (Karaton et al., 2021; Karaton et al., 2023).

In static pushover analysis, increasing horizontal forces are applied to the building exposed to vertical loads. The capacity curve is obtained by recording the displacement values corresponding to the increasing horizontal load. Horizontal loads are increased until the building collapses. Then, the target displacement value is calculated using the building's capacity curve and the damage conditions at this point are evaluated. In the time history analyses, earthquake records are applied to the buildings. Acceleration records can be used directly or scaled with the design earthquake. The damages occurring in the building during the earthquake are obtained.

3. Numerical analysis

In this study, nonlinear analysis of a 6-storey reinforced concrete building was performed with different methods. Fig. 1 shows the model of the designed building. The damage status of this building was compared by performing static pushover and time history analyses. In the building design, concrete with a compressive strength of 30 MPa and reinforcement with a yield strength of 420 MPa were used. All floor heights are equal and designed as 3 m. Column dimensions are designed as 50x50 cm and beam dimensions are designed as 30x50 cm. In the modeling of the building, slabs were not included in the model and rigid diaphragms were defined at each floor level. Floor and wall loads were applied on the beams. Plastic hinges are defined at the end regions of columns and beams. The first two periods of this building occurred as T_1: 0.85 s and T_2: 0.85 s with a mass participation ratio of 82%.

The fiber element method was used to reflect the nonlinear behavior of the reinforced concrete building. Plastic hinges were defined at the end regions of each column and beam element. In modeling the concrete material, the stress and strain graphs of confined and unconfined concrete were taken into account with the Mander model. Damage limits of confined concrete, unconfined concrete and reinforcement were calculated taking into account TBDY-2018 and defined in SAP2000 program. Table 1 shows the damage limits of these material.

Table 1. Damage limits of materials

Damage limits	Unconfined concrete	Confined concrete	Steel
Limited damage	0.0025	0.0025	0.0075
Controlled damage	0.0026	0.0133	0.024
Collapse prevention	0.0035	0.0177	0.032

In the static pushover analysis of a reinforced concrete building, the building is first subjected to vertical loads. Then, increasing horizontal forces are applied to the building and the horizontal load-displacement graph is obtained (Fig. 2). As a result of the analysis, the target displacement of the building is determined and the damage status at this displacement value is evaluated. The target displacement of this building was calculated as 0.132 m, taking into account TBDY-2018.

Nonlinear time history analyses of the designed reinforced concrete building were performed. In this analysis, the acceleration record of station number 4406 from the 2023 Elbistan earthquake was used (Fig. 3). Although the original record is longer, only the 35-second interval where the ground motion is most effective was used. In the time history analyses, the maximum peak displacement was obtained as 0.163 m. The damage states obtained as a result of the static pushover analysis and time history analysis of the 6-storey reinforced concrete building are given in Table 2.

Table 2. Damage status obtained by nonlinear analysis

		Static pushover analysis			Time history analysis		
		Immediate occupancy	Life safety	Collapse prevention	Immediate occupancy	Life safety	Collapse prevention
Ground floor	Column	4	12	-	-	16	-
	Beam	-	12	-	-	12	-
1	Column	2	-	-	12	-	-
	Beam	-	12	-	-	12	-
2	Column	4	-	-	10	-	-
	Beam	10	2	-	-	12	-
3	Column	4	-	-	12	-	-
	Beam	2	-	-	10	2	-
4	Column	-	-	-	10	-	-
	Beam	-	-	-	-	-	-
5	Column	-	-	-	2	-	-
	Beam	-	-	-	-	-	-

Conclusion

There are different methods for determining the nonlinear performance of reinforced concrete buildings. The methods used may have advantages over each other in terms of practicality and accuracy. The appropriate method should be selected according to the characteristics of the building to be analyzed. Within the scope of this study, the static pushover and nonlinear time history analyses of a reinforced concrete building consisting of a 6-storey frame system were performed and their damage conditions were compared. The results obtained from the analyses are summarized below:

- A symmetrical, 6-storey building consisting of frame elements was designed for numerical analysis. The first two periods of this building occurred as T_1: 0.85 s and T_2: 0.85 s with a mass participation rate of 82%.
- In static pushover analyses, the demand displacement of the building was calculated as 0.132 m according to TBDY-2018 and the damages at this displacement value were taken into account.
- In the nonlinear time history analyses, the acceleration records recorded at 4406 stations of the Elbistan earthquake were scaled according to the design earthquake and analyzed. As a result of the analysis, the maximum top displacement of the building was obtained as 0.163 m.
- The damage states obtained from nonlinear static pushover and time history analyses were compared. It was observed that there was a significant difference in the damages occurring in the structural elements. These results were obtained in a building that was symmetrical and had no structural irregularities. In future studies, it is necessary to evaluate which buildings static pushover analysis can be effectively applied, considering different floors and irregularities.

Buckling and load capacity of thin-walled variable cross-section columns: Influence of fiber orientation and weld lines

Gökçen Kurt*[1], Ayşe Polat[1], Mustafa Özgür Yaylı[1], Murat Yazıcı[2], Babür Deliktaş[1]

[1] *Bursa Uludag University, Department of Civil Engineering, Artificial Intelligence and Computational Mechanics Laboratory, 16059, Bursa, Turkey,*
[2] *Bursa Uludag University, Department of Automotive Engineering, Applied Mechanics and Advanced Materials Research Group Lab.16059, Bursa, Turkey,*

Abstract. The construction, automotive, and aerospace industries all make extensive use of short fiber-reinforced thermoplastic composites because of its remarkable mechanical qualities, lightweight nature, and ability to be recycled. However, anisotropic effects from injection molding, like fiber orientation and weld lines, make it difficult to anticipate their structural performance, especially under buckling stresses. To account for manufacturing-induced anisotropy in finite element calculations, this study offers an integrated computational framework that combines Moldex3D, Digimat RP, and ABAQUS. The framework assesses the buckling and nonlinear anisotropic behavior of hollow square cross-section columns made of Polyamide 6 reinforced with 40% glass fiber (PA6-GF40). J2 plasticity models the behavior of the elastoplastic matrix, whereas the Mori-Tanaka technique forecasts effective material properties. The findings provide a solid methodology for creating high-performance composite structures under challenging loading circumstances, emphasizing the important influence of fiber orientation and weld lines on structural stability.

Keywords: Finite element analysis (FEA); Mold flow simulation; Plastic injection; Buckling; Thermoplastic composites.

1. Introduction

Fiber-reinforced composites, a type of load- bearing component used in the aerospace, civil and automotive industries (Rozylo & Debski, 2024), have gained popularity due to their superior mechanical properties and light weight (Fu et al., 2009). However, these structures are particularly vulnerable to buckling failure modes (Kroon et al., 2024). There has been little research considering random fiber distributions to study the buckling behavior of fiber reinforced polymer plates (Schreiber et al., 2020). Conventional methods used to improve buckling stability include finite element method (Li & Kapania, 2018), finite difference method, boundary element method (Paiva, 2018) and finite integral transformation method.

Injection-molded short-fiber composites are ideal for large-scale applications due to their high mechanical qualities (Zhou et al., 2013), wear resistance (Chen et al., 2007), and recyclability. However, the complicated anisotropic behavior caused by local variations in microstructural properties during the injection molding process makes it difficult to correctly predict their performance and failure (Saraçoğlu & Uzun, 2020). In spite of advances in simulation tools, current approaches based on failure onset criteria are still not enough to accurately predict the failure of injection molded short fiber composites. To alleviate this constraint, numerical Finite Element Analysis (FEA) methods that explicitly account for the anisotropic and elastoplastic properties of these materials are required (Tseng et al., 2017). A comprehensive computational modeling technique for the full plastic injection molding process of fiber-reinforced thermoplastic composites is currently unavailable, and it must account for the anisotropic elastoplastic behavior caused by fiber orientations and weld lines (Polat et al., 2024).

In this study, Moldex3D, Digimat RP and ABAQUS software are used to provide a framework for complex simulation to integrate basic manufacturing data into finite element models. The study focuses on the buckling and nonlinear anisotropic behavior of columns with hollow square sections under different injection molding configurations, which improves the prediction reliability and contributes to the design and optimization of lightweight, high-performance composite structures for load demanding applications.

2. Method

Numerical analyses often use the homogenization method, which assumes a component to be isotropic. However, this method can lead to significant discrepancies between numerical predictions and actual parts due to the component's inherent anisotropic nature. In contrast, models incorporating mold flow information exhibit non-homogeneous distributions, with fiber orientation and content varying spatially. The recommended method closely replicates real-life material behavior, enhancing the specificity and accuracy of simulations for fiber-reinforced composites.

Optimization techniques are not included in this workflow, as it emphasizes the integration of material data and manufacturing parameters for precise initial simulations. The process involves several essential stages: collecting manufacturing data, collecting structural data, using Digimat MX, combining production data with material properties, and using a finite element analysis application like ABAQUS.

The manufacturing data involves collecting critical production process parameters, such as manufacturing mesh, fiber orientation, and weld lines, which significantly influence material properties. Structural data, including material characteristics, loading conditions, and assembly details, can be continuously modified and updated based on simulation outcomes, enabling iterative improvements and optimization of component designs.

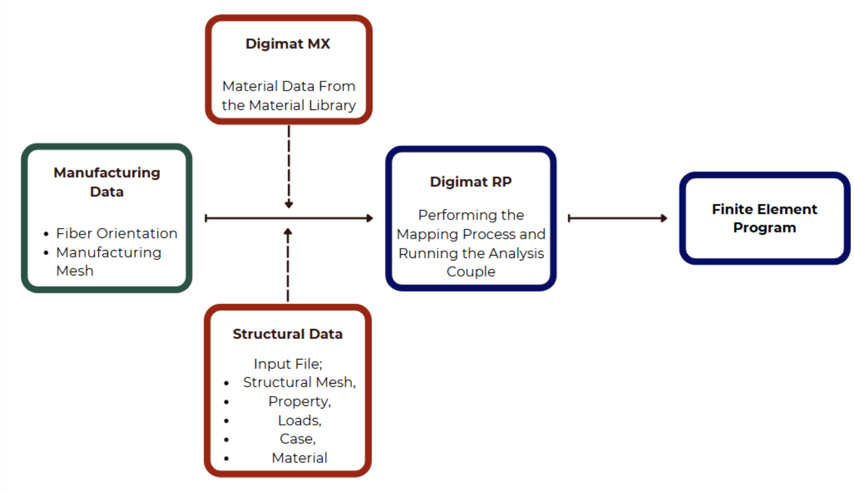

Fig. 1. Digimat RP working principle

2.1. Mori-Tanaka Method to fiber reinforced composite with elastoplastic matrix

A micromechanical method that independently assesses the mechanical characteristics of the matrix and fiber phases in order to forecast the effective properties of the heterogeneous material is used to study the mechanical behavior of short fiber reinforced composites. Digimat software—more especially, the MF and MX modules—was used to create the material model used in this investigation.

To determine the macroscopic properties of composite materials, Digimat MF, the software's homogenization tool, models each phase separately. It takes into account important microstructural information such as fiber volume fraction, aspect ratio and orientation to properly represent the microstructure of the material. Digimat offers two homogenization techniques: mean field homogenization (MFH) and direct finite element analysis of a representative volume element (RVE) at the microscale.

Two approaches are provided by the MFH framework: The Mori-Tanaka Method is commonly employed in most situations and provides accurate estimations for composites with acceptable fiber mass fractions (Mori & Tanaka, 1973). The Double Inclusion Method improves accuracy for composites with very high fiber mass fractions.

Anisotropic measurements and associated material models are comprehensively stored in the Digimat MX module. Elastic, plastic, elastic-plastic, elastic-viscoplastic, and viscoelastic-viscoplastic models are among the various mechanical behaviors and levels of complexity it supports. Because of its adaptability, materials' responses to various loads can be accurately depicted.

In this study, the Digimat MX tool was used, which is the library of the Digimat program provided by the manufacturers. The Mori-Tanaka method combined with a plasticity model was used to characterize the nonlinear behavior of short fiber reinforced composites, in particular PA6-GF40. The complex relationships between the polyamide matrix (PA6) and the glass fibers (GF40) are well captured by this method, allowing a comprehensive study of the behavior of the material under various loading scenarios.

The Mori-Tanaka method is particularly suitable for this type of analysis as it takes into account the anisotropic and heterogeneous properties of the composite. Thanks to the integration of these properties, the approach provides more precise predictions of the mechanical properties of the material, leading to a strong understanding of its behavior.

The goal of homogenization is to compute the instantaneous effective stiffness tensor (Ceff) at the macro level, using the mechanical properties of the microstructural components.

$$\dot{\boldsymbol{\sigma}} = \mathbf{C}_{eff}\colon \dot{\boldsymbol{\varepsilon}} \tag{1}$$

In this equation, $\dot{\boldsymbol{\sigma}}$ is the macroscopic stress rate tensor, $\dot{\boldsymbol{\varepsilon}}$ is the macroscopic strain rate tensor, and $\mathbf{C}_{eff}$ is the elastic stiffness tensor to be calculated.

The Mori-Tanaka (MT) method accepts that the interactions between various types of inhomogeneities with finite volume concentrations are approximated by embedding the inhomogeneities in a medium with effective thermomechanical properties.

The following formula is used by the MT method to determine the effective properties of composites (Jain, 2019):

$$\boldsymbol{C}_{eff} = \boldsymbol{C}_m + v_f\left(\boldsymbol{C}_f - \boldsymbol{C}_m\right)\boldsymbol{A}_f \tag{2}$$

In this case, $\boldsymbol{C}_m$; represents the matrix's stiffness tensor, $\boldsymbol{C}_f$; represents the fiber's stiffness tensor, and v_f; represents the fiber volume fraction. An expression for the instantaneous stress concentration factor is:

$$\mathbf{A}_f = \left[\mathbf{I} + \mathbf{S}\,(\mathbf{C}_{\boldsymbol{m}})^{-1}\,(\mathbf{C}_{\boldsymbol{f}} - \mathbf{C}_{\boldsymbol{m}})\right]^{-1} \tag{3}$$

In this case, $\boldsymbol{S}$ stands for the Eshelby tensor and $\boldsymbol{I}$ for the identity tensor. The shape, aspect ratios, and orientation of the fibers used in composite materials all affect the Eshelby tensor.

$$S_{ijkl} = \mathrm{f}(v_m, \text{aspect ratios, orientation of fibers}) \tag{4}$$

For a generic anisotropic material the Eshelby tensor is given by the following surface integral

$$S_{ijkl} = \frac{1}{8\pi}\boldsymbol{C}_{m_{pqkl}}\int_{-1}^{1} d\zeta_3 \int_0^{2\pi}\left\{G_{iqjp}(\bar{\xi}) + G_{jqip}(\bar{\xi})\right\}dw \tag{5}$$

where

$$\begin{gathered} G_{ijkl}(\bar{\xi}) = \bar{\xi}_k\bar{\xi}_l N_{ij}(\bar{\xi})/D(\bar{\xi}) \\ \bar{\xi}_i = \frac{\zeta_i}{a_i} \\ \zeta_1 = (1-\zeta_3^2)^{1/2}\ \cos w, \\ \zeta_2 = (1-\zeta_3^2)^{1/2}\ \sin w \\ D(\bar{\xi}) = \epsilon_{mnl}K_{ml}K_{n2}K_{l3} \\ N_{ij}(\bar{\xi}) = \frac{1}{2}\epsilon_{ikl}\epsilon_{jmn}K_{km}K_{ln} \\ K_{ik} = C_{m_{ijkl}}\bar{\xi}_j\bar{\xi}_l \end{gathered} \tag{6}$$

The tensor of permutations is represented by ϵ_{ikl}. The formula for a_i for spherical inculison is $(a_1 = a_2 = a_3)$. The impact of fiber orientations on the effective mechanical behavior of composites is taken into consideration by combining the orientation distribution tensor $\mathbf{\Theta}$ with the Eshelby tensor S_{ijkl}. The effective properties are calculated as an average across all possible fiber orientations when working with composites that contain randomly oriented fibers. This averaging is made possible by the orientation distribution tensor, $\mathbf{\Theta}$. When the orientation distribution tensor $\mathbf{\Theta}$ is incorporated into the micromechanical framework using the Eshelby tensor, the orientation-averaged Eshelby tensor that results is as follows:

$$\bar{S}_{ijkl} = \int S_{ijkl}\,(\boldsymbol{n}) \cdot f(\boldsymbol{n})d\Omega \tag{7}$$

The Eshelby tensor for a specific fiber orientation is denoted as $S_{ijkl}(\boldsymbol{n})$. $d\Omega$ is the differential solid angle over the unit sphere, and $\boldsymbol{n}$. $f(\boldsymbol{n})$ is the orientation distribution function (ODF) that characterizes the probability density of fibers being oriented in direction $\boldsymbol{n}$. The orientation distribution tensor can also be used to express the orientation-averaged Eshelby tensor:

$$\bar{S}_{ijkl} = \langle S_{ijkl}(\boldsymbol{n})\rangle = \int S_{ijkl}\, n_i n_j n_k n_l f(\boldsymbol{n})d\Omega \tag{8}$$

The orientation distribution tensor, $\mathbf{\Theta}$ is given as

$$\Theta_{ijkl} = \langle n_i n_j n_k n_l\rangle = \int n_i n_j n_k n_l\, f(\boldsymbol{n})d\Omega \tag{9}$$

Here $\boldsymbol{n}$ is the unit vector that defines the microscopic orientation of the fiber.

Digimat is a tool that efficiently integrates fiber orientation using symmetry and numerical optimization techniques. Advani and Tucker's formulation uses the orientation distribution tensor O (or more generally, a_{ij} and

a_{ijkl}), representing the average fiber orientation for randomly oriented fibers. The Mori-Tanaka method directly influences the stiffness matrix components, affecting the B coefficients used in the Advani-Tucker formulation (Advani & Tucker III, 1987). For randomly oriented fibers, O is included in the stiffness tensor computation (C_{ijkl}).

$$C_{ijkl} = B_1 a_{ijkl} + B_2(a_{ij}\delta_{kl} + a_{kl}\delta_{ij}) + B_3(a_{ik}\delta_{jl} + a_{il}\delta_{jk} + a_{jl}\delta_{ik} + a_{jk}\delta_{il}) + B_4(\delta_{ij}\delta_{kl}) + B_5(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}) \tag{10}$$

Short fiber reinforced composites are modeled using second order unit tensor components, δ_{ij}, and fourth order and second order fiber orientation tensor components, a_{ijkl} and a_{ij}. The coefficients B are related to the components of the stiffness matrix of a transversely isotropic unidirectional composite (Jong et al., 2018).

The matrix phase behaves elastoplastically, while the fiber phase is assumed elastic. The average concentration factors of the matrix phase are influenced by internal state variables such as damage, kinematic hardening and isotropic hardening as well as stress state variables. The following equations are used to describe the increasing elastoplastic response of the matrix phase:

$$\begin{gathered}
\dot{\boldsymbol{\sigma}} = \boldsymbol{C}:(\dot{\boldsymbol{\varepsilon}} - \dot{\boldsymbol{\varepsilon}}^p) \\
\dot{\boldsymbol{\varepsilon}}^p = \dot{\lambda}\frac{\partial f}{\partial \boldsymbol{\sigma}} \\
\dot{R} = [k(1+mp) - m(R - R_\infty)]\dot{p} \\
\dot{p} = \dot{\lambda} \\
\dot{f} = \frac{\partial f}{\partial \boldsymbol{\sigma}}\dot{\boldsymbol{\sigma}} + \frac{\partial f}{\partial R}\dot{R} = 0 \\
f = J_2(\boldsymbol{\sigma}) - R(p) - \sigma_{yp} \\
R(p) = kp + R_\infty[1 - \exp(-mp)]
\end{gathered} \tag{11}$$

The nonlinear isotropic hardening is modeled using a linear and exponential law, with material yield strength (σ_{yp}) and material-dependent constants (k , m, and R_∞). This approach helps optimize the mechanical behavior of short fiber-reinforced composites. However, the validity and applicability of these theories depend on precise determination of parameters like fiber orientation, elastic modulus, yield properties, and hardening behavior. Software tools like Digimat RP and Moldex3D provide essential capabilities for modeling these parameters, enabling more accurate simulations of composite materials.

Therefore, in order to guarantee accurate results in predicting the mechanical performance of composite materials, it is essential for advanced analyses to carefully evaluate fiber orientation, material parameters, and plasticity behavior. Using the values obtained from the Digimat material, the stress and strain curves for the PA6 GF40 material are displayed in Fig. 2.

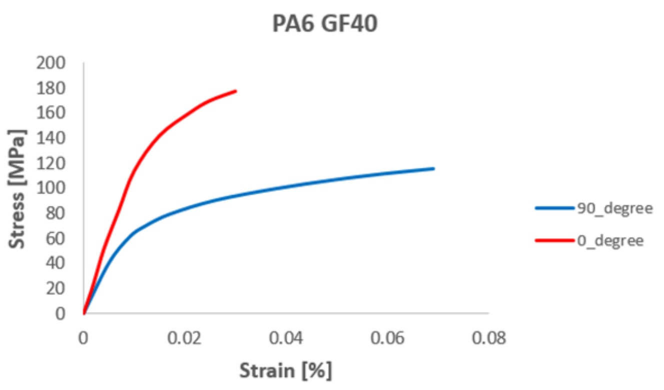

Fig. 2. Under tensile testing, the stress-strain curves of 40% glass fiber-reinforced PA6 were examined both in the fiber direction and perpendicular to it.

3. Finite element buckling analysis

The PA6-GF40 material was routinely modeled using Poisson's ratio and a single elastic modulus. Injection molding simulations were performed across four configurations to evaluate the impact of weld lines and fiber orientation on the critical buckling load and load-carrying capability. For the purpose of calculating critical buckling loads, the fiber orientation, distribution, and weld line data obtained from these simulations were imported into ABAQUS with Digimat RP. The load-carrying capacity of the columns were then compared using nonlinear anisotropic analysis.

3.1. Finite element buckling analyses of the conventional model

ABAQUS was used to examine a hollow square cross-section column with a consistent wall thickness of 4 mm. According to Fig. 3, the column's base cross-section measured 60 x 60 mm, decreasing to 30 x 30 mm at the top. Its overall length was 200 mm.

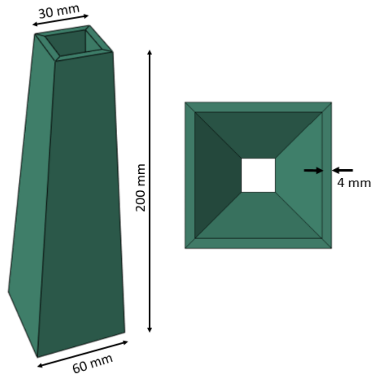

Fig. 3. Variable cross-section column geometry with thin walls

In accordance with the material parameters of the finite model, the 40% glass fiber reinforced polyamide's modulus of elasticity and Poisson's ratio were found to be 12.6 GPa and 0.35, respectively. While there are no restrictions on movement along the load axis, there are (DOF 1, 2) on other axes of motion at the upper side of the specimen. At the bottom, motion is restricted in all directions (DOF 1, 2, 3). Buckle analysis was performed to determine the critical buckling load after applying 1 N load to the column.

3.2.Finite element buckling analyses using the model integrating real material data

3.2.1.Mold flow simulation

A thin-walled variable cross-section column was simulated in four configurations using Moldex3D software with 40% glass fiber reinforced polyamide 6 material. The configurations varied the number and placement of injection gates in Moldex3D. (Filling began at the top or bottom, and two gates were positioned at corners or edges.) Fig 4.

The filling analysis was conducted at a melt temperature of 260°C and a mold temperature of 85°C, with a maximum mold pressure of 155 MPa. The melt storage times and cycle times for all fillings are as follows: For the two corners on top (A) filling type, the filling time is 2.18 seconds, and the cycle time is 19.58 seconds. For the two edges on top (B) filling type, the filling time is 2.17 seconds, and the cycle time is 19.56 seconds. For the two corners on bottom (C) filling type, the filling time is 2.20 seconds, and the cycle time is 18.90 seconds. For the two edges on bottom (D) filling type, the filling time is 2.19 seconds, and the cycle time is 19.59 seconds.

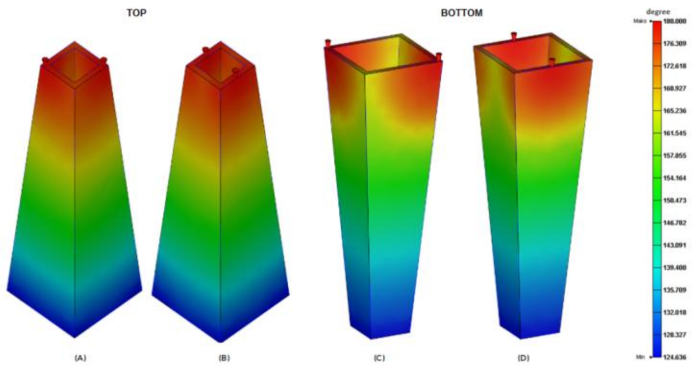

Fig. 4. Models made for mold flow simulation (A) two corners on top, (B) two edges on top, (C) two corners on bottom, (D) two edges on bottom.

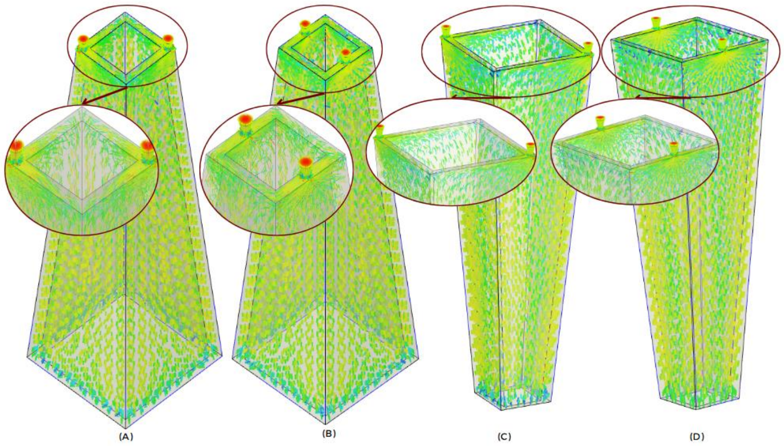

Fig. 5. Fiber orientation information according to filling type (A) two corners on top, (B) two edges on top, (C) two corners on bottom, (D) two edges on bottom.

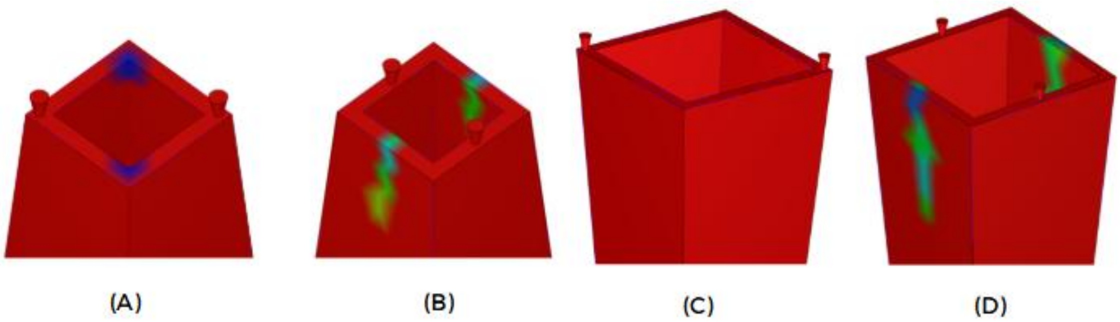

Fig. 6. Weldline information according to filling type (A) two corners on top, (B) two edges on top, (C) two corners on bottom, (D) two edges on bottom.

The simulation results provide crucial data for Digimat software, aiming to investigate the impact of altering fiber orientation (Fig. 5) and weld line regions (Fig. 6) on mechanical performance.

3.2.2. Transferring Real Material Data to the Finite Element Program
The Digimat RP software was used to import the structural mesh information (.inp file from Abaqus) of a thin-walled variable cross-section column. The properties of PA6 GF40 material were extracted using the Digimat MX tool. The production mesh was used for Digimat RP's mapping process, followed by matching fiber orientation and weldline data from the Moldex3D simulation. The plastic injection molding procedure for fiber-reinforced thermoplastic composites is depicted in Fig. 7.

Fig. 7. Process steps of transferring real material data (fiber orientation & weldline) to the finite element program with Digimat RP

4. Results & discussion

4.1. Conventinal model buckling analysis results
The CM simulation results in Table 1 showing the buckling modes of the column, with critical buckling loads calculated as 242 kN, 252 kN, and 295 kN in the first, second, and third modes, respectively.
Table 1. Conventional model column buckling analysis modes

	Mode 1	Mode 2	Mode 3
Conventional Model			
4.2. Column buckling analysis by transferring mold flow simulation data to finite element program
In the study, DIGIMAT RP was used to import the structural network, production network, fiber orientation, weld line data from mold flow simulation and PA6 GF40 material data from DIGIMAT MX. The mold flow simulation data was integrated into the structural mesh during the mapping procedure. The anisotropic material data were imported into the finite element model and the buckling analysis was repeated under the same boundary and loading conditions. The buckling modes of the column were obtained by integrating the results obtained from the MC simulation. As can be seen in Table 2, the first, second and third critical buckling loads obtained from the buckling analysis vary according to the gate location and number. In the models with mold flow data, the first mode values vary between 144-150 kN, the second between 152-158 kN and the third between 182-186 kN.

Table 2. Buckling modes and critical buckling loads in the first, second and third modes according to the filling type of the column for which the real material data model is integrated.

	Critical Bucklig Load (N)		
Filling Type	**Mode 1**	**Mode 2**	**Mode 3**
Two corners on top (A)	 144.123 N	 152.691 N	 182.739 N
Two edges on top (B)	 143.897 N	 152.510 N	 182.162 N
Two corners on bottom (C)	 149.559 N	 157.343 N	 185.115 N

Table 2. Continued

Two edges on bottom (D)	 145.209 N	 155.314 N	 179.81

4.3. Load carrying capacity analysis of thin walled variable cross-section column

The study analyzed the critical buckling loads for the first three modes of four different models, which integrated both conventional model and mold flow data. Variations in the number of gates and melt injection regions led to changes in fiber orientation and weldline data across each analysis. Nonlinear analyses were conducted to determine and compare the load-carrying capacity of these models. The columns were subjected to a compressive load of 295 kN. Additionally, arrangements were made to obtain 'Node fill' data in the .inp file for each buckling analysis. Stability was ensured through the use of 'Node fill' data, which illustrates how loads and deformations are distributed at nodes, facilitating a more stable progression of the solution. Convergence criteria were employed to maintain stability, and incremental load application helped prevent sudden large deformations that could lead to instability. Material modeling played a critical role in accurately defining the transition between elastic and plastic behavior, ensuring proper prediction of plastic deformation areas. The stability of the solution was ensured through careful load distribution, mesh refinement, and accurate material modeling. The comparison of results shows which areas of the material underwent plastic deformation during column loading and at which points these deformations occurred.

Load Proportionality Factor (LPF) and displacement (U) graphs are important for understanding a structure's load-bearing capacity and behavior, particularly in nonlinear analyses (Chai vd., 2023). The maximum load-bearing capacity is indicated by the peak of the LPF, which compares the applied load to a reference load level. The maximum load-bearing capacity is attained at higher displacement values in models that incorporate real material data, indicating lower resistance to deformation. Because there is more fiber concentrated in the top region of bottom-filled models, the critical buckling region in the narrower top section is strengthened, increasing the maximum load-bearing capacity. The significance of these tools in structural analysis was demonstrated by comparing the obtained LPF and U graphs with conventional models. Load proportionality factor (LPF) and displacement (U) graphs were acquired, and Fig. 8 shows a comparison between the conventional model and the model that incorporated real material data.

5. Conclusions

The study investigates the buckling behavior of PA6-GF40 columns, as well as the effects of manufacturing parameters such as fiber orientation and weld lines on mechanical performance. Initially, a conventional model was used to calculate critical buckling loads and modes. However, integrating fiber orientation and weld line data from Moldex3D simulations into ABAQUS using Digimat RP was a significant step forward. The real material data increased the load-bearing capacity of the columns, resulting in decreased deformation resistance. The placement of injection gates also had an impact on fiber orientation. Models filled from the bottom had a greater load-carrying capacity.

In conclusion, this study emphasizes the importance of taking into account real material data and injection molding parameters, demonstrating that their integration is critical in the design of fiber-reinforced thermoplastic components. It outlines strategies for improving the manufacturing process, allowing for the creation of more durable and efficient parts.

Abstract. The use of fibers to increase the mechanical properties of concrete has been a common practice for a long time. Although various materials can be used as fibers, steel fibers are preferred in applications where higher performance is required due to their superior mechanical properties. The effects of the length, aspect ratios, amount, and strength of steel fibers on concrete have been investigated by many researchers. In this study, steel fibers with different aspect ratio, were added to concrete at dosages of 0 kg/m³, 30 kg/m³, and 60 kg/m³. The fibers added to the concrete were obtained by adding a single type of fiber, and hybrid steel fiber-reinforced concrete samples were also produced by adding two steel fibers in equal amounts. In order to investigate the effect of hybrid steel fiber additive on the mechanical properties of concrete, compressive strength, splitting tensile, and flexural tensile strength tests were conducted on the samples. As a result of the experimental studies, it was observed that the use of steel fibers did not provide a significant contribution to improving the compressive strength of concrete. When the splitting tensile strength test results were examined, the highest increase in tensile strength was obtained in hybrid steel-reinforced concrete where the fiber dosage was 60 kg/m³. This increase was calculated to be 55% compared to the reference samples. When the consumed energy obtained from the load-CMOD curve as a result of the bending tensile tests was compared, the energy consumed by the hybrid steel fiber samples where the fiber dosage was 60 kg/m³ was 2.72 times the energy consumed by the hybrid steel fiber effect where the dosage was 30 kg/m³. As a result of the study, it was observed that the hybrid steel fiber additive had positive effects on the tensile strengths, which are among the mechanical properties of concrete.

Keywords: Concrete;Steel fiber; Hybrid steel fiber; Mechanical properties

1. Introduction

Concrete has inherently low tensile strength and ductility. To improve these deficiencies, various types of additives with different properties are incorporated into concrete. Among the most commonly used of these are steel fibers. Steel fiber reinforced concrete (SFRC) is a composite material produced by adding steel fibers to conventional concrete components such as aggregate, cement, and water, as well as mineral and/or chemical admixtures. Steel fibers are used to enhance the performance of both plain and reinforced concrete elements. Their inclusion improves the energy absorption capacity, increases ductility at the moment of fracture, and reduces the risk of cracking. Owing to these advantages, SFRC is widely used in applications such as highways, tunnel linings, industrial flooring, slope stabilization, dam structures, port construction and repair, fire protection, concrete pipes, and reinforced concrete frames (Köksal, 2004),(Mohod,2012), (Altun & Aktaş, 2011).

In concrete reinforced with a single type of fiber, the multi-scale and progressive failure mechanisms of concrete limit the effectiveness of the fiber to a specific range, resulting in suboptimal overall performance. To address this issue, it has been suggested that combining fibers of different sizes, functions, and structural responses can enhance the utilization of concrete's material properties and improve the mechanical performance of structural elements. Hybrid fiber reinforced concretes are defined as novel cement-based composite materials produced by incorporating more than one type and size of fiber, instead of relying on a single fiber type. The main purpose of using hybrid fibers is to achieve more controlled and ductile behavior in concrete by taking advantage of the complementary effects of different fiber types. This approach enables better control over crack initiation and propagation. While many previous studies have investigated the effects of various fiber combinations and hybrid fiber usage, research specifically focusing on steel–steel hybrid fiber reinforced concretes where both fibers are of the same type but with different geometries remains limited (Rossi, 2000) ,(Türk & Kına, 2017),(Ganesan et al., 2014), (Issa et al., 2011).

This study experimentally investigates the influence of hybrid steel fiber reinforcement, consisting of fibers with different aspect ratios, on the mechanical behavior of concrete.

2. Materials and methods

To investigate the effect of hybrid steel fiber reinforcement on the mechanical properties of concrete, experimental studies were conducted on both cylindrical and prismatic concrete specimens.Compressive strength and splitting tensile strength tests were performed on the cylindrical specimens, while the flexural behavior of steel fiber reinforced concrete was evaluated using prismatic beam specimens.

2.1. Steel fiber

In this study, two types of steel fibers with different aspect ratios, KMX 80/60 BG and KMX 65/60 BG, were added to concrete designed to achieve C30 strength class, at dosages of 0 kg/m³ (reference), 30 kg/m³, and 60 kg/m³. The fibers were incorporated into the concrete either as a single fiber type or as a hybrid combination, in which equal proportions of both fiber types were used. The steel fibers used in the study were hooked-end fibers bonded together in bundles using adhesive. The physical and mechanical properties of the fibers are presented in Table 1., and their general appearance is shown in Fig. 1.

Table 1. Steel fiber properties

Steel Fiber	Length,l (mm)	Diameter,d (mm)	Aspect Ratio (l/d)	Tensile Strength (N/mm^2)
KMX 65/60 BG	60	0,9	65	1150 N/mm^2
KMX 80/60 BG	60	0,75	80	1200 N/mm^2

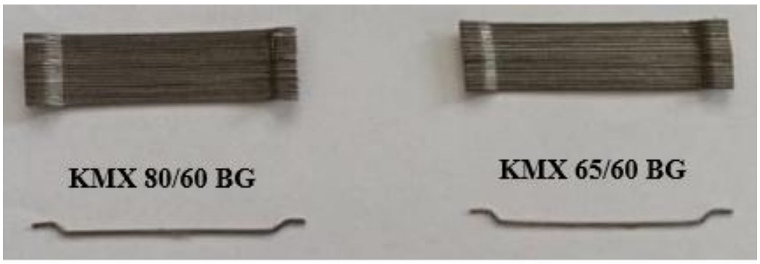

Fig. 1. Steel fibers

2.2. Experimental program

Within the scope of the study, two specimens were taken from each concrete mixture. Accordingly, a total of 28 cylindrical specimens were obtained 14 for compressive strength and 14 for splitting tensile strength tests. The cylindrical specimens had dimensions of Ø150×300 mm. Compressive strength tests were performed in accordance with TS EN 12390-3, and splitting tensile strength tests were carried out according to TS EN 12390-6.For the flexural tensile strength tests, 14 prismatic concrete beams with dimensions of 150 × 150 × 600 mm were produced, and the tests were conducted in accordance with TS EN 14651+A1. Notches with a depth of 25 mm were cut at the mid-span of the specimens. At the end of the tests, which were carried out up to a deflection of 4 mm, load–CMOD (Crack Mouth Opening Displacement) curves were obtained, and energy consumption was calculated.

The concrete mixtures used in this study were systematically named based on the type of steel fiber and the fiber dosage.In the sample codes, the expression "SF" denotes the presence of steel fiber reinforcement, the numerical value indicates the fiber dosage in kg/m³, and the term "Type" refers to the classification according to fiber type.All sample codes and their corresponding contents are presented in Table 2.

Table 2. Specimen codes and fiber compositions

Sample Code	Fiber Dosage (kg/m³)	Description
Ref	0	Reference concrete (no fiber)
SF30-Type65	30	Single-type fiber (100% KMX 65/60 BG)
SF30-Hybrid	30	Hybrid fiber (50% KMX 65/60 + 50% KMX 80/60)
SF30-Type80	30	Single-type fiber (100% KMX 80/60 BG)
SF60-Type65	60	Single-type fiber (100% KMX 65/60 BG)
SF60-Hybrid	60	Hybrid fiber (50% KMX 65/60 + 50% KMX 80/60)
SF60-Type80	60	Single-type fiber (100% KMX 80/60 BG)

3. Results and discussion

The test results were presented based on the average values of two specimens from each concrete mixture group.

The compressive strength results obtained from cylindrical concrete specimens are shown in Fig. 2. When the results are examined, it is observed that the compressive strength of SF30-Type65 specimens increased by approximately 7% compared to the reference group. However, a 15% decrease was observed in the SF30-Hybrid specimens. The SF30-Type80 group showed a 10% increase, while the SF60-Type80 group exhibited a 20% decrease in compressive strength. The SF60-Hybrid specimens experienced a 7% reduction, and SF60-Type80 showed a more significant decrease of approximately 16%. Overall, it was concluded that the addition of steel fibers did not consistently improve compressive strength. In some mixtures, the inclusion of fibers—particularly in hybrid combinations—resulted in a decrease in compressive strength.According to the experimental results, the use of steel fibers does not make a significant contribution to enhancing the compressive strength of concrete.

The average splitting tensile strength values of the cylindrical concrete specimens are presented in Fig. 4. When the results are examined, the splitting tensile strength of SF30-Type65 specimens increased by approximately 18% compared to the reference samples. A 6% decrease was observed in the SF30-Hybrid group, while SF30-Type80 showed a 13% increase. For SF60-Type65, the increase was approximately 15%, whereas the highest improvement was recorded in SF60-Hybrid specimens, with an increase of about 55%. In contrast, the increase in SF60-Type80 specimens was limited to around 5%. Overall, the test results indicate that the addition of steel fibers generally enhances the splitting tensile strength of concrete.The most significant improvement was achieved in the SF60-Hybrid group, where a fiber dosage of 60 kg/m³ and the use of hybrid steel fibers provided the highest contribution. These results suggest that steel fiber reinforcement is more effective in enhancing tensile strength compared to compressive strength. In particular, hybrid fiber combinations at higher dosages (60 kg/m³) significantly improve the tensile performance of concrete.

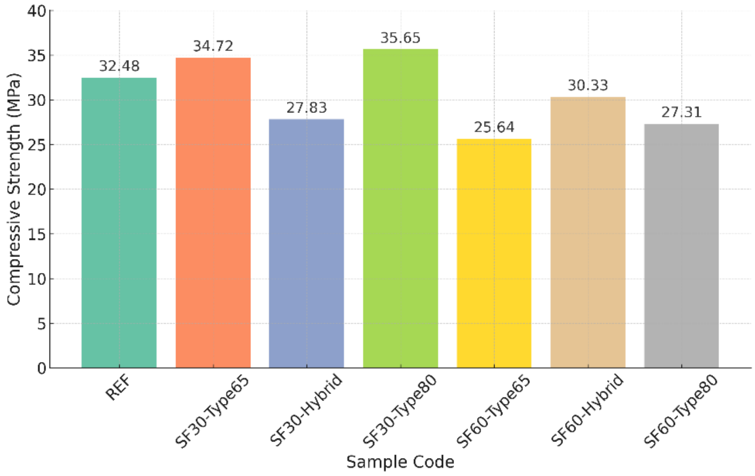

Fig. 3 Compressive strength of samples

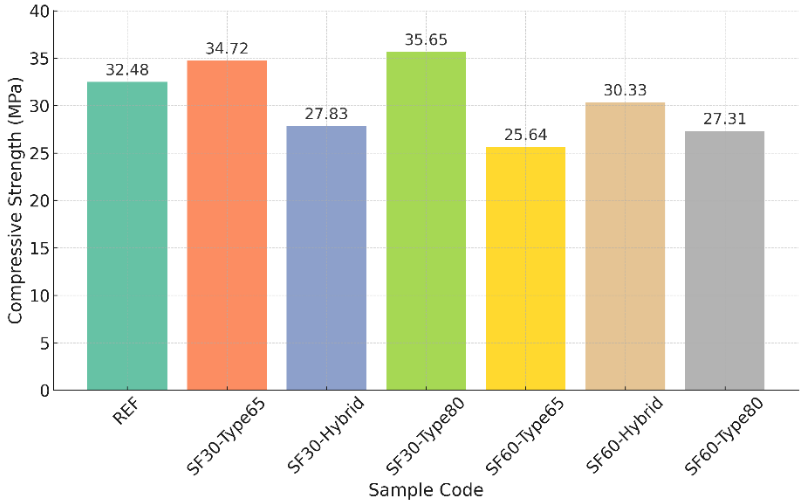

Fig. 4. Splitting tensile strength of samples

The load–CMOD curves obtained from the prismatic concrete beam tests are presented in Fig. 5.When the load–CMOD curves of the specimens are examined, SF60-Hybrid specimens are observed to carry the highest loads.The SF60-Type65, SF60-Hybrid, and SF60-Type80 specimens exhibited increasing load resistance with displacement up to the first crack, and after cracking, they maintained their load-carrying capacity due to the fiber–matrix interaction, without a sudden drop.In contrast, SF30-Type65, SF30-Hybrid, and SF30-Type80 specimens showed a noticeable decrease in load after the first crack, attributed to a lower fiber phase, but continued to dissipate energy.As expected, the reference beams, which contained no fibers, exhibited brittle failure and their energy consumption remained significantly lower compared to fiber-reinforced concretes.

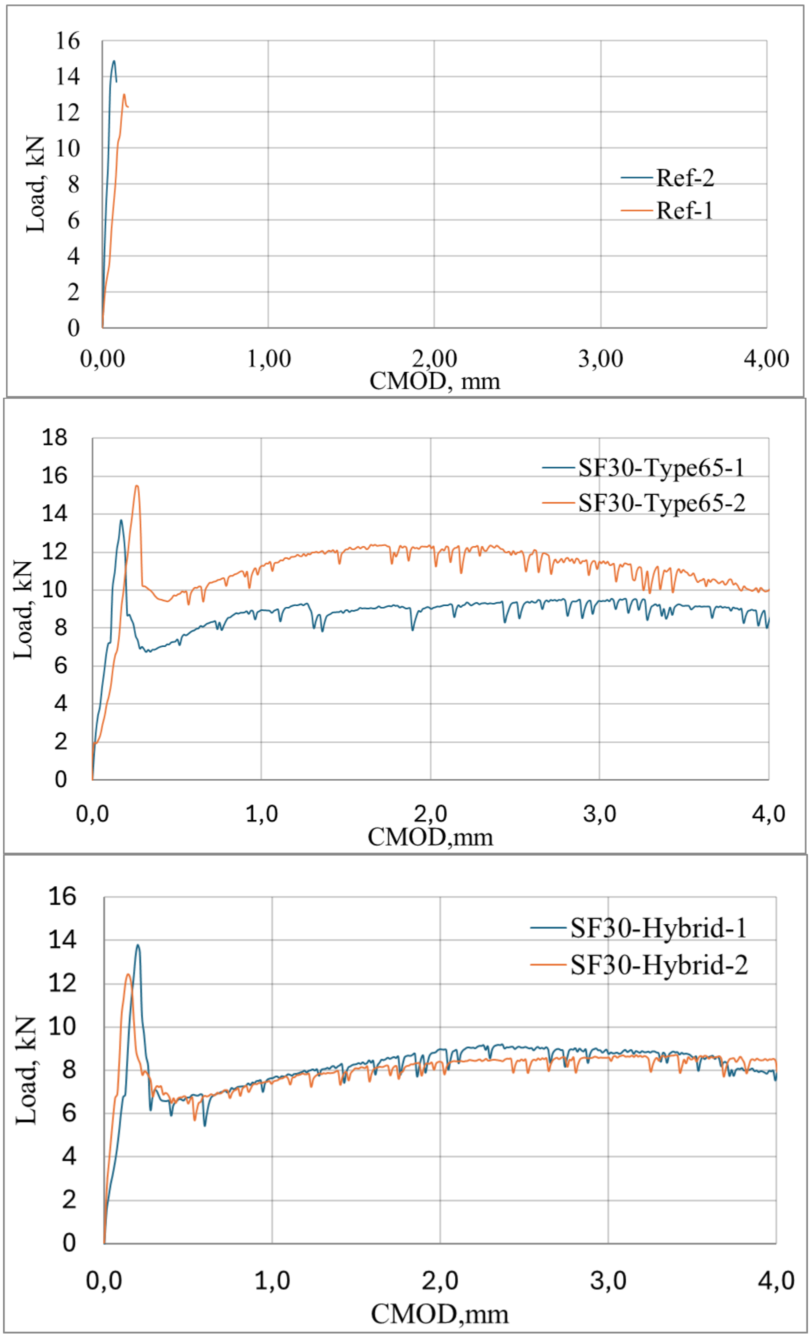

Fig. 5. Load- CMOD deflection

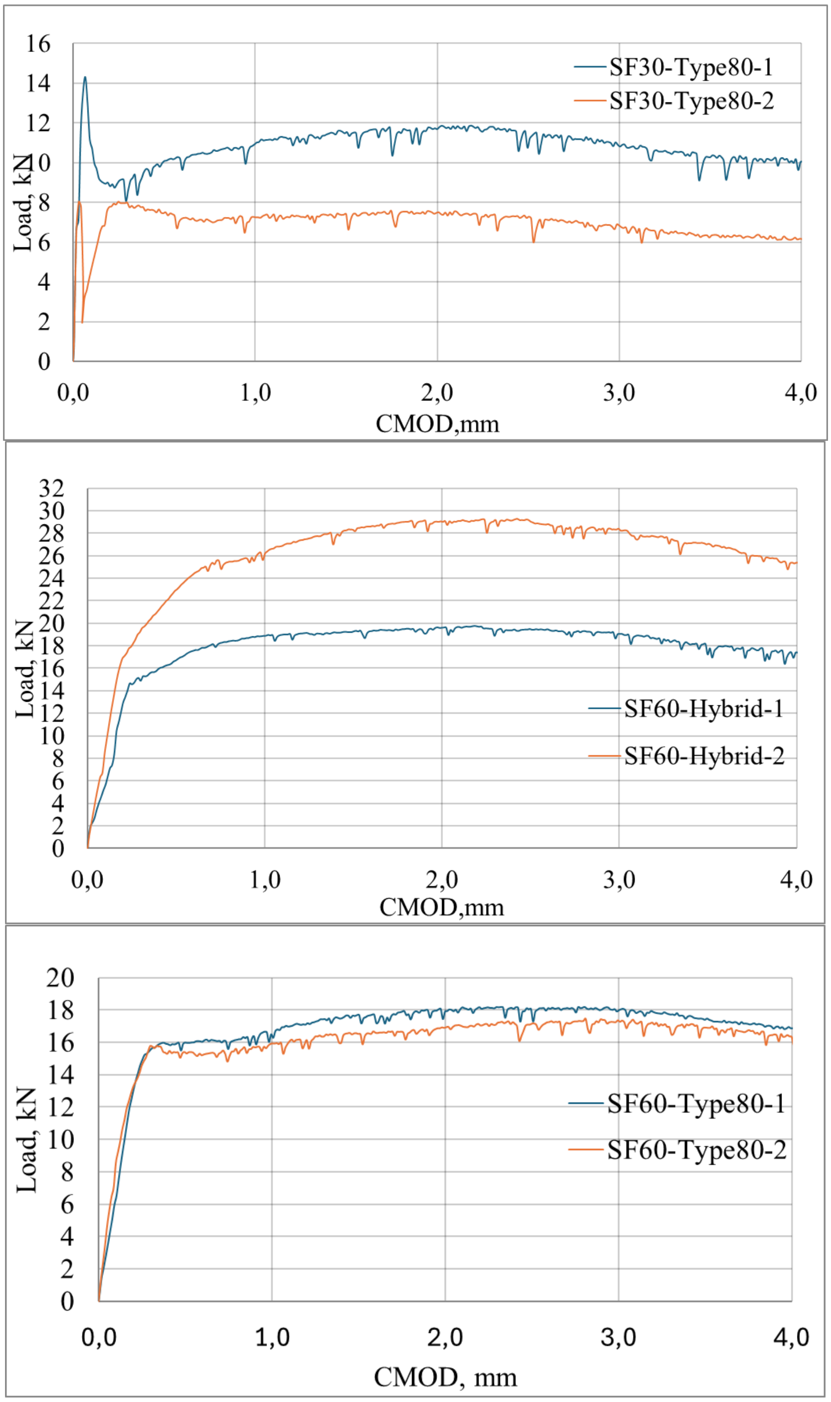

Fig. 5. Continued

The energy consumption of the prismatic concrete specimens is presented in Fig. 6. As shown in Fig. 6., the reference specimens, which did not contain steel fibers, failed abruptly at the first crack load and exhibited no energy consumption.A significant increase in energy consumption was observed in the specimens with a fiber dosage of 60 kg/m³.The highest increase was recorded in the SF60-Hybrid specimens, which incorporated hybrid fibers at this dosage.It was observed that doubling the fiber dosage approximately doubled the energy consumption.Specifically, the energy consumed in the SF60-Hybrid specimens was 2.72 times greater than that of the SF30-Hybrid specimens, indicating the pronounced effect of hybrid steel fibers at higher dosages.

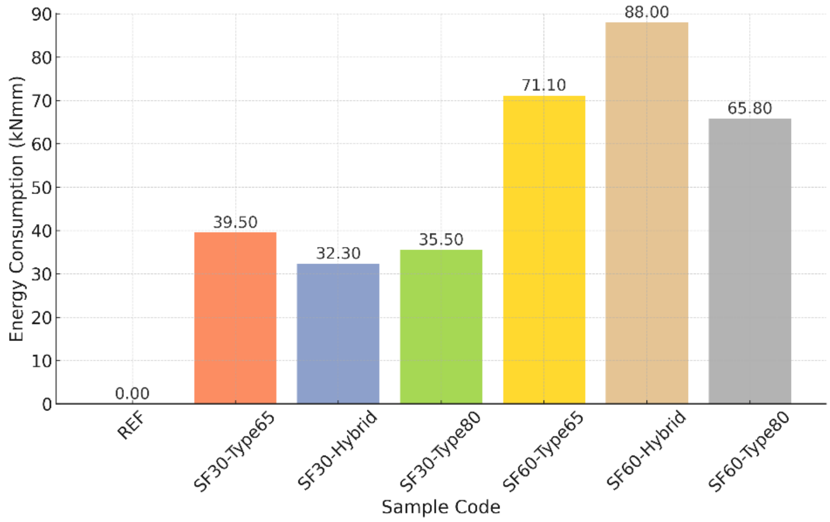

Fig. 6. Energy consumption of prismatic concrete

4. Conclusions

In this study, the effect of hybrid steel fiber reinforcement on the mechanical properties of concrete was investigated. Based on the results obtained, the following conclusions were drawn:

- It was concluded that the compressive strength of concrete did not increase with the addition of steel fibers. In fact, a reduction in compressive strength was observed at certain fiber dosages, including in mixtures with hybrid fibers. According to the test results, the use of steel fibers does not provide a significant contribution to improving the compressive strength of concrete.
- When the splitting tensile strength results were evaluated, it was found that the inclusion of steel fibers generally enhanced tensile strength. The most significant improvement—an increase of approximately 55% compared to the reference—was observed in the SF60-Hybrid specimens. This indicates that steel fiber reinforcement is more effective in improving tensile strength than compressive strength. In particular, a fiber dosage of 60 kg/m³ and the use of hybrid steel fibers significantly increased the tensile performance of concrete.
- When the load–CMOD curves of prismatic concrete specimens were examined, a sudden decrease in post-crack load-bearing capacity was observed at lower fiber dosages. However, with increasing fiber content, the specimens were able to sustain and transfer load more effectively after cracking. This behavior—attributed to the contribution of the steel fiber phase—was most evident in hybrid fiber-reinforced specimens with a dosage of 60 kg/m³. In addition to the improvement in strength, the energy consumption of SF60-Hybrid specimens was found to be 2.72 times higher than that of SF30-Hybrid, demonstrating the significant effect of higher hybrid fiber content on energy dissipation capacity.

Abstract. Mixed structures combining steel, wood and concrete represent a promising solution for sustainable construction, thanks to their ability to combine lightness, rigidity and durability. These systems exploit the complementary properties of materials: concrete offers exceptional rigidity and stability, wood provides lightness and flexibility, while steel guarantees high mechanical strength. By combining these advantages, these structures optimize performance while meeting today's ecological challenges. However, current solutions have two major limitations: they are essentially non-dismantlable, as concrete is often poured on site, and they lack suitable connections that would enable all three materials to work simultaneously. While wood-concrete and steel-wood connections have been extensively explored in literature, dismountable and efficient connections for steel-wood-concrete structures remain non-existent, posing a significant technical challenge. This study provides a detailed examination of existing research on composite structures, highlighting the mechanical performance and limitations of timber-concrete and steel-timber connections. In addition to this analysis, numerical models were developed on Abaqus to assess the behavior of three demountable composite floors combining steel, timber, and concrete connected using different types of connections in order to compare their performance.

Keywords: Hybrid structures; steel-timber-concrete systems; mechanical performance; demountable floor systems; sustainable design.

1. Introduction

Integrating several materials into a single structure optimizes their mechanical performance while meeting the challenges of sustainability and reducing environmental footprints. Among the most studied combinations in civil engineering, wood-concrete and steel-wood hybrid systems have been the focus of much research aimed at improving their structural efficiency and durability (Okutu et al., 2017), (Djoubissié Denouwe, 2018)

Integrating concrete, wood and steel in the same composite structure could offer significant advantages by combining the rigidity and durability of concrete, the lightness and flexibility of wood, and the mechanical strength of steel. However, this combination poses a number of challenges, not the least being the development of suitable connections that can be dismantled and ensure effective composite action between the three materials.

Connections play a key role in the mechanical behavior of hybrid structures. There are several existing wood-concrete connection types in the literature, , such as fastener-type connectors, longitudinal connectors or notches or glue connections, that enable efficient transmission of shear forces (Lecours, 2022). Steel-wood connections, on the other hand, use solutions such as bolts, screws or steel plates to guarantee structural stability (Loss et al., 2016a). While these connections have been extensively studied separately, there is little research on assemblies that simultaneously integrate steel, wood and concrete in a non-dismantling system (Winter et al., 2016), (Tavoussi et al., 2018), (Tavoussi et al., 2019).

One of the main technical challenges lies in the development of efficient connections, capable of ensuring optimum stress transfer between materials, while allowing components to be dismantled and reused. Indeed, the differences in stiffness, mechanical behavior and failure modes between concrete, wood and steel make designing a suitable connection a complex task. An optimal connection must therefore guarantee good mechanical resistance, limit the effects of slippage and enable simplified installation.

In order to better understand these interactions, this study uses a numerical approach to analyze the behavior of steel-wood-concrete demountable composite floors. Three types of connections, identified from the literature, were numerically modeled in order to assess their performance and ability to ensure effective composite action.

This article is structured into two main parts. The first section provides a review of the different connection solutions for timber-concrete and steel-timber composite structures found in the literature. The second section presents the numerical models developed in order to compare the performance of composite steel-timber-concrete structures for 3 different connection configuration systems.

2. State of the art on connections in composite floors

Connections between materials in wood-concrete, steel-wood and steel-wood-concrete composite structures are a subject of intense study, aimed at optimizing the stiffness, strength and demountability of assemblies. Connection systems are generally evaluated by means of large-scale shear (push-out) and bending tests, to analyze their mechanical behavior and determine their load-bearing capacity.

One of the main challenges lies in designing connections that are both high-performing and demountable, capable of withstanding mechanical loads while allowing for quick assembly and disassembly without damaging the materials. Mechanical fasteners such as screws, bolts, and perforated plates are generally preferred over epoxy adhesives, as they offer greater potential for component reuse. However, material compatibility, accessibility to fasteners, and durability after multiple assembly-disassembly cycles remain critical issues that are still insufficiently explored.

For wood-concrete connections, common systems include notches, bolts, screws and sometimes epoxy resins. Notches are particularly appreciated for their ability to transmit shear forces effectively through mechanical locking, but they do exhibit a certain fragility under heavy loading. Push-out tests show good initial rigidity with limited plastic deformation before failure, often at wood level. Bolts and screws provide a certain ductility and better removability, but their stiffness is lower than that of notches. Mixed bolt-notch connections show an interesting performance in terms of stiffness-strength compromise, but the question of their demountability remains little studied.

In terms of notch geometry, several studies show that conventional rectangular notches have high initial stiffness but are prone to brittle shear failure, mainly in the wood according to (Fragiacomo et al., 2008). Shear tests indicate that an increase in notch depth improves stiffness, but may also increase the brittleness of the system according to (Xu et al., 2023). Inclined or dovetail-shaped notches offer greater force transmission capacity, while improving assembly stability thanks to an increased mechanical locking effect. However, these geometries are less common, as they complicate the manufacturing process and may limit the system's demountability, according to the thesis by (Boccadoro, 2016).

The addition of bolts or screws to the notches is a common method of improving the rigidity and load-bearing capacity of the assembly. In effect, bolts or screws act as reinforcing devices that increase the sliding resistance between wood and concrete, (Boccadoro et al., 2017). Push-out tests generally show that this combination increases the overall system stiffness and improves its ultimate capacity compared to notches alone, according to (Xu et al., 2023). However, the use of screws or bolts can limit the demountability of the system, especially when combined with glue or sealed in concrete pockets.

Specific wood-concrete connections also include innovative systems such as perforated plates (Miotto & Dias, 2012), concrete shell (Auclair et al., 2016), connecting plywood plate with steel reinforcing (Daňková et al., 2019) , inclined full-thread screws and bonded reinforcing bars and dowels (Djoubissie et al., 2018) and (Fragiacomo et al., 2018). These methods provide better stress distribution, increased stiffness and higher load-bearing capacity than traditional connections. Perforated plates embedded in concrete show a good shear strength. Systems using inclined screws show a notable improvement in load-bearing capacity and stiffness, but their demountability remains limited when combined with epoxy adhesives or resins.

Steel-wood connections have evolved with the development of several systems aimed at improving rigidity, strength and, to a lesser extent, demountability. The most common methods include the use of self-tapping screws, Gang Nail Plates, bolts inserted in concrete pockets or epoxy resins, as well as devices combining several techniques to achieve better mechanical performance.

Self-tapping screws, particularly those with inclined full threads, are widely used for their ability to provide high rigidity and good ultimate strength due to their deep anchorage in wood. Shear tests show that these screws can offer significantly higher slip resistance than traditional connectors. However, these systems are generally non-removable when combined with epoxy glue, or when the screws are sealed in cement pockets (Loss et al., 2016).

Nail-on plates, although considered economical solutions, offer limited performance in terms of rigidity and strength, (Okutu et al., 2017). However, they do have the advantage of being removable if not combined with permanent adhesives.

Bolts inserted into concrete pockets or fixed with epoxy resins provide good load-bearing capacity but render the connection non-dismantlable (Hassanieh et al., 2017). However, the use of bolts alone (without chemical sealing) could allow some demountability, although this may reduce the overall stiffness of the system.

Combination systems incorporating screws, nailing plates and bolts are currently being explored to improve overall mechanical performance while seeking to maintain a certain degree of demountability. However, few studies specifically address the issue of demountability of steel-wood connections, which is a major gap in the current literature.

Steel-wood-concrete connections are still little explored in the literature. Researchers tackling this subject focus mainly on systems where concrete is poured in situ, often using perforated metal plates, screws or notches made in the wood. However, the experimental tests carried out to date are mainly push-out tests performed separately to evaluate steel-wood connections (perforated plates, inclined screws, bolts) on the one hand, and wood-concrete connections (notches, screws, perforated plates) on the other hand (Winter et al., 2016), (Tavoussi et al., 2018).

Very few studies combine all three materials steel, wood, and concrete into a single hybrid assembly subjected to shear or bending tests, which represents a major gap in the current research. Most existing work focuses on improving stiffness and strength through permanent joining methods, with little to no consideration for demountability. However, bending tests on systems that simultaneously combine steel, wood, and concrete are crucial to better understanding fatigue phenomena, the effects of repeated loading, and long-term deformations in such systems. The development of these types of connections requires optimization of connector geometry, selection of compatible materials, and a design strategy focused on reversibility and durability, in line with the principles of the circular economy.

Fig. 1 illustrates the shear force versus relative slip relationship obtained for different connection types using pushout tests.

This literature review highlights the diversity of connection types explored for composite floors, as well as the trade-offs between stiffness, strength, and demountability. Notched connections provide good stiffness but tend to be brittle and offer limited reversibility. Screws and bolts, on the other hand, allow for better demountability, often at the cost of lower stiffness. The use of epoxy adhesives improves bonding performance but significantly limits the potential for disassembly. Finally, hybrid solutions, such as perforated plates, appear promising, although they have been studied little in the context of demountable configurations.

In the first phase of our experimental work, we selected three types of connections: bolts alone, notched connections, and a combination of bots, in order to evaluate their mechanical performance and potential for disassembly. Depending on the results obtained, other configurations such as perforated plates or hybrid systems may be considered to refine the balance between stiffness, strength, and demountability. This progressive approach will help identify the most relevant solutions for the development of demountable, durable structures in line with circular economic principles.

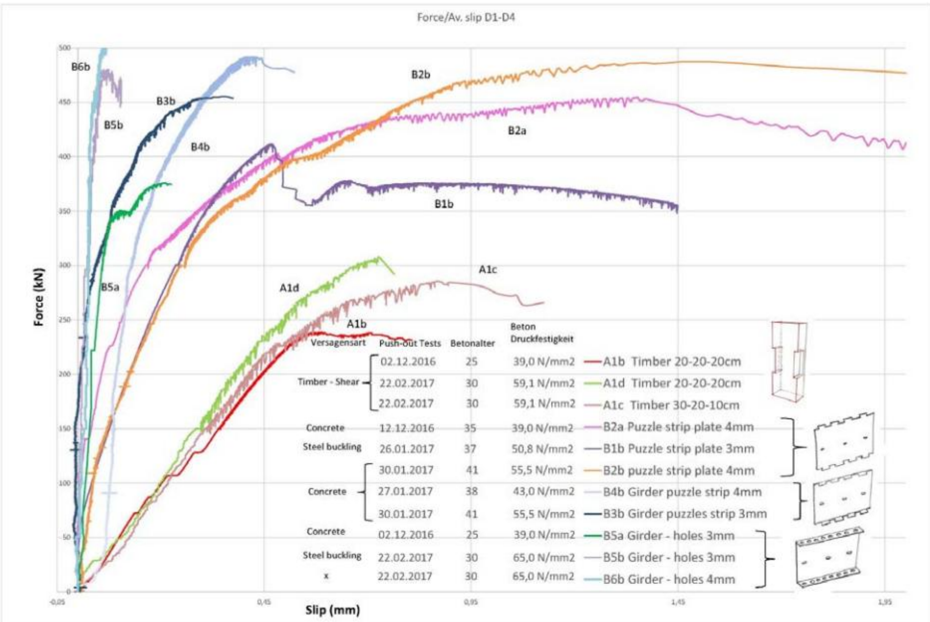

Fig. 1. Push-out test results for all specimens: Relationship between shear force and relative slip, (Tavoussi et al., 2018)

3. Numerical model and results

Once the literature review was achieved, a preliminary selection of connection configurations was made for numerical testing using the Abaqus finite element analysis software. The objective is to identify the most promising configurations for experimental validation.

In this study, five configurations of dismountable composite beams made of steel, wood, and concrete were analyzed. Three of them involve mechanical connection systems designed for disassembly: bolts only, notches only, and a combination of both. Two additional boundary cases were also introduced: one with perfect contact between the materials, simulating a fully rigid connection, and another without any mechanical linkage, where only frictional contact is modeled between interfaces.

This comparative analysis aims to evaluate the influence of connection systems on load transfer, global stiffness, and the disassembly potential of the structure.

3.1 Geometry and mechanical properties

Figure 3 illustrates the geometry of the demountable composite beams combining steel, timber, and concrete under study. Each configuration studied consists of a concrete block measuring 3000 mm in length and 1000 mm in width, connected to a cross-laminated timber (CLT) panel of the same dimensions. This CLT panel is composed of three spruce layers, with two longitudinal layers in C18 grade, 30 mm thick each and one transverse layer in C24 grade, 20 mm thick. The assembly is achieved using an HEA 160 steel profile, ensuring the transfer of forces between materials and guaranteeing the overall stiffness of the structure.

Three demountable connection configurations were studied to assess their mechanical efficiency. The first configuration relies exclusively on 32 M16 bolts to connect the materials. The second implementation features only rectangular notches of 200 mm in length and 20 mm in thickness between concrete and timber to exploit the mechanical interlock effect. The third configuration combines bolts and notches, aiming to optimize both the stiffness of the assembly and the disassembly capacity of the system.

This approach allowed us to compare the performance of the different connections in terms of force transfer and stiffness, while maintaining a consistent geometry for the comparative analysis of numerical results.

The mechanical properties used in this study are based on previous experimental results to best approximate the actual characteristics of the materials, (Kachouh et al., 2024).

Steel is considered homogeneous and isotropic. According to Eurocode 3 (AFNOR, 2005), it has a density of 7850 kg/m³, an elastic modulus of 210 GPa, and a Poisson's ratio of 0.3. To characterize its elasto-plastic behavior, a tensile test was conducted on a sample taken from the HEA 160 profile in order to get its stress-strain curve. Tensile tests were also performed on M16 bolts to determine their yield strength and ultimate tensile strength, considering the average value of the results obtained.

To ensure a more realistic modeling, the experimental values were corrected by applying the classical formulas for true strain and true stress. The true strain is defined by equation (1) and the true stress by equation (2), as described in **"Mechanical Behavior of Materials"** (E. Dowling, 2012) as shown in Fig. 2 (a) and (b).

$$\ln\left(\varepsilon_{exp} + 1\right) \tag{1}$$

$$\sigma_{exp} \times (1 + \varepsilon_{exp}) \tag{2}$$

Poisson's ratio adopted for concrete is equal to 0.2. Concrete blocks used have an average compressive strength of 35.46 MPa with a standard deviation of 1.23 MPa based on five compression tests. The behavior of concrete under load is simulated using the damage plasticity model available in Abaqus, allowing the representation of cracking and progressive degradation of the material (Abaqus 6.14 Documentation, 2014). This model is based on two main mechanisms: plasticity, which represents irreversible deformation, and damage, which reflects the progressive loss of stiffness and strength due to the formation of cracks. The evolution of damage is tracked through a degradation variable that reduces the concrete's load-bearing capacity as the applied loads increase. The required parameters were estimated from the Model Code and incorporated into the numerical simulation shown in Fig. 3 (Telford, 1993).

The CLT wood used exhibits anisotropic behavior, influencing its mechanical properties depending on the orientation of the layers. The average modulus of elasticity is 9000 MPa (C18) and 11,000 MPa (C24) in the direction parallel to the wood grain, while it is significantly lower in the perpendicular direction (300 to 370 MPa) according to the Hexapli technical approval (Hexapli, 2012). Poisson's ratios are equal to 0.48 in the principal directions and 0.22 in shear.

The Hill criterion was used to model the anisotropic plastic behavior of wood, with Hill's equivalent stress being equal to 31.17 MPa and 36.37 MPa for C18 and C24, respectively (Nowak et al., 2013).

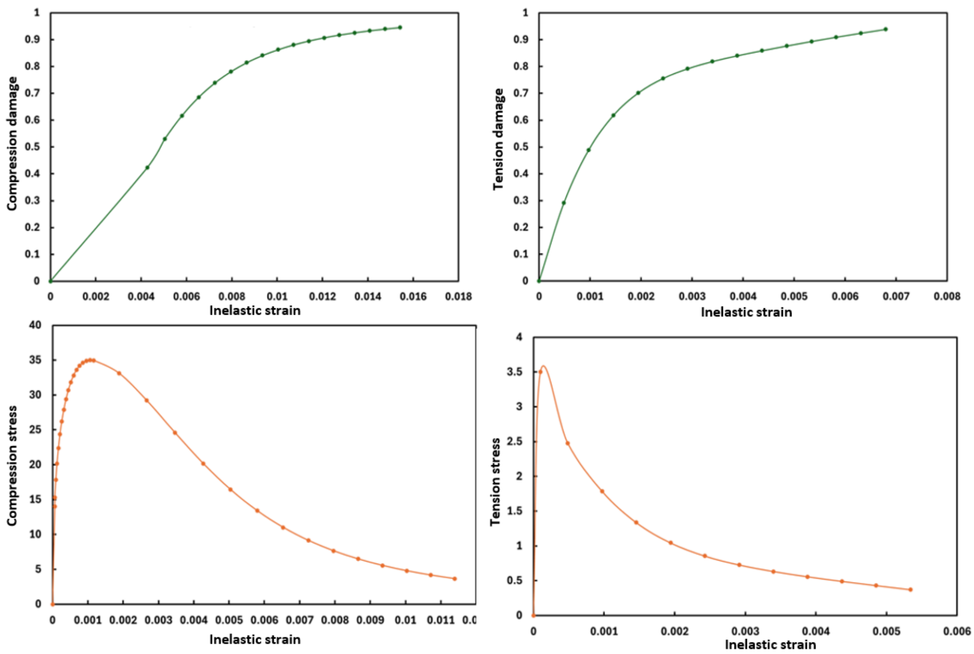

Fig. 3. Constitutive behavior of concrete under compression and tension

3.2 Numerical modelling assumptions

The 3D meshing of the steel profiles and CLT panels was performed using linear hexahedral solid elements (C3D8R). To reduce computation time, only a fraction of the structure, corresponding to a quarter of the model,

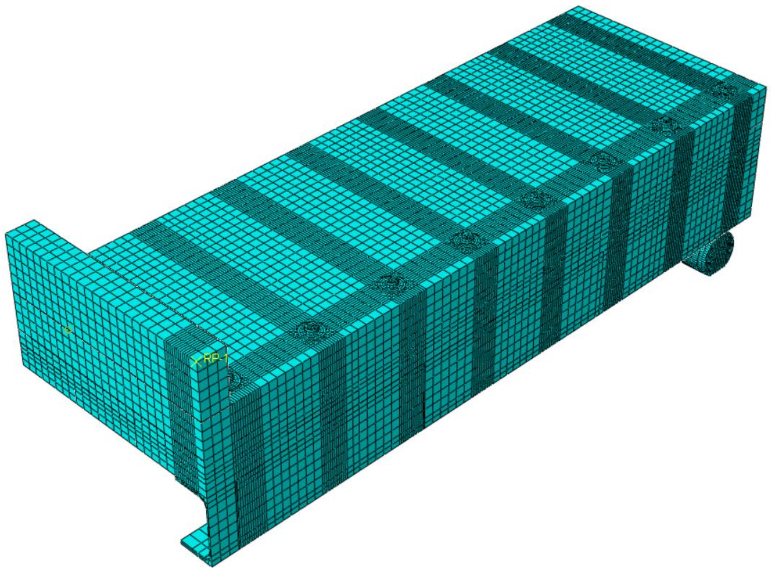

Fig. 4. Mesh adopted for the three-point bending test

was considered due to double symmetry. Unlike a homogenized modeling of wood, each individual lamella of the CLT was explicitly discretized.

The primary mesh size adopted is 20 mm. However, a parametric study showed that a local mesh refinement, ranging from 6 to 8 mm around the connections, was necessary to ensure optimal regularity and better representation of the interactions. Fig. 4 illustrates the final mesh configuration adopted.

Interactions between the CLT lamellae were modeled by incorporating frictional contact as well as cohesive contact between the different layers. Additionally, interactions between the steel profiles and the CLT, as well as between the CLT and concrete, were simulated using frictional contact with a friction coefficient of $\mu = 0.1$.

In addition to the three mechanical configurations, two limiting cases were also modeled to frame the performance range of the dismountable solutions. A perfect contact case was simulated using the tie constraint in Abaqus, enforcing a fully rigid connection between interface surfaces, with no relative slip or separation. Conversely, a no-connection case was considered. Such case relied solely on surface-to-surface frictional contact with the aforementioned coefficient, without any mechanical fasteners or interlocking elements.

3.3 Numerical results

The numerical results allowed evaluating the influence of the connection type on the global flexural behavior of the steel–timber–concrete composite beams. The five dismantlable configurations studied reveal significant differences depending on the nature of the connection system. Among the three configurations incorporating mechanical connectors (bolts only, notches only, and a combination of both), the configuration combining both bolts and notches appears to be the most effective, with an initial stiffness of 13.76 kN/mm and a maximum load of 329.65 kN. This performance results from the complementarity between two mechanisms: notches provide geometric interlock to limit longitudinal slip, while bolts ensure vertical force transfer and stabilize the assembly. The numerical values of the initial stiffness and maximum load of each configuration are summarized in Table 1.

The bolted configuration exhibits higher stiffness than the one using notches (10.74 kN/mm versus 8.35 kN/mm), along with greater load-bearing capacity 262.46 kN versus 187.13 kN. However, stress concentrations appear around the bolt holes, which may lead to localized damage over time. In the case of notches, concrete damage is more pronounced, especially at the ends of the recesses, limiting the structure's ability to carry load. The load–displacement curves in Fig. 5 confirm these observations: a lower initial slope and a more ductile behavior are observed for the notched connection, whereas the bolted and mixed configurations show a more linear and stiffer response.

To further assess the role of connections in activating composite behavior, two limit cases were modeled. The first, based on frictional contact only ($\mu = 0.1$), simulates a scenario without any mechanical linkage. The lack of force transfer between layers results in very low stiffness of 8.11 kN/mm and a limited maximum load of 165.62 kN, clearly reflecting the absence of composite action. The second case, modeled using a tie constraint, imposes perfect continuity of displacements at the interface, reproducing an ideal monolithic behavior. Although such a configuration is not feasible in practice, it serves as a theoretical upper bound. The stiffness obtained equal to 25.24 kN/mm is the highest, and the maximum load reaches 448.91 kN.

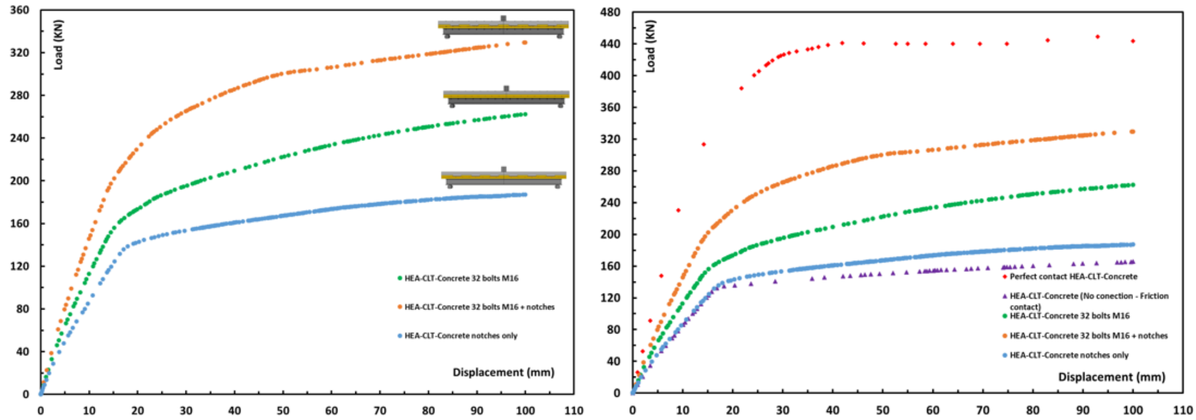

Fig. 5. Results of the three-point bending test on the composite beam: load-vertical displacement curve measured at mid-span

Table 1. Comparison of initial stiffness and maximum load for each connection configuration with the perfect contact case

Connection type	K(kN/mm)	Comparison between various cases and the perfect contact case	Maximum load (kN)	Comparison between various cases and the perfect contact case
With 6 notches	8.35	67%	187.13	58%
With 32 M16 bolts	10.74	57%	262.46	42%
With 32 M16 bolts + 6 notches	13.76	45%	329.65	27%
No connection – Friction contact	8.11	68%	165.62	63%

By comparison, the configuration combining bolts and notches develops a maximum load approximately 45% lower than that of the ideal case, while retaining nearly 73% of its initial stiffness. This demonstrates that a well-designed dismantlable system can closely approach the stiffness performance of a perfectly rigid assembly. The load-bearing capacity of the system can also be improved if an appropriate connection system is used. These results highlight the crucial role of connections in enabling composite behavior and emphasize the trade-offs to consider between strength, stiffness, and dismantlability.

4. Conclusions

This study provided a comprehensive review of connection systems used in composite floors combining timber, concrete, and steel. Timber-concrete and steel-timber connections have been widely studied, with solutions such as notches, bolts, and screws offering good mechanical performance. In contrast, assemblies combining all three materials simultaneously remain scarcely documented in the literature, particularly regarding their global flexural behavior.

To better understand these complex assemblies, a numerical study was conducted on five configurations, including three dismantlable connection systems and two theoretical limit cases: a perfect contact case and a frictional contact only case. These reference cases allowed quantifying the performance losses induced by using mechanical connections. Results highlight the crucial role of connections in enabling composite action. They also show that well-designed dismantlable systems can approach the stiffness of a monolithic structure while maintaining the potential for reversibility.

Results show that the mixed configuration (bolts + notches) offers the best overall compromise.

The perspectives of this work focus on the development of innovative connection solutions, aimed at improving composite interaction between materials and bringing the system's behavior closer to the ideal case simulated by perfect contact. These efforts include detailed analysis of stress and strain distributions within the different configurations, as well as the exploration of more efficient joining strategies. Full-scale prototypes will be developed to experimentally validate the performance observed in numerical simulations. Flexural tests on complete beams and instrumented push-out tests (with displacement sensors, accelerometers, and strain gauges) will allow a precise characterization of the mechanical behavior and dismantling potential. Finally, special attention will be given to the vibrational performance of this type of demountable composite floor system, with the aim of improving both comfort and long-term durability.

Decrease of the radius of gyration of the I-beam column due to long–term corrosion

Jurijus Tretjakovas*[1], Jolanta Pileckienė[2a]

[1] Vilniaus Kolegija, Higher Education Institution, Department of Mechnical Engineering, LT119651314 Vilnius, Lithuania
[2] Vilniaus Kolegija, Higher Education Institution, Department of Electrical and Electronics Engineering, LT119651314 Vilnius, Lithuania

Abstract. The buckling in axially loaded members is a critically important issue in structural engineering design. Long-term corrosion progressively reduces the geometrical characteristics of a column's cross-section, thereby increasing the risk of structural instability and failure. The key geometrical properties of columns include length, second moment of area, and radius of gyration. The radius of gyration depends on the moment of inertia and the cross-sectional area; thus, a reduction in either of these parameters directly affects it.

The decrease in area and moment of inertia is influenced by the corrosion rate and can be mathematically described as an average rate of material loss across different surfaces of the cross-section. The corrosion process gradually removes material from the column, leading to a yearly reduction in the radius of gyration. The corrosion rate is determined by various factors such as surface coating, environmental conditions, and the presence of localized corrosion sites. In this study, the corrosion effect is modeled based on annual corrosion intensity and projected over a period of up to 50 years. The degradation of steel columns is inevitably associated with the reduction of cross-sectional area and moment of inertia. It was concluded that special attention should be paid to columns after 20 to 30 years of service to prevent the development of critical corrosion zones.

Keywords: Buckling; Critical load; Radius of Gyration; Corossion, I-beam.

1. Introduction

When the internal stress state within a vertical structural member changes abruptly in response to gradually increasing axial loading, a sudden and unexpected structural failure may occur. In the case of a slender rod subjected to axial compressive forces, the member initially experiences uniform compression, and its longitudinal axis remains straight and stable, as illustrated in Fig. 1. However, if the applied compressive load exceeds a critical threshold - a value that depends on the rod's effective length, cross-sectional geometry, and boundary conditions - the structural behavior of the member may change significantly. At this point, the rod may become laterally unstable and experience a sudden lateral deflection, indicating the onset of buckling. This lateral deflection introduces additional internal forces in the form of bending moments, which in turn generate secondary stresses within the material. These combined stresses can accelerate structural failure even in the absence of material yielding.

As noted by Barry (2022), "the stability of slender members is often governed more by geometry and loading conditions than by the strength of the material itself," which emphasizes the importance of structural configuration in resisting instability.

This phenomenon is referred to as buckling, a mode of instability that is especially critical in slender, axially loaded elements. Buckling-induced failures are considered particularly hazardous in engineering practice because they often occur without significant prior deformation or visible warning, posing serious risks to structural safety.

The critical elastic stress corresponding to the critical force devided by cross section area in the column just before buckles defined as follows (Hibbeler, 2023).

$$\sigma_{cr} = \frac{\pi^2 \cdot E}{\left(L/i_{min}\right)^2} \tag{1}$$

where
E – modulus of elasticity of the material;
L – unsupported length of the column;

i_{min}– smallest radius of gyration of the column.

Fig. 1. Columns of the building

The slenderness ratio serves classify columns as long, intermediate and short. This geometrical parameter is a measure of the vertical rod flexibility and known as ratio

$$\lambda = \frac{\mu \cdot l}{i_{min}} \tag{2}$$

where
μ–effective length factor;
l – supported length of the column;
i_{min}– smallest radius of gyration of the column.

The radius of gyration determined from ratio

$$i_{min} = \sqrt{\frac{I_{min}}{A}} \tag{3}$$

where
I_{min}– smallest second moment of area (moment of inertia) of the cross section of the column;
A – area of the cross section of the column;

The service life of steel structures, including I-beams, is closely linked to corrosion effects. Long-term corrosion not only reduces material thickness but also causes significant geometric changes in structural elements, affecting their mechanical properties (Crespi at al., 2022; Gonzalez at al., 2018). This article examines the reduction of the gyroscopic radius of an I-beam column due to long-term corrosion, analyzes the main causes of corrosion, and evaluates its impact on structural stability. Metal structures are often affected by corrosion, which can significantly impact their strength and stability. I-beams are widely used in construction and infrastructure projects; however, their performance deteriorates over time due to corrosion.

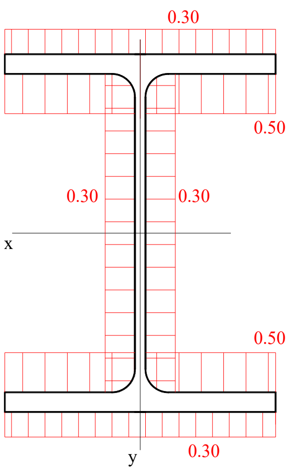

Fig. 2. Cross section of the IPE column and corrosion rates

Corrosion is a critical factor affecting the long-term stability and load-bearing capacity of steel structures. In axially loaded members, such as columns, long-term corrosion progressively reduces the cross-sectional area and moment of inertia, leading to a decrease in the radius of gyration. This deterioration weakens the structural integrity and increases the risk of buckling, a major concern in engineering design.

The aim of the work is to describe the decrease in radius of gyration of cross section in Fig. 2 of the IPE column due to long-term corrosion by mathematical expression.

Tasks for the achievement of the goal:

- To describe the influence of the corrosion over a period of one year and up to 40 years;
- To make an analytical model of the radius of gyration of the cross-section of the I-column;
- To model the influence of corrosion rusts on the radius of gyration.

The columns of a building usually have a rational cross-sectional shape, which is is close to the I-beam. Therefore, this paper investigates a computational model of cross section of the I-Beam column depending on a variable. The corrosion is modelled as degradation and loss of material in a long term process, in terms of corrosion intensity over one year and intensity up to 40 years.

The analytical model of corrosion describes the reduction of the cross-sectional area over a long period of time and its influence on the radius of gyration of the cross-section. It was found that radius of gyration don't depend on decrease of the area of cross section of the column. On the other hand special attention should be paid to the columns after the first 20 ... 30 years in order to stop the corrosion focal points.

2. The model of corrosion rate

The corrosion rate is influenced by various factors, including environmental conditions, protective coatings, and localized corrosion spots caused by external factors. Over time, material loss due to corrosion significantly impacts the geometric properties of a column.. Research indicates that after 20 to 30 years, intensified corrosion prevention measures should be implemented to mitigate further structural degradation (Akduman et al., 2024, Simoncelli at al., 2023). Modeling corrosion effects over periods of up to 50 years highlights the necessity of proactive monitoring and maintenance strategies to enhance the longevity and safety of steel columns.

2.1. The Effect of Corrosion on I-Beam Columns

Corrosion is an electrochemical process that leads to the formation of rust on the steel surface, reducing the effective cross-section of the structure. The main factors influencing the corrosion of I-beam columns include:

- Atmospheric humidity (>60%), which promotes electrochemical reactions (Bradford, 2015);
- Pollutants such as chlorides and sulfur oxides, which accelerate metal oxidation;
- Mechanical damage, leading to the wear of protective coatings.

Corrosion not only reduces metal thickness but also alters geometric parameters, including the gyroscopic radius.

2.2. Analysis of Gyroscopic Radius Reduction

Due to long-term corrosion, the flanges and web of the I-beam become thinner, decreasing their moment of inertia (I) and consequently reducing the radiuso f guyration (Wu, B. et al., 2017).

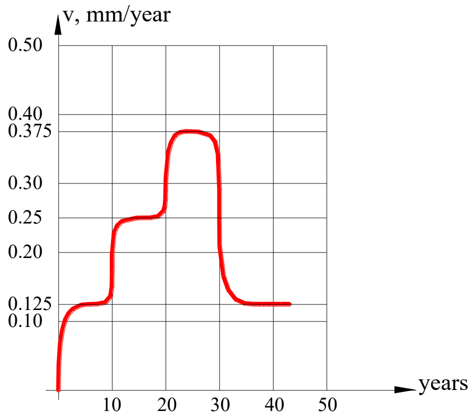

Fig. 3. Corrosion rate graph in 40 years

When modeling the corrosion rate, it is assumed that corrosion focuses appear in the structural element already in the first year, and the rate for the first 10 years is equal to 1/4 of the maximum rate, from 10 to 20 years the value is 1/2 of the maximum rate, from 20 years the rate can be 3/4 of the maximum rate described in the literature (Šulčius, 2006). After 30 years the rate of corrosion drop till 1/4 of the maximum rate. All this is illustrated in Fig. 4 as a graph of the change in rate over the time.

Surfaces of IPE with corrosion rates less than 0.50 mm/m will also maintain lower and proportional corrosion rates from the start throughout the modelling start.

3. The variation of the radius of gyration in mathematical model

3.1. The areas of rust in cross section

For analysis the IPE 500 according DIN 1025-5:1994-03 (Euronorm 19-57) was choosen. The mathematical model describes the radiuses of gyration about the x-axis and the y-axis. Rusts are modelled as a variable parameter in the model and are described as a time function. The rust zones are modeled as perfect rectangles are shown in Fig. 3 (figures from 1 to 7). They are marked with thick brown lines. Here we see the thickness t and the width l of each of the three corrosion zones, because areas from 4 to 7 are symetrical zones.

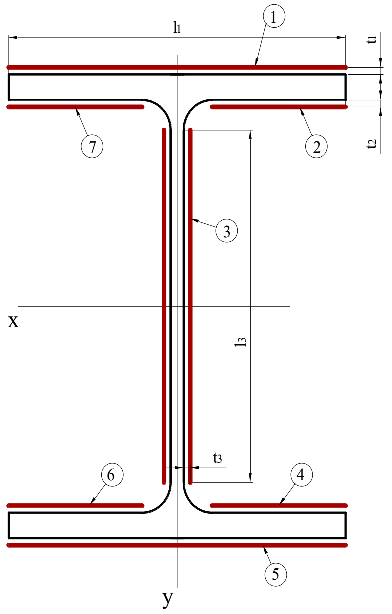

Fig. 4. Corosssion areas in cross section

The variable of the geometrical parameters during long-term corrosion is modeled as the elimination of corroded areas from the equations of the moments of inertia and eliminations of corroded area from primary area.

3.2. Influence of rusts to radius of gyration

The mathematical model of corrosion describes the reduction of these loss areas (Fig. 3) over time and their influence on the radius af gyration and moments of inertia of the entire cross-section.

Radius of gyration about x axis

$$i_x = \sqrt{\frac{I_x - \sum_{i=1}^{7}(I_{xci} + A_i \cdot y_{ci}^2)}{A - \sum_{i=1}^{7} A_i}} \tag{4}$$

where

I_{xci} – moment of inertia of area of rust about horizontal x-axis;

y_{ci} – distance from rust area center to x axis.

Geometrical characteristics about y axis are solved by the same algorithm.

3.3. Modellling results

The results of the modelling during 40 years of the IPE 500 geometrical parameters are presented in Table 1: the changes in the cross-sectional area A, moment of inertia I_x and I_y and radiuses of gyration i_x and i_y.

It should be noted that moment of inertia of the cross section dramatically after 20 years. The decrease of the radiuses of gyrations (Table 1) ir practicaly negligible, therefore we should note that slenderness ratio of column not depend on rusts.

Table 1. Area, moments of inertia and radiuses of gyration

Years	A, cm^2	Ix, cm^4	ix, cm	Iy, cm^4	iy, cm
0	115.5	48199	20.43	2142	4.306
10	114.2	47680	20.44	2115	4.304
20	111.6	46650	20.45	2062	4.300
30	72.3	31330	20.81	1266	4.184
40	71.1	30810	20.83	1240	4.178

Mathematical simulations were performed based on the described methodology, and the results are presented as graphs in this section. The change in moment of inertia about centroidal over time is shown in Figure 5.

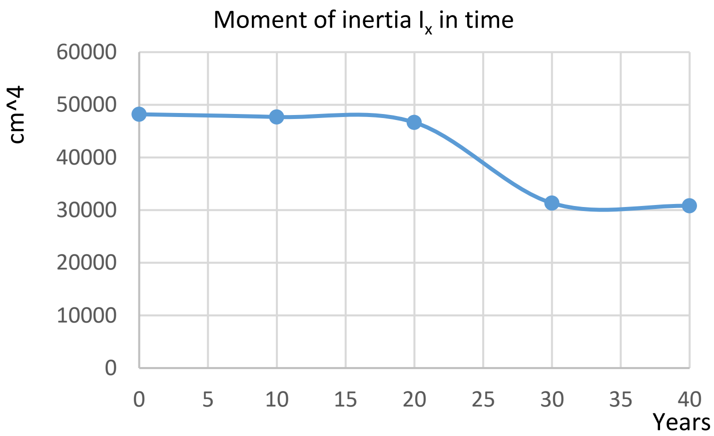

Fig. 5. Decrease of moment of inertia

The data obtained (Fig. 5) illustrate that for given corrosion rate moment of inertia of cross section in beginning of column exploatation is almost constant and after 20 years this geometrical parmeter decrease.

4. Conclusions and remarks

On the basis of the analytical modelling results obtained in the present investigation the following conclusions have been drawn.

- The study showed that special attention should be paid to columns from the first year in order to prevent the formation of corrosion focuses.
- The rusts surfaces are described as areas of corrosion that continuously increase over time, with the area decreasing by 1 % in the first 10 years, by 3,4 % between 10 and 20 years, by 37 % between 20 and 30 years, and by 40 years only 38 % of the total area remaining.
- The geometric parameter – moment of inertia - decreases by 1% during the first 10 years, from 10 to 20 years the decrease reaches 3,2%, from 20 to 30 years the decrease 35 %, and after 40 years - more 36%.
- The of the radiuses of gyrations in time are practicaly constants;
- To mitigate corossion effect, the following preventive measures are recommended: regular inspections – to identify early corrosion signs and apply protective measures, anti-corrosion coatings and galvanization – to slow down the corrosion rate, environmental control – to reduce humidity and pollutant concentration in the operational environment, systematic maintenance and repairs – reinforcement or replacement of damaged structures.

Abstract. This study investigates the effect of deformable springs on the axial vibration of Rayleigh bars reinforced with short fibers. The Rayleigh bar is reinforced with randomly distributed short fibers, and springs that can be deformed in the axial direction are added to both ends of the bar to determine the axial displacement effects. The Halpin-Tsai model is used to calculate the effective stiffness of the Rayleigh bar, and the mixture rule is used to calculate the effective mass density. In this study, where the axial displacement is considered a Fourier sine series, the Stokes' transformation is applied to obtain the solutions of the boundary conditions (rigid, semi-rigid, free) in the most general sense. An eigenvalue problem formulation, including the stiffnesses of the springs at both ends of the Rayleigh bars reinforced with short fibers, is obtained. In this eigenvalue problem, the eigenvalues that make the determinant of the coefficient matrix zero give the axial vibration frequencies of the Rayleigh bars. The effect of parameters such as fiber properties and stiffness of deformable springs on the axial vibration frequencies of Rayleigh bars is determined by solving the eigenvalue problem. In addition, the frequencies of the classical bar theory are also mentioned. Various examples are given to compare the axial vibration frequencies of classical and Rayleigh bars. Thus, the differences between the two bar theories mentioned are clearly shown.

1. Introduction

Composite materials are engineering materials formed by combining two or more materials, exhibiting superior properties that the components do not possess individually (Leite & da Rocha, 2024; Mohammed et al., 2015; Singh et al., 2024). These materials are replacing traditional materials in many fields such as aerospace, automotive, marine, and civil engineering (Civalek et al., 2022a). Short fiber reinforced composites (SFRCs) are created by embedding short fibers, cut to specific lengths, into a matrix in various arrangements (Hamza et al., 2017). They possess advantages such as ease of manufacturing processes, low costs, and suitability for manufacturing parts with complex geometries (Arumugam et al., 2022). The random or specific directional distribution of fibers within the matrix affects the macroscopic behavior of the material (Baniya & Tsegai, 2022)

Determining the dynamic and vibration characteristics of composite materials is necessary for identifying the resonance frequencies, estimating the fatigue life, and understanding the damping capacity of systems using these materials (Bonopera, 2023; Kalusuraman et al., 2023; Mortazavian & Fatemi, 2015; Wu et al., 2023). Determining the axial natural frequencies and mode shapes of such elements is important for avoiding resonance conditions, evaluating dynamic stability, and ensuring structural integrity (Lelkes et al., 2024).

The generally random distribution of short fibers within the matrix, although making the material appear homogeneous at the macroscopic level, harbors significant heterogeneity and anisotropy at the microscopic scale (Hao et al., 2020). This situation necessitates the use of micromechanical models, such as the Halpin-Tsai model (Zhou et al., 2024) or the rule of mixtures (Sotomayor & Pancho, 2024), to predict the effective (average) mechanical properties of the composite.

When considering axial vibrations, the most fundamental approach is the classical rod theory. This theory is based on the assumption that only axial deformations are considered, neglecting transverse movements and their associated inertia effects. This approach yields adequate results, especially for the low-frequency axial vibrations of slender (long and thin) rods (Han et al., 2014). However, when the cross-sectional dimensions of the rod are not negligible compared to its length, or when high-frequency vibrations are examined, the necessity arises to consider the lateral movements occurring during axial motion and their associated inertia effects. More advanced rod

https://doi.org/10.31462/icearc2025_ce_sme_178

theories have been proposed to model these effects (Fedotov et al., 2016; Leamy, 2014). Rayleigh rod theory accounts for the lateral inertia effect and the effect of the material's Poisson's ratio in axial vibration analysis (Ananthapuvirajah, 2019).

In the dynamic analysis of structural elements, using elastic boundary conditions (modeling supports with springs) instead of classical end conditions (clamped, simply supported, and free) offers a more realistic approach (Fernández-Sáez et al., 2017). Beyond offering a more realistic approach, elastic end conditions allow the use of spring stiffnesses as a design variable (Civalek et al., 2022b). For example, if resonance at specific frequencies is undesirable for a structure, or if a specific dynamic response is targeted, the stiffnesses of the springs at the support points can be adjusted to achieve these goals (M. Kamal & İnel, 2021). This offers potential for applications such as passive vibration control or vibration isolation. Furthermore, elastic boundary conditions encompass classical boundary conditions as special cases (Yaylı et al., 2014).

The mechanical and dynamic behaviors of short fiber reinforced composites, particularly their vibration characteristics, have been investigated in numerous studies (Akpınar et al., 2024; Amsalu et al., 2024; Geethamma et al., 2005; Y. Huang et al., 2023; Kalusuraman et al., 2023; A. M. Kamal & Taha, 2010; Kumar & Kumar, 2024; Nciri et al., 2017; Nurazzi et al., 2021). The effect of lateral inertia and Poisson's ratio on axial vibration has been emphasized in many studies (Bordiga et al., 2019; Chang et al., 2010; Farshbaf Zinati et al., 2020; Ghayesh & Balar, 2008; X. F. Li et al., 2013; Yaylı, 2020; Zhu & Chung, 2019). The effect of elastic boundary conditions on vibration behavior has been examined using various analytical and numerical methods (Ding et al., 2024; Lee & Lin, 1996; Lv et al., 2015; Ratazzi et al., 2013; L. Wang et al., 2022; Y.-R. Wang & Fang, 2015; Yang & Yang, 2017). Fourier series and Stokes' transformation (Jeong & Lee, 1996; Kadıoğlu & Yaylı, 2017; Khalili et al., 2005; W. L. Li & Xu, 2009), the differential quadrature method (X. Huang et al., 2024; Jena & Chakraverty, 2018; Laura & Gutierrez, 1993; Liu et al., 2022), and the finite element method (Belabed et al., 2024; Friswell et al., 2007; Hien et al., 2023; Z. Huang et al., 2019; Wen & Yi, 2014) are some of the approaches used to solve such problems.

In this study, an analytical approach has been adopted for the axial vibration analysis of a Rayleigh rod reinforced with short fibers and supported by axially deformable springs at both ends. The effective elasticity modulus of the rod is determined using the Halpin-Tsai model and the effective mass density is determined using the rule of mixtures. The equation of motion is obtained using Hamilton's principle. The axial displacement function is expressed as a Fourier sine series. Stokes' transformation is applied to systematically address the elastic boundary conditions at the ends of the rod. Stokes' transformation allows the derivatives of the Fourier series to be expressed in terms of the series itself and the boundary values, enabling the incorporation of boundary conditions into the equation of motion and providing an analytical framework even for non-homogeneous boundary conditions. Axial natural vibration frequencies are obtained from the solution of the eigenvalue problem. The vibration frequencies obtained for the Rayleigh rod are compared with the frequencies obtained according to the classical rod theory. The developed model comprehensively reveals the effects of fundamental parameters such as fiber properties (volume fraction, aspect ratio), rod geometry, and spring stiffnesses on the axial natural vibration frequencies.

Upon reviewing the existing literature, a lack of analytical studies addressing the combination of three topics – (1) short fiber reinforced composite material, (2) Rayleigh rod model including lateral inertia effects for axial vibration, and (3) elastic boundary conditions – has been identified. The presented analytical solution and frequency equation offer the possibility to analytically evaluate the effect of different material and boundary condition parameters on the system's dynamic behavior without the need for complex numerical simulations. This formulation provides a valuable fundamental and practical solution capability for the preliminary design, optimization, and more accurate dynamic analysis of similar structural elements. Furthermore, thanks to the approach combining Fourier series with Stokes' transformation, an analytical solution has been obtained for the boundary value problem that could not be solved with classical methods.

In Section 2, the mathematical modeling for the axial vibration of the short fiber reinforced Rayleigh bar is detailed, the calculation of effective material properties is explained, and the eigenvalue problem formulation using Fourier series and Stokes' transformation is derived. In Section 3, the obtained frequency equation is solved numerically, the effects of various parameters on the axial natural frequencies are comprehensively examined, and the results are presented through graphs. This section also includes comparisons between the Rayleigh theory and the classical theory. Finally, in Section 4, the main findings obtained from the study are summarized, and the conclusions reached are discussed.

2. Definition and solution of the problem

This chapter deals with the axial vibration behavior of short fiber reinforced Rayleigh bars in an analytical framework. First, the transformation of micromechanical scale heterogeneity caused by randomly oriented fiber reinforcement into macro-scale effective elastic parameters is described. Then, the equation of motion derived using a variational approach based on Hamilton's principle is reduced to an eigenvalue problem using Fourier sine series and Stokes' transformation. Thus, the effects of design variables such as fiber property and volume fraction on the natural frequencies are revealed through closed formulas.

2.1. Material properties

In this section, the effective modulus of elasticity and bulk density are presented in closed form to provide input for the axial vibration analysis of rod-type elements reinforced with short fibers and modeled by the Rayleigh approach. As given in Fig. 1, the fibers are assumed to be completely randomly oriented. Hence, the macroscopic behavior of the composite is represented by isotropic singular parameters.

Parameters such as length/diameter ratio and volume fraction of short fibers directly affect the overall mechanical behavior of the composite material. In this study, the widely used Halpin-Tsai equations are used to predict the modulus of elasticity of short fiber reinforced materials (Agarwal et al., 2006) . Halpin-Tsai equations, which are widely used to estimate Young's moduli of short fiber reinforced composites, allow both longitudinal and transverse stiffnesses to be calculated analytically by taking into account the effect of fibers in the matrix phase (Agarwal et al., 2006). With this approach, the longitudinal and transverse Young's moduli are expressed by as follows (Agarwal et al., 2006):

$$E_l = E_m \left[\frac{1+2(l/d)V_f\left(\frac{(E_f/E_m)-1}{(E_f/E_m)+2(l/d)}\right)}{1-V_f\left(\frac{(E_f/E_m)-1}{(E_f/E_m)+2(l/d)}\right)} \right] \tag{1}$$

$$E_t = E_m \left[\frac{1+2V_f\left(\frac{(E_f/E_m)-1}{(E_f/E_m)+2}\right)}{1-V_f\left(\frac{(E_f/E_m)-1}{(E_f/E_m)+2}\right)} \right] \tag{2}$$

Where E_l, E_t, E_m and E_f are the longitudinal Young's modulus of the composite, transverse Young's modulus of the composite, Young's modulus of the matrix, and Young's modulus of the short-fiber, l/d is the short-fiber length/diameter ratio, and V_f is the short-fiber volume distribution, respectively.

Using Equations (1) and (2), the Young's modulus (E_{RSF}) and shear modulus (G_{RSF}) of the composite material reinforced with randomly oriented short fibers can be calculated as follows (Agarwal et al., 2006):

$$E_{RSF} = \frac{3}{8}E_l + \frac{5}{8}E_t \tag{3}$$

$$G_{RSF} = \frac{1}{8}E_l + \frac{1}{4}E_t \tag{4}$$

The Poisson's ratio of a reinforced with randomly aligned short fibers composite (ν_{RSF}) can be calculated using E_{RSF} and G_{RSF} as follows (Agarwal et al., 2006):

$$\nu_{RSF} = \frac{E_{RSF}}{2G_{RSF}} - 1 \tag{5}$$

With the matrix density (ρ_m) and short-fiber density (ρ_f), the density (ρ_{RSF}) of randomly distributed short-fiber reinforced composite material can be calculated as follows (Pan, 1993):

$$\rho_{RSF} = \rho_m(1 - V_f) + \rho_f V_f \tag{6}$$

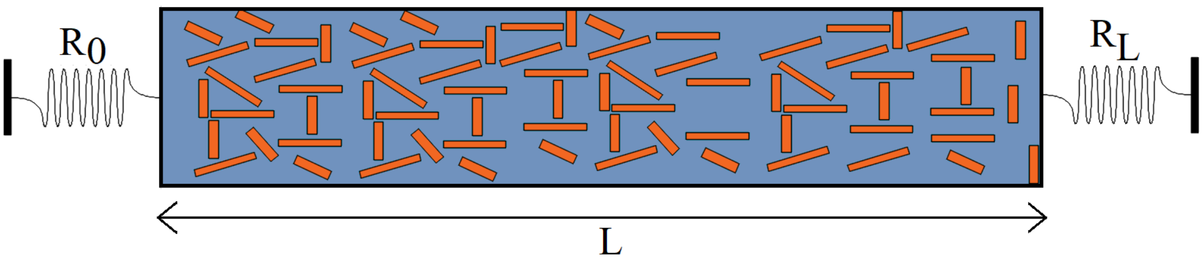

Fig. 1. Axially restrained short fiber reinforced Rayleigh bar

2.2. Rayleigh model

This subsection details the kinematic definitions, energy functionals, equation of motion and boundary conditions derived based on Rayleigh rod theory to describe the axial vibration of randomly oriented short fiber reinforced rod-type elements.

In the Rayleigh approach, the section planes remain flat without rotation relative to their initial position, but inertia effects are taken into account at points far from the axial axis. The displacement field is defined as (Yayli, 2020):

$$w = w(z, t) \tag{7}$$

$$u = -\nu \frac{\partial w}{\partial z} x \tag{8}$$

$$v = -\nu \frac{\partial w}{\partial z} y \tag{9}$$

Where w represents the axial displacement along the bar axis, u and v represent the axial-plane shrinkage in the x and y directions, respectively. ν represents Poisson's ratio.

Since the Rayleigh model includes the section rotational inertia, the total kinetic energy can be expressed as follows:

$$T = \frac{1}{2}\int_0^L \int_A \rho\left[\left(\frac{\partial u}{\partial t}\right)^2 + \left(\frac{\partial v}{\partial t}\right)^2 + \left(\frac{\partial w}{\partial t}\right)^2\right] dA dz = \int_0^L \left[A\left(\frac{\partial w}{\partial t}\right)^2 + v^2 I\left(\frac{\partial^2 w}{\partial z \partial t}\right)^2\right] dz \tag{10}$$

Where A is the cross-sectional area, t is the time, I is the polar moment of inertia of the cross-section, and I is calculated as follows:

$$I = \int_A (x^2 + y^2)\, dA \tag{11}$$

The longitudinal load (N) can be represented as follows:

$$N = \int_A \sigma_z\, dA = EA\frac{\partial w}{\partial z} \tag{12}$$

The axial derivative of N can be given as follows:

$$\frac{\partial N}{\partial z} = \rho A\frac{\partial^2 w}{\partial t^2} \tag{13}$$

By applying the variational form of Hamilton's principle, the following partial differential equation can be obtained (Li et al., 2017):

$$\rho A\frac{\partial^2 w}{\partial t^2} - \rho I v^2\frac{\partial^4 w}{\partial z^2 \partial t^2} - EA\frac{\partial^2 w}{\partial z^2} = 0 \tag{14}$$

This equation is the equation valid along the bar. For the supports at the two endpoints of the bar, the differential equation can be given in the following form:

$$\left[\rho I v^2\frac{\partial^3 w}{\partial z \partial t^2} + EA\frac{\partial w}{\partial z}\right]\delta w = 0 \tag{15}$$

For a rod-type element reinforced with randomly oriented short fibers, the equations of motion can be written as follows:

$$\rho_{RSF} A\frac{\partial^2 w}{\partial t^2} - \rho_{RSF} I v_{RSF}^2\frac{\partial^4 w}{\partial z^2 \partial t^2} - E_{RSF} A\frac{\partial^2 w}{\partial z^2} = 0, \quad 0 < z < L \tag{16}$$

$$\left[\rho_{RSF} I v_{RSF}^2\frac{\partial^3 w}{\partial z \partial t^2} + E_{RSF} A\frac{\partial w}{\partial z}\right]\delta w = 0, \quad z = 0, z = L \tag{17}$$

2.3. Solution procedure

When the displacement for free vibration is assumed as$w(z,t) = \phi(z)\, cos[\,\omega t]$, the equation of motion can be given as follows:

$$\rho_{RSF} I v_{RSF}^2 \omega^2\frac{d^2\phi}{dz^2} - E_{RSF} A\frac{d^2\phi}{dz^2} - \rho_{RSF} A\omega^2\phi = 0, \quad 0 < z < L \tag{18}$$

Where ω is the natural frequency, the force boundary conditions can be written as follows:

$$E_{RSF} A\frac{d\phi}{dz} - \rho_{RSF} I v_{RSF}^2 \omega^2\frac{d\phi}{dz} = \Gamma_0, \quad z = 0 \tag{19}$$

$$E_{RSF} A\frac{d\phi}{dz} - \rho_{RSF} I v_{RSF}^2 \omega^2\frac{d\phi}{dz} = -\Gamma_L, \quad z = L \tag{20}$$

In this context, Γ_0 and Γ_L represent the axial forces acting at both ends of the bar. The relevant relations can be rewritten using the axial spring stiffnesses at the end points (R_0 and R_L) and the axial displacements at those points:

$$R_0\phi_0 = E_{RSF} A\frac{d\phi}{dz} - \rho_{RSF} I v_{RSF}^2 \omega^2\frac{d\phi}{dz}, z = 0 \tag{21}$$

$$-R_L\phi_L = E_{RSF} A\frac{d\phi}{dz} - \rho_{RSF} I v_{RSF}^2 \omega^2\frac{d\phi}{dz}, z = L \tag{22}$$

2.4. Solution procedure

The axial displacement function in Eq. (18) can be defined as follows (Uzun et al., 2020):

$$\phi(z) = \begin{bmatrix} \phi_0 & z = 0 \\ \phi_L & z = L \\ \sum_{n=1}^{\infty} A_n\, sin(\frac{n\pi z}{L}) & 0 < z < L \end{bmatrix} \tag{23}$$

In the context of this study using the Stokes transformation, the coefficient (A_n) in Eq. (23) can be represented as follows:

$$A_n = \frac{2}{L}\int_0^L \phi\,(z)\, sin(\frac{n\pi z}{L})dz \tag{24}$$

The derivative of Eq. (23) with respect to z is as follows:

$$\phi'(z) = \sum_{n=1}^{\infty}\frac{n\pi}{L} A_n\, cos(\frac{n\pi z}{L}) \tag{25}$$

Eq. (25) is expressed as a Fourier cosine series:

$$\phi'(z) = \frac{f_0}{L} + \sum_{n=1}^{\infty} f_n\, cos(\frac{n\pi z}{L}) \tag{26}$$

here,

$$f_0 = \frac{2}{L}\int_0^L \phi'(z)dz = \frac{2}{L}[\phi(L) - \phi(0)] \tag{27}$$

$$f_n = \frac{2}{L}\int_0^L \phi'(z)\, cos(\frac{n\pi z}{L})dz \quad (n = 1,2,\ldots) \tag{28}$$

If Eq. (28) is integrated according to the integral by parts rule (Uzun et al., 2020):

$$f_n = \frac{2}{L}[\phi(z)\,cos(\frac{n\pi z}{L})]_0^L + \frac{2}{L}\left[\frac{n\pi}{L}\int_0^L \phi\,(z)\,sin(\frac{n\pi z}{L})dz\right] \tag{29}$$

$$f_n = \frac{2}{L}[(-1)^n\phi(L) - \phi(0)] + \frac{n\pi}{L}A_n \tag{30}$$

Using the equations obtained, higher-order derivatives can be calculated as follows:

$$\frac{d\phi(z)}{dz} = \frac{\phi_L - \phi_0}{L} + \sum_{n=1}^{\infty}\frac{n\pi}{L}cos(\frac{n\pi z}{L})\left[\frac{2}{L}((-1)^n\phi_L - \phi_0) + \frac{n\pi}{L}A_n\right] \tag{31}$$

$$\frac{d^2\phi(z)}{dz^2} = -\sum_{n=1}^{\infty}\frac{n\pi}{L}sin(\frac{n\pi z}{L})\left[\frac{2}{L}((-1)^n\phi_L - \phi_0) + \frac{n\pi}{L}A_n\right] \tag{32}$$

Substituting Eqs. (23) and (32) into Eq. (18) allows the coefficient A_n and the angular rotation field $\phi(z,t)$ to be reformulated in terms of ϕ_0 and ϕ_L as follows:

$$A_n = \frac{2n\pi(E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2)(-\phi_0 + (-1)^n\phi_L)}{-E_{RSF}An^2\pi^2 + AL^2\rho_{RSF}\omega^2 + n^2\pi^2\rho_{RSF}Iv_{RSF}^2\omega^2} \tag{33}$$

Using the above relation, the axial deflection function can be defined as follows:

$$\phi(z) = \sum_{n=1}^{\infty}\frac{2n\pi(E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2)(-\phi_0 + (-1)^n\phi_L)}{-E_{RSF}An^2\pi^2 + AL^2\rho_{RSF}\omega^2 + n^2\pi^2\rho_{RSF}Iv_{RSF}^2\omega^2}sin(\frac{n\pi z}{L}) \tag{34}$$

Then, based on the force boundary conditions and A_n, the following equation sets are written:

$$\left(-R_0 - \frac{E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2}{L} - \sum_{n=1}^{\infty}\frac{2AL\rho\omega^2(E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2)}{-E_{RSF}An^2\pi^2 + AL^2\rho_{RSF}\omega^2 + n^2\pi^2\rho_{RSF}Iv_{RSF}^2\omega^2}\right)\phi_0$$
$$+\left(\frac{E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2}{L} + \sum_{n=1}^{\infty}\frac{2(-1)^nAL\rho\omega^2(E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2)}{-E_{RSF}An^2\pi^2 + AL^2\rho_{RSF}\omega^2 + n^2\pi^2\rho_{RSF}Iv_{RSF}^2\omega^2}\right)\phi_L = 0 \tag{35}$$

$$\left(\frac{E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2}{L} + \sum_{n=1}^{\infty}\frac{2(-1)^nAL\rho\omega^2(E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2)}{-E_{RSF}An^2\pi^2 + AL^2\rho_{RSF}\omega^2 + n^2\pi^2\rho_{RSF}Iv_{RSF}^2\omega^2}\right)\phi_0$$
$$+\left(-R_L - \frac{E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2}{L} - \sum_{n=1}^{\infty}\frac{2AL\rho\omega^2(E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2)}{-E_{RSF}An^2\pi^2 + AL^2\rho_{RSF}\omega^2 + n^2\pi^2\rho_{RSF}Iv_{RSF}^2\omega^2}\right)\phi_L = 0 \tag{36}$$

By writing this set of equations in matrix form, the following equation is obtained:

$$\begin{bmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{bmatrix}\begin{bmatrix} \phi_0 \\ \phi_L \end{bmatrix} = 0 \tag{37}$$

In the above expression, axial vibration frequencies are obtained by setting the determinant of the coefficients matrix equal to zero and the elements of this coefficients matrix are as follows:

$$H_{11} = -R_0 - \frac{E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2}{L} - \sum_{n=1}^{\infty}\frac{2AL\rho\omega^2(E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2)}{-E_{RSF}An^2\pi^2 + AL^2\rho_{RSF}\omega^2 + n^2\pi^2\rho_{RSF}Iv_{RSF}^2\omega^2} \tag{38}$$

$$H_{12} = H_{21} = \frac{E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2}{L} + \sum_{n=1}^{\infty}\frac{2(-1)^nAL\rho\omega^2(E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2)}{-E_{RSF}An^2\pi^2 + AL^2\rho_{RSF}\omega^2 + n^2\pi^2\rho_{RSF}Iv_{RSF}^2\omega^2} \tag{39}$$

$$H_{22} = -R_L - \frac{E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2}{L} - \sum_{n=1}^{\infty}\frac{2AL\rho\omega^2(E_{RSF}A - \rho_{RSF}Iv_{RSF}^2\omega^2)}{-E_{RSF}An^2\pi^2 + AL^2\rho_{RSF}\omega^2 + n^2\pi^2\rho_{RSF}Iv_{RSF}^2\omega^2} \tag{40}$$

3. Numerical results

In this part of the study, the effects of important parameters for short fiber reinforced Rayleigh bars are investigated. These are E_f/E_m, ρ_f/ρ_m, V_f, l/d and spring stiffnesses. In this study, the analyses are carried out with the following parameters considered constant unless otherwise stated: Bar radius $r = 0.2\ m.$, bar length $L = 40r\ m.$, $d = r/10, l/d = 5, V_f = 0.2, E_f/E_f = 5, \rho_f/\rho_m = 2, n = 60$. In the study, the stiffnesses of the springs at both ends of the bar are considered equal to each other and are included in the analysis in the following dimensionless forms:

$$\overline{R_0} = \frac{R_0L}{E_mA} \tag{41}$$

$$\overline{R_L} = \frac{R_LL}{E_mA} \tag{42}$$

Here, $\overline{R_0}$ and $\overline{R_L}$ are the non-dimensional spring stiffnesses at the ends of bar. The study deals with first mode frequencies except for the last figure. In addition, the study shows the dimensionless frequencies ($\overline{\omega}$) as output and the calculation of the dimensionless frequencies is realized with the following equation:

$$\overline{\omega} = \omega L\sqrt{\frac{\rho_m}{E_m}} \tag{43}$$

All the graphs presented in the study include different parameters against $\overline{R_0} = \overline{R_L}$ values ranging from 200 to 1200. In Fig. 2 the effect of varying E_f/E_m ratios from 5 to 25 is investigated. E_f/E_m increases the dimensionless axial vibration frequencies of the Rayleigh bar reinforced with short fibers. Although the E_f/E_m ratios increase regularly at intervals of 5, the change in frequencies is not regular. The increase at higher values of E_f/E_m plays less role in the increase of frequencies. It is clear from this and other graphs that the increase in spring stiffnesses increases $\overline{\omega}$. This increase is more pronounced at lower values of spring stiffness and the increase in stiffness affects $\overline{\omega}$ much less. This is because as the spring stiffnesses increase, the Rayleigh bar limits are very close to the full stiffness and the change in frequencies is no longer noticeable.

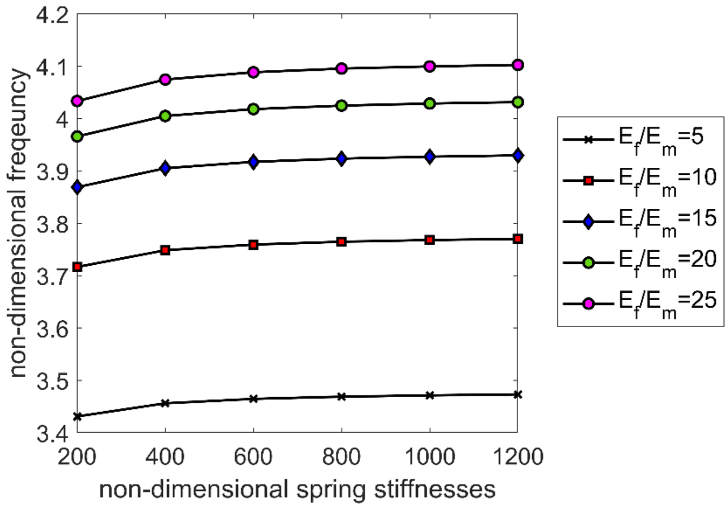

Fig. 2. Effect of E_f/E_m on non-dimensional frequencies

In Fig. 3, the effect of the ρ_f/ρ_m ratio considered in five different values from 2 to 10 is analyzed. The increase in the ρ_f/ρ_m ratio decreases the axial vibration frequencies. This can be explained by the increasing effective mass density of the bar. It is expected that the frequencies decrease when the effective mass density increases. Similar to the previous example, the increase in the ρ_f/ρ_m ratio starts to decrease at higher values.

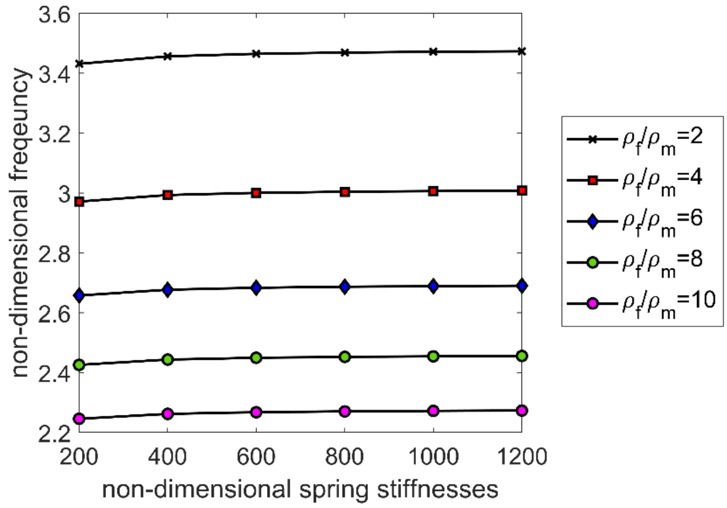

Fig. 3. Effect of ρ_f/ρ_m on non-dimensional frequencies

Fig. 4 focuses on the effect of fiber volume fraction on axial vibration frequencies. For this analysis, fiber volume fraction ranges from 0.2 to 0.4 are considered. The increase in $\bar{\omega}$ with increasing fiber volume fraction is clearly seen. The reason for this increase can be explained by the increasing stiffness of the bar with increasing V_f. As can be predicted, increasing V_f increases both the effective modulus of elasticity and the effective mass density. However, it is clear from this that the effective modulus of elasticity of the bar increases at a higher rate, leading to higher frequencies. Also, another conclusion from this analysis is that the spring stiffnesses have a greater effect on the frequencies at higher values of V_f.

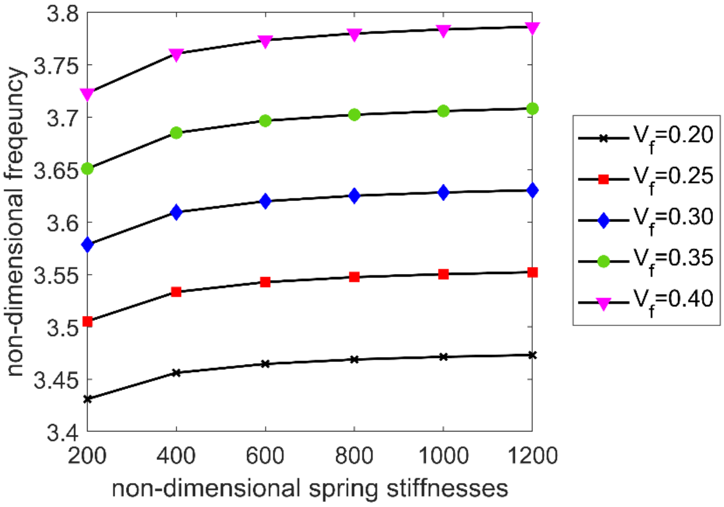

Fig. 4. Effect of V_f on non-dimensional frequencies

The Halpin-Tsai model is an approach that takes into account the geometric properties of short fibers. In this model, the length and diameter values of short fibers contribute to the effective modulus of elasticity. For this reason, axial vibration frequencies for five different l/d values ranging from 5 to 9 are analyzed in Fig. 5. Since the increase in the l/d ratio of the fibers provides a more rigid form of the bar, it also causes an increase in $\overline{\omega}$.

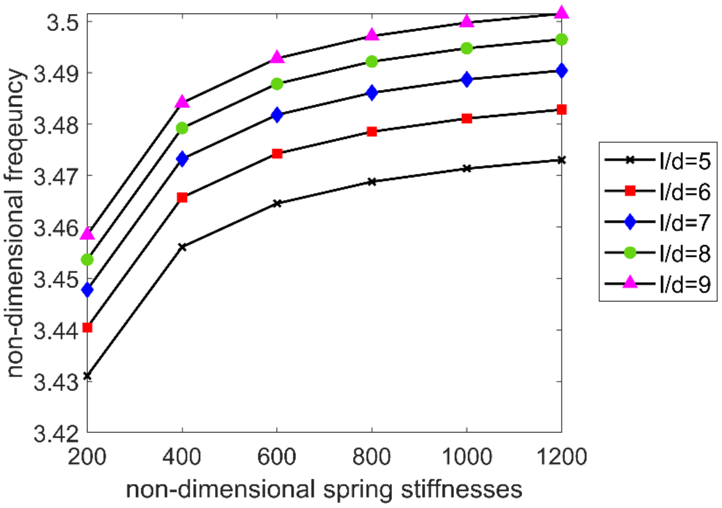

Fig. 5. Effect of $\mathrm{l/d}$ on non-dimensional frequencies

Finally, frequency ratios against non-dimensional spring stiffnesses are presented for the first three modes. The frequency ratios given in this graph are calculated as the ratio of the Rayleigh theory frequencies to the frequencies based on the classical theory for the relevant mode. Since the values of the frequency ratios are less than 1, it is easily understood that the classical theory calculates the frequencies higher. The decrease in frequency ratios as the mode number increases is explained by the fact that Rayleigh rod theory is more effective at higher ratios. In addition, while the frequency ratios for mode 1 remain constant despite the change in spring stiffness, the frequency ratios change in higher modes. The second and third mode frequency ratios decrease as the spring stiffnesses increase. The conclusion to be drawn from this is that rigid boundary conditions are more important in the use of Rayleigh theory.

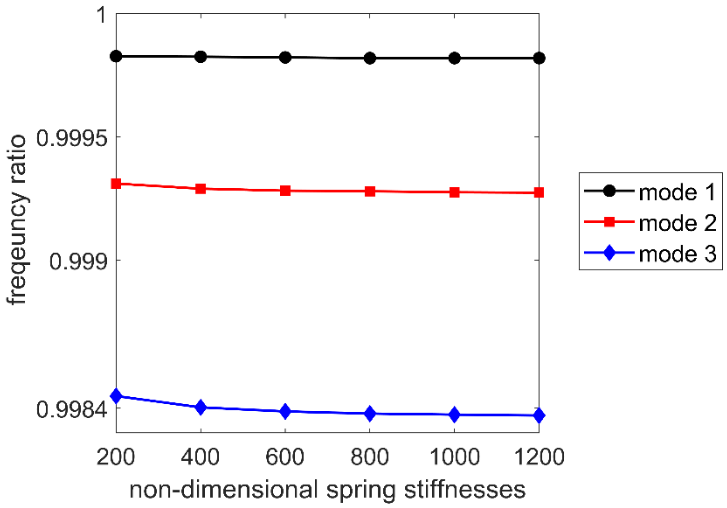

Fig. 6. Effect of theory ($l/d = 10$)

4. Conclusions

The aim of this study is to investigate the axial vibration frequencies of short fiber reinforced Rayleigh bars under deformable boundary conditions. For this purpose, short fiber reinforced Rayleigh bars are modeled as deformable axial springs at both ends. The study is finally based on an eigenvalue solution, which is derived in a form that allows to analyze the effects of arbitrary (both rigid and deformable) boundary conditions. The matrix of coefficients whose solution gives the axial vibration frequencies of short fiber reinforced Rayleigh bars includes the axial spring stiffnesses at both ends. These spring stiffnesses can be set arbitrarily and give rigid boundary conditions at their specific values. Following this effective eigenvalue solution, the effect of a number of parameters important for short fiber reinforced Rayleigh bars is investigated. These parameters are E_f/E_m, ρ_f/ρ_m, V_f, l/d, spring stiffnesses and lateral inertia effect. As a result of the analyzes, the following conclusions are reached: Increases in E_f/E_m, V_f and l/d make the structure of the Rayleigh bar more rigid and thus increase the axial vibration frequencies. The increase of ρ_f/ρ_m increases the effective mass density and causes the frequencies to decrease. The increase in the stiffness of the springs at both ends of the bar makes the boundary conditions stiffer, leading to an increase in axial vibration frequencies. Finally, the lateral inertia effect causes the axial frequencies to decrease slightly.

A study on methods to increase ductility of timber beams

Gokhan Sakar*[1], Huseyin Kursat Celik[1,2]

[1] *Department of Civil Engineering, Dokuz Eylul University, 35300, Türkiye*
[2] *Department of Civil Engineering, Izmir University of Economics, 35300, Türkiye*

Abstract. Timber has many advantages in its nature like high strength over density ratio. Due to this, timber is getting more common in construction works in general, especially in seismic regions. However, there are some concerns about its ductility. Although it behaves ductile under compression, brittle failure occurs under tension. Literature knowledge on this topic is also limited with a few results. To clarify this, the ductility of timber beam was studied by means of material, elemental and structural ductility. Methods to increase the ductility of timber beams were evaluated, and effectiveness of the methods was investigated using complete nonlinear moment-curvature analysis. As a result of the study, various conclusion was highlighted regarding the methods to increase ductility of timber beams and recommendations were made.

Keywords: Timber beam; Ductility; Moment-curvature; Nonlinear; Strengthening

1. Introduction

Timber is a natural composite material widely used in construction. It possesses several advantageous properties for this purpose. Timber is easily shaped to form structural elements, it is a sustainable material, and it has a high strength-to-weight ratio. This last property is particularly important in seismic design, as it results in lower seismic forces acting on the structure due to the material's lightweight. However, timber structures also have certain disadvantages when it comes to seismic design. In brief, a building should be designed to possess sufficient stiffness, ductility, and strength (Turkish Building Seismic Code, 2018). As a material, timber has limitations in terms of both stiffness and ductility, which present challenges in seismic design.

From a material perspective, timber is an anisotropic material, meaning its strength properties vary depending on the direction (Fig. 1). Specifically, the longitudinal direction exhibits higher strength parameters compared to the transverse direction. However, the behaviour of timber is more influenced by the type of stress than by the load direction. Under compression, timber can undergo plastic deformation without experiencing a reduction in strength. In contrast, under tension, timber fails in a brittle manner. From a design perspective, the required stiffness can be achieved through structural configurations such as relatively high sectional dimensions or the use of braces or shear walls. However, controlling the behaviour of timber under different stress conditions is a more complex issue. If failure occurs due to tensile stress, it will be brittle, which is an undesirable condition during seismic excitation. This has led to increased attention on studies regarding the ductility of timber.

Several pioneering studies proposed in the literature. Jorissen A. et al. (2011) critiqued the ductility of timber structures from a design perspective, demonstrating that a ductile design can be achieved through the use of steel connectors. This idea has been further supported by several subsequent studies (Brühl et al., 2011; Ottenhaus et al., 2021; Rebouças et al., 2022). Another research area focuses on enhancing the performance of timber elements by incorporating materials such as steel and fibre-reinforced polymers (FRP). It should be noted that this approach has primarily been studied for strengthening purposes, rather than specifically targeting the enhancement of ductility or the improvement of the behaviour of timber elements.

Based on the current literature, several key points should be highlighted. Steel connectors have gained attention as ductile details; however, their role as the ductile reserve of a structure can be questioned, as their primary function is to hold elements together, ensuring the continuity of the structure. To achieve ductile behaviour, timber members should not fail while the connections undergo plastic rotation. In this context, timber members may not perform effectively, as they will not be subjected to the capacity loads required to yield the steel connectors. Furthermore, the plastic deformation of the timber elements will not be utilized. On the other and, from a general perspective, the goal is for the structural members to undergo yielding while the connections are designed to accommodate the plastic rotation of the elements. Another option for enhancing ductility involves using external materials such as steel or FRP. However, there is limited research on enhancing ductility using these materials.

https://doi.org/10.31462/icearc2025_ce_sme_210

Therefore, to explore alternative solutions, this study is proposed by the authors. The primary objective of this study is to utilize the existing plastic behaviour of timber. Since timber can undergo plastic deformation under compression, the failure of timber elements can be controlled to prevent tensile failure. As timber, by itself, is prone to failure under tension, its tensile strength needs to be enhanced. To achieve this, in line with existing literature, steel, FRP, or other materials with higher tensile strength can be employed. For the study of ductility, timber beams were selected as the focus, as plastic rotation is directly related to bending behaviour. To analyse this, moment-curvature analysis (or sectional analysis) was chosen. A reference timber beam was considered, and several strengthening options were evaluated. Conclusions were drawn regarding the effectiveness of these methods.

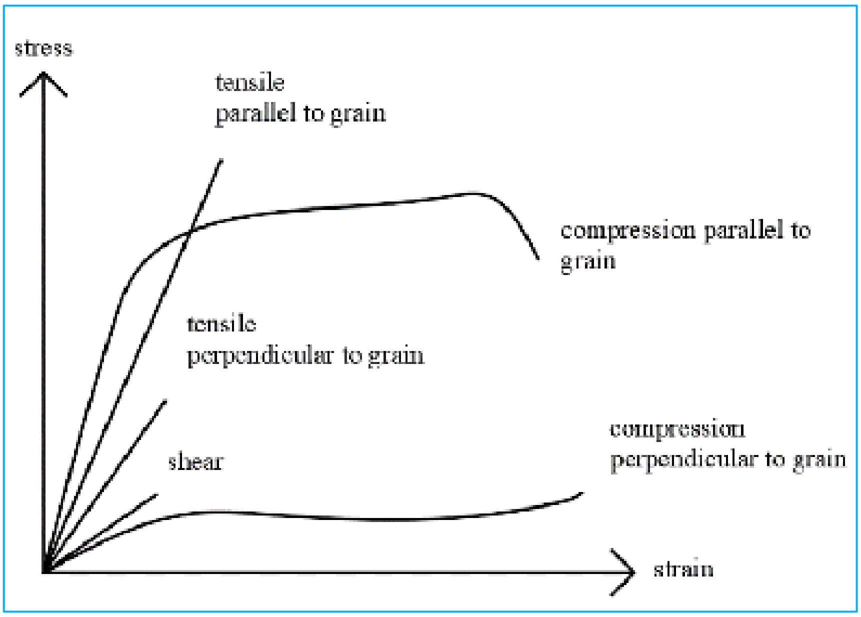

Fig. 1. Stress-strain relationship of timber in different loading directions

2. Material and method

In this study, a simply supported beam and three-point bending scheme was used as the reference. Timber of grade was selected as C16 (Regulation on the Design, Analysis and Construction of Timber Buildings, 2024). Steel plates with a thickness of 2 mm and FRP bonding were regarded as strengthening. For the steel, S235 grade was assumed, and CFRP was selected for the FRP material. The loading scheme is shown in Fig. 2, the material properties are given in Table 1.

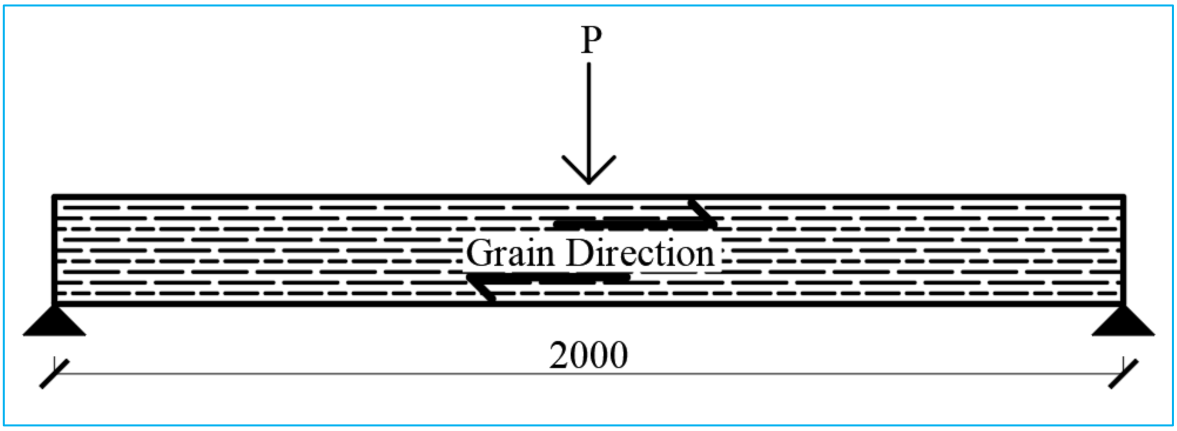

Fig. 2. Loading scheme

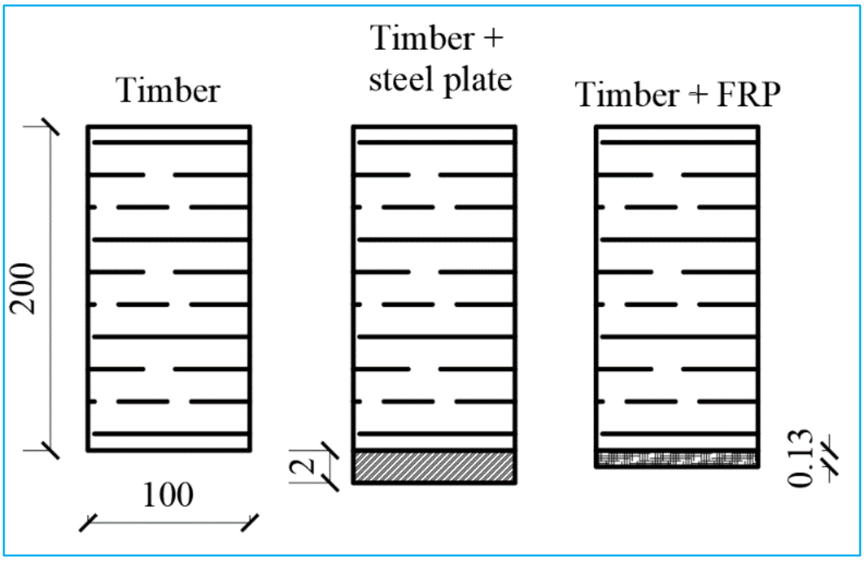

Fig. 3. Strengthening configurations

Table 1. Material properties

Properties	Timber	Steel	FRP
Width (mm)	100	100	100
Height (mm)	200	2	0.13
Elastic Modulus (MPa)	8000	210000	231000
Yield Compressive Strength (MPa)	16	-	-
Yield Compressive Strain	0.002	-	-
Compressive Strength, Ultimate (MPa)	16	-	-
Compressive Strain, Ultimate	0.01	-	-
Yield Tensile Strength (MPa)	-	235	-
Yield Tensile Strain	-	0.0012	-
Ultimate Tensile Strength (MPa)	8	235	4100
Ultimate Tensile Strain	0.001	0.15	0.016

3. Analytical method

To capture the full load-displacement curve of a beam, section analysis can be employed, rather than directly calculating the ultimate states. This requires the material constitutive laws, section properties, and the loading scheme. Based on these factors and Euler beam theory, the load-displacement curve can be obtained using the moment (M) - curvature ($\emptyset$) relationship, as shown in Equation 1. Additionally, strain (ε) can be defined using Equation 2, which relates strain to curvature and the height of the layer (y). If the section is discretized by fibres, the strain distribution along the height of the section can be computed. By using the strain values and material models, stresses (σ) along the section can be obtained, as shown in Equation 3. The forces (F) can then be defined as components along the fibres, as expressed in Equation 4. By taking the moments of these forces, the moment at a given curvature can be captured, as shown in Equation 5. For a three-point bending scheme, the corresponding load (P) can be calculated using Equation 6, and the displacement (δ) can be determined by Equation 7. Using Equations 1-7, the complete load-displacement curve can be constructed. The material models for timber, steel, and FRP are provided in Equations 8 to 11, respectively.

Several assumptions made during the analysis should be stated. Timber is assumed to behave as elastic-perfectly plastic in compression and elastic-brittle in tension, as outlined in Eurocode 5 (1995). For steel, an elastic-perfectly plastic model was adopted. FRP was assumed to behave in a linear elastic manner up to failure. Full composite action was assumed, and the plane section assumption, as in general beam theory, was applied, meaning that the plane section remains plane during deformation. Since the study focuses on exploring potential, the debonding of the FRP and steel plates was disregarded during the analysis, and the ultimate strain was considered without any reduction. The slip between timber, steel, and FRP was neglected. Curves were constructed up to the point of reaching the ultimate strain of the materials. After the complete construction of these curves, ductility was determined as the ratio between the ultimate and yielding displacements.

$$\emptyset = \frac{M}{E * I_{eff}} \tag{1}$$

$$\varepsilon(y) = \emptyset * y \tag{2}$$

$$\sigma(y) = f\big(\varepsilon(y)\big) \tag{3}$$

$$F_{i.fiber} = \sigma_{i.fiber} * b * d_y \tag{4}$$

$$M = \sum F_i * y_i \tag{5}$$

$$P = \frac{4M}{L} \tag{6}$$

$$\delta = \frac{\emptyset * (L)^2}{8} \tag{7}$$

$$\sigma_{timber,tension} = \begin{cases} E * \varepsilon, & \varepsilon \leq \dfrac{f_t}{E} \\ 0, & \varepsilon > \dfrac{f_t}{E} \end{cases} \tag{8}$$

$$\sigma_{timber,compression} = \begin{cases} E * \varepsilon, & \varepsilon \leq \dfrac{f_c}{E} \\ f_c, & \varepsilon > \dfrac{f_c}{E} \end{cases} \tag{9}$$

$$\sigma_{FRP} = \begin{cases} E * \varepsilon, & \varepsilon \leq \dfrac{f_f}{E} \\ 0, & \varepsilon > \dfrac{f_f}{E} \end{cases} \tag{10}$$

$$\sigma_{steel} = \begin{cases} E * \varepsilon, & \varepsilon \leq \dfrac{f_s}{E} \\ f_{yield}, & \varepsilon > \dfrac{f_s}{E} \end{cases} \tag{11}$$

4. Results and discussion

According to the study results, the timber beam failed when the stress reached the tensile strength. Since the tensile strength is lower than the compressive strength, the beam did not exhibit any plastic deformation. In the case of steel strengthening, the timber beam initially cracked when it reached its tensile strength. With the addition of steel, the beam was able to bear a higher load and exhibit plastic deformation. Furthermore, steel strengthening increased the beam's initial stiffness. The FRP-strengthened beam showed a similar initial load-displacement curve to the unstrengthened timber beam, as there was a limited increase in stiffness. However, the FRP-strengthened beam was able to undergo plastic deformation up to the point of timber crushing. The load-displacement curves of the beams are presented in Fig. 4. The failure load, displacement, and ductility ratio of the beams are summarised in Table 2.

Table 2. Results

Beam	Failure Load (kN)	Yield Displacement (mm)	Ultimate Displacement (mm)	Ductility
Timber	18	-	9.5	Brittle
Timber + Steel	32	20	50	2.5
Timber + FRP	23	20	50	2.5

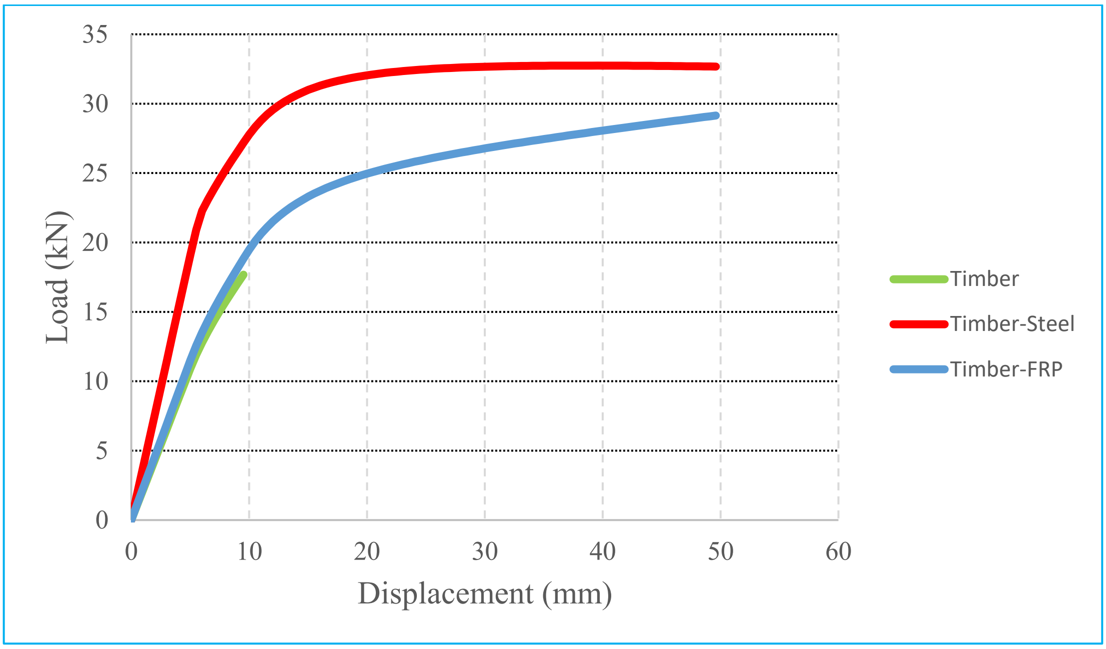

Fig. 4. Load-displacement curves of the beams

5. Conclusion

In this study, the ductility of timber structures is briefly discussed. The ductile potential of timber beams, particularly based on their compressive behaviour, is critically examined. To assess the ductility, section analysis was employed. To construct the load-displacement curve, the moment-curvature relationship, incorporating nonlinear material behaviour and fibre section idealisation, was utilised. Initially, a reference beam made of C16 grade timber was considered. Then, steel plate and FRP strengthening options were analysed. According to the study results, strengthened beams were able to undergo plastic deformation. The steel plate strengthening option also increased the initial stiffness of the beam. Based on these findings, the ductility of timber beams can be enhanced through strengthening methods. Although FRP is brittle, the plastic behaviour of timber contributes to the overall ductility of the beam. Further studies should investigate cyclic behaviour and the semi-composite interaction between the strengthening materials and timber. This study demonstrated that strengthened timber beams possess significant ductility potential. Additionally, structural details that ensure and enhance ductility should be further improved.

Comparative analysis of ribbed and solid slabs in enhancing progressive collapse resistance of rc buildings following multiple column loss

Muneeb Jadallah*[1], Adem Doğangün[1]

[1] *Bursa Uludağ University, Faculty of Engineering, Department of Civil Engineering, Turkey*

Abstract. This study examines the influence of slab types on the progressive collapse resistance of reinforced concrete (RC) buildings, with a specific focus on comparing one-way ribbed slabs and solid slabs under multiple-column removal scenarios. The models 3- and 5-story RC buildings were designed following the 2018 Turkish Building Earthquake Code and analyzed using 3D nonlinear dynamic simulations via the Applied Element Method (AEM) in Extreme Loading for Structures (ELS) software. Two distinct column removal scenarios were considered to evaluate the performance of each slab type.The analysis revealed that buildings with ribbed slabs exhibit significantly greater resistance to progressive collapse than those with solid slabs. Ribbed slab systems showed lower vertical deformations (≤ 60 mm) and plastic rotations (≤ 0.01 rad), remaining within the acceptable limits defined by the Unified Facilities Criteria (UFC). In contrast, buildings with solid slabs often exceeded UFC thresholds, leading to partial or total collapse. The superior performance of ribbed slabs is attributed to their ability to engage both membrane and flexural actions, facilitating effective load redistribution during failure.Although ribbed slabs are generally considered less favorable in seismic design due to increased drift and resulting limitations on story height, their behavior under progressive collapse differs substantially. These findings underscore the potential of ribbed slabs to enhance the resilience of RC buildings under extreme loading. The study advocates for further research on ribbed slab systems to refine design strategies and improve structural safety against progressive collapse.

Keywords: Progressive Collapse; Reinforced concrete; Ribbed slab; Solid slab; Applied element method (AEM)

1. Introduction

The Unified Facilities Criteria (UFC) defines progressive collapse as "a chain reaction of failure of building members to an extent disproportionate to the original localized damage." Such failures can result in the collapse of upper floors onto lower ones. Various factors can lead to column loss in reinforced concrete (RC) structures, including vehicle impacts, earthquakes, and explosive blasts. Several notable progressive collapse incidents have occurred globally, such as the Ronan Point apartment collapse in the UK (1968), the Alfred P. Murrah Federal Building in Oklahoma City (1995), and the World Trade Center in New York City (2001). These events have prompted structural engineers to develop and improve design methodologies aimed at preventing or minimizing the effects of progressive collapse.

Design guidelines such as UFC (2009) and GSA (2003) have been established to address progressive collapse mechanisms. In this study, the UFC 2009 guidelines are employed to assess the response of RC buildings under simultaneous removal of multiple columns, including corner and interior columns. Numerical models were developed using the Applied Element Method (AEM) in the Extreme Loading for Structures (ELS) software (ASI, 2004), and structural designs were based on the Turkish Building Earthquake Code (TBEC-2018).

Previous studies investigating progressive collapse mechanisms include both experimental testing and numerical modeling approaches. With increasing threats such as war, strong earthquakes, and terrorist attacks, scenarios involving the loss of more than one column are becoming more relevant. Such scenarios often lead to the failure of a large portion or the entirety of a building. This paper investigates the potential of RC slab systems, particularly ribbed versus solid slabs, in enhancing progressive collapse resistance. The analysis is conducted using the Alternative Path Method, a widely adopted direct design approach.

Pachenari et al. (2013) modeled a multistory RC building using nonlinear static and dynamic analysis and found that static analysis tends to overestimate shear forces compared to dynamic analysis. Kim and Kim (2009) studied 2D steel moment frames and concluded that an increased number of stories tends to reduce the progressive collapse potential. Gamaniouk (2014) analyzed 2D steel frames of various heights and observed that taller structures developed fewer plastic hinges, and the use of bracing was ineffective due to a lack of continuity in the models.

Kim et al. (2011) examined eight different bracing configurations in 2D steel frames using FEM analysis and found that inverted V-bracing exhibited the best ductile behavior under progressive collapse. Nassir et al. (2019) studied a multi-story building under single and multiple column removal scenarios, finding that dual column loss, especially at corner and edge locations, was more critical. Bhatta (2023) demonstrated experimentally that infill walls significantly improve resistance to progressive collapse.

Yi et al. (2008) tested a one-third scale RC frame under quasi-static loading and found failure at a displacement of 43.6 cm and rotation of 10.3°, with a capacity exceeding the plastic limit state by 1.4 times. Sasani et al. (2008) highlighted the importance of beam reinforcement in resisting collapse after interior column loss. Su (2009) studied 12 RC beam-column specimens under quasi-static loading and showed that beams with higher span-to-depth ratios or longitudinal reinforcement ratios exhibit greater load resistance due to enhanced catenary action (CAA).

Farhang Vesali et al. (2013) assessed the influence of longitudinal and transverse reinforcement and found that stirrups have a minor effect on CAA. Yu and Tan (2013) investigated seismic detailing and span-depth ratios and concluded that higher ratios lead to faster engagement of catenary action. Alogla et al. (2016) showed that adding mid-layer longitudinal reinforcement improves beam ductility. Dmitriev and Lalin (2021) compared different analysis methods and confirmed that nonlinear dynamic analysis, such as that used in AEM, is more accurate and consistent with experimental results.

As highlighted in the literature review, most existing studies on progressive collapse primarily focus on single-column removal scenarios in buildings with solid or flat slabs. However, research on the behavior of ribbed slab systems, particularly under multiple-column removal conditions, remains limited. This gap emphasizes the need for further investigation into the performance of ribbed slabs and a comparative assessment with solid slabs to evaluate their effectiveness in enhancing the progressive collapse resistance of RC structures.

2. Model analysis

This study follows the guidelines provided by the Unified Facilities Criteria (UFC) (2009), which outlines two main approaches for progressive collapse analysis: the direct design method and the indirect design method. Among the direct methods, the Alternative Path Method (APM) is the most widely used by researchers. APM allows the load from a failed column to be redistributed to adjacent columns through connecting beams.

Following UFC 2009, the applied load depends on the selected analysis type, static or dynamic. In this study, nonlinear dynamic analysis is adopted, and the load combination used is 1.2DL + 0.5LL, where *DL* represents the dead load and *LL* the live load. UFC guidelines assume that the failure of a primary structural element (e.g., a column) occurs suddenly, simulating an extreme event.

To simulate the behavior of the RC buildings under progressive collapse, the Applied Element Method (AEM) is utilized in this research. While most previous studies have used the Finite Element Method (FEM), AEM offers a more comprehensive approach, as it models the entire structural response from the initial loading phase through to complete failure. AEM uniquely combines the strengths of both FEM (before element separation) and the Discrete Element Method (DEM) (after separation occurs).

In AEM, each structural component is divided into a mesh of small elements interconnected by springs representing material stiffness and interaction forces, as shown in Fig. 1. These springs simulate the stress–strain relationship between adjacent elements and can fail under extreme loading, allowing for realistic modeling of structural separation. Each element possesses six degrees of freedom, three translational and three rotational, as depicted in Fig. 2.

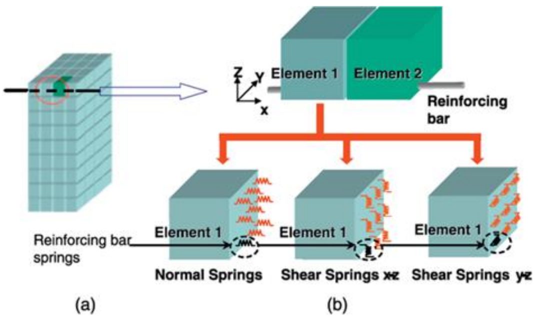

Fig.1 Element of structure modeled by AEM

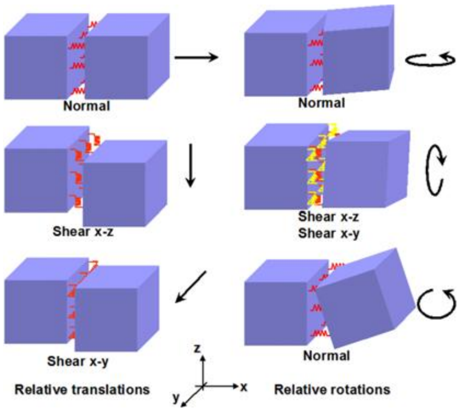

Fig. 2 Element degrees of freedom

3. Methodology of work

The primary objective of this study is to evaluate the progressive collapse resistance of 3-story and 5-story reinforced concrete (RC) buildings, designed following TBEC-2018, under scenarios involving the removal of two external columns. The investigation compares the structural performance of two slab systems, solid slabs and ribbed slabs, in resisting progressive collapse. Various scenarios of removing multiple columns will be studied in this paper using the extreme loading element program (ELS).

3.1. Description of the model

A 3 and 5-story RC 3D structure with solid slab and ribbed slab, as shown in Fig. 3, is analyzed considering various scenarios of removing columns using ELS software. Table 1 shows the general properties of the RC structure elements; Table 2 shows the designed dimensions of the RC structures.

Table 1: General properties and dimensions of RC structure

No.	Description	Value
1.	Concrete Grade	C30
2.	Steel Grade	F420
3.	Story height	3.2m
4.	Span distance between columns – Center to Center –	6.0m
5.	Live load	0.20 ton/m^2
6.	Dead Load (covering material + equivalent partition load)	0.362 ton/m^2

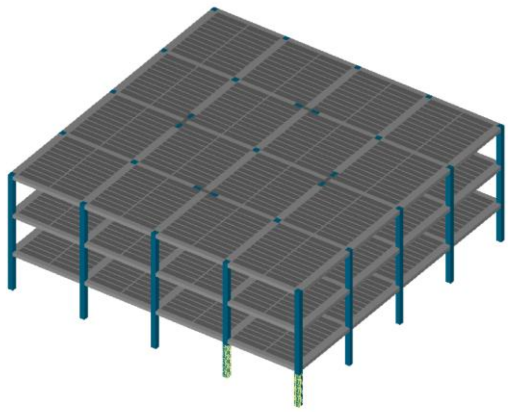
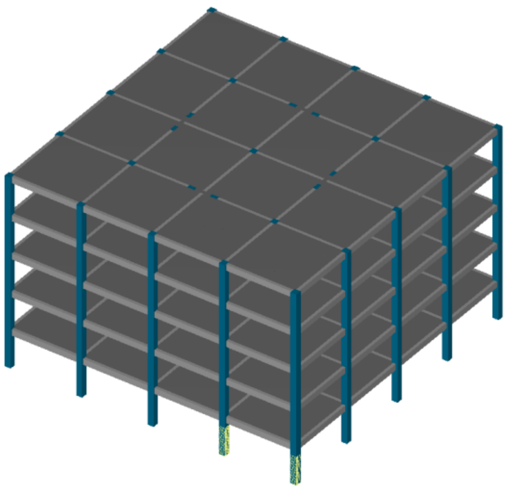
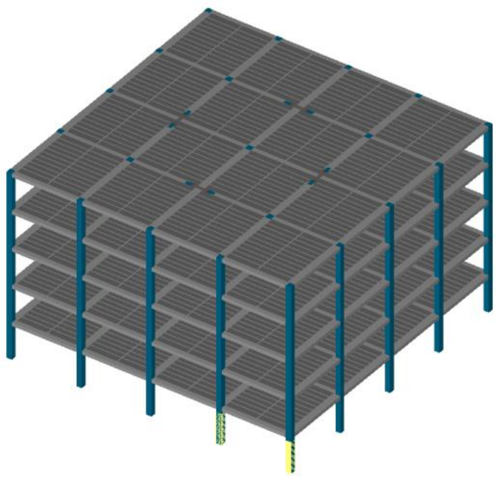
3-Floors – Solid Slab



3-Floors – Ribbed Slab



5-Floors – Solid Slab



5-Floors – Ribbed Slab

Fig.3. 3D RC structure for 3 and 5-story

In this study, multiple-column removal scenarios were considered by simultaneously removing two columns, one located at the corner and the other at the preultimate position, as illustrated in Fig. 3. This approach was applied to both 3-story and 5-story RC building models with solid and ribbed slab systems.

4. Results and discussion

The progressive collapse analysis of reinforced concrete (RC) frame structures with shear walls was performed using the *Extreme Loading for Structures* (ELS) software. A simulation duration of one second was used for all column removal scenarios, which was sufficient to capture the peak vertical displacement or to observe the full cycle of vertical motion at the point of column removal. This duration proved effective for evaluating structural behavior under progressive collapse conditions for both solid and ribbed slab systems across all scenarios.

Fig. 4 presents the vertical displacement results for the 3-story and 5-story models under the removal of two ground-floor columns, one at the corner and one at the preultimate position. The analysis revealed substantial differences in the structural response based on the slab type.

Solid slab systems exhibited a more brittle behavior under column loss, where a large portion of the structure experienced partial failure. The inability of solid slabs to effectively redistribute loads following sudden column loss led to excessive deformation and local collapse, highlighting their vulnerability in progressive collapse scenarios involving multiple column removals.

In contrast, ribbed slab systems showed significantly improved performance. Both the 3-story and 5-story ribbed slab models remained stable throughout the analysis period, with no signs of collapse or excessive damage. The 5-story ribbed slab model demonstrated a maximum vertical displacement below 60 mm, and all observed plastic rotations remained under 0.0035 radians (as illustrated in Fig. 5), which is well below the UFC's permissible limit of 0.063 radians. This confirms that ribbed slab systems have superior energy absorption and load redistribution capacity under extreme loading conditions, making them more resilient against progressive collapse.

These findings clearly underscore the importance of slab type in the structural integrity of RC buildings during column removal events. Ribbed slabs not only performed within safe UFC-defined limits but also maintained overall structural stability, whereas solid slabs failed to do so under similar conditions.

5. Conclusion

This study investigated the progressive collapse behavior of reinforced concrete (RC) buildings designed in accordance with the Turkish Building Earthquake Code (TBEC-2018), focusing on two different slab systems, solid and ribbed slabs, under scenarios involving the sudden removal of two ground-floor columns. The analyses were performed using the Alternative Path Method (APM) in the Extreme Loading for Structures (ELS) software, with a dynamic load combination as recommended by UFC guidelines.

The key findings of this study can be summarized as follows:

- Slab type plays a critical role in progressive collapse resistance. Buildings with ribbed slabs exhibited superior performance compared to those with solid slabs when subjected to multiple column removal scenarios.
- Solid slab systems showed vulnerability to local collapse, where the structure was unable to redistribute loads effectively after the sudden loss of support elements. This led to large displacements and partial structural failure.
- Ribbed slab systems maintained structural integrity under all tested scenarios. In the 3-story and 5-story building models, maximum vertical displacements remained below 60 mm, and plastic rotations were significantly lower than the UFC limit of 0.063 radians, demonstrating the ribbed slabs' ability to dissipate energy and redistribute internal forces more effectively.
- The use of AEM in this study provided valuable insights into both the global and local failure mechanisms, offering an advantage over conventional FEM approaches in capturing progressive collapse phenomena.

In conclusion, ribbed slab systems offer enhanced robustness against progressive collapse in RC buildings, especially under multiple column removal scenarios. These results highlight the need to consider slab configuration as a key design parameter in the assessment and mitigation of progressive collapse risks, particularly for mid-rise structures designed under TBEC-2018.

Nonlinear analysis of flush end-plate beam-to-column connections under cyclic loading

Alper Demir*[1], Cüneyt Vatansever[1]

[1] *Istanbul Technical University, Department of Civil Engineering, Istanbul, Türkiye*

Abstract. This study numerically investigates the nonlinear cyclic behavior of flush end-plate beam-to-column connections, which are widely used as semi-rigid structural connections. Two configurations, a two-bolt and a four-bolt semi-rigid partial-strength connection, were modeled using ABAQUS software to examine their moment-rotation behavior under cyclic loading. To validate the finite element modeling methodology, experimental data from a previously tested two-bolt flush end-plate connection were utilized. The numerical model accurately replicated the cyclic behavior observed experimentally, with deviations of 1.30% and 6.1% in moment capacity and initial stiffness, respectively. Following validation, finite element analyses were conducted to evaluate the nonlinear cyclic performance of both configurations. The moment capacities of the connections were calculated using the yield line method specified in AISC 341-16 and the component method outlined in Eurocode 1993-1-8. The initial stiffness values were also determined using the component method. Comparative analyses showed that the yield line method underestimated moment capacities by 13.6%, 20.8%, and 52.8% for the two-bolt and four-bolt configurations, respectively, relative to finite element results. Similarly, the component method underestimated moment capacities by 11%, 17.7%, and 31%. Conversely, initial stiffness predictions by the component method exceeded finite element results by 20%, 26%, and 37% for the respective configurations. These findings highlight the conservative nature of both the yield line and component methods in estimating connection performance and emphasize the need for refined analytical approaches to accurately predict the cyclic behavior of flush end-plate connections.

Keywords: Steel connections; Finite element analysis; Cyclic loading; Nonlinear analysis

1. Introduction

Flush end-plate beam-to-column connections are widely used in gravity load frames due to their simplicity, economy, and ease of fabrication with a wide design range to satisfy different structural demands. These connections, typically classified as semi-rigid and partial-strength, offer a favorable balance between stiffness and ductility while enabling energy dissipation during seismic events. Unlike fully rigid joints, semi-rigid connections may be used to provide plastic deformations that can enhance global structural performance by delaying plastic hinge formation in beams and reducing force demands on adjacent members.

This study investigates the nonlinear cyclic behavior of two semi-rigid flush end-plate connections designed using a thin-plate design philosophy. The aim is to dissipate seismic energy through plastic deformation caused by yielding of the end-plate while keeping bolt stresses below their tensile capacity under prying forces. Two different configurations, a two-bolt and a four-bolt connection, were analyzed numerically using ABAQUS finite element software under cyclic loading protocols consistent with AISC 341-16.

A nonlinear material model based on true stress-strain behavior was adopted for S275 structural steel and grade 10.9 high-strength bolts. The numerical model was validated using experimental data for a two-bolt flush end-plate connection. Subsequently, the validated models were used to analyze the moment-rotation behavior and assess the effectiveness of Eurocode's component method and AISC's yield line theory in predicting moment capacity and initial stiffness. The results provide insights into the conservative nature of current design methodologies and their implications for performance-based seismic design.

2. Materials and methods

The investigated connections employ a thin end-plate intended to yield before bolt fracture. This design philosophy aims to localize plastic deformation in the end-plate, effectively forming a plastic hinge at the connection zone and enhancing the seismic energy dissipation capacity of the joint. Two configurations were studied: FEB-2B, two-

golden light publishing

bolt flush end-plate connection, and FEP-4B, four-bolt flush end-plate connection. Both connections are aimed to be classified as semi-rigid partial-strength, as their rotational stiffness and moment capacity are less than those of the connected beams, thereby conforming to Eurocode 1993-1-8 classification.

The finite element analysis was conducted using ABAQUS/Standard, with a focus on capturing the complex cyclic behavior of the connections. The model includes detailed geometry of the beam, column, end-plate, bolts, and welds. Solid elements (C3D8R) were used for all components. Contact interactions between end-plates and column flanges, including nut, hole edge, bolt head and bolt shank, as well as bolt pretension, were explicitly modeled.

2.1. Connection design

The connections investigated in this study are aimed to display thin-plate behaviour, where the end-plate yielding governs the connection strength. The two flush end-plate connections used in this study are shown in Fig. 1.

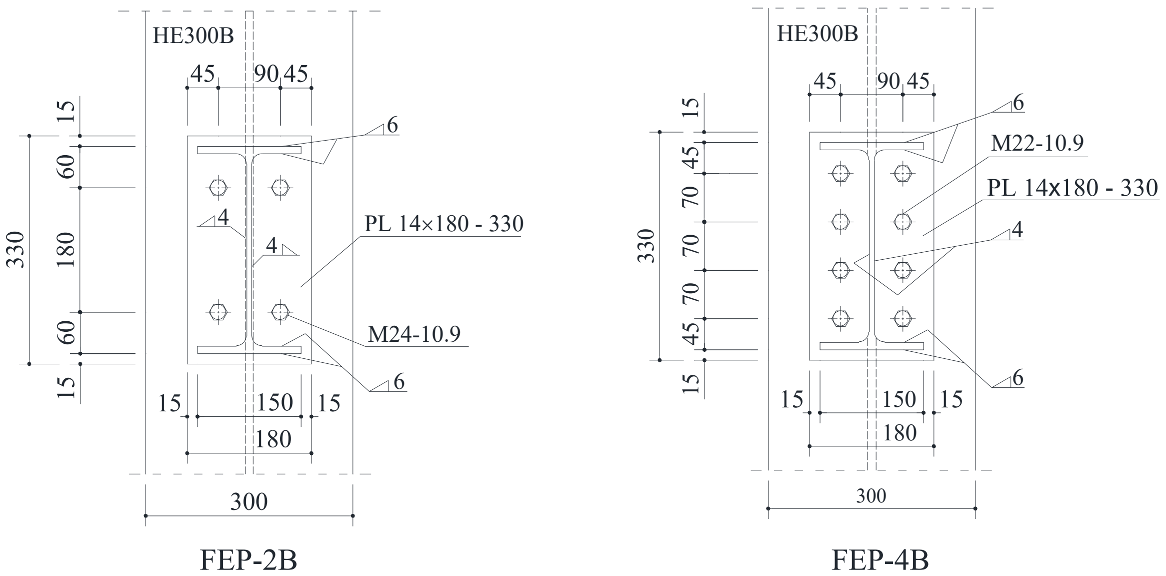

Fig. 1. Flush end-plate configurations

The column ends are assumed to be pinned, restricting displacements and axial torsion. Beam displacement is applied with out-of-plane displacement restricted.

2.2. Material models

The engineering stress-strain values are determined using the tri-linear material models (Baei et al., 2012) shown in Fig. 2. Young's Modulus and Poisson's Ratio are assumed as E = 200 GPa and v = 0.3 respectively. Yielding and ultimate strength of steel are assumed as 1.3×275=357.5 MPa, while F_y=900 MPa and F_u=1000 MPa are taken for bolts.

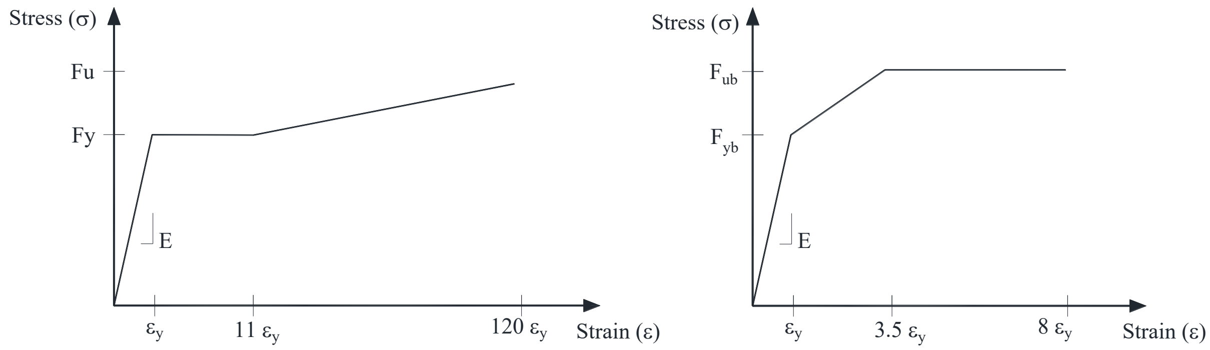

Fig. 2. Engineering stress-strain material models

After determining the engineering stress-strain curves, Equation 1 is used to obtain the true stress-strain values of both the bolt and steel material.

$$\sigma_{true} = \sigma_{eng}(1 + \varepsilon_{true}) \qquad \varepsilon_{true} = \ln(1 + \varepsilon_{eng}) \tag{1}$$

Based on the yield and ultimate stress-strain values obtained from Equation 1, the nonlinear material behavior is modeled using the relationship $\sigma = K\varepsilon^n$, as described by Kaufmann et. al. (2001). In this approach, appropriate values for the material constants K and n are determined to accurately match the nonlinear stress-strain curve. The plastic stress-strain values, observed after the yield point, are taken to use in ABAQUS as shown in Fig. 3.

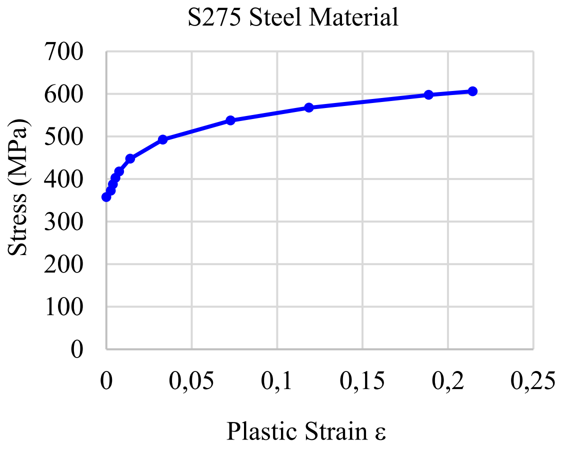

Fig. 3. Plastic stress-strain curves used in FE models

2.3. Loading history and bolt pre-tensioning

The loading history, illustrated in Fig. 4, followed the AISC 341-16 recommendations for qualification testing of beam-to-column moment connections. A symmetric cyclic displacement-controlled protocol was applied to the beam tip, incrementally increasing the amplitude of rotations until strength degradation was observed.

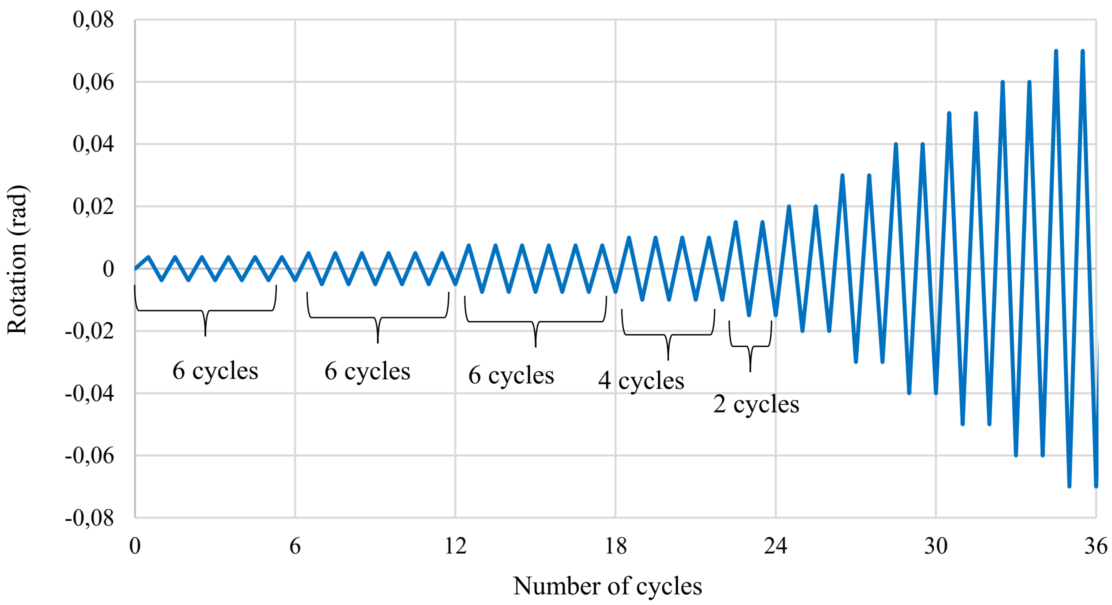

Fig. 4. Cyclic loading protocol

The cyclic loading protocol was continued until drift ratios of approximately 0.06 radians and 0.08 radians were reached for the FEP-2B and FEP-4B connections, respectively. These target drift values were selected to ensure the development of significant inelastic behavior and to assess the full cyclic performance of the connections up to the point of notable strength degradation.

Bolt pretension was simulated using ABAQUS's pre-tension section method to accurately reflect bolt clamping forces. For the M22 and M24 10.9 grade bolts, 212 kN and 247 kN bolt pre-tension force was applied to each bolt respectiely, as recomended by TCDCSS (2018).

2.4. Meshing of elements

A refined meshing approach was employed to capture localized stress concentrations and plastic deformation accurately, particularly in regions expected to undergo significant yielding. Smaller mesh sizes were applied to bolt components and end-plates, where high stress gradients were anticipated due to contact and bearing interactions. Fig. 5 illustrates the meshing scheme adopted for the end-plate and bolts, highlighting the enhanced resolution in critical areas to ensure convergence and result accuracy in nonlinear cyclic simulations.

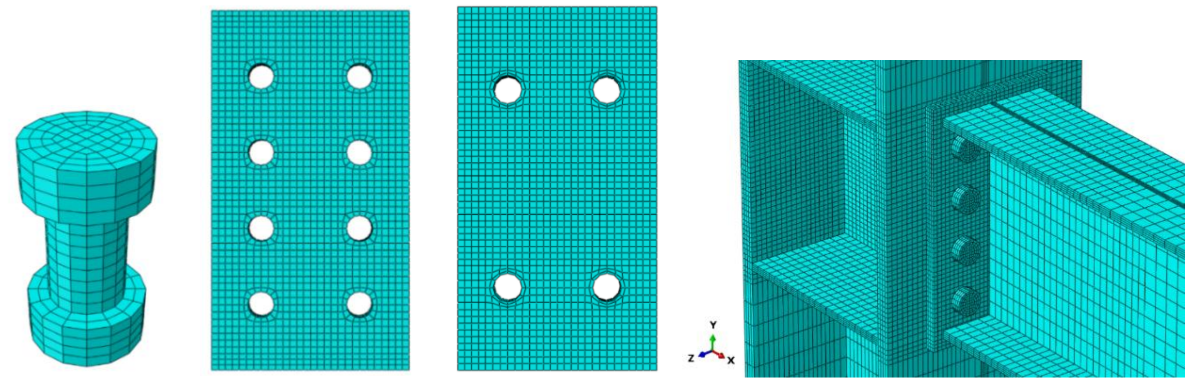

Fig. 5. Mesh sizes used in models

2.5. Surface interactions

Accurate definition of surface-to-surface contact is essential in finite element analysis, as the interaction between different connection components significantly influences the moment-rotation response of the joint. In this study, individual contact interactions were explicitly defined for critical interfaces, including:

- Between the bolt head and the end-plate
- Between the nut and the column flange
- Between the bolt shank and bolt hole edge
- Between the end-plate and the column flange

Normal contact behavior was modeled using the penalty formulation, allowing limited interpenetration with appropriate contact stiffness to simulate compressive behavior. Tangential contact behavior was modeled using the penalty method with a friction coefficient of 0.3 applied to all interfaces. This friction value was selected based on typical steel-to-steel contact conditions, ensuring realistic representation of sliding resistance and load transfer mechanisms within the joint.

2.6. Finite Element Model Validation with Experimental Data

The finite element model was validated against experimental results of a previously tested two-bolt flush end-plate connection. Comparisons were made in terms of moment capacity, initial rotational stiffness and hysteretic response. Test set-up is shown in Fig. 6.

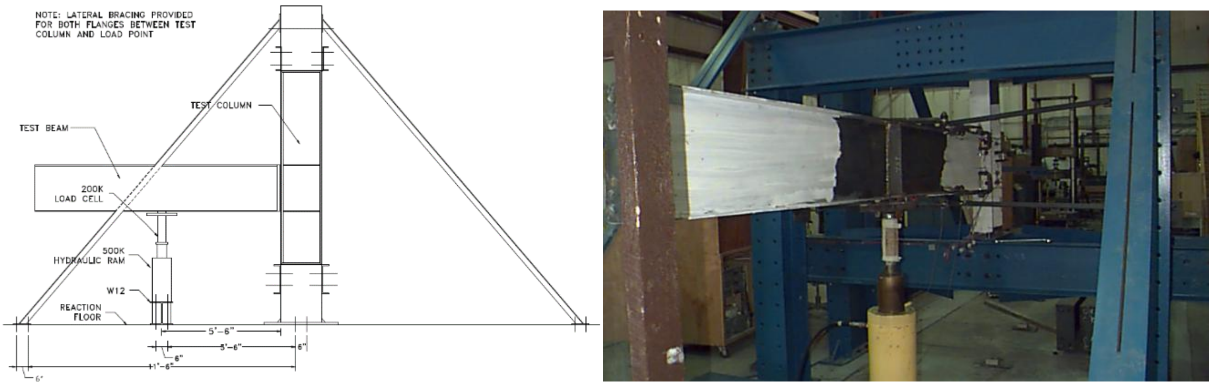

Fig. 6. Experimental setup (Boorse, 1999)

The connection detail is illustrated in Fig. 7. The connecion is named F1-3/4-3/8-16 indicating the bolt diameter (3/4 inches, or 19.05 mm), end-plate thickness (3/8 inches, or 9.525 mm) and beam depth (16 inches, or 406.4mm).

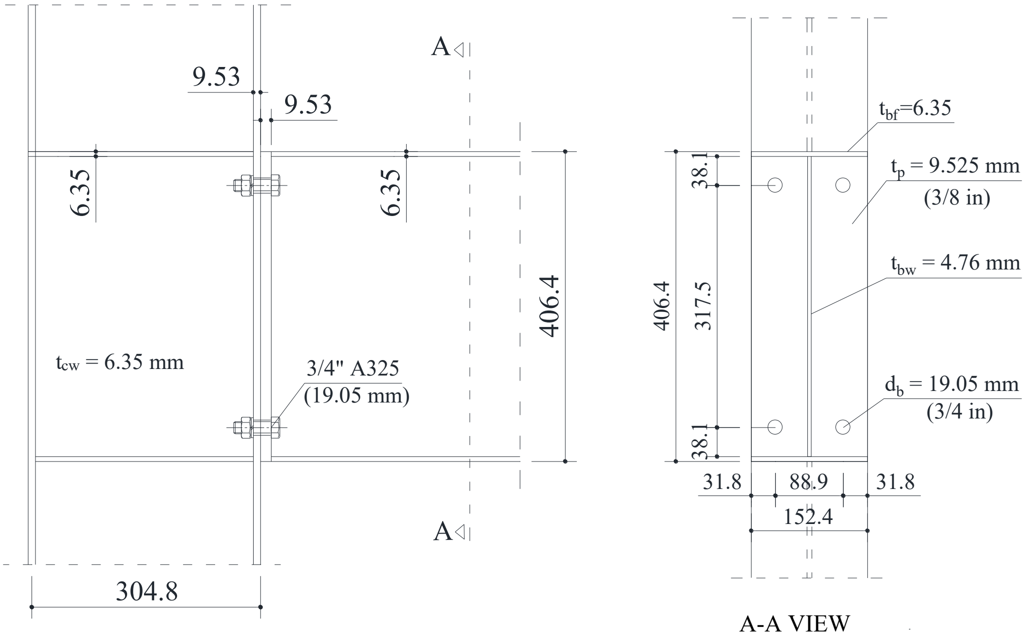

Fig. 7. Connection detail

Grade 50 steel is used for all components, while the yield and tensile strength values obtained from coupon tests are used to identify detailed stress-strain behaviour of the connection elements, using the same material model shown in Fig. 1. Bolt pretension force of 137kN is applied to the middle section of bolts.

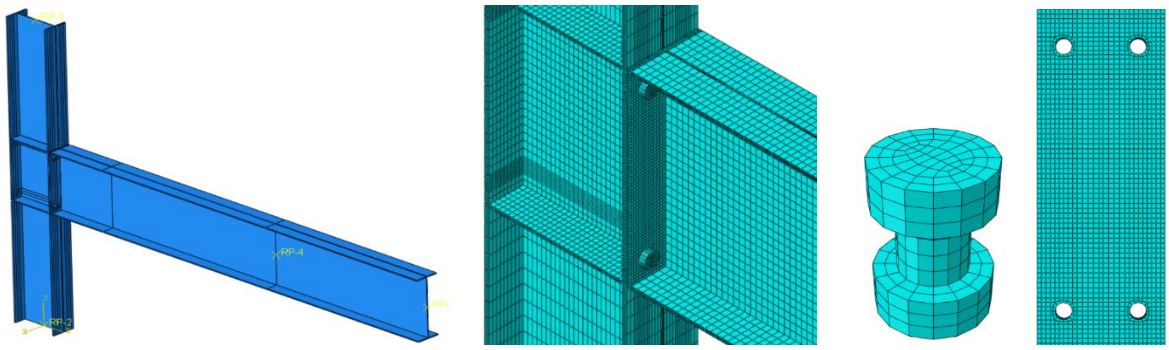

Fig. 8. Finite element model and meshing of the elements involved in the connection

Moment-rotation curves obtained from the experimental work is compared with the FEA results obtained in this study as shown in Fig. 9.

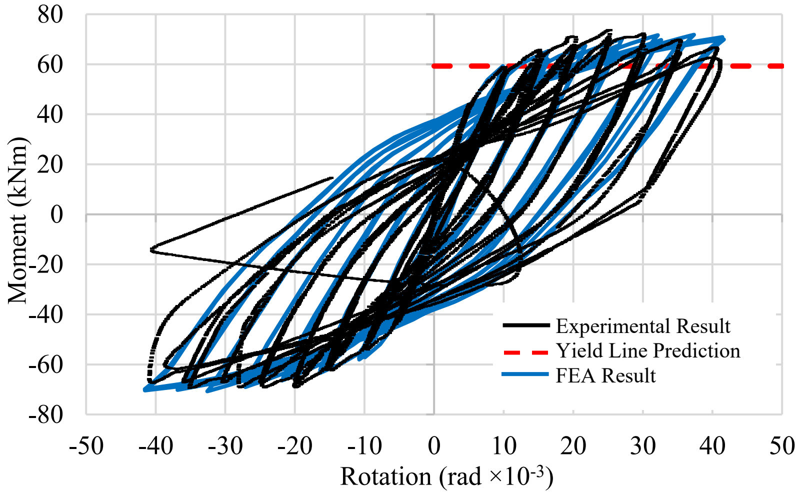

Fig. 9. Moment-rotation curve comparison between FEA and experimental results

The FE model accurately captured the experimental behavior, with only 0.6% difference in moment capacity and 3.5% difference in initial stiffness, confirming the reliability of the modeling methodology.

While the FEA result accurately reflects the initial stiffness and maximum moment capacity, the unloading stiffness is differing close to last cycles, most likely due to the material properties. Since the detailed material properties are not explained in the experimental work such as modulus of elasticity and curve.

3. Analytical methods for comparison

Two analytical methods were used to estimate the performance of the connections: AISC Yield Line Theory (AISC 341-16) which provides a simplified analytical estimation of plastic moment capacity based on yield mechanisms in the end-plate and Eurocode component method (EN 1993-1-8) used to estimate both moment capacity and initial stiffness by modeling the joint as an assembly of individual mechanical components (e.g., bolts in tension, end-plate in bending, column flange in compression). These methods were compared against finite element analysis to assess their accuracy and conservatism. The maximum end-plate yielding strength ($\phi_b M_{pl}$) is calculated by using Equation 2.

$$\phi M_n = \phi_b M_{pl} = \phi_b F_y t_p^2 Y_p \tag{2}$$

Where Y_p stands for yield line parameter dependant on the geometry and F_y and t_p represent end-plate's yield stress and thickness. Equations 3 and 4 are used to obtain the yield line parameter Y_p for the 2-bolted and 4-bolted connections respectively.

$$Y_p = \frac{b_p}{2}\left[h_1\left(\frac{1}{p_{fi}}+\frac{1}{s}\right)\right]+\frac{2}{g}\left[h_1\left(p_{fi}+s\right)\right] \tag{3}$$

$$Y_p = \frac{b_p}{2}\left[h_1\left(\frac{1}{p_{fi}}\right)+h_2\left(\frac{1}{s}\right)\right]+\frac{2}{g}\left[h_1\left(p_{fi}+0.75p_b\right)+h_2\left(s+0.25p_b\right)\right]+\frac{g}{2} \tag{4}$$

The parameters h_1 and h_2 are the moment arms for first and second bolt group, g is the bolt gauge and b_p is the width of the plate. Equation 5 is used to calculate the geometric paremeter s.

$$s = \frac{1}{2}\sqrt{b_p g} \tag{5}$$

As another limit state, the bolt rupture strength is calculated considering the prying forces in action for the thin-plate design. Equation 6 is used to determine the connection strength in this case.

$$\phi M_n = \phi_r M_q = \phi_r \sum \alpha_i P_{qi} n_i h_i \tag{6}$$

Each horizontal bolt group are considered seperately to reduce the tensile strength with maximum possible prying forces. The number of bolts in the bolt group, n_i, is taken as 2 for both 2-bolted and 4-bolted connections. The moment arm h_i is the distance between the bolt axis to the center of the compression flange of the beam. The moment capacities calculated for end-plate yielding and bolt rupture considering the prying forces are shown in Table 1.

Table. 1. Moment capacity predictions based on the yield line theory

Connection	End-plate yielding (kNm)	Bolt rupture with prying action (kNm)
F1-3/4-3/8-16	63.18	71.51
FEP-2B	85.08	96.52
FEP-4B	110.96	150.60

End-plate yielding governs the flexural strength for all the connections as seen in Table 1. The initial stiffnesses calculated using component method are shown in Table 2. In order to classify the connections as semi-rigid, the initial stiffness of the connections should be at least 25% of the beam's stiffness.

Table. 2. Initial stiffness and moment capacity predictions calculated using component method

Connection	Calculated initial stiffness $S_{j,ini}$ (kNm/rad)	Initial stiffness of the beam S_b (kNm/rad)	$S_{j,ini}/S_b$	Connection flexural strength calculated M_j (kNm)	Beam flexural strength M_b (kNm)	M_j/M_b
F1-3/4-3/8-16	11578.40	5809.64	1.99	64.67	262.97	0.25
FEP-2B	13690.53	5570.67	2.46	87.35	269.41	0.32
FEP-4B	17305.91		3.11	129.29		0.48

As it can be seen from Table 2, all connections satisfy the partial strength and semi-rigid classifications, which aligns well with the dissipative connection approach aimed.

4. Results and discussion

Both connection configurations exhibited stable cyclic performance with distinct hysteretic loops. The moment-rotation curves obtained from the finite element analyses are shown in Fig. 10. Predictions based on the yield line theory are also compared with the FEA results, which shows the conservative strength predictions.

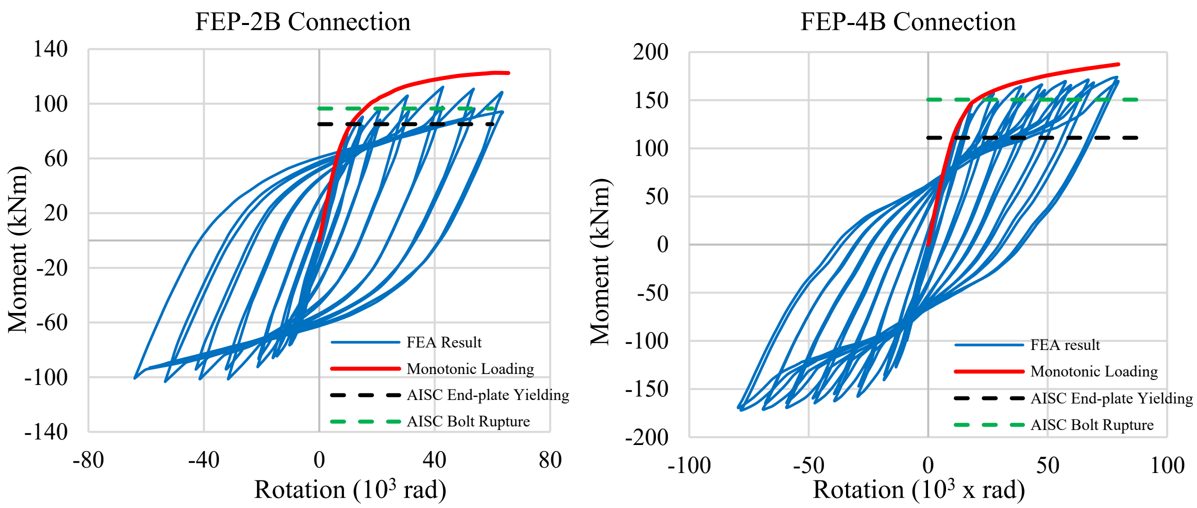

Fig. 10. Moment-rotation curves obtained from FEA

The green line represents bolt rupture with prying action while dashed black line represents end-plate yielding strength in Fig. 10. according to AISC. Monotonic moment-rotation curves are shown in red, with a close agreement to the backbone curve of the cyclic loading, which is shown in blue.

The finite element analysis results can be summarized as follows:

- Configuration FEP-2B (2-bolt): This configuration demonstrated a ductile response, characterized by substantial plastic deformation concentrated in the end-plate. The unloading stiffness was observed to be higher than that of the 4-bolt configuration. Ultimate strength was attained when the end-plate underwent full plasticization.
- Configuration FEE-4B (4-bolt): This configuration also exhibited a ductile behavior; however, it achieved higher initial stiffness and greater energy dissipation capacity compared to the 2-bolt configuration.

The hysteresis loops indicated stable and symmetric energy dissipation, verifying the effectiveness of the thin-plate design in achieving controlled plastic hinge formation.

4.1. Moment-rotation behavior

The moment-rotation curves demonstrated nonlinear behavior characterized by; an initial elastic region, a gradual transition into plasticity, a peak moment capacity followed by slight strength degradation.

The validated FE model closely matched the experimental moment-rotation behavior. For the four-bolt configuration, the moment capacity increased by approximately 35% compared to the two-bolt configuration, primarily due to improved force transfer and reduced local yielding.

4.2. Moment capacity comparison

The moment capacities derived from the finite element model were compared to predictions by the yield line and component methods. The results are summarized below in Table 3.

Table. 3. Moment capacity comparisons

Connection	Experimental moment capacity (kNm)	FEA moment capacity (ABAQUS, kNm)	Yield line theory (AISC, kNm)	Component method (Eurocode, kNm)
F1-3/4-3/8-16	72.73	71.80	63.18	64.67
FEP-2B	-	102.82	85.08	87.35
FEP-4B	-	169.52	110.96	129.29

The results confirm that both analytical methods underestimate the moment capacity compared to FE analysis, with deviations up to 52% and 31% for the yield line theory and component method respectively. The conservative nature of these methods is due to simplified assumptions, such as rigid body mechanisms and neglect of strain hardening effects.

4.3. Initial stiffness comparison

Initial stiffness values from finite element results were also compared with those predicted by the Eurocode component method in Table 4.

Table. 4. Initial Stiffness comparisons

Connection	Experiment result (kNm/rad)	Component method ($S_{i,CM}$) (kNm/rad)	FEA result ($S_{i,FEM}$) (kNm/rad)	$S_{i,CM}$ /$S_{i,FEM}$
F1-3/4-3/8-16	10235	11578.40	9647	1.20
FEP-2B	-	13690.53	10851	1.26
FEP-4B	-	17305.91	12562	1.37

The component method consistently overestimates the initial stiffness, likely due to idealized assumptions of component rigidity and lack of consideration for bolt slippage and localized deformation in plates.

5. Conclusions

This study presented a detailed numerical investigation of two semi-rigid flush end-plate connections subjected to cyclic loading. The main conclusions are:

- Thin-plate design philosophy, which promotes yielding of the end-plate while preventing bolt failure, effectively facilitates plastic hinge formation and energy dissipation.
- Finite element models in ABAQUS, using nonlinear true stress-strain relationships, accurately captured the cyclic behavior of the connections, as validated against experimental results.
- Yield line theory and the component method significantly underestimated the moment capacity of the connections by up to 52%, underscoring their conservative nature.
- The Eurocode component method overestimated initial stiffness by up to 37% due to simplified assumptions and exclusion of deformation mechanisms.

These findings emphasize the conservative nature of current analytical methods. While such conservatism ensures safety, it may lead to overdesign or underutilization of joint capacity. Finite element modeling, although computationally intensive, offers a more accurate assessment of connection performance under realistic loading conditions.

The thin-plate design philosophy proves effective in ensuring ductile behavior and predictable plastic hinge formation. However, the disparity between analytical and numerical predictions highlights the need for refined analytical tools that incorporate nonlinear effects, material hardening, and prying action more realistically.

There is a clear need for enhanced analytical methods that can accurately predict the nonlinear cyclic behavior of semi-rigid connections for performance-based seismic design.

Future work will include parametric studies to evaluate the influence of bolt diameter, end-plate thickness, and beam/column size on connection performance, as well as potential development of modified analytical expressions based on calibrated finite element models.

Structural health monitoring through vibration-based feature extraction and machine learning: a comparative study of AR, VAR, and SVD methods

Mohamad Alhasan*[1], Volkan Kahya[1], Kemal Hacıefendioğlu[1], Sebahat Şimşek[1]

[1] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. Ensuring the durability and safety of infrastructure relies heavily on SHM, which facilitates the prompt identification of structural damage.This study introduces a vision-based approach that utilizes ambient vibration measurements extracted from high-speed video recordings. Optical flow techniques are employed to track structural displacements, providing a non-contact method for vibration analysis. Three feature extraction methods Autoregressive (AR), Vector Autoregressive (VAR) and Singular Value Decomposition (SVD) are assessed for their effectiveness in identifying structural damage. Residual errors derived from these methods are used as input features for a Support Vector Machine (SVM) classifier to differentiate between healthy and damaged states. The findings reveal that AR offers the best future extraction method for ambient vibration, SVD exhibits high sensitivity in SVM but is prone to noise induced variations, and VAR captures system interactions with relatively lower sensitivity than AR. The SVM classifier demonstrates high accuracy in damage detection, highlighting the potential of video-based ambient vibration analysis combined with machine learning for reliable structural health assessment.

Keywords: Structural Health Monitoring (SHM); Support Vector Machine (SVM); Autoregressive (AR); Vector Autoregresive (VAR), Singular Value Decomposition (SVD)

---

1. Introduction

Structural Health Monitoring (SHM) plays a crucial role in ensuring the safety, functionality, and longevity of civil infrastructure. As structures age and environmental challenges increase, the demand for advanced SHM methods capable of detecting and diagnosing structural damage in real-time has intensified (Farrar et al., 2025). Traditional SHM approaches have relied on manual inspections and physics-based models that utilize sensor-collected dynamic responses to assess structural conditions (Malekloo et al., 2022). While these methods provide valuable insights, they are often labor-intensive, costly, and less effective in capturing early-stage damage (Tahat et al., 2022).

To address these limitations, modern SHM systems integrate various sensor technologies for enhanced data acquisition. Piezoelectric energy harvesters convert mechanical vibrations into electrical energy, enabling self-powered SHM in wind turbines. They are lightweight and flexible, making them ideal for dynamic environments, but their low power output restricts broader applications (Kullukçu et al., 2022). Similarly, Surface Acoustic Wave (SAW) sensors provide wireless, battery-free strain and temperature monitoring in reinforced concrete, offering localized, long-term durability but suffering from signal interference and limited range (Jeltiri et al., 2023). Radio Frequency (RF) energy-powered sensor nodes (RF-SNs) further support wireless SHM by harvesting RF energy for sustainable, maintenance-free monitoring, though signal attenuation and low power efficiency remain challenges (Luo et al., 2023).

With advancements in IoT and edge computing, smart SHM systems leverage wireless sensors, cloud computing, and AI for real-time monitoring. IoT-enabled SHM solutions provide cost-effective, remote data collection, yet cybersecurity risks and network reliability issues persist (Bhatta & Dang, 2024). MEMS-based wireless sensor networks (WSNs) offer scalable, low-cost earthquake monitoring, but power consumption and unstable data transmission limit their reliability (López-Castro et al., 2022). Similarly, MEMS accelerometers and geophone sensors, when paired with Raspberry Pi-based data loggers, enable affordable, real-time structural vibration monitoring, but their noise levels and time drift issues affect long-term accuracy (Özdemir & Kömeç Mutlu, 2024).

Beyond traditional sensors, advanced SHM technologies have emerged to enhance damage detection accuracy. Field programmable gate arrays-based SHM systems, using torsional ultrasonic guided waves, allow real-time defect localization in pipelines while maintaining low power consumption. However, hardware limitations and the need for FPGA expertise restrict adoption (Patil et al., 2024). Infrared (IR) cameras detect thermal variations that indicate hidden fatigue damage and subsurface cracks, proving effective in harsh environments, though environmental fluctuations can impact accuracy (He et al., 2020). Laser vibrometers provide non-contact, high-precision vibration monitoring, but lighting conditions and airborne particles may degrade accuracy (Klun et al., 2019). Fiber optic sensors, particularly Fiber Bragg Gratings (FBGs), offer high sensitivity to strain and temperature with immunity to electromagnetic interference, yet installation complexity remains a barrier (Kinet et al., 2014; Mohapatra et al., 2022; Qiu et al., 2013). For large-scale SHM, wireless sensor networks (WSNs) support real-time, multi-node data acquisition with event-triggered sensing and edge computing, but scalability and power efficiency challenges persist (Yu et al., 2024).

While these advanced sensing techniques have significantly improved data collection, the challenge now lies in effectively interpreting the vast and complex datasets a challenge that Machine Learning (ML) methods are well positioned to address Machine Learning (ML) and Artificial Intelligence (AI) have advanced traditional Structural Health Monitoring (SHM), enhancing its capabilities in damage detection and structural anomaly classification. However, a critical challenge in ML-driven SHM arises: the selection of a suitable damage detection method. In recent years Support Vector Machines (SVMs) and Random Forests (RFs) have been widely used in structural health monitoring (SHM) for damage classification. These models excel in detecting structural anomalies based on sensor data, with Random Forests particularly effective in capturing complex vibration patterns, achieving high classification accuracy (Vélez et al., 2024). Autoencoder-based models, such as the Mechanics-Informed Autoencoder (MIAE), have shown significant improvements in structural damage detection. Li et al. (2024) introduced this model, which relies on passive sensor data to learn from the undamaged state of a structure, enhancing its ability to detect and localize unforeseen damage without requiring extensive labeled datasets. A probabilistic approach to SHM was proposed by Torzoni et al. (2024), who developed a Bayesian model updating framework combined with deep learning-based feature extraction. This method employs learnable mappings to improve damage sensitivity while reducing computational costs, making it particularly effective for long-term monitoring. Transformer-based foundation models have also emerged as powerful tools in SHM. According to Benfenati et al. (2024), these models leverage self-supervised learning to extract generalizable structural representations, significantly outperforming traditional methods in anomaly detection and traffic load estimation tasks. Reinforcement learning (RL) is another promising technique for optimizing SHM strategies. Plevris & Papazafeiropoulos (2024) demonstrated that RL models can dynamically adjust monitoring parameters, improving both detection efficiency and cost-effectiveness by learning from past decisions. These advancements highlight the versatility of machine learning in SHM, ranging from classification models to self-learning frameworks that adapt to evolving structural conditions, ultimately enabling proactive maintenance and increased infrastructure safety.

Against this backdrop, the present study aims to develop a vision-based, data-driven framework for structural diagnosis and anomaly detection by integrating optical flow techniques, advanced feature extraction methods, and Support Vector Machines (SVMs). Unlike traditional SHM methods that depend on direct sensor contact, this approach leverages high-speed video recordings to capture ambient vibrations, offering a non-contact, precise, and scalable monitoring solution. Vibration data is extracted using optical flow algorithms, specifically the Lucas-Kanade method, which tracks pixel displacement in successive video frames to estimate structural motion. This method enables high-precision displacement measurements without the need for physical sensors. In our setup, four high-resolution cameras are used to monitor predefined measurement points (MPs) marked with QR codes, ensuring accurate tracking of even minute structural displacements. To analyze the extracted displacement signals, three feature extraction techniques are evaluated for their ability to capture damage-sensitive patterns: Autoregressive (AR) model, Vector Autoregressive (VAR) model, and Singular Value Decomposition (SVD). The residual errors from these methods serve as input features for an SVM classifier, which distinguishes between healthy and damaged states. A comprehensive benchmarking process compares the sensitivity and reliability of each feature extraction method, ensuring the optimal selection for SHM applications.

By integrating vision-based sensing with advanced ML techniques, this study presents a scalable, non-invasive, and accurate framework for real-time structural monitoring. The proposed system reduces the dependence on manual inspections also enhances early-stage damage detection in critical infrastructures across civil and mechanical engineering applications.

2. Methodological framework

Machine learning techniques provide a robust framework for data mining, as illustrated in Fig. 1. In the context of SHM, the structural diagnosis process generally consists of three main stages: (a) data acquisition and preprocessing; (b) feature extraction; and (c) model training and development using support vector machines.

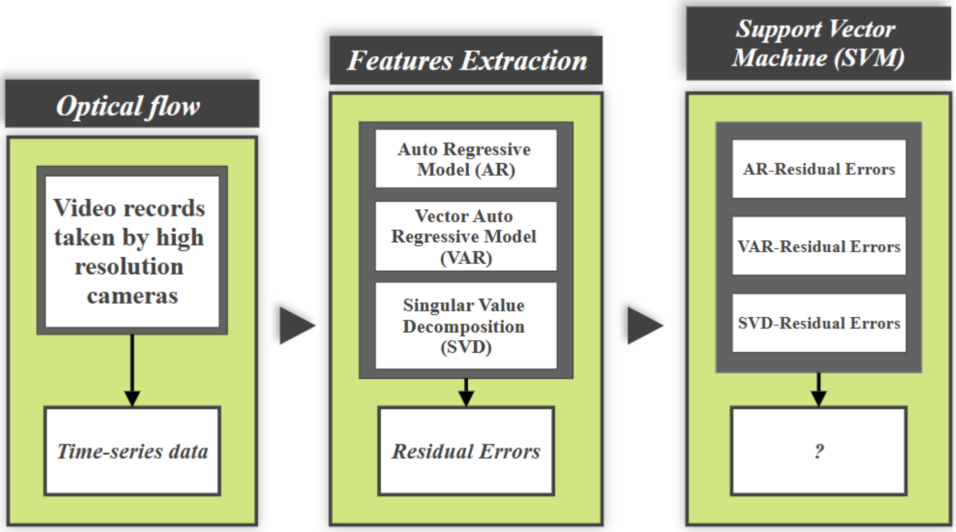

Fig. 1. Workflow of structural health monitoring using optical flow,
feature extraction, and SVM classification

Data-driven SHM involves acquiring and preprocessing data to remove noise and standardize inputs. Features such as (AR), (VAR), and (SVD) are extracted to highlight structural anomalies. Residual errors (REs) are particularly sensitive indicators, providing valuable insights into damage. Machine learning models like support vector machines (SVMs) are then trained on these features to classify structural health states with high accuracy.

2.1. Optical flow (Lucas-Kanade Method)

To precisely quantify the temporal movement of different structural components, An optical flow-based displacement measurement approach is employed.. In this method, each frame of a high-speed video captures the structural state at a specific moment. A Region of Interest (ROI), representing a small subset of pixels corresponding to a structural feature, is identified in the initial reference frame to establish a fixed reference point. As subsequent frames are processed, the Lucas-Kanade method is utilized to track the ROI's position, enabling the detection of pixel-level displacements across frames. This frame-by-frame tracking of ROIs generates a continuous time series of displacements, serving as the foundational dataset for subsequent causal analysis. Fig. 2 illustrates this concept, showing how a chosen ROI is tracked from the reference frame to subsequent frames, how pixel coordinate displacements are computed, and how these displacements are converted into physical units using a known scaling factor.

The Lucas-Kanade algorithm assumes brightness constancy, spatial coherence, and temporal persistence. It computes the local displacement of image features by solving a set of equations derived from intensity gradients(Kanade & Lucas, 1981). In essence, it finds the pixel shift between the initial ROI and its position in the next frame that best explains how the image intensities have changed. Once the algorithm determines the new pixel coordinates of the ROI in the jth frame, the pixel-level displacement $(X_{p,i}, Y_{p,i})$ is obtained by subtracting the original (reference) coordinates $(x_{p,1}, y_{p,1})$ as follows:

$$(X_{p,i}\,, Y_{p,i}) = (x_{p,i}\,, y_{p,i}) - (x_{p,1}\,, y_{p,1}) \tag{1}$$

This calculation yields displacement in pixel units. To convert pixel displacement to a physical displacement measure (e.g., millimeters), a scaling factor (SF) is introduced. This factor is determined by known geometric relationships between the image and the actual structure (such as calibration targets, known dimensions, or camera parameters). Multiplying the pixel displacement by the scaling factor provides the physical displacement as

$$(X_{p,i}\,, Y_{p,i}) = SF \times (x_{p,i}\,, y_{p,i}) \tag{2}$$

where SF is expressed in mm/pixel (or another suitable unit ratio).

By integrating the Lucas-Kanade optical flow technique with ROI tracking and scaling procedures, an accurate, non-contact measurement of structural displacements over time is achieved. This approach utilizes standard camera footage to systematically capture frame-by-frame structural movements, ultimately producing precise physical displacement data suitable for SHM and damage detection analyses.

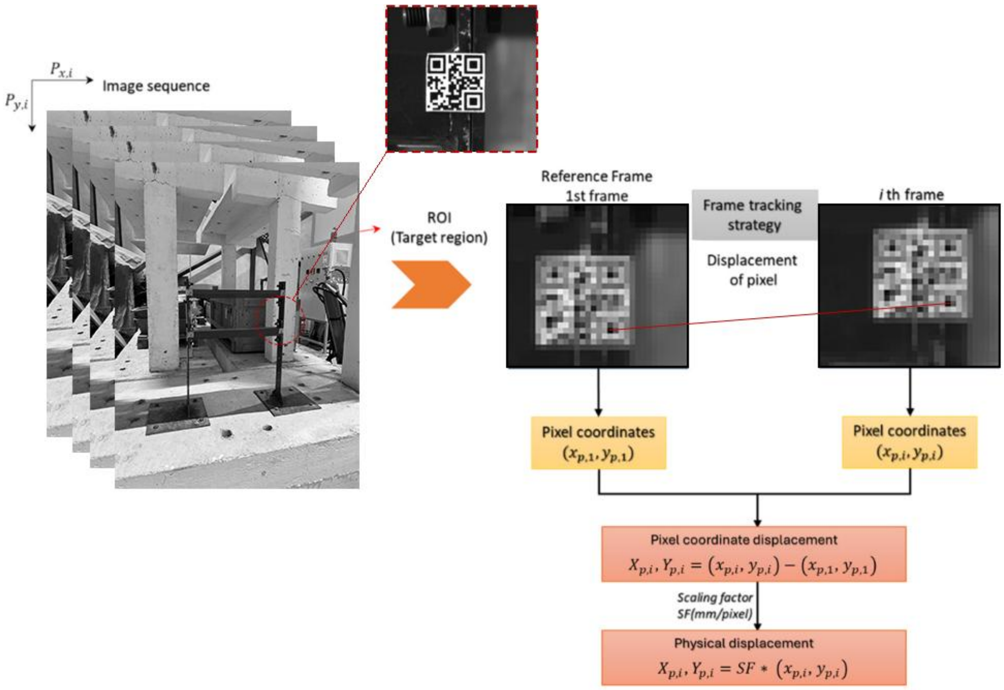

Fig. 2. A QR-code-based displacement tracking schemati

2.2. Features Extraction

2.2.1. Autoregresive (AR)

The AR model is a fundamental time-series analysis technique that predicts the current value of a signal based on a linear combination of its previous values (see Fig 3). Mathematically, the AR model of order p is expressed as:

$$x_i = \sum_{j=1}^{p} \phi_j \, x_{i-j} + e_i \tag{3}$$

where x_i represents the time-series data at time i, ϕ_j are the AR coefficients to be determined, and $e_i$is the error term (residual).

The selection of the model order p is critical for accurately capturing the temporal dependencies in the data The Akaike Information Criterion (AIC) was used to identify the optimal AR model order. AIC evaluates the trade-off between model complexity and goodness of fit. It is mathematically defined as:

$$AIC(p) = N \cdot ln(\hat{\sigma}^2) + 2p \tag{4}$$

where N is the number of data points, $\hat{\sigma}^2$ is the residual variance of the AR model of order p and p is the number of parameters in the model. The model with the smallest AIC value is considered optimal, effectively balancing model accuracy with simplicity.

AR enhances damage detection by emphasizing point-level sensitivity. Its reliance on past values from the same sensor allows it to build a highly personalized prediction model for each measurement point. When structural behavior shifts due to damage, even minor inconsistencies trigger a noticeable increase in residuals. This method is especially effective for detecting early-stage or highly localized faults that may not yet affect the broader system (Zhang et al., 2024).

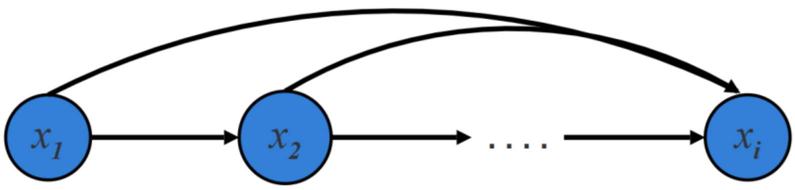

Fig. 3. Representation of the AR process

2.2.2.Vector autoregressive (VAR)

The VAR model is a multivariate time-series analysis technique designed to capture the temporal dependencies among multiple variables. In the VAR(p) model, each variable is represented as a linear combination of its own past values and the past values of other variables in the system (see Fig 4).

Mathematically, the VAR(p) model is expressed as:

$$y_t = a_0 + \sum_{j=1}^{p} A_j y_{t-j} + e_t \tag{5}$$

where y_t is an $M \times 1$ vector of M data acquisition sensors at time t, a_0 is an $M \times 1$ intercept vector, A_j are $M \times 1$ coefficient matrices, and e_t is an $M \times 1$ vector of errors, assumed to follow a zero-mean Gaussian distribution with covariance $\sum$.

Choosing the appropriate lag order p is vital for capturing the system's dynamics. The Akaike Information Criterion (AIC) was employed to determine the optimal p. AIC evaluates the balance between model complexity and goodness of fit, and for the VAR(p) model is defined as:

$$AIC(p) = 2 \cdot dof - 2 \cdot ln(L) \tag{6}$$

where $dof = K \cdot M$ denotes the number of parameters (K is the number of regressors per variable and M is the number of variables), and L is the log-likelihood of the model.

VAR contributes by modeling the interdependencies between multiple measurement points. Instead of treating each point in isolation, it accounts for how vibrations at one location influence others over time. This allows the method to uncover system-level anomalies, such as coordinated or cascading structural changes. It's particularly useful for identifying damage that alters the dynamic relationship between different regions of the structure (Liu et al., 2019).

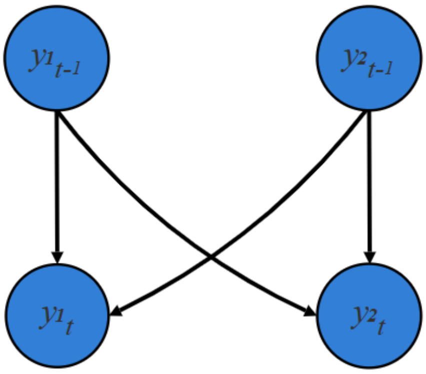

Fig. 4. Representation of the VAR process

2.2.3. Singular value decomposition (SVD)

The singular value decomposition (SVD) is a robust matrix factorization technique applied to time-series signals in structural health monitoring. By transforming the signal into a Hankel matrix, SVD decomposes it into its singular components, isolating the dominant dynamic patterns and facilitating damage detection. The SVD of a matrix H is expressed as:

$$H = USV^T \tag{7}$$

In this formulation, U is an $m \times m$ orthonormal matrix of left singular vectors, S is an $m \times n$ diagonal matrix containing the singular values $\sigma_1, \sigma_2, \cdots, \sigma_n$ and V is an $n \times n$ matrix of right singular vectors (see Fig 5). The singular values $\sigma_1, \sigma_2, \cdots, \sigma_n$ are arranged in descending order ($\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n \geq 0$). The dominant singular vectors, associated with the largest singular values, define a reduced subspace that encapsulates the most significant information in the original signal.

The SVD enables a subspace-based representation of H. Assuming $\gamma \leq N$, where γ is the number of dominant variables in the data, the decomposition can be written as:

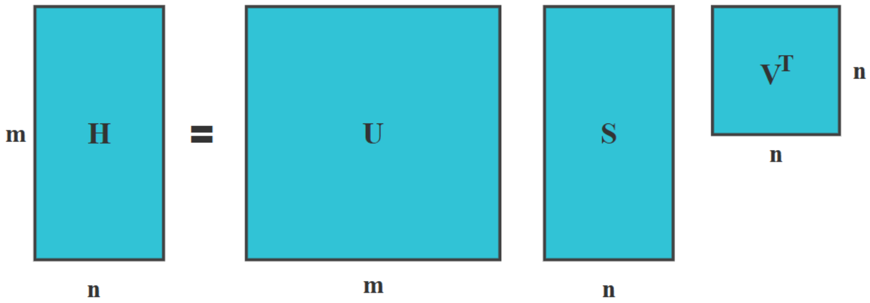

Fig. 5. Decomposition of matrix H into singular value components using SVD.

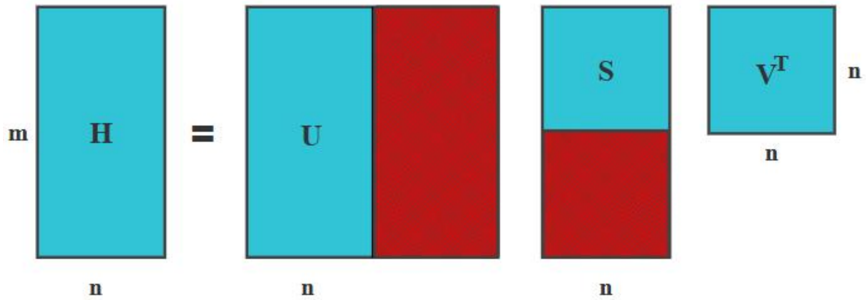

Fig. 6. Representation of SVD in the dominant subspace

$$H = USV^T = \begin{bmatrix} U_\gamma & U_\gamma^\perp \end{bmatrix} \begin{bmatrix} S_\gamma & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} V_\gamma^T \\ (V_\gamma^\perp)^T \end{bmatrix} \tag{8}$$

Here, $U_\gamma$and $U_\gamma^\perp$ are the dominant and complementary left singular vectors, respectively, while V_γ and $V_\gamma^\perp$ are the dominant and complementary right singular vectors. The diagonal matrix $S_\gamma = diag(\sigma_1, \ldots, \sigma_\gamma)$ contains the dominant singular values, which represent the most significant dynamic patterns in the system .

The complementary subspaces and the corresponding smaller singular values are assumed to represent noise or less relevant variations. These components are discarded, and their influence is effectively reduced to zero in the decomposition (see Fig 5).

The singular vectors $\mu_i$or v_i are regarded as the dominant singular vectors. For the signal X , the number of dominant orthonormal dimensions can be determined based on the Frobenius norm as:

$$\| H \|_F = \sum_{i=1}^{m} \sum_{j=1}^{n} H_{ij}^2 = \| S \|_F = \sigma_1^2 + \sigma_2^2 + \cdots + \sigma_n^2 \tag{9}$$

The energy of the data is preserved within the singular value spectrum σ_i. For noise-corrupted signals, the denoising process can be regarded as removing certain minimal σ_i. values. In the general decomposition process, the signal is first reshaped into a Hankel matrix.

SVD is then applied to decompose the Hankel matrix, determine the number of selected singular values , and subsequently reconstruct the denoised signal and noise components as:

$$X = X_0 + X_{noise} \tag{10}$$

where X_0 represents the first row of $H_{\{X_0\}}$, and X_{noise} corresponds to the residual of the denoised signal.

The SVD aids in damage detection by transforming vibration signals into a set of orthogonal modes based on energy content. This decomposition filters out noise and isolates the most structurally meaningful behaviors. When damage occurs, the energy distribution among these modes changes subtly but detectably. SVD’s strength lies in identifying global structural changes and maintaining accuracy even under complex, ambient vibration conditions (Tomassini et al., 2024).

2.2.4.Residual errors

To evaluate the performance of the AR, VAR, and SVD models, the residual errors were computed by comparing the measured signal $x_i$with the predicted signal $\hat{x}_i$. the residual error e_i^D is calculated as:

$$e_i^D = x_i - \hat{x}_i \tag{11}$$

Following this, damage detection is performed by defining thresholds based on the healthy (undamaged) condition. Specifically, the maximum and minimum thresholds $T_{\_max}$ and T_{min} , are obtained from the residuals of the undamaged state e^{UD}, as:

$$T_{\max} = \max(e^{UD}), T_{\min} = \min(e^{UD}) \tag{12}$$

A total of sixteen statistical features were extracted from the residual errors, following the methodologies summarized in Table 1. These features serve as damage-sensitive indicators for structural health monitoring applications (Boldt et al., 2013; Sharma et al., 2016).

Table 1. Definition of statistical features

Feature	Description	Formulation
RE1	Maximum value of the residual error	$\max(e_i)$
RE2	Minimum value of the residual error	$min\ (e_i)$
RE3	Mean of the residual error	$\mu = \frac{1}{N}\sum_{j=1}^{N} e_i$
RE4	The peak-to-peak value of the residual error	$\max(e_i) - \min(e_i)$
RE5	Mean of the absolute residual error	$\frac{1}{N}\sum_{j=1}^{N} \lvert e_i \rvert$
RE6	The standard deviation of the residual error	$\sigma = \sqrt{\sum_{j=1}^{N} \frac{(e_i - \bar{e}_i)}{N}}$
RE7	Skewness of the residual error	$\sqrt{\frac{1}{6N}\sum_{j=1}^{N}\left(\frac{e_i - \mu}{\sigma}\right)^3}$
RE8	Kurtosis of the residual error	$\sqrt{\frac{N}{24}\left[\frac{1}{N}\sum_{j=1}^{N} -3\right]}$
RE9	Root mean square of the residual error	$rms = \sqrt{\frac{1}{N}\sum_{j=1}^{N} e_i^2}$
RE10	Form factor	$\frac{rms}{\frac{1}{N}\sum_{j=1}^{N}\lvert e_i \rvert}$
RE11	Crest factor	$\frac{\max(e_i) - \min(e_i)}{rms}$
RE12	Kurtosis factor	$\frac{\sum_{i=11}^{N} e_i^4}{\sqrt{\sum_{i=1}^{N} e_i^2}}$
RE13	Pulse factor	$\frac{\max(e_i) - \min(e_i)}{\frac{1}{N}\sum_{j=1}^{N}\lvert e_i \rvert}$
RE14	Margin factor	$\frac{\max(e_i) - \min(e_i)}{\left[\frac{1}{N}\sum_{j=1}^{N}\lvert e_i \rvert\right]^2}$
RE15	Upper control limit	$UCL = \mu + 3\frac{\sigma}{\sqrt{n}}$
RE16	Lower control limit	$lCL = \mu - 3\frac{\sigma}{\sqrt{n}}$

2.2.5. Support vector machine (SVM)

Support Vector Machine (SVM) is a supervised learning algorithm widely used in classification problems due to its robust generalization capabilities. In the context of Structural Health Monitoring (SHM), SVM has gained significant traction because of its ability to effectively distinguish between healthy and damaged structural states. The core idea behind SVM is to find a decision boundary or hyperplanethat maximizes the margin between two classes of data points . This is formulated in the binary classification setting as:

$$f(X) = W^T X_i + b \tag{13}$$

where W is the weight vector , X_i is the feature vector of the i-th sampl, and b is the bias.

For damage detection tasks involving only one class (typically healthy data), One-Class Support Vector Machines (OC-SVM) are applied as reported by Pollastro et al. (2023). The OC-SVM seeks to estimate a function that returns positive values for most training data and negative values for anomalies. The optimization objective for the OC-SVM is:

$$\min_{W,b} \frac{1}{2} \|W\|^2 + \frac{1}{\upsilon N} \sum_{i=1}^{N} \xi_i - \rho \tag{14}$$

here, ξ_i is the slack variables allowing for outlires, And ρ defines the margin threshold

3.Case study

3.1. Testbed structure

The study's lab model is a steel frame consisting of two vertical bars supported by bolted base plates, connected by horizontal bars to create a stable and rigid configuration (Fig. 7). Assembled with adjustable bolts, it allows for flexible configurations suited to various testing needs. The material properties are Young's modulus $E = 2 \times 10^{11}$ N/m^2, Poisson's ratio $\upsilon = 0.30$, and density $\rho = 7850$ kg/m^3. The robust construction and stable alignment of the model provide a reliable setup for accurately tracking its responses under different conditions.

Using four high-resolution cameras the data collection process was conducted as shown in Fig. 8, each aimed at a specific QR code attached to the corners of the model, as detailed in Fig. 9, which also shows the damage scenarios considered. The cameras were strategically positioned to capture the vibrations and movements of the QR codes, providing precise time series data.

3.2. Data acquisition system

To capture ambient vibration data from the laboratory steel frame model, a vision-based measurement system composed of four high-speed cameras and corresponding optical lenses was employed (see Fig. 10). The integrated hardware system comprising four high-speed CMOS cameras, each with its precision lens, and a versatile CoaXPress video recorder, supported by a capable computing unit provided a robust platform for capturing, recording, and analyzing the ambient vibrations of the steel frame model. This configuration ensured that the collected image data met the temporal resolution and clarity demands necessary for accurate displacement tracking and reliable analysis.

Video signals from the four cameras were streamed to an IO Industries DVR Express Core 2 CoaXPress (CORE2CX) video recorder. This recorder supported multiple CoaXPress link configurations (CXP–1, CXP–2, and CXP–3) and adhered to CoaXPress v1.1 and GenICam Rev. 2.4 standards. Furthermore, it accommodated various video formats—8/10/12/14/16-bit monochrome and Bayer or RGB modes—ensuring that the recorded image data maintained the fidelity required for subsequent data analysis.

Data processing and analysis were performed on a computing unit (HP Victus 16-d1006nt) equipped with a 12th Gen Intel® Core™ i5-12500H processor running at 2.50 GHz, 16 GB of RAM, and a 512 GB SSD.

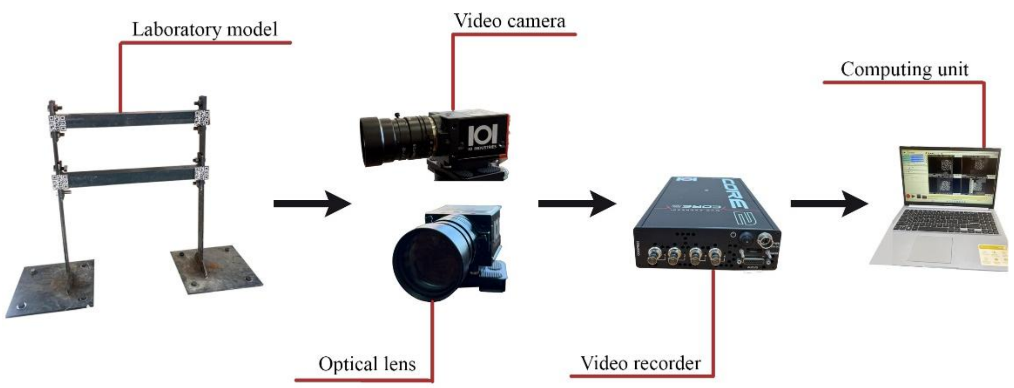

Fig. 10. Monitoring system

4.Results

In the experiment, vibration data were recorded along both the x-axis and y-axis. However, the primary focus was placed on horizontal (x-axis) displacement, as it provided a clear, one-dimensional representation of the movement of each measurement point over time. While structural vibrations can occur in multiple directions, selecting a single principal axis in this case, the x-axis simplifies data acquisition and processing while still capturing the dominant motion relevant to damage detection objectives. Tracking x-axis displacement enabled the generation of straightforward time series inputs for the causal analysis framework, ensuring clarity and consistency in sensor behavior comparisons across different damage scenarios. In Figs 11 and 12, the time series data for healthy and D2 cases obtained by the optical flow approach at the relevant MPs are, respectively, shown.

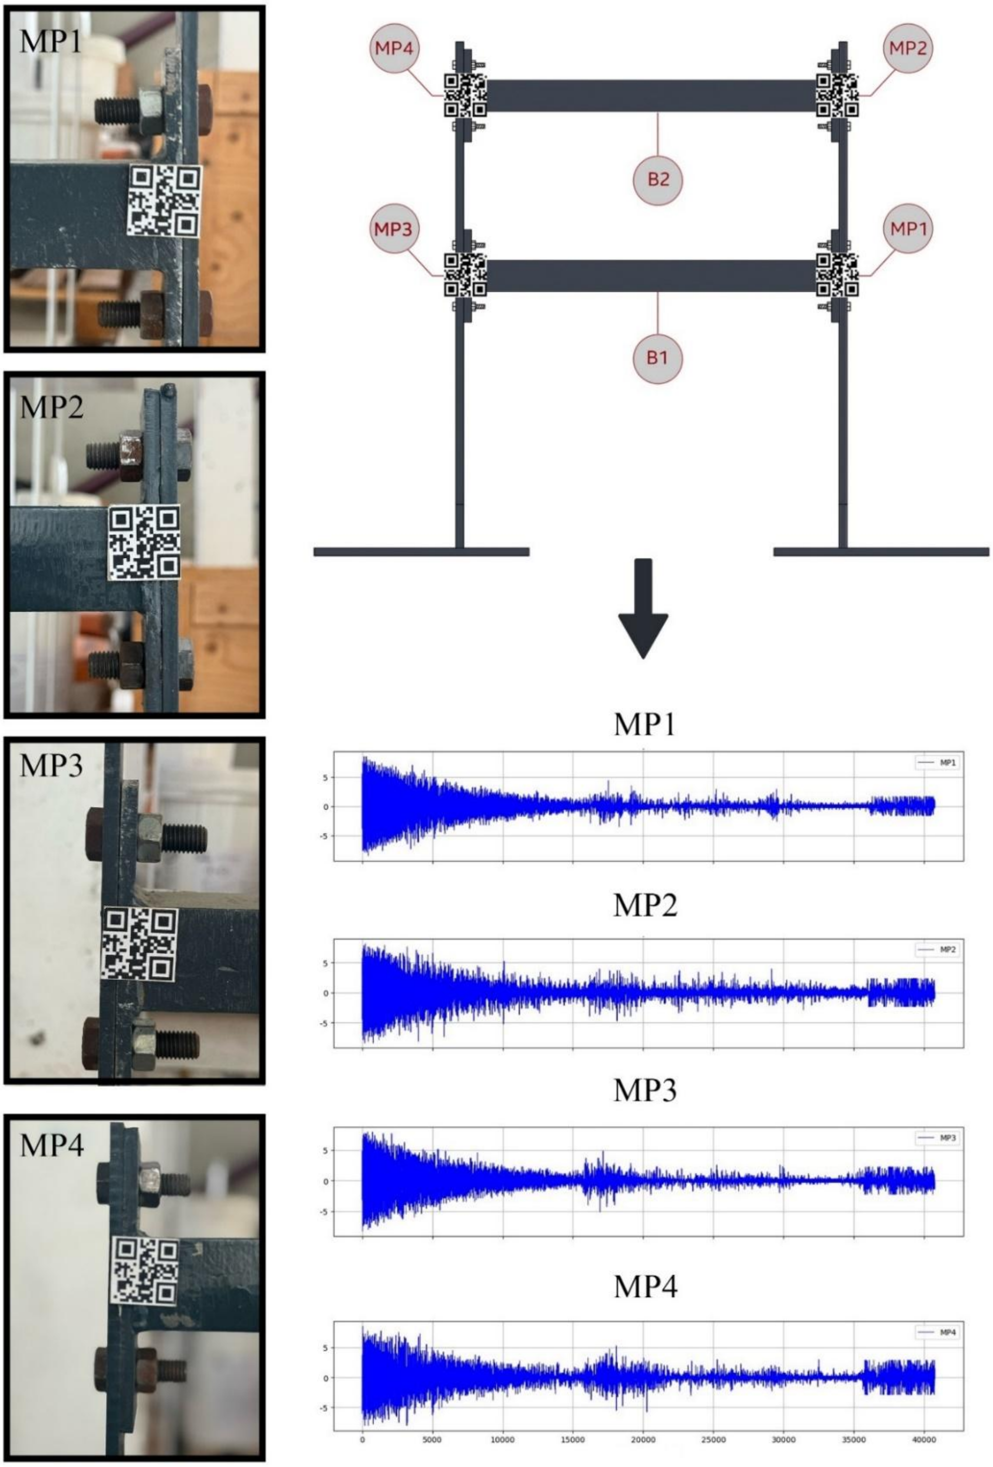

Fig. 11. Displacement time series data for the healthy condition

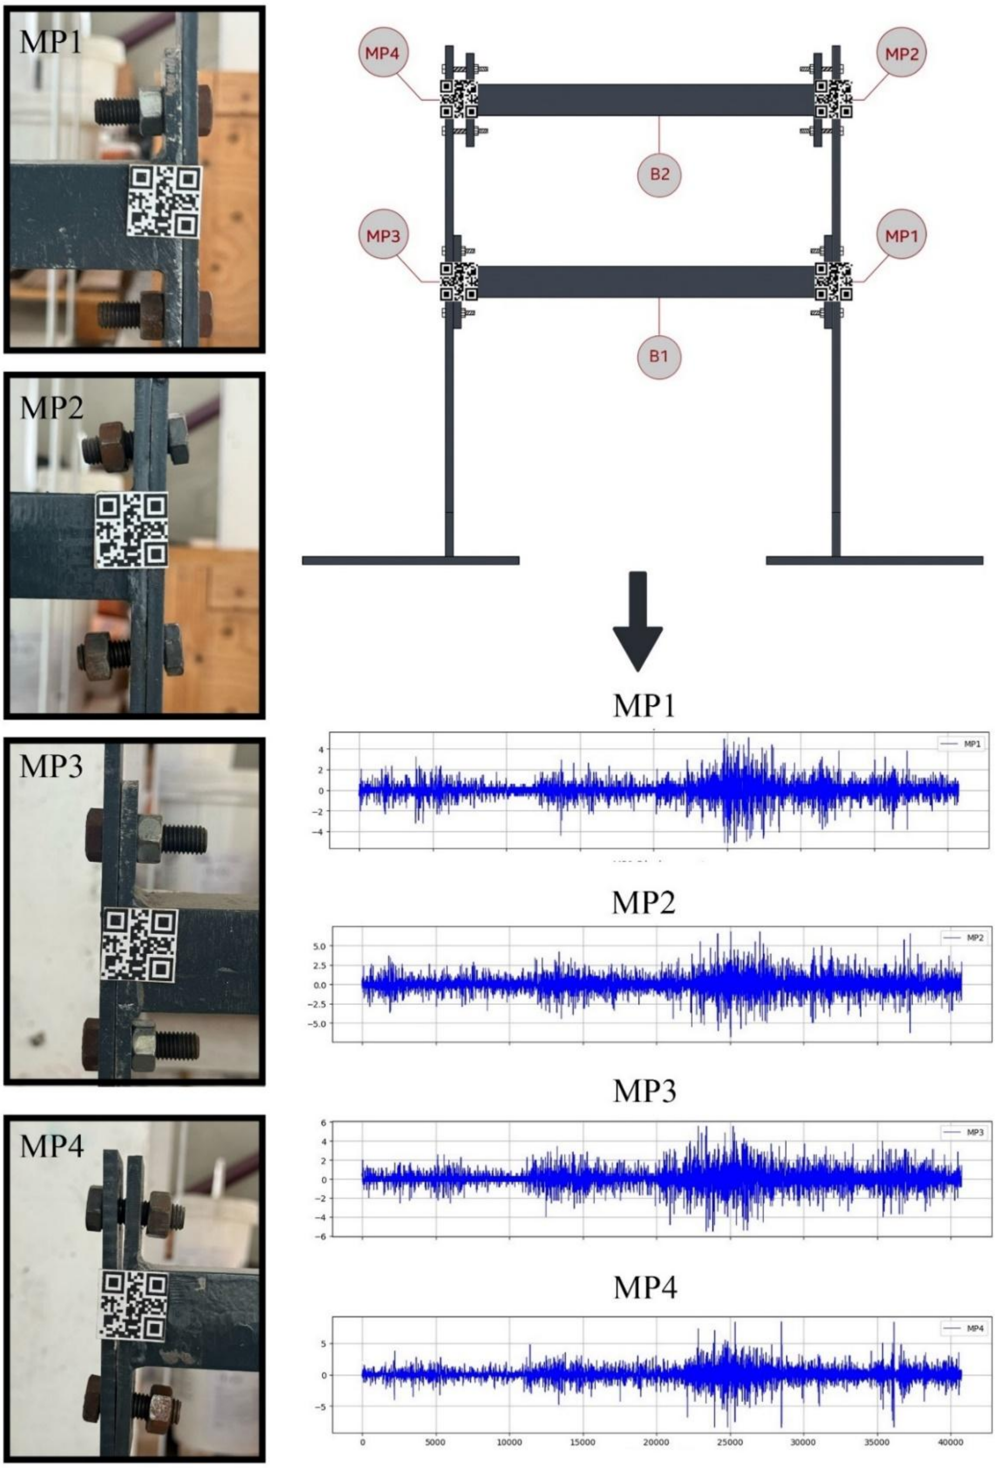

Fig. 12. Displacement time series data for the damaged condition D2

Feature extraction methods were evaluated using residuals from AR, VAR, and SVD, as stated in Eq. (X), to assess their effectiveness in distinguishing between undamaged and damaged states. The results showed differences in each model's ability to detect structural anomalies under ambient vibration conditions.

Figs 13–15 present the computed data from AR, VAR, and SVD models. The red dashed lines indicate the threshold range of healthy structural behavior, defined by Eq. (12). When the computed time series exceed these thresholds, the structure is identified as damaged. Blue segments correspond to the UD dataset, while purple segments represent the damaged cases (D1, D2, D3). Each MP (MP1–MP4) is displayed side by side across the scenarios to allow direct comparison between the normal behavior in the UD data and deviations observed in the damaged datasets.

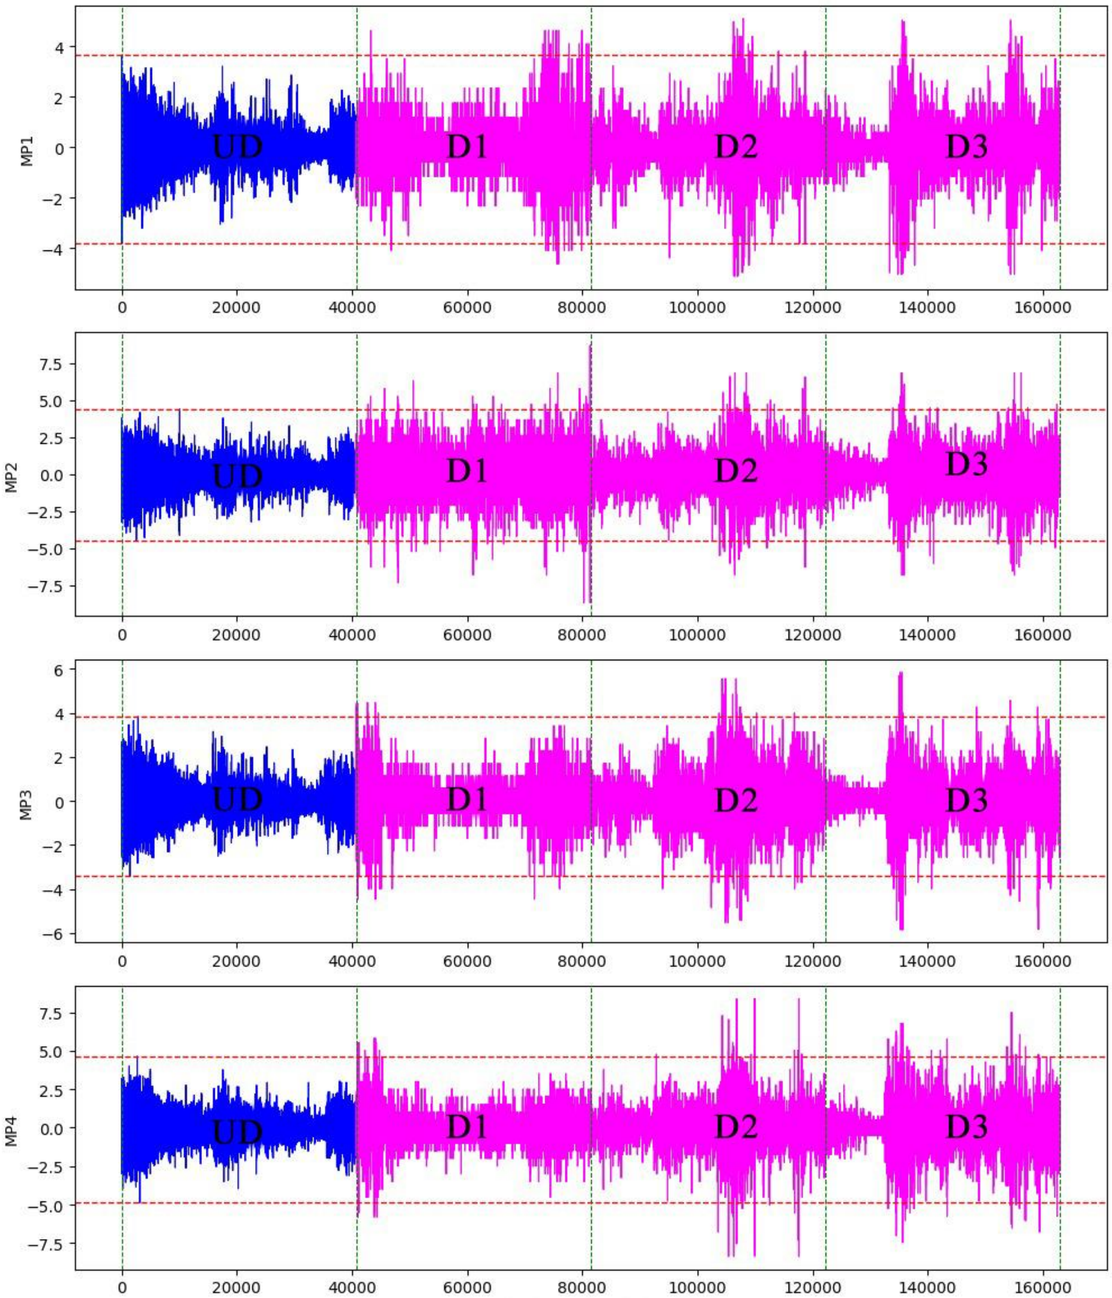

Fig. 13. AR model features .

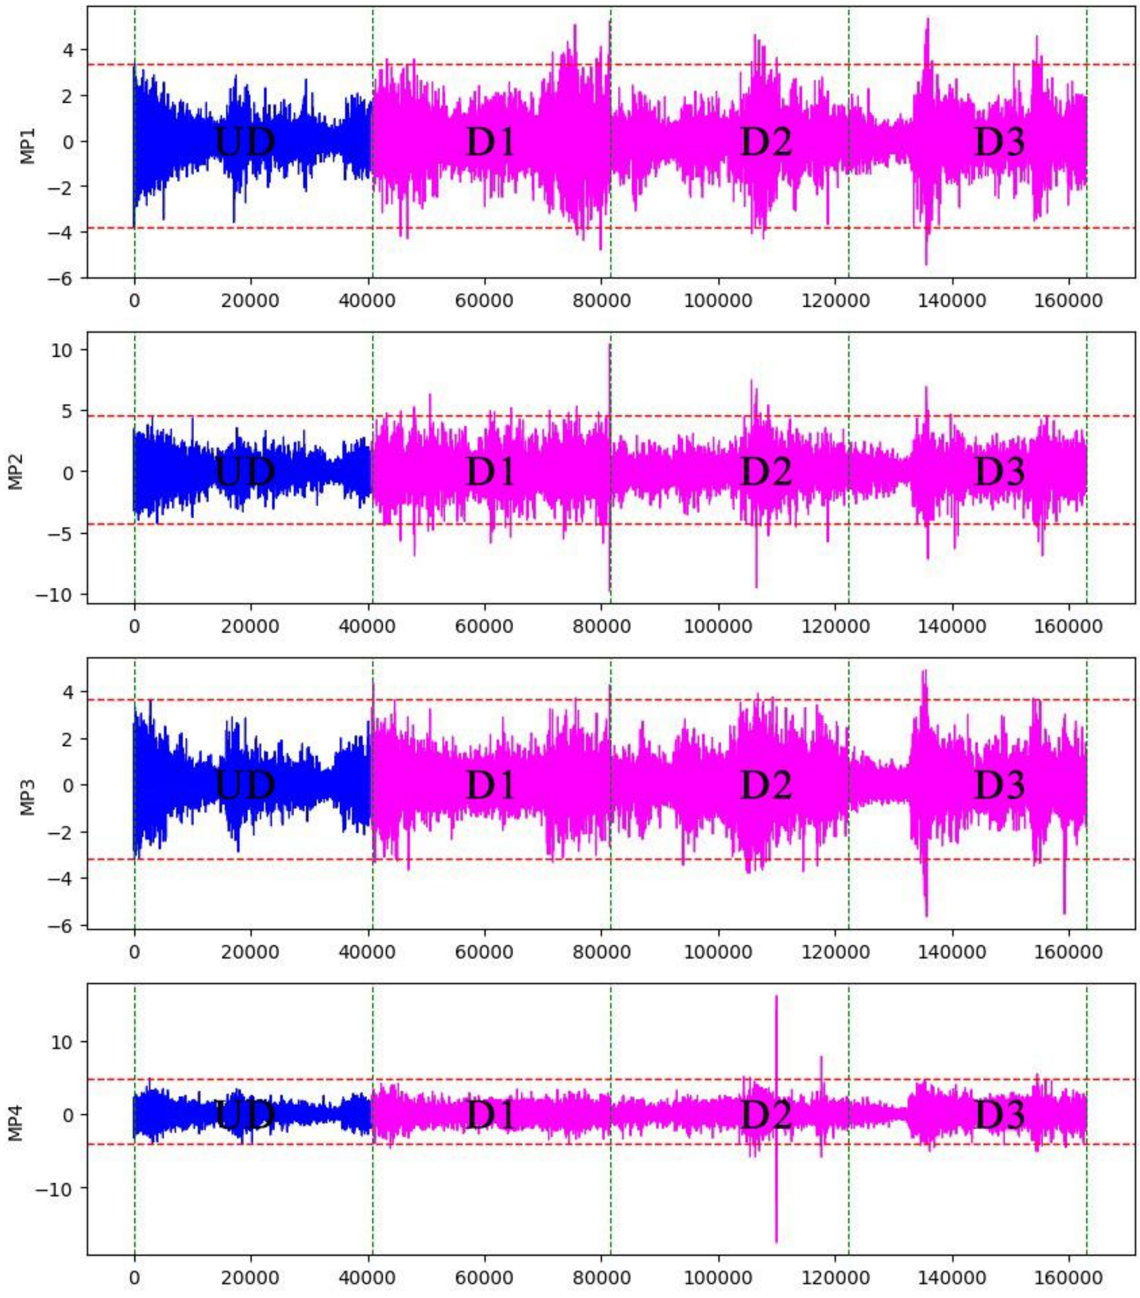

Fig. 14. VAR model features

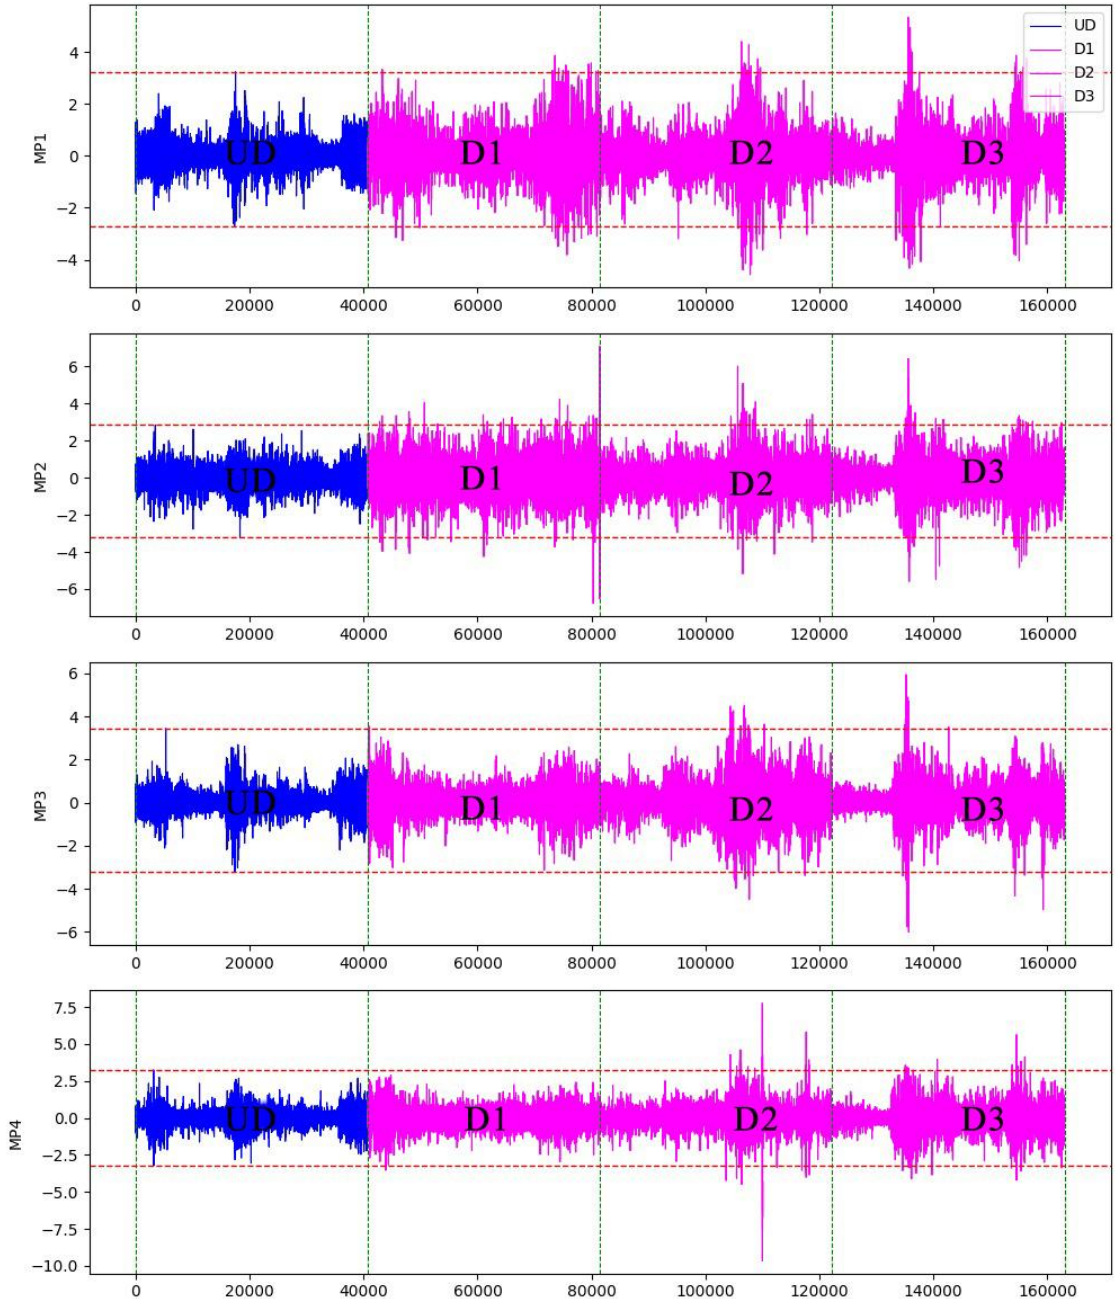

Fig. 15. SVD model features

While all three methods AR, VAR, and SVD performed satisfactorily overall, AR-based features demonstrated superior effectiveness in detecting structural damage. This advantage is clearly illustrated in Fig. 16, particularly for MP3, where the AR model distinctly captured deviation patterns under both D1 and D2 conditions. Fig. 17 further underscores the robustness of the AR model in MP4, as it successfully identified all three damage scenarios (D1, D2, D3) with residuals exceeding the defined thresholds.

The strength of the AR model lies in its reliance on the temporal history of a single measurement point, as described in Eq. (3). This formulation enables the model to establish a highly accurate baseline for each point individually. When applied to damaged data, any deviation from the learned healthy behavior produces pronounced residuals, enhancing its capability to detect localized anomalies.

In contrast, the VAR model defined in Eq. (5) accounts for interactions across multiple measurement points, capturing broader system dynamics. While this multivariate approach is valuable for understanding global behavior, it may reduce sensitivity to localized damage. Similarly, the SVD method reconstructs structural behavior by decomposing vibration signals into dominant oscillatory components and retaining those with the highest energy, as shown in Eq. (8). Although effective in capturing global trends, this method may be less responsive to subtle changes induced by ambient vibrations

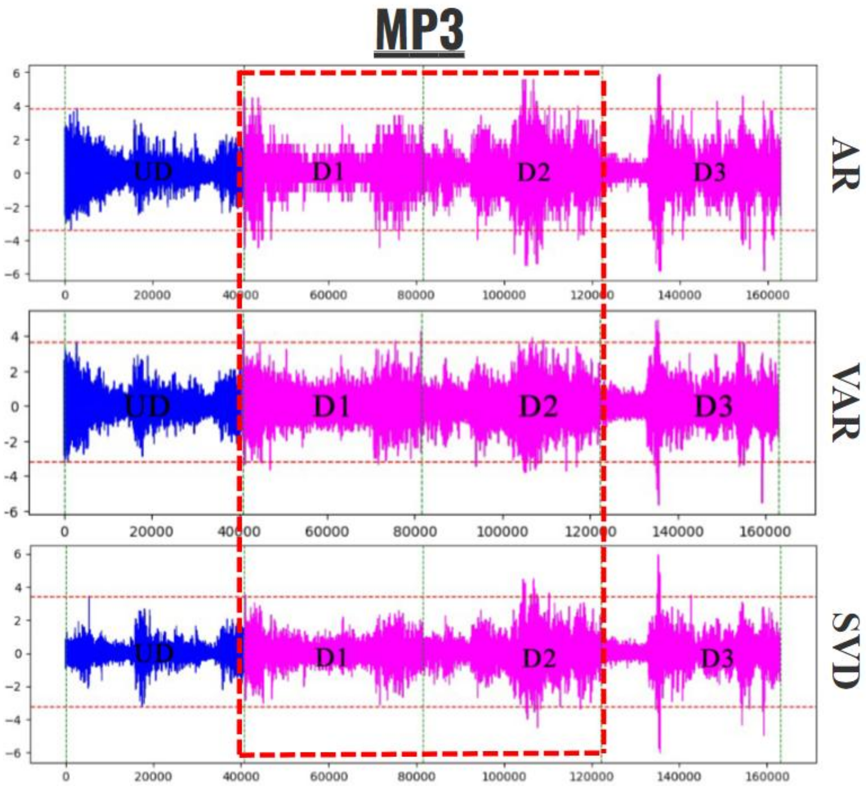

Fig. 16. Comparison of AR, VAR, and SVD Performance
in Damage Detection at MP3

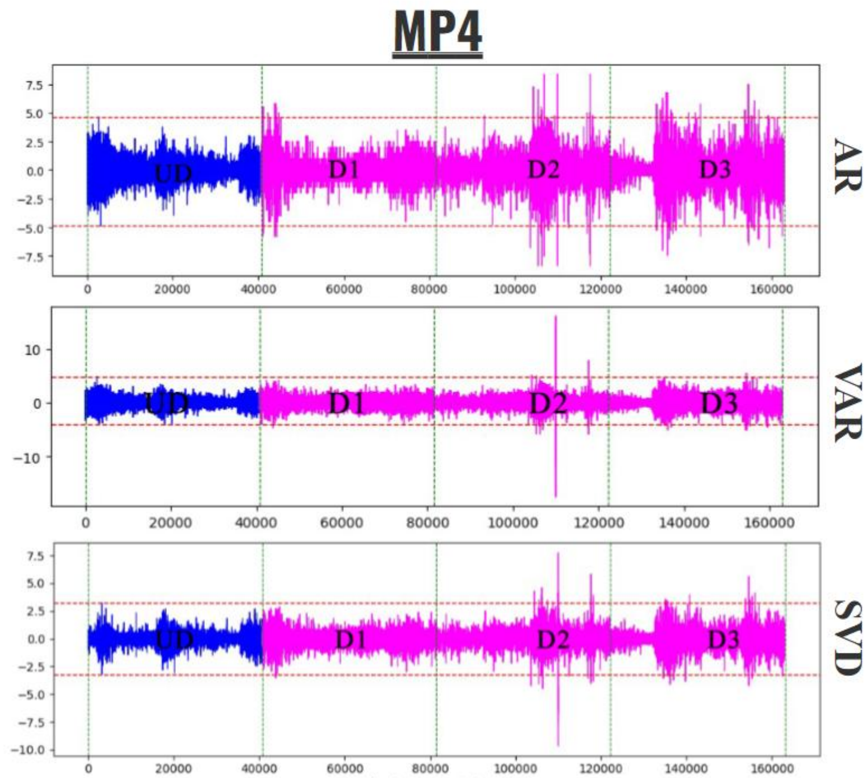

Fig 17. Comparison of AR, VAR, and SVD Performance
in Damage Detection at MP4

The primary goal of SHM is to detect even subtle indications of structural damage at an early stage. By analyzing how residual errors vary between the undamaged (UD) and damaged (D1–D3) states, the proposed model effectively achieves this objective.

Figs 18 to 20 depict the distribution of 16 statistical features (RE1–RE16) extracted from the residuals produced by the AR, VAR, and SVD methods, respectively, as summarized in Table 1. Each data point in these plots represents a specific feature (e.g., maximum, mean, RMS, kurtosis) calculated for a given measurement point (MP). The structural condition is indicated through color coding: blue for D1, green for D2, red for D3, and yellow for UD.

The observed spread and separation in feature values across the different conditions highlight underlying structural differences. Notably, the damaged datasets (D1–D3) exhibit increased variability and outliers in several statistical features, while the UD data remains tightly clustered. This divergence in feature distributions underscores the presence of distinct residual patterns across structural states, offering strong discriminatory potential. Consequently, the model can accurately classify the data into healthy or damaged categories, minimizing the risk of false negatives—i.e., cases where damage might otherwise go undetected.

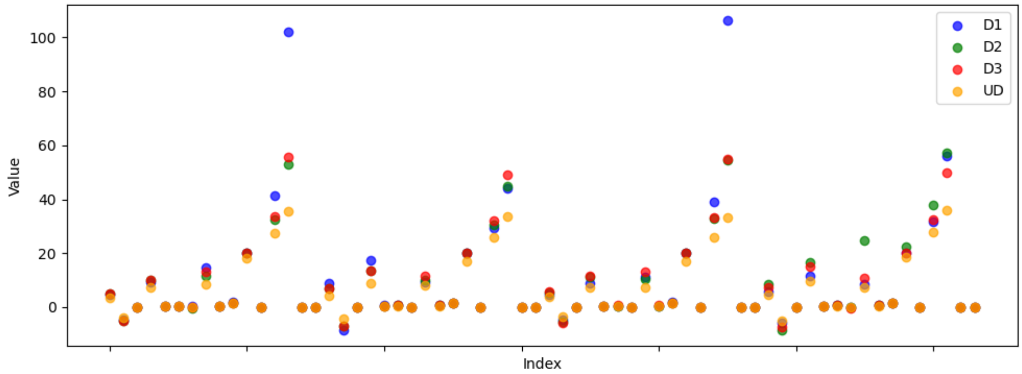

Fig. 18. Distribution of AR statistical features

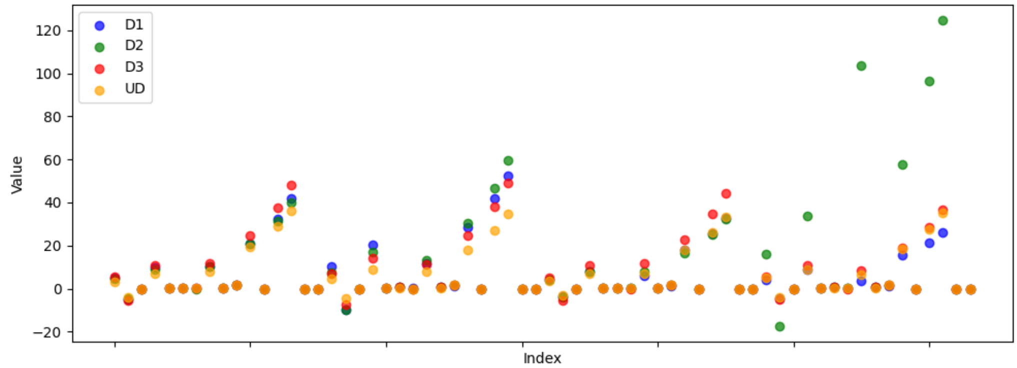

Fig. 19. Distribution of VAR statistical features

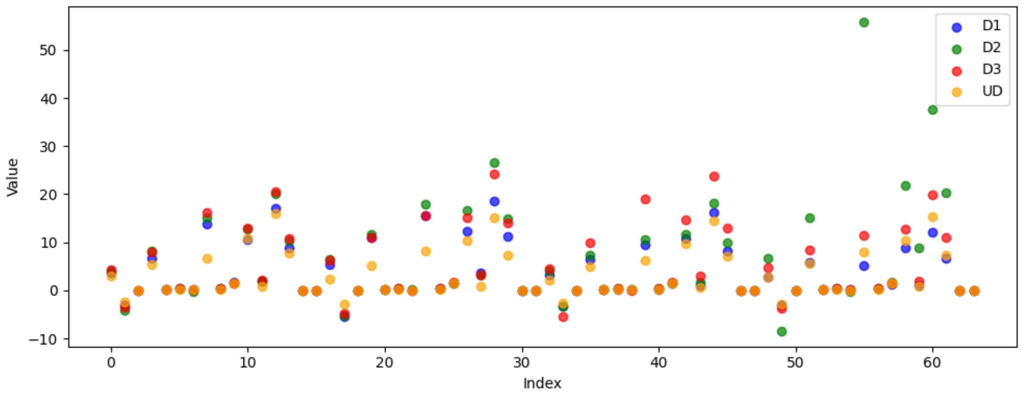

Fig. 20. Distribution of SVD statistical features

Fig. 21 presents the confusion matrix based on the AR-derived statistical features (RE1–RE16). The AR residuals demonstrate excellent overall performance, with no missed damaged cases (i.e., zero false negatives) and an accuracy of approximately 93%. Specifically, 19 undamaged samples are correctly classified, 7 are incorrectly flagged as damaged, and all 77 damaged samples are accurately identified.

Fig. 22 displays the confusion matrix using statistical features extracted from the VAR residuals. Similar to the AR-based results, the VAR model achieves strong performance, with 18 undamaged samples correctly classified, 8 misclassified as damaged, and all 77 damaged samples correctly detected. This results in an overall accuracy of 92%, further confirming the effectiveness of VAR residuals in distinguishing between UD (labeled as 0) and damaged states (labeled as 1).

Fig. 23 shows the confusion matrix for the SVD-based statistical features. The classifier maintains perfect recall by correctly identifying all 77 damaged samples, while also improving classification of the undamaged class: 21 UD samples are correctly labeled, with only 5 false positives. This yields the highest accuracy among the three methods approximately 95%—highlighting the strong classification capability of the SVD-based approach.

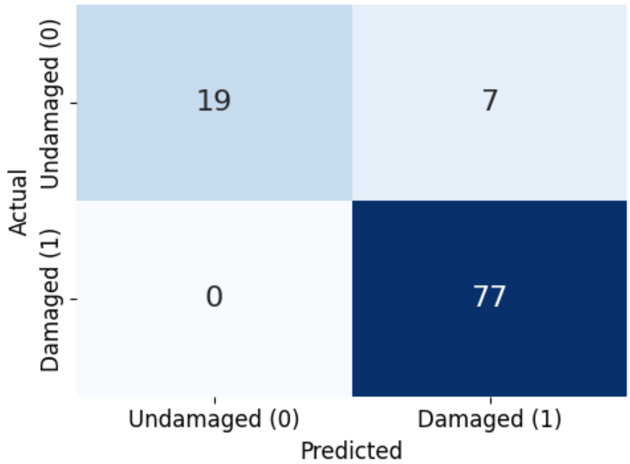

Fig. 21. Confusion matrix for AR residual

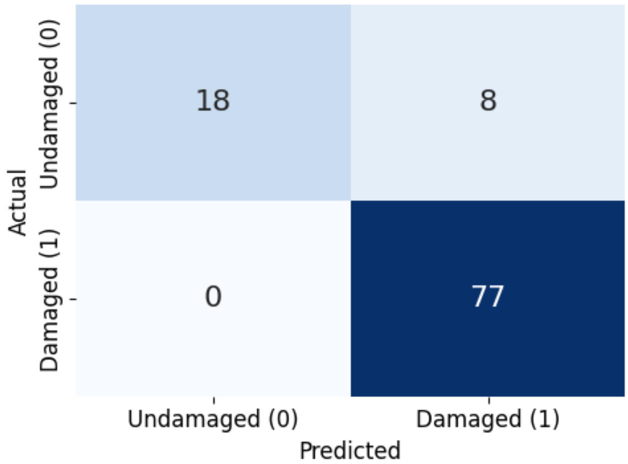

Fig. 22. Confusion matrix for VAR residual

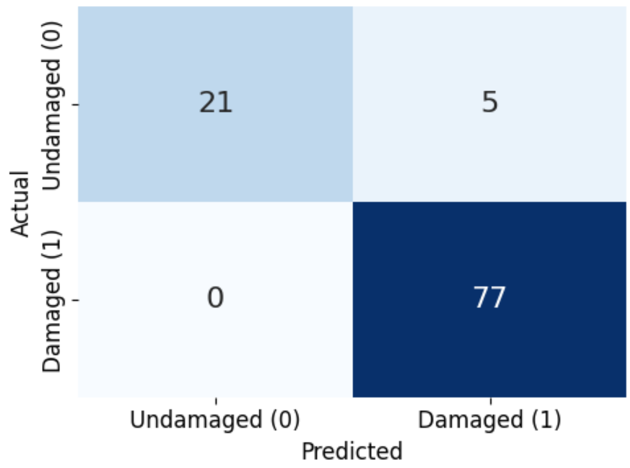

Fig. 23. Confusion matrix for SVD residual

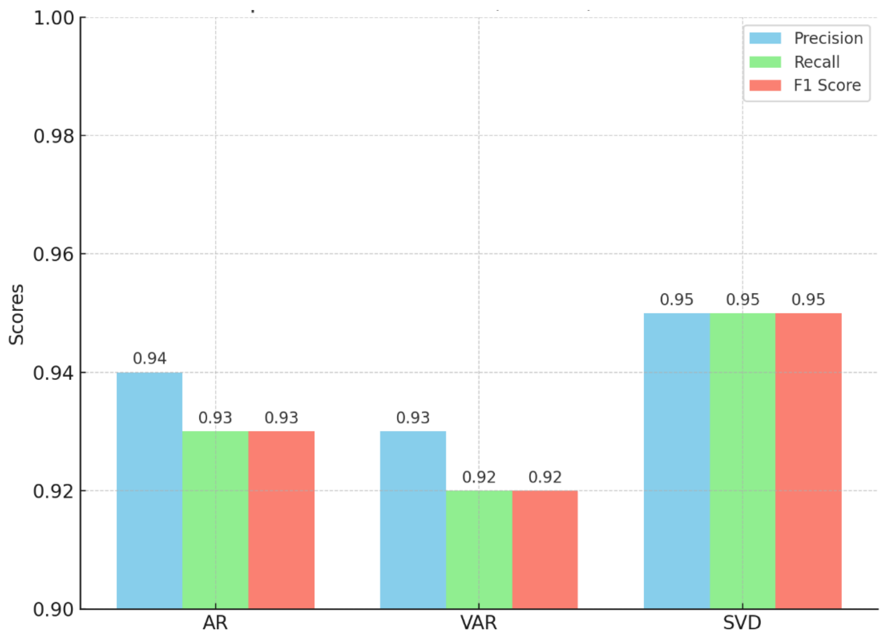

Fig. 24. Performance comparison of precision (Blue), recall (Green), and F1 score (Red) for AR, VAR, and SVD

Despite minor variations in false positive rates, all three methods AR, VAR, and SVD xhibit strong damage detection performance, underscoring the effectiveness of residual error-based classification in distinguishing between healthy and damaged structural states. Notably, the statistical feature distributions shown in Figs 18–20 reveal that SVD provides the most distinct separation across the UD, D1, D2, and D3 conditions. This enhanced separability contributes to superior classification performance, with the SVD-based model achieving 95% precision, recall, and F1-score, as illustrated in Fig. 24.

5.Conclusions

This thesis presents a vision-based Structural Health Monitoring (SHM) framework that integrates high-speed imaging, optical flow analysis, and machine learning to detect damage in a steel frame structure. Displacement time-series data were extracted non-contactly from QR-coded Regions of Interest (ROIs) using the Lucas-Kanade optical flow technique.

A key limitation of the proposed system is its reduced effectiveness under ambient vibration conditions, which introduced noise and made it difficult for VAR and SVD models to capture subtle interactions. This limitation contributed to their lower performance compared to the AR model.

Three main feature extraction techniques—Autoregressive (AR), Vector Autoregressive (VAR), and Singular Value Decomposition (SVD)—were used to generate residual signals, later transformed into 16 statistical features and classified via Support Vector Machine (SVM). The key findings are:

- AR model effectively captured localized temporal deviations with high sensitivity, achieving 93% accuracy. It is particularly suitable for passive monitoring under ambient vibrations due to its responsiveness to subtle signal changes.
- VAR model showed moderate performance under ambient conditions, with a classification accuracy of around 92%. Its dependency on cross-sensor interactions makes it more appropriate for setups involving forced excitation.
- SVD model delivered the best classification results, with a precision, recall, and F1-score of 0.95. It excels in detecting dominant oscillatory patterns but may overlook minor amplitude variations linked to early-stage damage.

These results confirm the potential of the proposed framework for practical SHM applications, offering reliable damage detection

Numerical investigation on the out-of-plane behavior of unreinforced masonry walls with and without opening

Ahmet Yıldırım*[1], Bilge Doran[1], Sema Alacalı[1], Zeynep Ünsal Aslan[2]

[1] Yildiz Technical University, Department of Civil Engineering, 34220 İstanbul, Türkiye
[2] Batman University, Department of Civil Engineering, 72000 Batman, Türkiye

Abstract. Masonry walls are highly vulnerable to out-of-plane (OOP) effects, especially in the case of lateral loadings such as seismic loads. Observations after strong earthquakes show that the main reason for the collapse of masonry walls is the OOP impacts. Therefore, many researchers have investigated to understand and model the actual behavior of masonry walls in this type of loading. This paper aims to examine the behavior of unreinforced masonry walls (URM) with and without openings under OOP loading using the macro-modeling technique. For this purpose, a three-dimensional (3D) nonlinear finite element analysis (NLFEA) was conducted using ANSYS software, utilizing the Extended Drucker-Prager (EDP) plasticity model. The model was validated by comparison with one-way OOP-loaded walls from the literature. The results of the NLFEA exhibited high accuracy in terms of OOP strength capacities and the initial stiffness of the load-displacement relationship. The numerical investigations indicate that the model has the potential to realistically simulate the out-of-plane behavior of URM walls for practical engineering applications.

Keywords: Out-of-plane; Unreinforced masonry wall; Opening; Finite element method; Extended drucker-prager

1. Introduction

Masonry structures, whose most important feature is their simple construction, are among the oldest structural systems in the world (Lourenço, 1996). This type of structure constitutes a high percentage of the building inventory worldwide. For instance, the percentage of unreinforced masonry (URM) buildings among all structures is 93% in Pakistan, 73.2% in Peru, and 52.9% in Australia, based on data from 1998, 2007, and 2000, respectively (Frankie, 2013). A similar situation is observed in Türkiye, where a building census conducted in 2002 revealed that masonry structures accounted for 44.43% of residential buildings and 6.72% of other types, totaling 51.15% of the overall building stock (Özer Ay & Eroğlu Azak, 2021). The masonry building stock highlights the importance of understanding their behavior and developing numerical techniques to simulate it effectively.

In the context of understanding structural behavior, URM walls serve as the primary load-bearing components in buildings. URM walls are particularly vulnerable to earthquake loads due to their nonhomogeneous and complex nature. Despite its critical importance, the out-of-plane (OOP) behavior of URM walls remains less explored. Research on URM walls has predominantly focused on their in-plane performance because it is the main load path in the load transfer mechanism (Noor-E-Khuda et al., 2016); however, there is a limited amount of research available to fully understand the OOP behavior. In this regard, the OOP behavior of URM walls has been investigated both experimentally and numerically by some researchers (Vaculik, 2012; Graziotti, Tomassetti, Sharma, Grottoli, & Magenes, 2019; Messali, Ravenshorst, Esposito, & Rots, 2017). It is vital to highlight that the OOP strength of URM walls with openings, also known as perforated URM walls, decreases when compared to solid walls (Graziotti et al., 2019; Messali et al., 2017; Chong, 1993; Singh & Munjal, 2020; Kahya et al., 2024). Eventually, experiments are necessary to understand the OOP mechanism and also to model the OOP behavior of URM walls (Graziotti et al., 2019). On the other hand, it is highly important to study numerical simulations of the URM walls because the experimental programs are costly and time-consuming (Noor-E-Khuda et al., 2016). Chang, Rots, and Esposito (2022) conducted a numerical study to obtain the two-way bending capacity of unreinforced masonry walls. They used three distinct modeling techniques for the S1 wall (Vaculik, 2012) studied in this paper, namely macro, simplified micro, and micro modeling techniques. They found that the macro-modeling technique is a very computationally cost-effective method to simulate the OOP behavior of the URM walls; to exemplify, it is nearly four times faster than the simplified and micro-modeling techniques, respectively. They have also shown that calibrating the elastic modulus and other related parameters in the numerical model

*Corresponding author, E-mail: ahmet.yildirim@yildiz.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_248

leads to good agreement with experimental results, particularly in estimating the OOP strength and displacement capacity. Noor-E-Khuda et al. (2016) formulated an explicit finite element (EFE) model, which considers masonry as a macro-homogenized material. They also calibrated the EFE macro-model parameters using the trial and error method based on wall test data (Vaculik, 2012) and found that the numerical results were well consistent with the experimental results.

This study aims to examine the OOP behavior of URM walls with and without openings under constant vertical loads and OOP loading, using the NLFEA macro-modeling technique. In this context, the EDP plasticity model was used in ANSYS software (Mechanical APDL Enterprise Academic Research, Release 23.2). The numerical model results were calibrated with the experimental findings of the S1 Solid Wall Test (Vaculik, 2012).

2. Constitutive modeling

In the macro modeling technique, masonry units and mortar are modelled as a single material. In this chapter, the constitutive model and material properties used in the model will be explained in detail.

The Extended Drucker-Prager (EDP) criterion is used as a constitutive model. This criterion was first developed by Drucker and Prager (Drucker & Prager, 1952) as a pressure-dependent 3D model (Alejano & Bobet, 2012) based on a close approximation to the Mohr-Coulomb yield criterion (De Souza Neto & Perić, 2008). The original form of the Drucker-Prager criterion proposed that if the hydrostatic stress, p, and the invariant of the deviatoric stress, $J_2(s)$, take the value of the critical combination, $\bar{c}$, this is the onset of the plastic yielding (De Souza Neto et al., 2008), as expressed:

$$\sqrt{J_2(s)} + \eta p = \bar{c} \tag{1}$$

In the approximation of the Drucker-Prager criterion to the Mohr-Coulomb criterion, the yield function can be expressed as (De Souza Neto et al., 2008):

$$\sqrt{J_2(s(\sigma))} + \eta p(\sigma) - \xi c = 0 \tag{2}$$

Here, c is defined as the cohesion, while the parameters η and ξ can be named as the parameters determined as the necessary approximation of the Drucker-Prager to the Mohr-Coulomb criterion (De Souza Neto et al., 2008). In the analysis of solid materials like concrete and, as in this study, masonry, it is convenient to use the biaxial fit approximation of the Drucker-Prager to the Mohr-Coulomb criterion in the principal stress axis, as seen in Fig. 1. This is because masonry exhibits a very high compressive-to-tensile strength ratio, and using the uniaxial fit can significantly overestimate the OOP strength or the limit load (De Souza Neto et al., 2008). The biaxial fit parameters η and ξ can be defined as (De Souza Neto et al., 2008):

$$\eta = \frac{3sin\phi}{2\sqrt{3}} \tag{3}$$

$$\xi = \frac{2cos\phi}{\sqrt{3}} \tag{4}$$

According to Ansys® Material Reference Guide, the EDP criterion is an extension of the linear Drucker-Prager yield criterion, allowing the definition of both yield surface and the flow potential as linear, hyperbolic, or power law independently, and thus results in either an associated or nonassociated flow rule. The EDP linear yield criterion form in the ANSYS Software could be defined as (Release 25.1):

$$f(\sigma, \sigma_y) = \sigma_e + \alpha \frac{1}{3} tr(\sigma) - \sigma_y = 0 \tag{5}$$

The α and σ_y parameters in Eq. (5) correspond to the properties of “pressure sensitivity” and “uniaxial yield stress”, respectively. These two parameters can be expressed as in Eqs. (8) and (9) after defining the Eqs. (6) and (7) (De Souza Neto et al., 2008; Ansys® Material Reference Guide):

$$\sigma_e = \sqrt{3J_2(s)} \tag{6}$$

$$\frac{1}{3} tr(\sigma) = p(\sigma) \tag{7}$$

$$\alpha = \eta\sqrt{3} \tag{8}$$

$$\sigma_y = \xi c\sqrt{3} \tag{9}$$

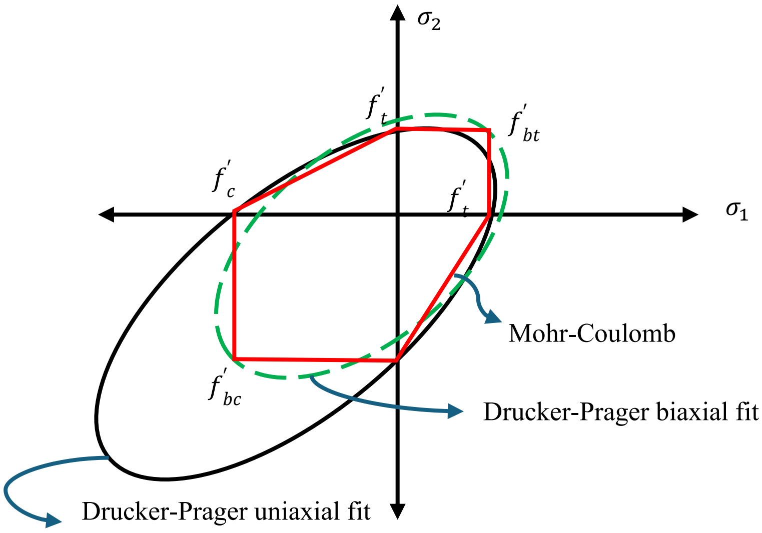

Fig. 1. EDP biaxial fit used in the model (De Souza Neto et al., 2008)

To determine the parameters α and σ_y according to Eqs. (8) and (9), ϕ and c must be known to determine η and ξ parameters given in Eqs. (3) and (4), respectively. Then, the following equations are used to define ϕ and c using compressive strength (f_c) and tensile strength (f_t) of the masonry (De Souza Neto et al., 2008):

$$\phi = sin^{-1}\left(\frac{f_c - f_t}{f_c + f_t}\right) \tag{10}$$

$$c = \frac{f_c f_t}{f_c - f_t} tan\phi \tag{11}$$

Eventually, the parameters α and σ_y can be expressed based on Eqs. (12) and (13) as follows:

$$\alpha = \frac{3sin\phi}{2} \tag{12}$$

$$\sigma_y = 2ccos\phi \tag{13}$$

Moreover, it should also be noted here that the plastic flow potentials are defined by the plasticity model as associative instead of non-associative for the sake of simplicity. The evolution of plastic strain is controlled by the flow rules: When the associative flow is used, plastic strain increases proportionally to the stress increment of the material (Ansys® Material Reference Guide). Obviously, this results in dilation (expansion) of the volume of the material with plastic deformations. In the space of stresses, the plastic strain rate is normal to the yield surface when an associative flow model is used (De Souza Neto et al., 2008). To define the plasticity model as associative in ANSYS Software, associativity is selected as the linear form (Ansys® Material Reference Guide):

$$Q(\sigma, \sigma_y) = \sigma_e + \bar{\alpha}\frac{1}{3}tr(\sigma) \tag{14}$$

The parameter $\bar{\alpha}$, defined as flow potential pressure sensitivity, was taken equal to α as defined in Eq. (12) in order to realize associative flow.

After the constituting material model, the study was conducted to calibrate the elastic and plastic parameters in the S1 wall. The calibration process for the material properties of the model is executed using four key parameters: Elastic Modulus, Poisson's ratio, compressive strength (f_c), and tensile strength (f_t). The value of compressive strength is taken from the experiment (Vaculik, 2012) as 17.6 MPa. Poisson's ratio is assumed as 0.2, generally preferred in the masonry materials (Graziotti et al., 2019; Noor-E-Khuda et al., 2016; Singh et al., 2020). The Elastic Modulus is calibrated to reflect the experimental behavior of the wall accurately; specifically, it is selected as a value of 7000 MPa, as reported in the literature (Chang et al., 2022). The tensile strength is established at 0.15 MPa with the trial-and-error method, reflecting the low tensile capacity typically associated with masonry materials. Table 1 shows the summary of the material parameters used in this study.

Table 1. Material parameters

Elastic Parameters	Modulus of Elasticity (MPa)	Poisson's Ratio	Compressive Strength (MPa)	Tensile Strength (MPa)
	7000	0.2	17.6	0.15
Plastic Parameters	Pressure Sensitivity	Uniaxial Yield Stress (MPa)	Flow Potential Pressure Sensitivity	
	1.4746	0.2975	1.4746	

3. Numerical simulation

The increasing emphasis on preserving historic structures and buildings has increased the need for advanced numerical methods for structural analysis (Koksal et al., 2016). The main objective in numerical analysis is to simulate the actual behavior of structural elements using computerized methods. One of them is the finite element (FE) method, which discretizes structural parts into smaller finite elements with certain properties like degree of freedom and shape to create a mathematical model. FE analysis for masonry is generally achieved by the macro-modeling approach, in which masonry is taken as a homogenous continuum. The reason for using the macro-modeling technique is the efficiency, computational cost, and analysis time (Doran, Karslioglu, Unsal Aslan, & Vatansever, 2023).

In the numerical simulation, the model is constructed utilizing the experimental data presented by Vaculik (Vaculik, 2012). The analysis focuses on the solid S1 and S3 walls with a window opening, initially subjected to a precompression of 0.1 MPa. Upon the complete application of this load, a unidirectional lateral pressure to the main wall is imposed via airbags, inducing compression in the return walls. This one-way loading test is designed to evaluate the ultimate load-bearing capacity of the wall.

For numerical model calibration, the EDP model was used to accurately capture the nonlinear behavior of the wall in the finite element analysis software ANSYS Mechanical APDL. The boundary conditions, mesh, and the exerted loads are shown in Fig. 2. It is highly important to mention that SOLID186, a 3D 20-node solid element, is used as a finite element type (Ansys® Element Reference Guide, Release 25.1). The mesh size of 55 mm is selected after a sensitivity analysis by considering accuracy and efficiency. The boundary conditions were selected so that the sides of the walls behave like fixed supports (F), the upper and lower parts of the wall are simply supported (SS), and the base is supported vertically. These boundary conditions are also illustrated in the bottom-right sections of Figs. 3 and 4, adapted from the literature (Vaculik, 2012). The dimensions are in “mm” in these Figs.

The pre-compression load of 0.1 MPa is applied during the first time step over both the return walls and the main wall, as shown in Fig. 2. It should be noted that, there is a window opening at the middle left for the S3 wall, shown in the bottom-right section of Fig. 4. In the second time step, the OOP pressure load is applied uniformly and monotonically to push the main face of the wall to simulate the airbag pressure load.

It is noteworthy to mention that nonlinearity in the model is introduced through the material scale, and geometric nonlinearity is not considered within the model framework. It should also be noted that including geometric nonlinearity and prestress effects can lead to a reduction in OOP strength by approximately 1% to 5%. However, this effect is often considered negligible in the macro-modeling of such structures, allowing for simplification of the analysis. The experimental data were evaluated by examining the relationship between the applied pressure and the midpoint displacement of the wall (Vaculik, 2012). The total OOP support force versus the maximum OOP displacement of the midpoint graph was obtained. The total OOP support force is calculated by the applied pressure times the area of the wall, and the OOP displacement of the midpoint is taken as given in the literature (Vaculik, 2012). Then, the results of the numerical model are compared with the experimental results. The displacement is limited to approximately 16 mm, considering near-collapse conditions (Beyer, Araya, & Saloustros, 2022).

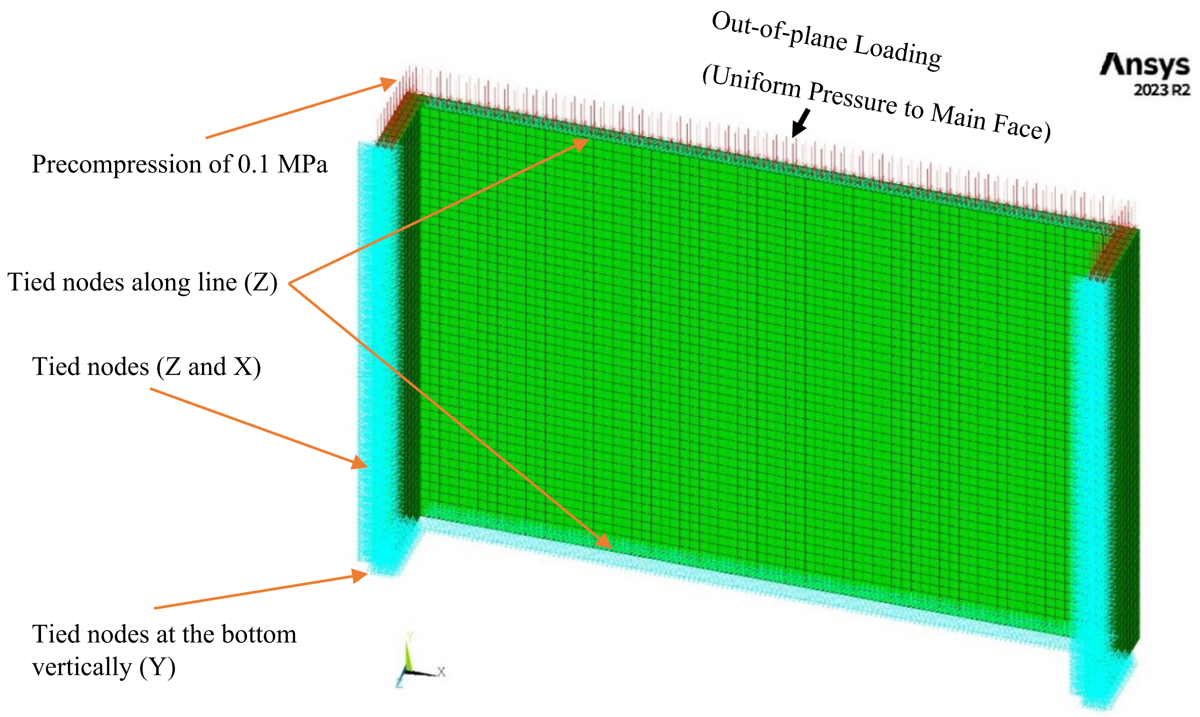

Fig. 2. FE mesh with boundary and loading conditions

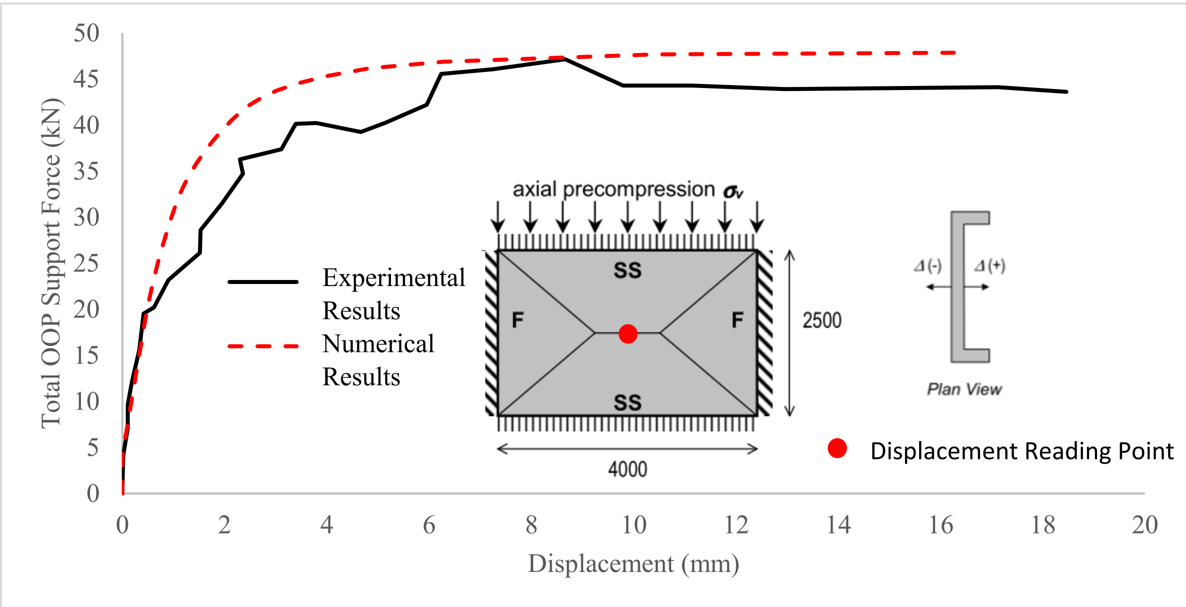

Fig. 3. Out-of-plane load – displacement response of S1 wall

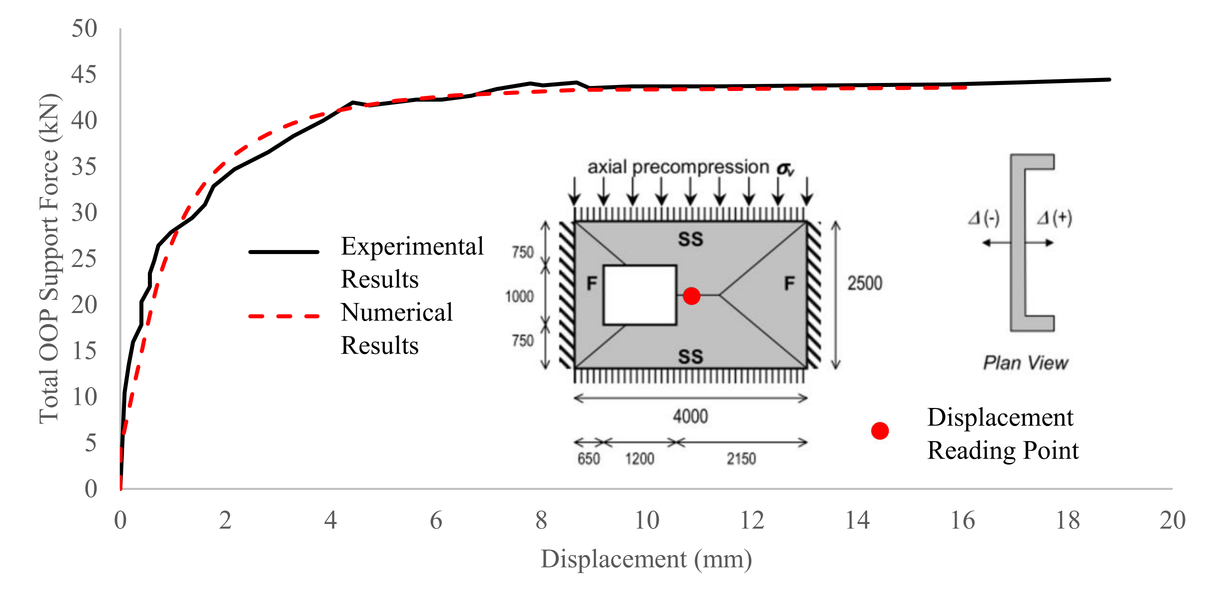

Fig. 4. Out-of-plane load – displacement response of S3 wall

Table 2. Comparison of model and experimental results

		S1 Wall	S3 Wall
OOP Strength (kN)	Experiment	47.14	44.12
	Model	47.85	43.57

It can be seen from the numerical results and Table 2 that the model proposed in this study accurately captures the OOP strength of the walls and initial stiffness to some degree. In Table 2, it is clear that the OOP strength decreases when an opening exists in the solid wall, as expected. In Figs. 3 and 4, OOP responses of the experimental results and numerical results also demonstrate a strong correlation with the overall load-displacement relation.

Finally, it is important to mention computational cost, which can be defined as the total amount of time required for an analysis. Maximum analysis time can be mentioned as 20 minutes for an analysis studied in this paper with the processor of the employed desktop of Intel(R) Core(TM) i5-10400 CPU @ 2.90GHz. This suggests that the numerical strategy is computationally efficient when compared to other studies, for instance, Chang et al. (2022).

4. Conclusions

Masonry structures, maintaining their existence from the beginning of humanity, will continue to play a significant role in our built environment. The efforts to understand the behavior of these structures are highly important to ensure their presence for both historic and new buildings. Based on the evaluations conducted on solid walls and those with openings, using a macro-modeling approach and the EDP criterion, the following conclusions can be drawn:

- The proposed macro-modeling strategy provides a computationally efficient alternative by requiring few parameters and less computational cost for capturing the nonlinear behavior of masonry walls under out-of-plane loading.
- Sensitivity to material parameters, such as compressive and tensile strength, was observed to significantly influence the predicted capacity, highlighting the importance of accurate material calibration.
- The inclusion of an opening in URM walls was found to reduce their OOP strength when compared to solid walls.
- The initial stiffness of the wall could be correctly determined with the calibration of the elasticity modulus while still in line with the overall load-displacement response.

Abstract. Earthquakes are one of the most significant natural disasters that cause ground shaking and challenge the durability and rigidity capacities of structures. Particularly, high-magnitude earthquakes can lead to the collapse of poorly engineered or substandard structures, resulting in substantial loss of life and property. To minimize such devastating effects, earthquake-resistant building design is important. One of the significant structural elements used in the earthquake resistance of structures is basement walls. These walls increase the lateral stiffness and strength of structures, limit the inter-story drifts and reduce the torsional effects. In this study, the effects of different basement wall configurations on seismic performance of structures were investigated. For this purpose, four different building models were generated with SAP2000 software for numerical analyses. The first model represents a regular system with basement walls at all four sides of the building. In the second model there are basement walls at three sides of the building, while third one includes at two sides. In the fourth model, a single basement wall was present. The January 24, 2020 Elazığ earthquake (Mw: 6.8) was used in time history analyses. As a result of the dynamic analyses, it was revealed that the placement of basement walls significantly affects the behavior of buildings during earthquakes.

Keywords: Reinfoced concrete buildings; Basement wall; Dynamic analysis

1. Introduction

Earthquakes have caused significant loss of life and demonstrated that the design and construction of the building are among the most critical issues. Especially last earthqauekes occurred in Pazarcık-Kahramanmaraş (M_w=7.8) and Elbistan-Kahramanmaraş (M_w=7.5) have exhibited that the design of reinforced concrete (RC) buildings, which constitute the majority of the building stock, is of critical importance in terms of both reducing loss of life and preventing damage (İnce, 2024; Özmen et al., 2024). Understanding the specific damage mechanisms and the factors that influence the response of RC buildings to seismic loads is essential for improving their resilience. The seismic behavior of the RC structures is strengthened by using the structural elements that have more shear force capacity, especially for the basement level. Although the basement walls provide a significant advantages for the RC buildings, the unusual deisgn and different location configuration of these structural elements may cause negative effects under earthquake loading.

The behavior of the RC basement walls was investigated in the literature based on several parameters that effective on the buildings that are designed with basement walls. The number of stories that constructed with basement walls was investigated for 7, 20, and 40 floor RC buildings in 2018 (Kılıç Erdim, 2018). In the study, the basement wall stories was changed by 3, 5, and 7 floor for the building models and compared with the buildings that has no basement walls. The behavior, stiffness and period of the building was investigated. By increasing the stiffness, the period of the building with basement walls decreases between 6% and 25% depending on the building floor plans. In the low-rise frame building, the base shear forces of buildings with basement walls increased by 1%-16%, and the base shear forces of high-rise rigid buildings increased by 1%-13% compared to the base shear forces of buildings with non-basement wall buildings. Gökçeoğlu investigated the nonlinear behavior of a 26-storey RC building based on the Türkiye Building Earthquake Code 2018 (TBEC 2018) considering basement wall placement (Gökçeoğlu, 2020). Performance criterias were determined with the approaches specified in TBDY 2018, and the Collapse Prevention criteria level was achieved. Perform3D software was used for nonlinear analyses. The RC structural elements were modeled by taking into account of nonlinear behavior of the elements. In the study, the design of the building was changed; a shear wall was added to one axis of the building, the height

*Corresponding author, E-mail: burakk.cakill@gmail.com

https://doi.org/10.31462/icearc2025_ce_sme_258

golden light publishing

was changed, and the design method was re-evaluated. The effects of the changes were investigated by comparing the new design with the previous design. Based on the results of the study, no significant base shear force or amount of reinforcement differences are observed throughout the buildings. The reason for this situation can be explained by a lot of reinforced concrete shear walls in the second building and the limited number of shear walls added to the first designed building. Öztemel et al. were analysed the building models with and without basement walls in order to investigate the effects of the placement of shear walls in the plan on the structural behavior in RC buildings (Öztemel et al. 2022). 6 numerical models with different shear wall placements were produced with the İdeCad software. In the analyses, parameters such as vibration period, base shear force, horizontal displacement, torsion coefficient, relative story drift and cost were evaluated. As a result, it was determined that the earthquake effects were decrased in the model where the basement floor was completely surrounded by shear walls, but the cost increased, and that the use of additional shear walls was required in the model that designed with only RC frame system. Özcan was compared the 9-story two type of RC building with and without basement wall by using ETABS software (Özcan, 2024). The comparisons were achieved for two different solution method by considering the base shear forces, maximum floor displacements, irregularities available in TBEC 2018, and relative floor displacements.

In this study, the effects of different basement wall configurations on structural seismic behavior of the buildings was investigated. Four different building model was constituted in SAP2000 software for the time-history analyses. The basement walls was located on all around the building basement, third side, two adjesent side, and only single side of the basement for the 1st , 2nd , 3rd and the 4th building models respectively. Elazığ 2020 earthquake record was applied to the buildings for x, y, and the z directions. the comparisons was achieved in terms of story displacements, rotation angle, angular velocity, and angular acceleration values.

2. Materials and methods

In this study, four different structural models were generated to investigate the effects of RC basement walls, on the structural dynamics of RC buildings. The buildings consist of a basement, a ground storey, and four typical storey (B+G+4), with identical cross-sectional properties for all structural elements.

- **Model 1**: The basement is entirely enclosed by RC walls.
- **Model 2**: The basement has RC walls on three sides.
- **Model 3**: The basement has RC walls on two sides.
- **Model 4**: The basement has an RC wall on only one side.

The basement storey plans and the corresponding three-dimensional structural models are presented in Fig. 1–4.

(a) (b)

Fig. 4. Model 4 (a) Basement storey plan (cm) (b) Three-dimensional finite element model

In the design of the RC buildings, C25/30 concrete grade and B420C reinforcing steel were considered. The columns were designed with cross-sections of 50×50 cm, while the beams had cross-sections of 30×50 cm. The analyses accounted for the effective section stiffness of the structural elements. To improve the realistic representation of the basement, spring stiffness values derived from the subgrade modulus were incorporated into the foundation system. The subgrade modulus was assumed to be approximately 17000 kN/m³, corresponding to an average foundation excavation on ZD-type soil in Elazığ. Based on this value, the spring stiffness was calculated as 1050 kN/m and integrated into the model. The spring elements are illustrated in Fig. 5.

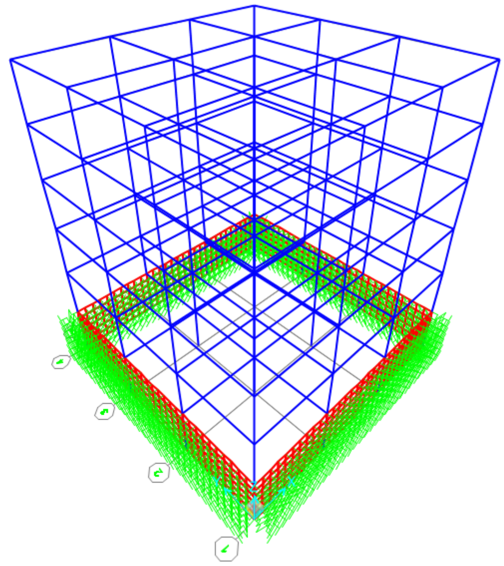

Fig. 5. Ground spring model

To investigate the seismic behavior of the buildings, linear time-history analysis was performed. In this study, the buildings were assumed to be located in Elazığ, and accordingly, the original ground motion records from the 24 January 2020 Elazığ Earthquake (Mw 6.8) were used. The earthquake data were obtained from AFAD's Station No. 2308 [AFAD]. The acceleration-time histories of the earthquake in the East-West (E-W), North-South (N-S), and Up directions are presented in Fig. 6–8, respectively. The seismic records were applied to the structure as follows: E-W component in the x-direction, N-S component in the y-direction, and Up component in the z-direction for the analyses. As a result of the analysis, the displacement values of the structures in the x, y and z directions as well as the rotation angle, angular velocity and angular acceleration values in the z direction were examined.

3. Results and discussion

This section presents and discusses the results of the analyses conducted to evaluate the effect of basement walls on the torsional behavior of the structure. The assessment is based on displacement, rotation angle, angular velocity, and angular acceleration values obtained at different storey levels for the four structural models with varying basement wall configurations. According to the analysis results, displacement values in the x, y, and z directions are presented in Table 1, Table 2, and Table 3, respectively. The results indicate that displacements in the x and y directions increase significantly as the number of basement walls decreases (Fig. 9–10). In Model 1, where the structure is fully enclosed by basement walls, the lowest displacement values are observed. In contrast, Model 4, with only one basement wall, exhibits notably higher displacements, particularly at the upper storey levels. For instance, at the fourth storey, the displacement in the x direction increases from 0.1397 m in Model 1 to 0.2024 m in Model 4. Similarly, displacements in the y direction also show a clear increase from Model 1 to Model 4. This finding highlights the significant contribution of basement walls to the overall stiffness of the structural system. However, when examining the displacement values in the z direction, the variation appears to be quite limited (Fig. 11). While there is no significant difference between Model 1 and Model 2, slight increases are observed in Models 3 and 4. This suggests that as stiffness decreases from the ground level upward, greater movement occurs in the upper stories.

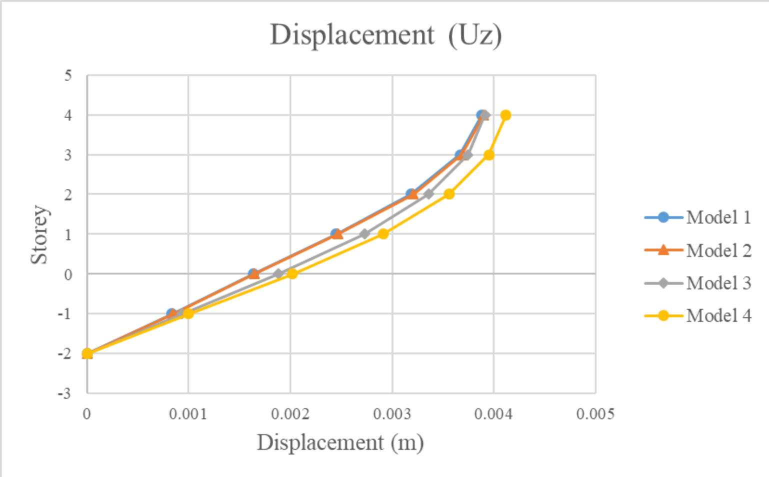

Fig. 11. Storey-displacement graph in z direction

When examining the rotation angle values calculated in the z direction, it is observed that the torsional effect increases as the number of basement walls decreases (Table 4, Fig. 12). For instance, at the fourth storey, the rotation angle in Model 1 is 0.0000079 rad, whereas in Model 4, this value increases to 0.0112 rad. This indicates that the reduction in basement walls leads to a decrease in structural stiffness, resulting in an increased torsional effect at storey levels.

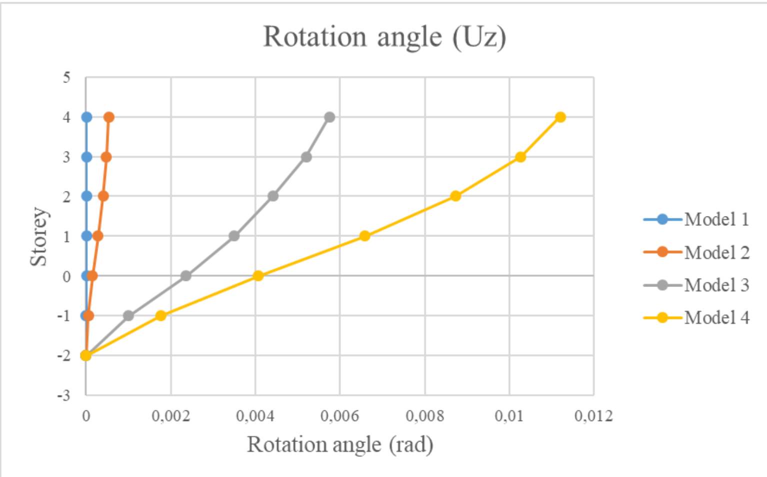

Fig. 12. Storey-rotation angle graph in the z direction

Table 4. Results of rotation angle in z direction

Storey level	Rotation angle (rad)			
	Model 1	Model 2	Model 3	Model 4
Foundation (-2)	0	0	0	0
Basement (-1)	0.000000053	0.000052	0.001008	0.001762
Ground (0)	0.000007072	0.000156	0.00236	0.004066
1. Storey (1)	0.000011	0.000287	0.003499	0.006588
2. Storey (2)	0.000009391	0.000399	0.004407	0.00872
3. Storey (3)	0.000005955	0.00048	0.005198	0.010268
4. Storey (4)	0.000007946	0.000532	0.00575	0.011199

The angular velocity results exhibit a similar trend. While the angular velocity values remain low in Models 1 and 2, a significant increase is observed in Model 3, and especially in Model 4, due to torsional effects (Table 5, Fig. 13). For instance, at the fourth storey, the angular velocity increases from 0.000165 rad/s in Model 1 to 0.083 rad/s in Model 4.

Table 5. Angular velocity results in the z direction

Storey level	Angular velocity (rad/s)			
	Model 1	Model 2	Model 3	Model 4
Foundation (-2)	0	0	0	0
Basement (-1)	0.000002218	0.0004409	0.00727	0.012

4. Storey (4)	0.0001652	0.004367	0.044	0.083

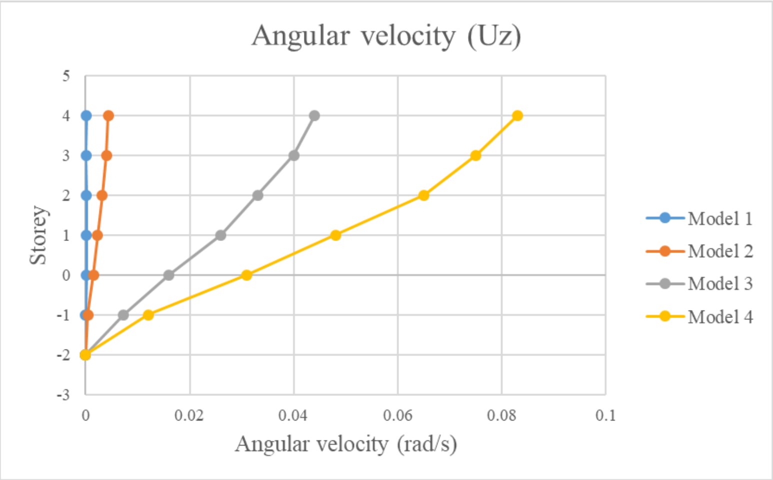

Fig. 13. Storey-angular velocity graph in the z direction

A similar trend is observed in the angular acceleration values, with the highest values recorded in Model 4 (Table 6, Fig. 14). For instance, at the fourth storey, the angular acceleration increases from 0.0049 rad/s² in Model 1 to 0.704 rad/s² in Model 4.

Table 6. Angular acceleration results in the z direction

Storey level	Angular acceleration (rad/s^2)

4. Storey (4)	0.004909	0.045	0.385	0.704

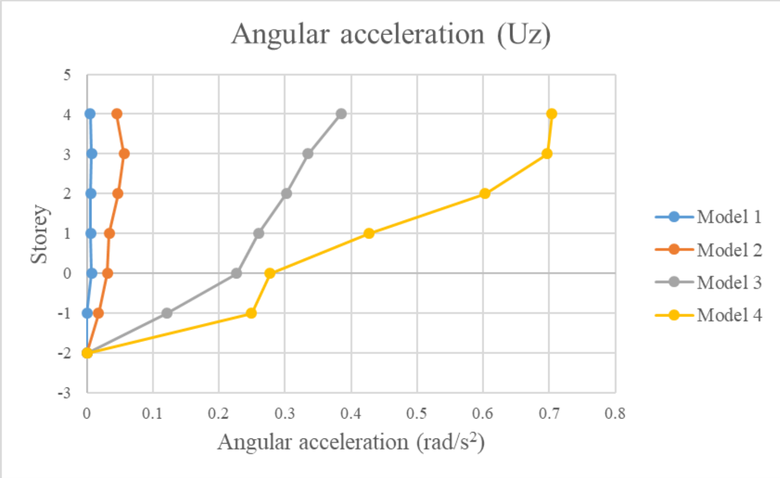

Fig. 14. Storey-angular acceleration graph in the z direction

4. Conclusions

The analysis results indicate that basement walls directly influence the structural rigidity and significantly reduce torsional effects. Model 1, which includes basement walls on all four sides, exhibits the lowest displacement, rotation angle, and angular velocity values. In contrast, Model 4, with only one basement wall, shows the highest values for these parameters.

Based on these findings, it is concluded that basement walls play a critical role in the torsional rigidity of a structure, and the absence of such walls negatively impacts structural performance. In particular, for buildings with irregular basement walls, it is recommended to implement stiffness-enhancing measures to mitigate torsional effects. Additionally, the obtained results support the definitions related to A3 irregularity in the TBEC 2018.

In summary, the lack of basement walls increases torsional effects at storey levels, adversely affecting the seismic performance of the building. Therefore, the inclusion of basement walls should be carefully considered, especially in the design of structures susceptible to high torsional effects. Furthermore, it is recommended that the performance of structures exhibiting torsional irregularities be analyzed in greater detail and, if necessary, that stiffness-enhancing measures be implemented.

Abstract. This study estimated the first frequency values of masonry stone arches subjected to high-temperature effects by classical regression analysis (CRA). Within the scope of the study, 450 heat transfer and 5850 modal analysis results of masonry stone arches with different dimensions and temperature histories were used. The first mode frequencies of the arch members were obtained with 6300 finite element analysis. Then, the first mode frequencies of the arch members were estimated by CRA using the geometrical parameters of the arch member (span, height, width, thickness) and the temperature history condition (0, 15, 30, 45, 60, 75, 90, 105, 120, 135, 150, 165, 180 min) to which the arch members were exposed. In the CRA method, four different functions, namely linear function (LF), power function (PF), exponential function (EF), and quadratic function (QF), were applied, and the coefficients of these functions were calculated. While developing the prediction models, %70 of the data was used for training and the remaining %30 for testing the models. Various performance statistics (square root of mean squared error, mean absolute error, scatter index, and Nash Sutcliffe (NS) efficiency coefficient) were used to evaluate the prediction performance of the developed models. The NS performances of the models developed using LF, PF, EF, and QF functions in the CRA method are calculated as 0.448, 0.923, 0.975, and 0.772 for the training data set and 0.449, 0.922, 0.975, and 0.722 for the test data set, respectively. When the performance statistics obtained are compared, it is seen that the most successful prediction results are obtained from EF. The performance statistics obtained from the modeling studies showed that the first mode frequency values of masonry stone arches with different dimensions and temperature histories could quickly be predicted with high performance, with less model and cost.

Keywords: Masonry stone arch; Heat transfer analysis; Modal analysis; Classical regression analysis

1. Introduction

It is seen that arch elements are used in many buildings (mosques, bridges, churches, water channels, etc.), especially in historical buildings. Arches are curved structural elements that transfer the loads onto the load-bearing vertical elements and allow the openings between these elements to be passed (Morgan, 1970). These arches, mainly used in the structural system of historical masonry structures, are used to transform small volumes into a more extensive form and pass large openings.

During their service life, structural damages may occur in arches that may be exposed to different dynamic effects (earthquake, wind, fire, explosion, traffic load, etc.). These damages can be determined by analyzing the changes in the element's dynamic characteristics (natural frequency, mode shape, and damping ratio) or stiffness. Experimental and numerical methods can be used to obtain dynamic characteristics (Bovo et al., 2015; Albuerne et al., 2019; Altunışık et al., 2024). Altunışık et al. (2024) in their study, investigated the changes in the dynamic behavior of masonry stone arches subjected to high-temperature effects using experimental and numerical methods. Within the scope of the study, finite element models were used to determine the dynamic characteristics of arch models with different spans, heights, widths, and thicknesses for different temperature history conditions. Subsequently, formulations and graphs/plots based on these results were obtained.

In recent years, it has been seen that many modeling-based studies have been carried out to solve engineering problems with the developing computer technology (Deifalla, 2021; Cho et al., 2022; Saxena et al., 2024). When the studies in the literature are examined, it is seen that the frequency and mode shape parameters of masonry structures can be estimated using different methods Diaferio et al., 2018; Onat, 2020). Moser & Moaveni (2011),

* Corresponding author, E-mail: mmustafa.ozturk@gop.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_278

investigated the effect of environmental factors such as temperature, humidity, and vibration amplitude on dynamic modal parameters using the results of a continuous monitoring system installed on the Dowling Hall Pedestrian Bridge at Tufts University. In the study, a significant variability in the natural frequencies of the bridge was observed, and these changes were found to be strongly related to temperature. Several non-linear models were proposed to model the relationship between natural frequencies and temperature. The final model was validated with independent data sets, and confidence intervals were estimated for natural frequencies as a function of temperature. Serhatoğlu & Livaoğlu (2019) in their study, investigated the dynamic and structural properties of eighteen Ottoman minarets in Bursa using experimental and numerical techniques. They developed empirical formula to estimate the initial periods of historical Ottoman minarets. They stated that the obtained formulae can be used as a practical and valuable method for determining the first periods of historical minarets.

Although masonry structures have survived to the present day by showing resistance against various disasters throughout history, most of them have been damaged or destroyed due to earthquakes, fires, wars, and environmental impacts. The behavior of arches plays a vital role in determining the damaged conditions of these structures. For this purpose, the first mode frequencies of masonry stone arches with different dimensions (span, height, width, thickness) and temperature history were obtained by finite element analysis. Then, the first mode frequencies of the arch elements were estimated using the classical regression analysis (CRA) method using the geometrical parameters of the arch element and the independent variables of the temperature history condition to which the arch elements were exposed. Four different functions, namely linear (LF), exponential (UF), exponential (EF), and quadratic (KF), were applied in the KRA method, and the coefficients of these functions were calculated. While developing the prediction models, %70 of the data was used for training and the remaining %30 for testing the models. The results obtained were compared by using different performance statistics, and the functions and coefficients of these functions that gave the closest values to the experimental results were determined.

2. Finite element analysis of arches

The first mode frequency (f_{FE}) values of masonry arch elements with different cross-sectional dimensions subjected to high-temperature effects are taken from our previous study (Altunışık et al., 2024). Within the scope of the study, 450 heat transfer and 4850 modal analyses were performed using the finite element (FE) method to determine f_{FE}. Due to the variable parameters considered, many numerical analyses were performed, and a data pool was created based on the results obtained.

The FE analyses first generated 450 FE models of arch elements with different section properties listed in Table 1. In order to determine the temperature distributions along the cross-sections of these arch elements under high-temperature effect, heat transfer analyses were performed on the FE models considering the transient regime. Then, depending on the results of these analyses, 4850 modal analyses were performed for exposure times of 0, 15, 30, 45, 60, 75, 90, 105, 120, 135, 150, 165, and 180 minutes of ISO 834 standard temperature-time graph. The same FE model was used in both analyses performed using the ABAQUS package program. Detailed information on FE analyses (FE models, thermal and mechanical material properties, etc.) can be found in (Altunışık et al., 2024).

Table 1. Arch dimensions considered in FE analyses

Group	Arch dimension (m)										
	Span (s)	Height (h)		Width (w)			Thickness (t)				
1	1-3						0.2	0.3	0.4	0.5	0.6
2	4-7	$\frac{s}{2}$	$\frac{s}{2}x0.8$	0.5	1.0	1.5	0.4	0.5	0.6	0.7	0.8
3	8-11						0.6	0.7	0.8	0.9	1.0
4	12-15						0.8	0.9	1.0	1.1	1.2

3. Classical regression analysis (CRA)

Regression is a statistical method used to estimate the relationship between a dependent variable and two or more independent variables. Regression equations are mathematical expressions showing these variables' relationship (Bayazıt & Yeğen, 2005). Four different regression functions, namely LF, PF, EF and QF were used in this study. The functions used are given in Equations 1-4:

$$y_{LF} = w_0 + w_1 x_1 + w_2 x_2 + w_3 x_3 + \cdots + w_n x_n \tag{1}$$

$$y_{PF} = w_0 x_1^{w_1} x_2^{w_2} x_3^{w_3} \ldots x_n^{w_n} \tag{2}$$

$$y_{EF} = w_0 + \exp\left(w_1 + w_2 x_1 + w_3 x_2 + \cdots + w_{n-1} x_n\right) \tag{3}$$

$$y_{QF} = w_0 + w_1x_1 + w_2x_2 + \cdots + w_6x_1x_2 + w_7x_1x_3 + \cdots + w_{15}x_1^2 + w_{16}x_2^2 \ldots + w_{20}x_5^2 \quad (4)$$

In the given equations, w's represent the regression coefficients, x's represent the independent variables, and y's represent the frequency values of the first modes of the arches, which are the dependent variables. Determining the regression equation that best predicts the value of the dependent variable is called regression analysis (Bayazıt, 1981).

3.1. Modelling

In the modeling studies, the geometrical parameters of the arch elements (span, height, width, thickness) and the temperature history condition (0, 15, 30, 45, 60, 75, 90, 105, 120, 135, 150, 165, 180 min) to which the arch elements were exposed were used as independent variables, and the first mode frequencies (f_{FE}) of the arches were used as the dependent variable. In the model prepared by using 5315 data in total, 3985 data were allocated for training, and 1330 data were allocated for testing. While dividing the data into training and test sets, care was taken to ensure that both sets had values that could represent the entire data group. The models with the highest performance for the training data set were also evaluated using the test data set. Table 2 shows the minimum, maximum, mean, and standard deviation fundamental statistical values for training, test, and all data.

Since the value ranges of the dependent and independent variables in the data set are different, modeling may become difficult. For this reason, a normalization process was applied to the data in order to obtain the solution faster and easier. As a result of this process, the data of the dependent and independent variables in the data set were normalized between 0.1 and 0.9. The formulation used in this process is given in Equation 5 (Bayram et al., 2015)

$$Normalized\ value = \left[\frac{Raw\ value - Minimum\ Value}{Maximum\ value - Minimum\ Value}\right] x(0.8) + 0.1 \quad (5)$$

Table 2. Basic statistics of the variables in the modeling

Data Set	Variable	Unit	The smallest	Average	The biggest	Standard Deviation
All of them	Span	m	1.000	8.468	15.00	4.220
	Height	m	0.400	3.809	7.500	1.958
	Width	m	0.500	0.961	1.500	0.403

	Temperature	℃	0.000	90.03	180.0	56.12
	f_{FE}	Hz	0.430	10.65	121.6	19.70

3.2. Evaluation of modeling results

As a result of CRA modeling studies, the coefficient values in Table 3 were obtained for LF, PF, EF, and QF functions as a result of the application of CRA methods, training, and test data sets were generated by substituting the coefficients of the functions in the equations.

Table 3. Coefficients of LF, PF, EF, and QF functions obtained from regression analysis

Coefficients obtained from regression analysis	Model functions			
	LF	PF	EF	QF
w_0	0.327	0.064	0.113	0.637
w_1	-0.295	-0.658	0.721	6.655
w_2	-0.048	-0.328	-2.602	-8.985
w_3	0.060	0.192	-11.13	0.286
w_4	-0.003	-0.040	0.823	-0.134

w_7				-0.220
w_8				0.211
w_9				0.074
w_{10}				-0.029
w_{11}				0.001
w_{12}				0.015
w_{13}				-0.098
w_{14}				0.003
w_{15}				0.041
w_{16}				199.91
w_{17}				256.11
w_{18}				-0.030
w_{19}				0.024
w_{20}				0.018

3.3. Evaluation of model performance

Root mean square error (RMSE), mean absolute error (MAE), and Nash Sutcliffe efficiency coefficient (NS) performance statistics were used to compare the forecasting performance of the models. The formulae used are given in Equations 6-8:

$$RMSE = \left[\frac{1}{n}\sum_{i=1}^{n}(t_i - td_i)^2\right]^{1/2} \tag{6}$$

$$MAE = \frac{1}{n}\sum_{i=1}^{n}|(t_i - td_i)| \tag{7}$$

$$NS = 1 - \frac{\sum_{i=1}^{n}(t_i - td_i)^2}{\sum_{i=1}^{n}(t_i - \bar{t})^2} \tag{8}$$

In the given equations, t_i indicates measurement values, td_i indicates prediction values, $\bar{t}$ indicates the mean of measurement values, and n indicates the number of data. NS value is between -∞ and 1. NS=1 indicates that the method used is perfect (Moriasi et. Al., 2007) proposed a range for NS, as shown in Table 4.

The performance statistics calculated between the prediction and measurement values of f_{FE} training and test data sets are given in Table 5. When Table 5 is analyzed, it is determined that EF is the function type that gives the lowest RMSE and MAE and the highest NS values for both training and testing. As can be seen in Table 5, the EF function predicted an 'excellent' level according to the NS performance statistic for training (Moriasi et al., 2007). Fig. 1 shows the scatter plots of the prediction and measurement values of the training and test data obtained with the EF function for f_{FE}.

The distribution of the data on the diagonal in the scatter plots shows that the prediction values are very close to the measurement values. In other words, it means that the RMSE and MAE values of the points on the diagonal are zero (Bayram & Kankal, 2015; Nacar et al., 2020). Fig. 1 shows that the majority of the training and test data of f_{FE} are distributed on the diagonal. This indicates that the prediction data are close to the FE data. Fig. 2 and Fig. 3 shows the comparison of the training and test data estimated with the EF function, which performs the best in the CRA method, with the FE data as a time series. When the figure is analyzed, the results are close to the FE data.

Table 4. NS value range

Parameter	Very good	Good	Adequate	Inadequate
NS	0.75-1.00	0.65-0.75	0.50-0.65	<0.50

Table 5. RMSE, MAE, and NS values of training and test data for f_{FE}

Data Set	Training				Testing			
Model functions	LF	PF	EF	QF	LF	PF	EF	QF
RMSE	14.85	5.554	**3.155**	9.555	14.62	5.512	**3.112**	9.411
MAE	9.945	4.499	**2.129**	6.892	9.891	4.479	**2.114**	6.845

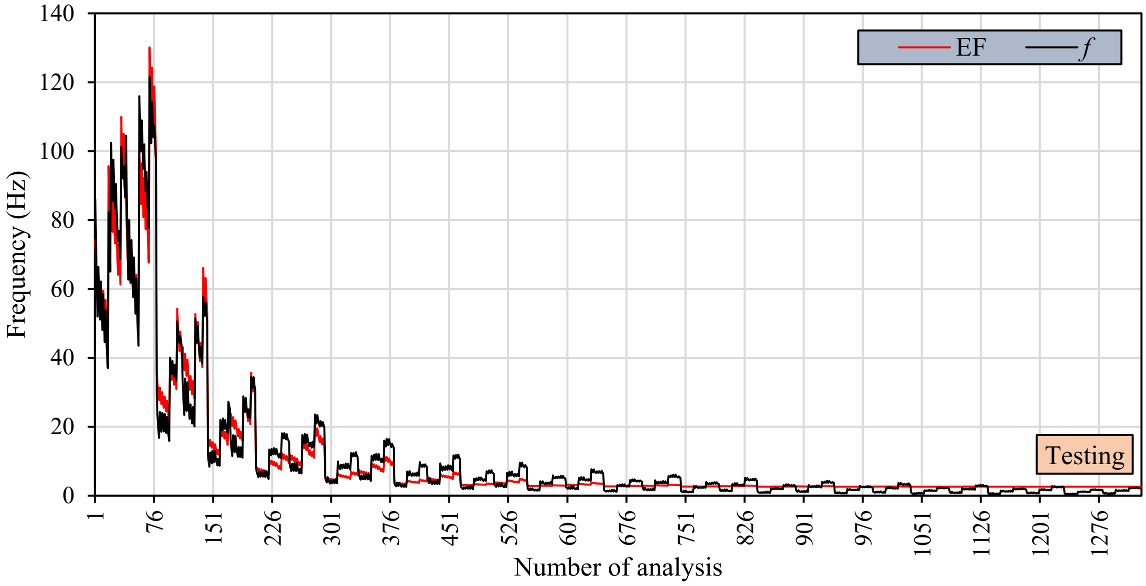

Fig. 3. Comparison of FE-predictive values of testing datasets for f_{FE}

4. Conclusions

In this study, the first frequency values of masonry stone arches subjected to high-temperature effects are estimated by classical regression analysis (CRA) using numerical methods. Within the scope of the study, 6300 FE analysis results of masonry stone arches with different geometries and temperature histories were used. As a result of the analyses, a data set was created with the first mode frequencies of 5315 arch elements. Then, CRA was performed using geometrical parameters such as span, height, width, thickness of the arch element, and the temperature history condition (0, 15, 30, 30, 45, 60, 75, 90, 105, 120, 135, 150, 165, 180 min) to which the arch elements were exposed. As a result of this analysis, the first mode frequencies of the arch members were estimated. Four different functions, namely linear function (LF), power function (PF), exponential function (EF), and quadratic function (QF), were used in the CRA method, and the coefficients of these functions were calculated. While developing the prediction models, 70% of the data was used for training and the remaining 30% for testing the models. Finally, performance statistics such as the square root of the mean squared error, the mean absolute error, and the Nash Sutcliffe (NS) efficiency coefficient were used to evaluate the prediction performance of the developed models. The results obtained from the study are summarised below;

- It was found that the FE parameter can be estimated with high accuracy by CRA functions from the dynamic characteristics of masonry stone arches with different geometries and temperature histories.
- The NS performances of the models developed using LF, PF, EF, and QF functions in the CRA method are calculated as 0.448, 0.923, 0.975, and 0.772 for the training data set and 0.449, 0.922, 0.975, and 0.722 for the test data set, respectively.
- Considering the performance statistics obtained from CRA models, it is seen that the closest prediction values to the f_{FE} data obtained by FE analysis are obtained from EF.
- FE analyses to determine the f_{FE} parameter can be tiring and time-consuming. The models proposed in this study show that f_{FE} can be determined with less data, less time, and high accuracy.

Dynamic characteristics of structures play a vital role in determining their behavior. It is known that the dynamic behavior of structures does not only depend on the frequency of the first mode. It depends on many parameters, such as mode shape, frequency value, and damping ratio. Therefore, in future studies, the dynamic behavior of structures can be predicted by using methods such as fuzzy logic, genetic programming, and different types of regression analysis by considering different criteria.

Abstract. The use of numerical homogenization methods has become essential for accurately estimating the mechanical properties of composites and lattice structures. These techniques help minimize the reliance on expensive and time-consuming experiments while providing reliable predictions of material behavior. At the core of numerical homogenization lies the concept of a representative volume element (RVE), which encapsulates the necessary microstructural details within a smaller, computationally efficient domain. Proper boundary conditions applied to the RVE enable effective evaluation of the overall structural properties. This research explores the application of finite element (FE) homogenization methods for analyzing lattice structures. The FE approach is well-regarded for its straightforward implementation, capacity to model complex microstructures, and accuracy in determining effective material properties. Lattice structures, valued for their superior strength-to-weight ratios, energy absorption capabilities, and porosity, are widely used in aerospace, automotive, and medical applications. Enhancing their performance requires careful consideration of topology choices (such as octet-truss, honeycomb, and foam), unit cell configurations, and material characteristics. In this study, the mechanical properties of the octet-truss unit cell are examined alongside combinations with other unit cells, including simple cubic (SC), cross struts, and body-centered cubic (BCC). Simulations are conducted using the finite element software ABAQUS, incorporating periodic boundary conditions (PBC) to ensure accurate homogenization. By analyzing the effects of varying relative densities and unit cell arrangements, this work provides valuable insights for optimizing lattice structures in advanced engineering applications.

Keywords: Homogenization; Lattice structures; Octet-truss; Periodic boundary conditions; Representative volume element

1. Introduction

Cellular structure is a type of a porous structure which is naturally found in the nature, such as corals, leaves and bones. Artificial cellular structures have been manufactured and structured based on these natural designs. Such materials are classified into two categories based on the structures, the stochastic and the periodic (Gibson & Ashby, 1997). Periodic cellular solids with three-dimensional spatial architectures of unit cells are called lattice structures. These extraordinary materials derive properties that are unique because of their unique structural design. With a low density, these materials can certainly be used as lightweight structural components (Tancogne-Dejean et al., 2018). The characteristic plateau behavior under compression generates enhanced energy absorption capacity (Qiu et al., 2022). Furthermore, due to their unique flow characteristics, lattice structures find uses as sound absorbers and thermal exchangers (Dixit et al., 2021). Thus, these structures find applications in many fields, including aerospace, defense, biomedical engineering, automotive design, and sports equipment manufacturing.

Unit cells of the lattice structures can be strut-based (composed of struts and nodes) or TPMS-based (Triply Periodic Minimal Surfaces). The mechanical behavior of strut-based lattice structures is categorized as bending or stretch-dominated according to the Maxwell number $M = b - 3j + 6$, where b and j are the numbers of struts and joints in unit cell, respectively (Deshpande et al., 2001). When $M < 0$, struts primarily experience bending. In cases where $M = 0$, the structure is statically determinate and deformation is dominated by tension or compression and when $M > 0$, excess stiffness leads to stretch-dominated behavior. Stretch-dominated structures typically exhibit higher stiffness and initial collapse strength compared to bending-dominated structures. This characteristic makes stretch-dominated lattices particularly suitable for lightweight, load-bearing applications. In contrast, bending-dominated structures are characterized by greater compliance and a prolonged flat plateau in the post-

golden light publishing

yield regime, which makes them highly advantageous for applications where energy absorption is the primary focus (Habib et al., 2018).

The structural behavior of lattice structures can be fine-tuned by adjusting factors such as cell topology, strut shape, cell size and base material (Morrish et al., 2017; Qi et al., 2019). Several attempts have been made to optimize and improve the mechanical properties of lattice structures. For example, in Body-centered (BC) unit cell, stress concentrations have been occurred at the joints. In order to reduce that, the nodal regions were modified by considering fillets causes increase in stiffness by 55% (Wang et al., 2021). Also, by changing the strut shape of unit cell, the mechanical properties can be improved. Tancogne-Dejean et al. (2016) simulated octet-truss (OT) unit cell with cylindrical and tapered struts, which have circular cross-section. Tapered strut ends are cylindrical shape over a length of twice the radius of strut (R), and the strut radius changes gradually reaching its maximum value of αR at the center. They showed that in the unit cells with strongly tapered struts $(\alpha \leq 0.6)$ increases the stability of the microstructure, and the ones with $\alpha = 0.8$ have higher strength and specific energy absorption (SEA). Also, Tancogne-Dejean & Mohr (2018) simulated the BC unit cell with tapered beams and they found that the effective Young's modulus and SEA increased up to 70% and 45%, respectively. In another attempt, the cross-section of struts has been altered. For example, Zhao et al. (2023) created a BC unit cell with bamboo-inspired struts which were tapered and hollow. They found that the mentioned parameters changed the deformation behavior from bending to stretch-dominated under uniaxial compression. Also, they showed that by modeling bamboo-inspired BC, elastic modulus can be increased by $271.24 - 1335\%$. Another approach is changing the cell configuration by inserting additional struts. Smith et al. (2013) designed BC-Z unit cell by inserting an additional vertical strut. The deformation behavior was changed from bending-dominated to stretch-dominated and the stiffness was significantly increased due to the existence of the vertical strut in BC.

At the microscopic scale, the fundamental unit cell of a lattice structure, referred to as the Representative Volume Element (RVE), exhibits a heterogeneous nature, with varying material properties across its structure. However, when considered at the macroscopic level, the RVE can be approximated as homogenous, anisotropic continuum. To simplify the analysis and design of lattice structures, a homogenization approach is commonly employed. This technique replaces the complex, detailed geometry of the RVE with an equivalent homogenous material at the macroscopic scale. The mechanical properties of this equivalent material are characterized by effective material parameters, which are derived from the microscale geometry. Although the base material of the lattice is isotropic, the overall mechanical response of homogenized structure can become fully anisotropic. This occurs because the effective elastic properties are strongly influenced by the geometry and orientation of the RVE at the microscale (De Pasquale et al., 2018). In literature, there are several homogenization methods including, average stress method, mathematical homogenization method and asymptotic homogenization. During the homogenization process on the RVE, three types of boundary conditions are applied including displacement-type, force-type and periodic boundary conditions (PBC). As it stands, the use of homogeneous displacement boundary conditions has been proved to yield upper bounds on the effective mechanical properties, and the lower bound brought about by using homogeneous traction boundary conditions in comparison to those obtained using PBCs. Also, it was proven that during analysis of a periodic RVE, PBCs is the best boundary condition type (Yu, 2016).

The octet truss unit cell (OT) is considered as the base RVE in this study. Homogenization process will be done by finite element analysis software (ABAQUS, 2022) using average stress method. Due to the periodicity of the RVE, periodic boundary conditions (PBCs) will be used. By this procedure, the effective material properties of OT will be extracted. Also, by combining the body-centered (BC), simple cubic (SC) and cross rods (C) with the OT, new three configurations are developed to investigate how these combinations affect the homogenized material properties of the OT unit cell. The struts of all unit cells are cylindrical with circular cross-section. Whole models exhibit cubic symmetry. These simulations are done by different relative densities varying from 0.05 to 0.4. Spatial dependence of homogenized material properties is presented graphically. The change of anisotropy of each material constant is also given for the combinations of OT.

2. Materials and methods

In this section, first the geometry of unit cells and the bulk material properties are presented in section 2.1 and then the methodology of the homogenization process is given in section 2.2.

2.1. Geometry and material

In this study, the side length of each unit cell was considered as $L_{uc} = 6mm$. A unit cell of the octet truss with relative density of $\bar{\rho} = 0.2$ is sketched in Fig. 1 and clearly shows its face-centered nature. It is composed by an octahedron at the center of unit cell, which is shown with red color, and eight tetrahedrons, which are attached to the eight faces of the octahedron. The new configurations are modeled by inserting Cross, SC and BC unit cells inside the OT. These new unit cells are named as OT+C, OT+SC and OT+BC, respectively and shown in Fig. 2 for the same relative density of $\bar{\rho} = 0.2$. In Fig. 2, the OT was shown by yellow color and the inserted unit cell was depicted by blue color.

The relative density of a lattice material $\bar{\rho}$ is defined as the ratio of the density of the cellular material and the density of the bulk material. Relative density of OT unit cell is already given with Equation.1 for cylindrical struts by Tancogne-Dejean et al. (2016).

$$\bar{\rho} = 6\pi\sqrt{2}\left(\frac{R}{l}\right)^2 - \frac{32}{2-\sqrt{2}}\left(\frac{R}{l}\right)^3 \tag{1}$$

Here, R and l is the radius and the length of each strut, respectively. The second term in this equation is the correction term in order to consider the complex geometry of the joints. Equation.1 was solved for different relative densities varying from 0.05 to 0.40, and the corresponded radius of strut were calculated for the OT unit cell. Also, the relative densities and radius of new configurations were calculated by Python scripting in ABAQUS/CAE. In order to make a comparison between the unit cells with different configurations, the relative density is kept constant and the required radius values of the struts were calculated and tabulated in Table 1.

In all simulations, the isotropic linear elastic material, Nylon-12 (PA-12) is used as the bulk material. This material has elastic modulus of $E = 969.52\ MPa$ and Poisson's ratio of $\upsilon = 0.33$.

2.2. RVE homogenization process using finite element analysis

In this study, as it was mentioned, average stress method is used by implying the PBCs on the RVE. ABAQUS/CAE software is used for the simulations. The homogenization process involves applying uniform strain conditions. These conditions are presented in Fig. 4 for OT+BC with relative density of $\bar{\rho} = 0.4$. In the software, there is not any predefined boundary condition for implying PBCs. These PBCs are implemented using EasyPBC plugin which is written in Python scripts using the commands of ABAQUS (Omairey et al., 2019). By using this plug-in, the uniform strains are imposed on the RVE to calculate the homogenized elastic properties. Also, the constrained equations and displacement boundary conditions are automatically applied to keep the periodicity of the RVE. It generates node sets for each side, edge and corner of the RVE and by utilizing the derived constraint equations, each node is linked with its corresponding node on the other side to maintain the periodicity of the deformation. During the process, some reference points are constructed automatically to imply the required displacement boundary condition for each homogenized property. Then, the reaction force data are requested from the reference points. This reaction force is divided by the affected surface area to calculate the stress value and then Young's modulus is determined by dividing the stress value to the applied strain. Also, the same output is used to obtain the Poisson's ratio in the two transverse directions by dividing the transverse strain by applied axial strain. Shear moduli are calculated by the ratio of shear stress to shear strain in the corresponding directions.

This plug-in calculates all homogenized elastic moduli, shear moduli and Poisson's ratios. For each unit cell, a stiffness matrix is constructed using Equation.2. The subsequent calculation of anisotropy and examination of spatial variation of Young's moduli, shear moduli and Poisson's ratios for the unit cells is performed using ELATE, which is an open-source online tool for analyzing and visualizing elastic tensors (Gaillac et al., 2016).

In all simulations, Hexagonal linear element type C3D8R, that is available in ABAQUS library, is used with mesh seed size of $0.2\ mm$. Mesh of OT, OT+BC, OT+SC and OT+C unit cells are presented for relative density of $\bar{\rho} = 0.2$ in Fig. 3.

$$\begin{bmatrix} E_1(v_{23}v_{32}-1)/D & -E_1(v_{21}+v_{23}v_{31})/D & -E_1(v_{31}+v_{21}v_{32})/D & 0 & 0 & 0 \\ -E_2(v_{12}+v_{13}v_{32})/D & E_2(v_{13}v_{31}-1)/D & -E_2(v_{12}v_{31}+v_{32})/D & 0 & 0 & 0 \\ -E_3(v_{13}+v_{12}v_{23})/D & -E_3(v_{13}v_{21}+v_{23})/D & E_3(v_{12}v_{21}-1)/D & 0 & 0 & 0 \\ 0 & 0 & 0 & G_{23} & 0 & 0 \\ 0 & 0 & 0 & 0 & G_{13} & 0 \\ 0 & 0 & 0 & 0 & 0 & G_{12} \end{bmatrix} \quad (2)$$

$$D = v_{12}(v_{21}+v_{23}v_{31}) + v_{23}v_{32} + v_{13}(v_{31}+v_{21}v_{32}) - 1$$

3. Results and discussion

The unit cells considered in this study have cubic symmetry which has three independent material constants. Three dimentional plot of material constants of OT is shown in Fig. 5 for $\bar{\rho} = 0.05$. This figure is obtained from open source online tool Elate (Gaillac et al., 2016). The material constants have minimum and maximum values in different directions. For example elastic modulus has minimum value E_{min} in [100] direction and maximum value E_{max} in [111] direction. Shear modulus has minimum value G_{min} in [110] direction and maximum value G_{max} in [100] direction. Variation of elastic and shear modulus on xy plane is shown in Fig. 6. The homogenized values found in this study belong to [100] direction, those are E_{min} and G_{max}. Transformation matrix operations can be applied to the stiffness matrix obtained from homogenization process to find the variation of moduli in other directions, as it is done by the open source online tool Elate, and E_{max} and G_{min} can be determined.

Anisotropy of a material constant is described by the ratio of maximum to minimum values of this material constant (Gaillac et al., 2016). Minimum and maximum elastic modulus values of Octet-Truss unit cell are plotted with solid lines in Fig. 7. On the same figure, anisotropy of all unit cells are also presented on the secondary vertical axis. As a general rule, elastic anisotropy decreases with increasing relative density, in other words, material approaches to isotropy. In order to inspect the contribution of Cross, SC and BC unit cells one by one in the OT unit cell, they are presented in the same figure. Recall that the combined unit cell dimensions are not changed but the radius of struts are changed to provide the same relative volume density of OT alone for proper comparison in this study. Change in E_{min} and E_{max} are calculated by $(E_{comb} - E_{OT})/E_{OT}$ and elastic anisotropy are tabulated in Table 2.

Introduction of Cross or SC unit cells have approximately the same effect on the material properties, but Cross unit cell has slightly better contribution compared to SC unit cell. Since the struts of Cross and SC unit cells are parallel to the [100], [010], [001] directions, they increase E_{min} which is in the same directions, but decrease E_{max} which is in [111] direction. The maximum contribution to elastic modulus is 35.2% with Cross UC for $\bar{\rho} = 0.05$ and the contribution decreases to 19.6% for $\bar{\rho} = 0.40$. On the contrary, the struts of BC unit cell are in [111] direction, its presence decreases E_{min} of OT seriously with 30.4% for $\bar{\rho} = 0.4$. Besides this, contribution of BC unit cell on E_{max} is very small.

Minimum and maximum shear modulus values of OT unit cell and its combinations are plotted in Fig. 8. Change in G_{min} and G_{max} are calculated with the same manner as for elastic modulus and tabulated in Table 3.

Addition of Cross or SC unit cells have approximately the same effect on the shear modulus of OT. Their presence increases G_{min} which is in [110] direction around 20-40%, but decreases G_{max} which is in [100] direction around 11-16%. Presence of BC unit cell decreases G_{min} seriously around 29-32%, but does not have any significant increase on G_{max}.

In order to observe the effect of relative density on OT unit cell and its combinations, x-y plane projection plots showing the variation of elastic and shear modulus of OT and its combinations for $\bar{\rho} = 0.05 - 0.4$ are tabulated in Table 4 and Table 5. Poisson Ratio of OT and its combinations are plotted on xy plane in Table 6. These figures are obtained from open source tool ELATE. Blue curves represent the maximum positive, green curves shows minimum positive and red curves are for minimum negative values (Gaillac et al., 2016). The Poisson anisotropy of OT was 22.24 for $\bar{\rho} = 0.05$, by the combinations of Cross and SC unit cells, it decreases significantly down to 1.48 and 1.46, respectively. It is shown from the last row of Table 6 that by adding BC unit cell, the material experiences negative Poissons ratio values. For low values of relative density unit cell becomes highly auxetic material and negative Poisson ratio value decreases by increasing relative density.

Finally, it is observed that, addition of BC unit cell which have the similar strut directions with the OT unit cell, did not have favorable improvement on the material properties. On the contrary, contribution of Cross and SC unit cells, those have struts in other directions than the struts of OT unit cell, its material constants are improved.

Table 4. Effect of added unit cells on the material constants of OT plotted on xy plane for relative density values of 0.05, 0.2 and 0.4

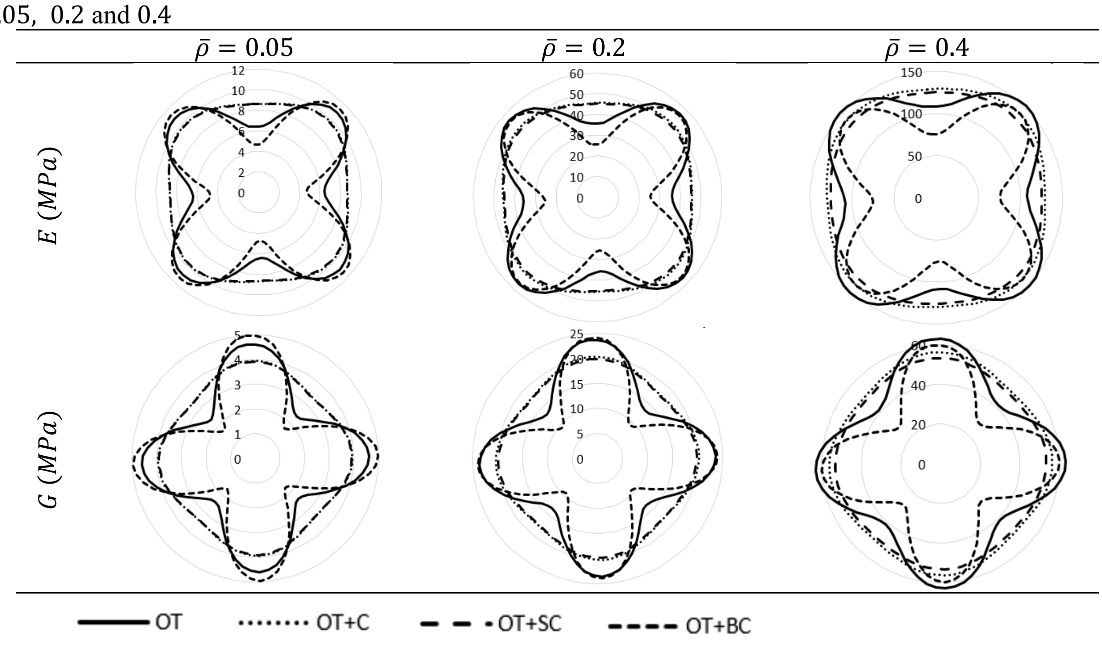

Table 5. Effect of relative density on the material constants of OT and its combinations plotted on xy plane

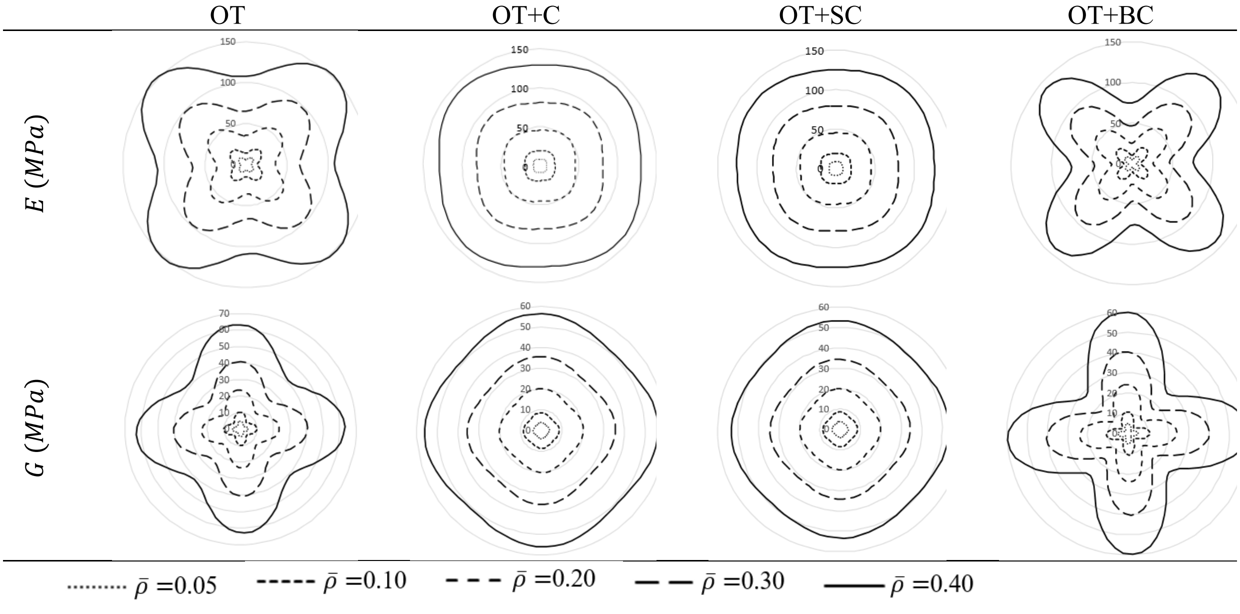

Table 6. Poisson Ratio of OT and its combinations plotted on xy plane. Blue: maximum positive, green: minimum positive, red: minimum negative (Gaillac et al., 2016)

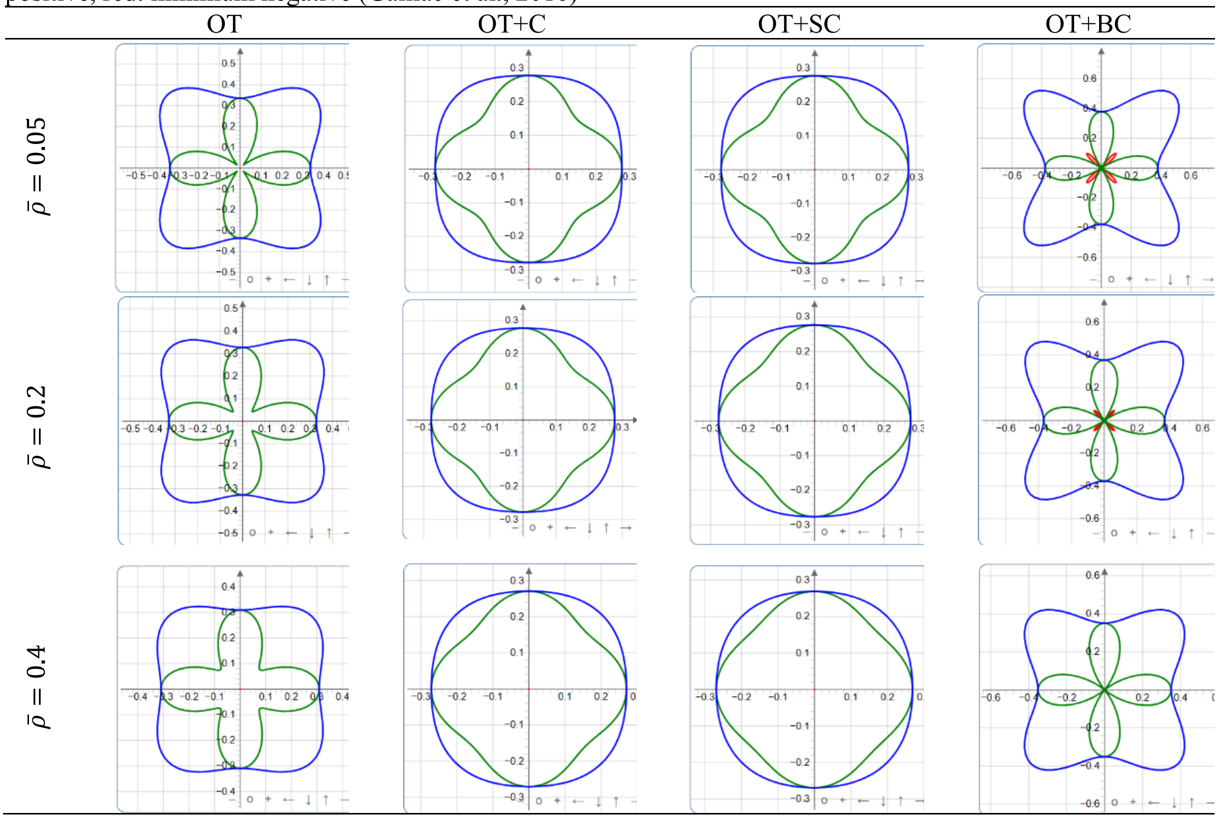

4. Conclusions

- It is verified that the anisotropy of lattice material constants decreases with the increase of relative volume density as expected. In other words, lattice material deviates from isotropy when relative density is decreased.
- OT unit cell and its combinations with Cross, SC, BC unit cells are compared in this study, provided that they have the same relative density. In order to accomplish this, required radius of the struts are calculated and used in the homogenization simulations.
- With the addition of Cross, SC, BC unit cells, the change in elastic and shear modulus are presented with tables and figures.

- Combination of Cross or SC unit cells to OT have approximately the same effect on its material properties, but Cross unit cell has slightly better contribution compared to SC unit cell.
- Cross and SC unit cells presence increases E_{min}, but decreases E_{max}. The maximum contribution to elastic modulus is 35.2% with Cross UC for $\bar{\rho} = 0.05$. On the contrary, BC unit cell's presence decreases E_{min} of OT seriously with 30.4% for $\bar{\rho} = 0.4$. Besides this, contribution of BC unit cell on E_{max} is very small.
- Addition of Cross or SC unit cells increases G_{min} around 20-40%, but decreases G_{max} around 11-16%. Presence of BC unit cell decreases G_{min} seriously around 29-32%, but does not have significant increase on G_{max}.
- Addition of Cross and SC unit cells, decreased the Poisson anisotropy of OT from 22.24 to 1.4-1.5 for $\bar{\rho} = 0.05$. Addition of BC unit cell to OT unit cell yielded an auxetic material.
- It is concluded that, addition of BC unit cell which have the similar strut directions with the OT unit cell, did not have favorable improvement on the material properties. On the contrary, contribution of Cross and SC unit cells , those have struts in other directions than the struts of OT unit cell, material constants are improved.

Abstract. Cold-formed steel structural members have distinct advantages over reinforced concrete and structural steel members. These include fast manufacturing in roll-forming machines indoors for 12 months of the year, light weight, and easy construction on site. A comparative analysis of cold-formed steel structures with other building systems reveals their superiority across the entire construction period, from initiation to completion. Cold-formed steel structures have been demonstrated to conserve natural resources due to the low level of waste generation and the recyclability of the structures during the production process. Following two significant seismic events measuring Mw 7.7 and Mw 7.6, respectively, which occurred in our nation on 6 February 2023, with epicenters located in Pazarcık (Kahramanmaraş) and Elbistan (Kahramanmaraş), the significance of cold-formed steel structures has been accentuated. In the context of this study, cold-formed steel stud (column) members were conceptualised in five distinct configurations, and their load-bearing capacities under compression were examined through a combination of finite element method (FEM) simulations and experimental methodologies.The tensile stress-strain values of the material in question are derived from the experimental data collected from the steel samples utilised in the tensile tests. The material properties under investigation were defined within the ABAQUS program, and the studs were modelled and analysed. Load-displacement results were obtained and then compared with the results of the experimentally tested columns. Furthermore, an investigation was conducted into the buckling conditions of the studs.

Keywords: Cold-formed steel stud; Load carrying capacity; Abaqus; Material behavior, Buckling

1. Introduction

Schafer et al. (2018) conducted experimental research into the phenomenon of buckling and collapse in built-up columns. A total of 32 test specimens with different cross-sections, thicknesses and joints were created for the purpose of the study. This study demonstrated that the displacements of elements connected with screws were greater than those of elements without joints, i.e. elements without screws.

Sang vd. (2022) conducted an investigation into the buckling behaviour of columns formed by three sections, with a particular focus on corner joints in light-weight steel structures. A total of 54 experimental studies were conducted. The experimental studies were modelled in the CUFSM Program and the results compared. The experimental specimens were prepared by altering the lengths, screw spacings, thicknesses, and head widths of the columns formed from C and U profiles that were contacted into each other. The screws utilised in the study were identified as ST 4.8 self-drilling screws. The findings of the study indicated that the effect of screw spacing was minimal in L and D type joints. However, an increase in screw spacing from 300 mm to 1000 mm in G-type columns resulted in a 11.71% decrease in ultimate load-bearing capacity. This decrease reduced the ultimate load-bearing capacity to 14.54%.Schafer et al. (2018) conducted experimental studies on the buckling and collapse of built-up columns. A total of 32 test specimens with different cross-sections, thicknesses and joints were created for the purpose of the study. This study demonstrated that the displacements of elements connected with screws were greater than those of elements without joints, i.e. elements without screws.

Mohan et al. (2022) conducted a study in which they tested 36 built-up specimens of varying dimensions. The test specimens were analysed numerically using the Abaqus programme. Consequently, the load-displacement graphs yielded divergent results. It was observed that the buckling conditions obtained from the experimental study occurred in similar locations to those obtained from the numerical study.

2. Material and method

The objective of this study is to investigate and compare the load-carrying capacities of five 2-metre-long constructed columns under pressure using a combination of experimental and numerical methods. In this study,

* Corresponding author, E-mail: nefyasoysal@gmail.com

the C140x35x10x1.5 and U144x24x1.5 profiles will be used. As shown in Fig. 1, the net dimensions of the sections were calculated using the CUFSM programs.

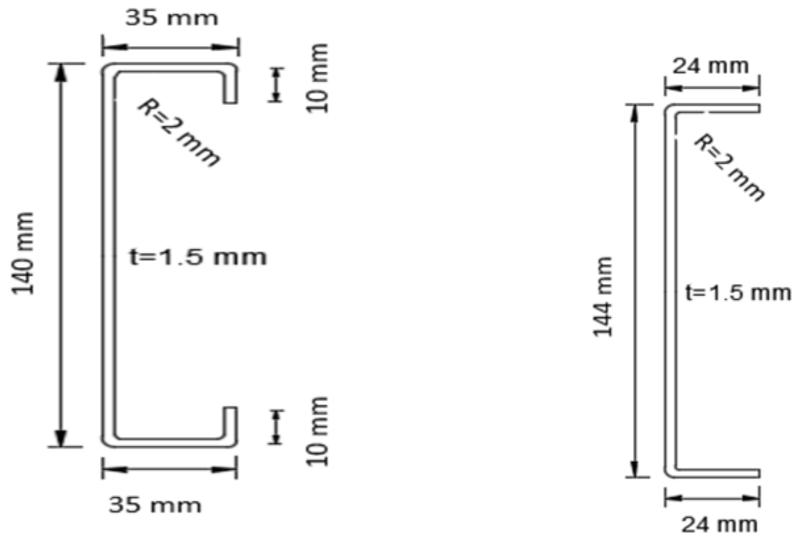

Fig. 1. Cross-sectional dimensions of the C140x35x10x1.5 and U144x24x1.5 profiles used

2.1 Cross-sectional properties of the profiles used

The profiles to be used are defined in the CUFSM program, and the cross-section properties obtained are given below. It is evident that the cross-sections are also defined in the Sap2000 program, and a comparison is made between the properties of these cross-sections as defined in the two programs. The findings indicate a high degree of similarity between the results. Fig. 2 and Fig. 3 show the results of the cross-sectional properties of the profiles in the CUFSM program.

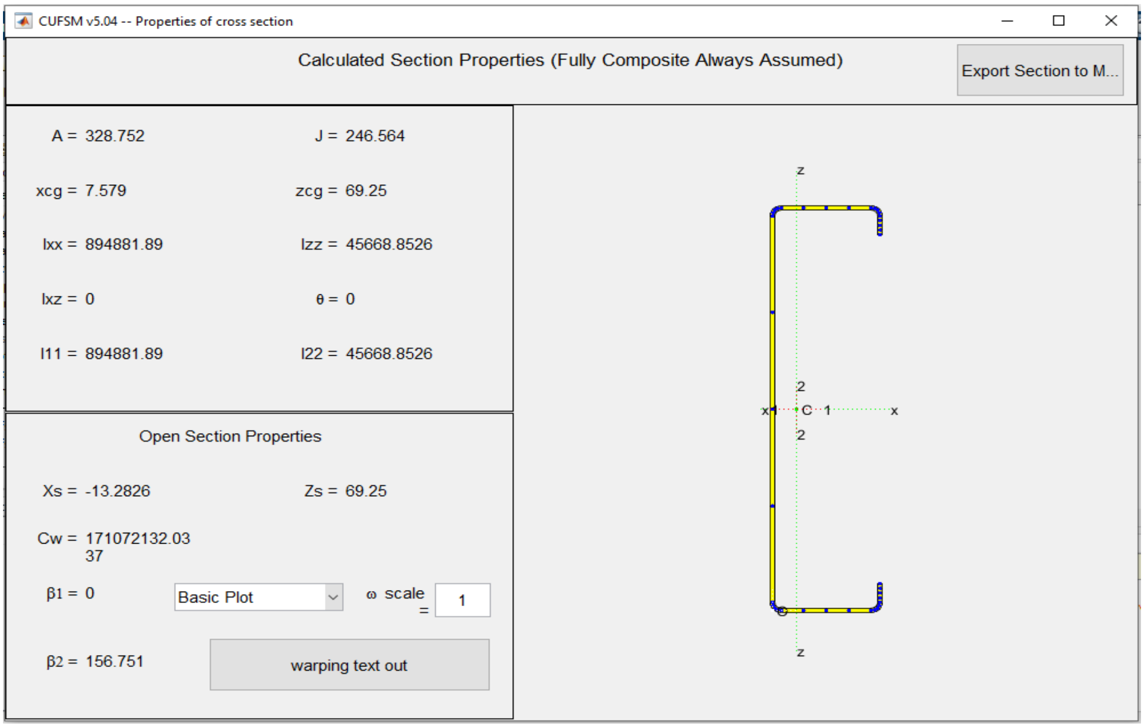

Fig. 2. Cross-sectional properties of C140x35x10x1.5 section

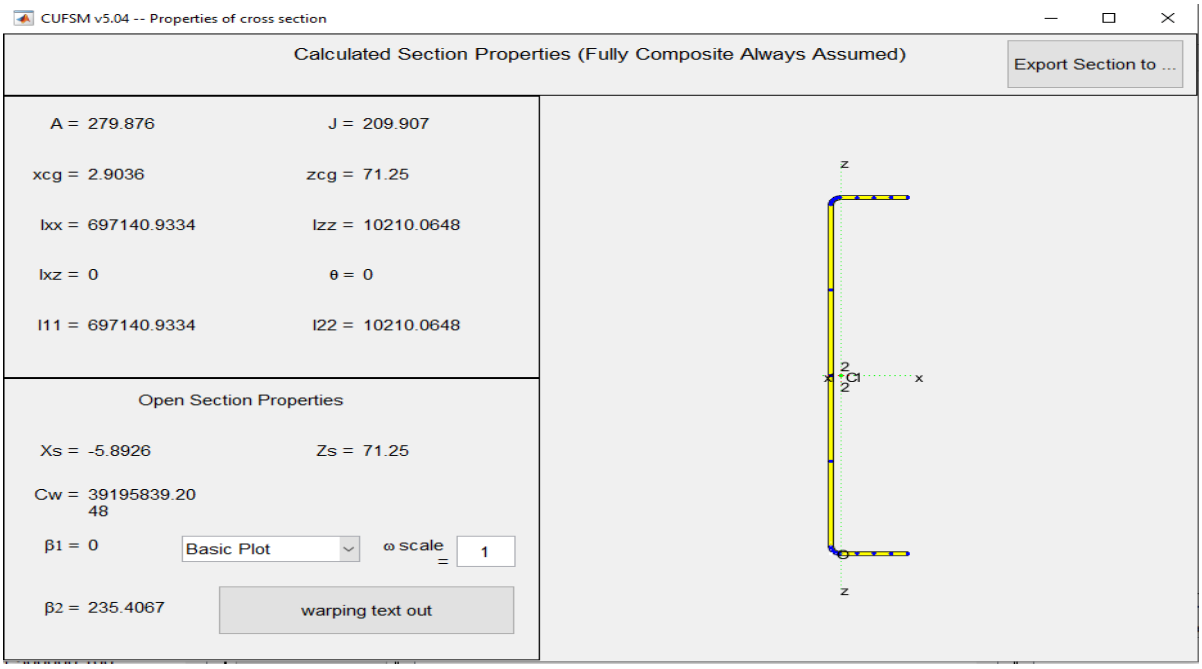

Fig. 3. The following cross-sectional details of U144x24x1.5 section

2.2 Experimental setup system

The 3D model of the test setup where the test specimens will be tested is given below. During the test, 25 mm thick elements shown with black plates were used to avoid out-of-plane behavior. The same plate is mounted on the load cell in the upper section. No out-of-plane behavior was detected during the test. Fig.4 shows the experimental setup and 3D images.

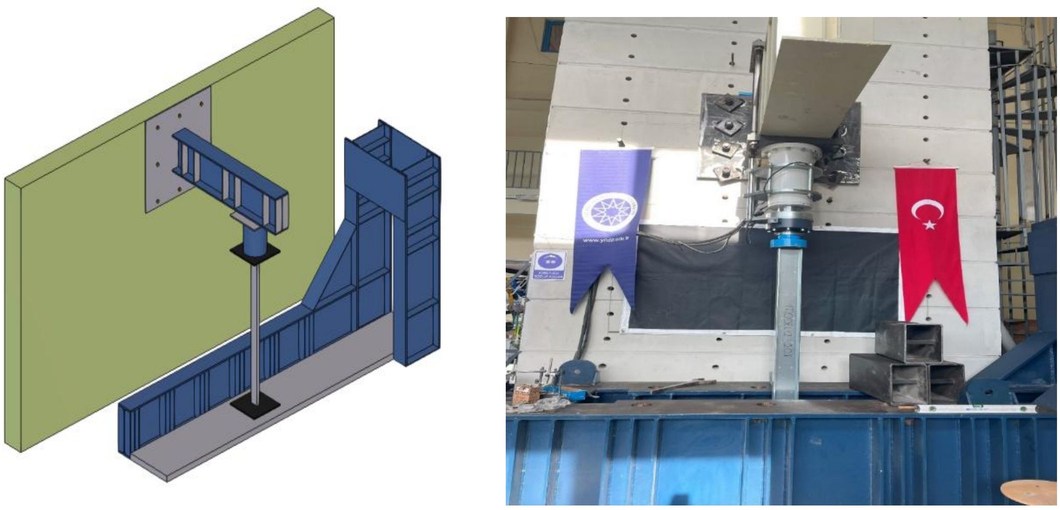

Fig. 4. The 3D design of the experimental setup

2.3 Material properties

In the experimental study, four samples were tested in accordance with BS EN ISO 6892-1. Tensile tests were performed on samples made from galvanized sheet metal. Four samples were taken from the profiles, consisting of two main bodies and one side panel, and tensile tests were conducted at Yıldız Technical University. As a result, the material was identified as S355GD. Using these values, nonlinear analysis data were defined for the models in Abaqus analyses. Fig. 5 shows the images of the materials before and after the tensile test and Fig. 6 shows the stress strain graphs obtained as a result of the experiment

Fig. 5. Test specimens used in tensile testing

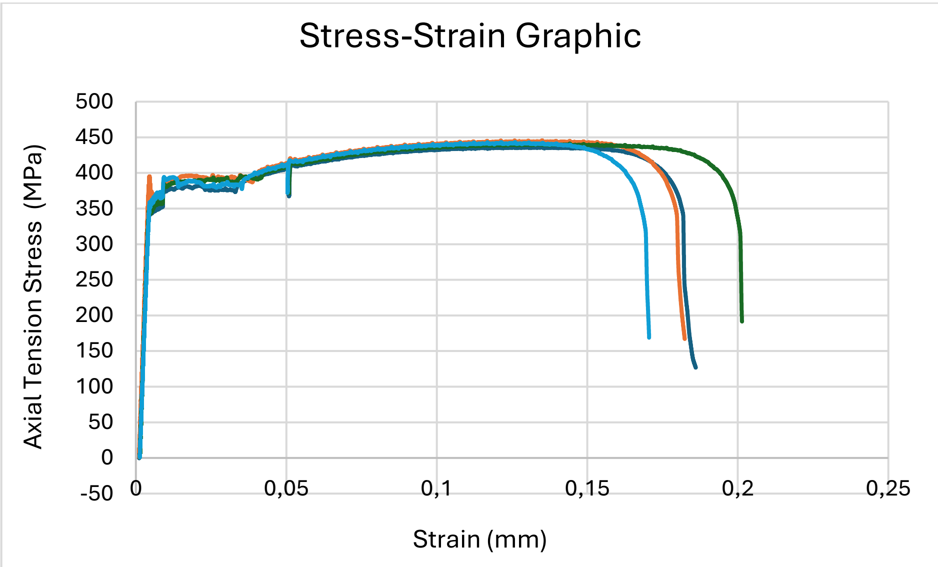

Fig. 6. Stress – strain curved

2.4 Experimental studies

Within the scope of experimental studies, 2 m long studs were fabricated and analysed. The cross-sectional views of the column studs are presented in the Fig. 7. The construction of the specimens involved the utilisation of screws with a diameter of 3.9 mm, which were employed to facilitate the connection of the built-up columns at 20 cm intervals. In the Model-3 and Model-4 designs, the connection of the studs was achieved through the use of 2 mm thick plates, with dimensions of 10x5 cm. The studs were positioned in a flat configuration, with a 25 cm thick plate acting as a foundation before being inserted into the test specimen. During the experiment, the specimens were positioned between these plates, thereby restricting their movement. It was observed that no shear occurred in the connection parts of the specimens after the experiment.

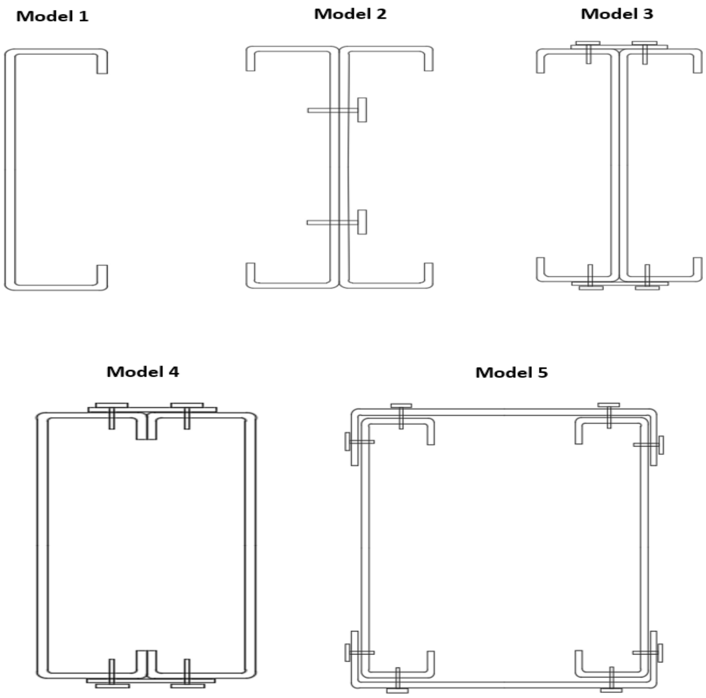

Fig. 7. The cross-sectional views of the columns.

2.5 Numerical studies

The numerical solutions were analyzed by defining initial imperfection in the Abaqus program. In Fig. 8, the boundary conditions of the load and support related to model 1 in the abaqus program are given.The sections in the models were defined as Shell element. The mesh intervals selected in the models were changed and it was decided that the most appropriate one should be defined as 10 mm meshing initial imperfection were selected in the range specified in the studies of Schafer and Peköz(1998) and defined by buckle analysis to the models as seen in the Fig. 9. Fig. 10 shows the Abaqus models of the 5 columns studied.

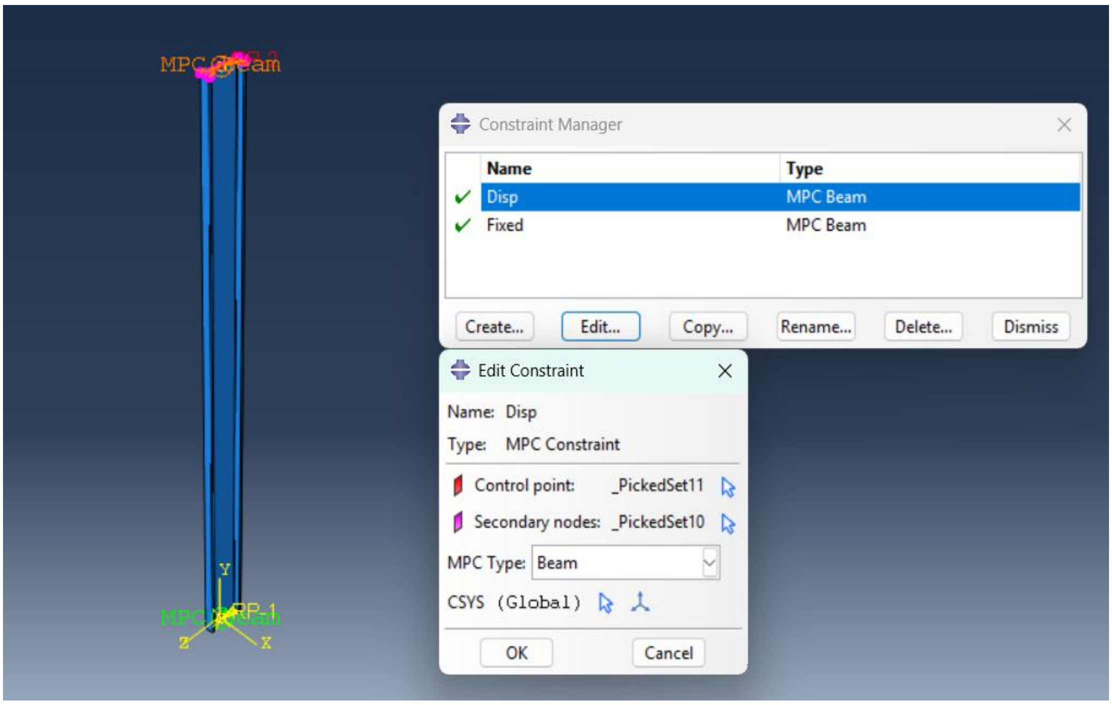

Fig. 8 Column 1 support conditions

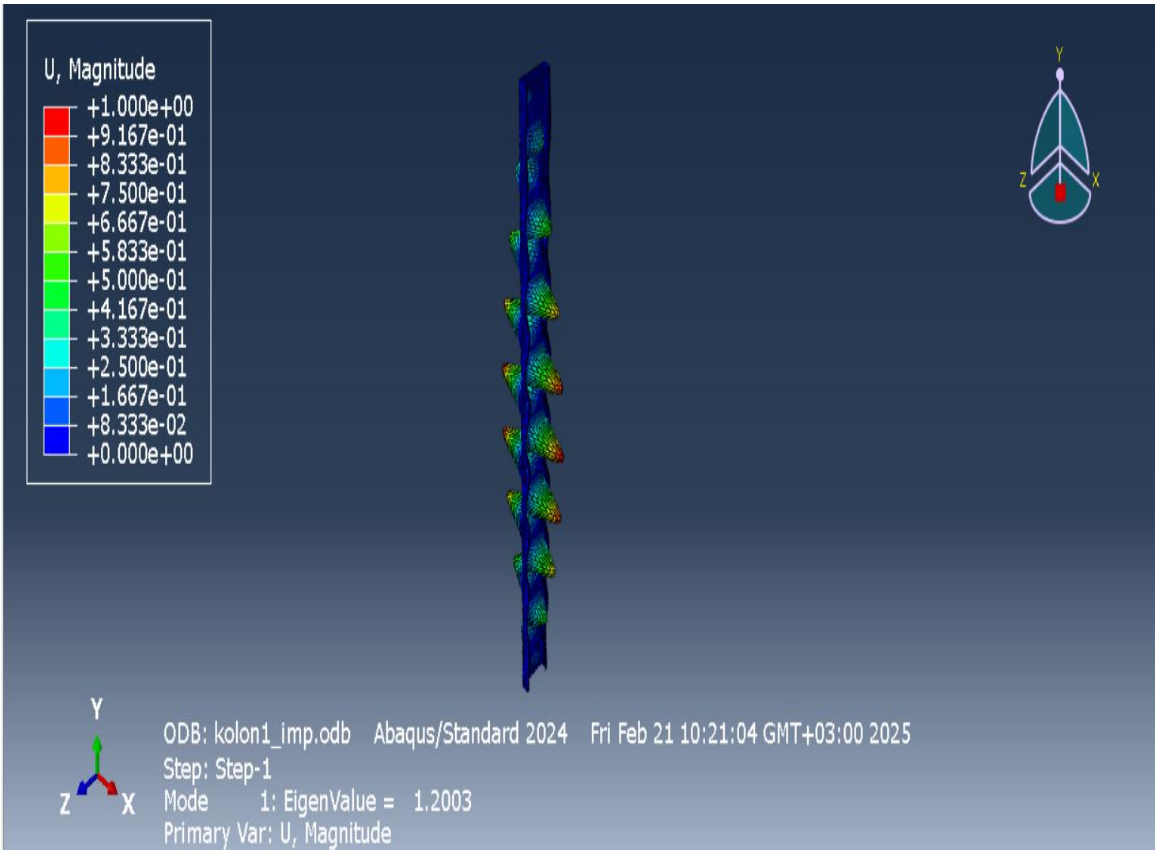

Fig. 9. Deformation occurring in the model after buckling analysis

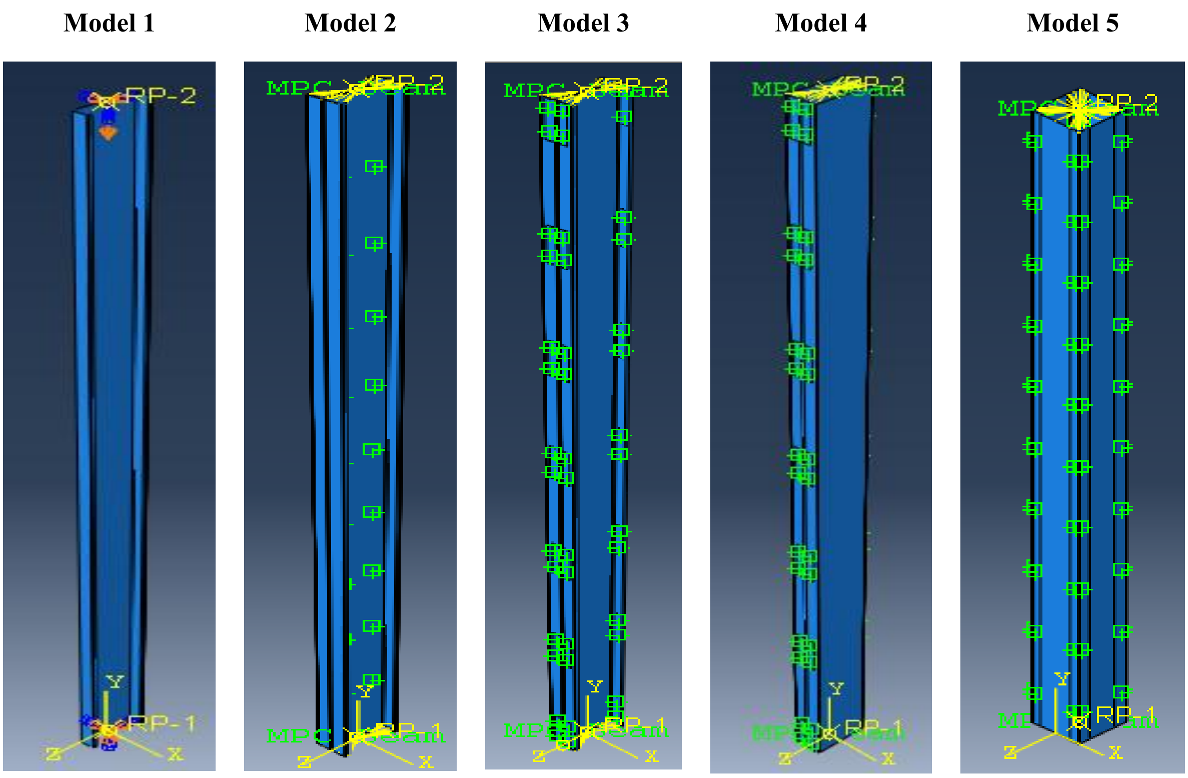

Fig 10. Models created in the Abaqus

3. Short column test

Within the study's parameters, an 80-centimetre short column test was conducted, as can be seen in the Fig.11 accompanying image. The C140x35x10x1.5 profile, which exhibited equivalent cross-section and material properties to those of the stud, was utilised as the primary profile. Fig.12 shows the load-displacement graph obtained as a result of the experiment. The experiment yielded a maximum load-bearing capacity of 67.65 kN.

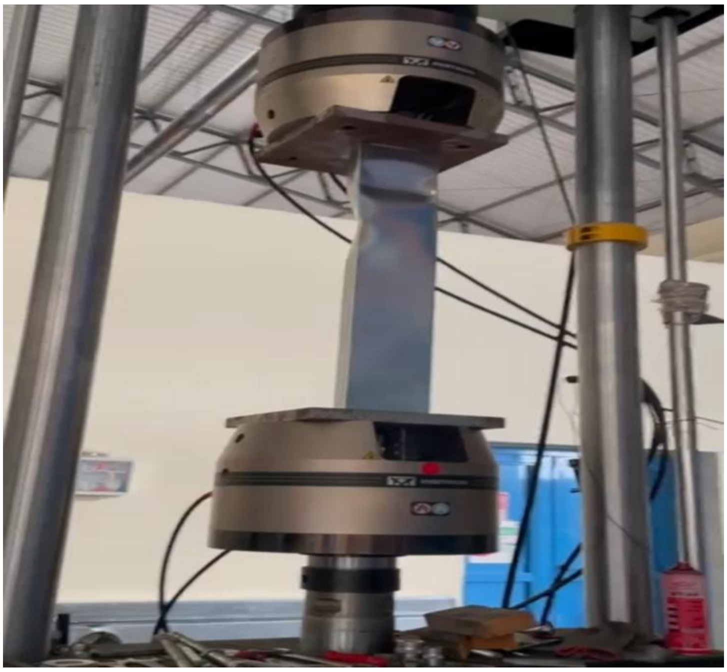

Fig. 11. The deformation of the column during the test

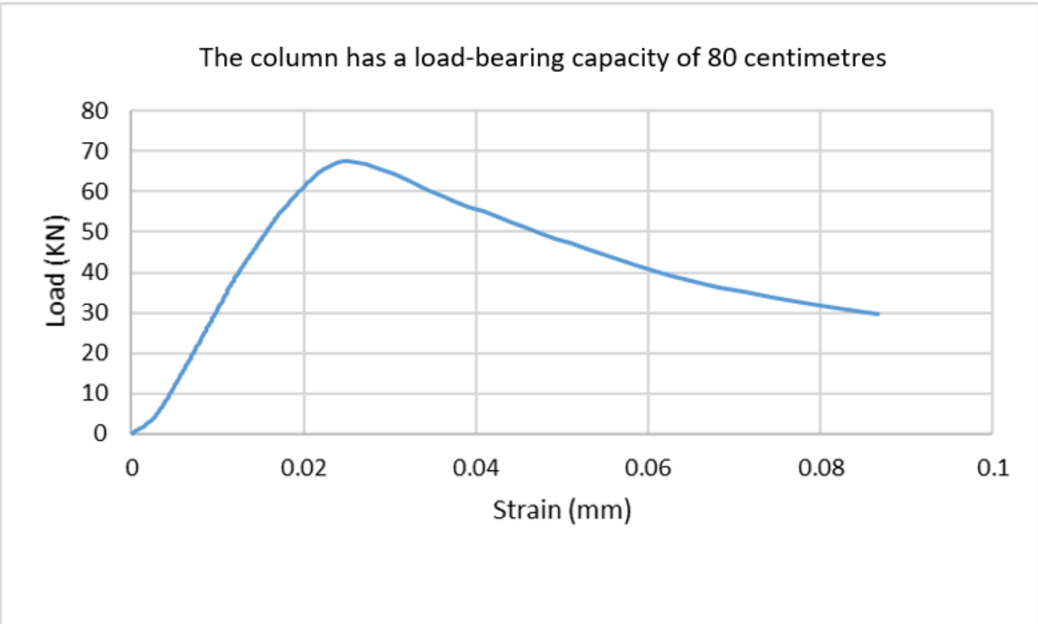

Fig. 12. The column load carrying capacity graph is 80 centimetres in length

4. Results

In the studies conducted in the literature on studs, Phan D. (2022) and Yilmaz. Y (2024) obtained similar load-displacement curves with this study. It is reason for the observed difference in value that the material quality of the profile employed is believed to be the cause, variations in the profile's cross-sectional dimensions, differences in thickness, and variations in connection types. In Tab.1, numerical analysis results and experimental results are compared with each other.

5. Conclusion

Within the course of this project, load-displacement graphs were obtained for five different columns. Consequently, it was observed that the load-bearing capacity of the column designated Column 5 was the highest. In Columns 2, 3, and 4, the loads were found to be in close proximity to each other. The column with the lowest capacity was identified as Column 1. It was thus determined that the utilization of built-up (fabricated) columns within the system results in a significantly increased capacity of lightweight steel elements.

It has been observed that the most stress under load occurs on the sides and corners of the profiles. In each sample, buckling was found to occur in different areas rather than in the same areas. It was evident that the maximum stress was observed at the covers and studs, where the panels are attached to the floor.

Consequently, it was determined that the local buckling behaviour exhibited by cold formed steel elements under load affects the overall buckling behaviour of the system. Consequently, when designing lightweight steel elements, connections that prevent local buckling must be incorporated. The calculation of the behaviour of the thickness of the profiles under load should be conducted using programs such as CUFSM or CFS. Furthermore, the behaviour of the profile under pressure and bending effects should be determined prior to design. The selection of profiles is to be made on the basis of their buckling modes.

Contact analysis loaded with a block on a functionally graded layer

Ezgi Ayhan[1], Berivan Y. Polat[*2], Jitendra Khatti[3]

[1] Munzur University, Department of Civil Engineering, 62000, Tunceli, Türkiye
[2] Munzur University, Disaster and Emergency Management, 62000, Tunceli, Türkiye

Abstract. In this study, the analysis of the continuous contact problem of a functionally graded material was realized by the finite element method (FEM). The problem consists of a functionally graded plate resting between two semi-infinite elastic planes and loaded with a rigid block. A rigid block transmits the external load (P) to the slab. It is supposed that there is no friction on the surfaces. The finite element model of the functionally graded layer was created using the ANSYS package program, and a two-dimensional analysis of the problem was performed.

Keywords: Functionally graded material; Stress analysis; Contact pressure; Finite element method; Homogenous layer

---

1. Introduction

The contact problem has become a subject studied in many engineering fields. İn most mechanical systems, the elements are in contact, and this causes some problems. Because when two or more components come into contact, stresses and displacement behaviors occur in these areas. Contact problems cause damage to the structure and elements as a result of stress and displacement behaviors. For engineers, knowing the nature of the contact occurring in these systems, their lengths, and the stress distributions in the contact areas provides great convenience in the design and production of the material.Since the contact problem causes much damage to the structure and elements, it has been studied in many engineering fields from the past to the present. Hertz first studied classical contact mechanics at the University of Berlin in 1882. Hertz studied the equilibrium of two elastic bodies in contact, assuming the contact region to be elliptical, and developed formulations for contact stress and deformations (Hertz, Heinric*h*, 1882). After Hertz's inspiring research, many researchers have conducted various studies on the contact problem. The contact problem remains a subject of study in many engineering fields. In layered systems where contact problems occur, sudden changes in material properties can also cause systemic deterioration. As a solution to this problem, with the advancement of technology, it has become clear that the structure of materials can change along their homogeneity or continuously. Functionally graded materials (FGM) are specially structured materials whose components' mechanical and thermal properties are continuously changing (Alagöz et al., 2004). In other words, materials with a composition or structure that varies throughout the volume of the material are defined as Functionally Grade Materials (Alagöz et al., 2004). Due to their ability to reduce surface stress, FGMs have found applications in a wide range of fields since their emergence, including aerospace, electronics, energy, chemical engineering, optical materials, and biomedical engineering. Functionally graded materials have a wide range of applications in the aerospace, automotive, and biomedical industries due to their lightweight, high strength, thermal resistance properties, and resistance to corrosion and wear (Alagöz et al., 2004). The first steps of functionally graded materials were taken during the studies of spacecraft and aircraft at a university in Japan in 1984-1985. In 1987, researchers who worked on FGM were brought together for a large project with the support of the Japanese Ministry of Education and Science. Later, many researchers conducted studies on FGM. Koizumi (1997) has studied these materials. The author examined this material's properties, usage areas, and advantages. Ke and Wang (2006) studied the contact problem that occurs when a single force from an elastic punch and friction forces perpendicular to the force acting on an elastic half-plane covered with a thin layer. Polat (Polat, 2021) examined the continuous contact problem in a functionally graded (FGM) layer loaded with an FG flat punch sitting on an elastic semi-infinite plane using the finite element method (FEM). Balci and Dag (Balci & Dag, 2020) examined the problem of moving contact on functionally graded coating loaded with a rigid

---

[*] Corresponding author, E-mail: bpolat@munzur.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_342

punch. Further, this study is the first to examine the effect of FGM punch on the FGM layer.Yan and Mi (Yan & Mi, 2019) performed contact analysis for an elastic sheet strengthened with a functionally graded coating and pressed into a half-plane.At the end of this study, the results were compared using analytical and finite element methods.This study investigated the effects of the material changing parameters such as punch speed, friction coefficient, material homogeneity, and coating thickness on the contact stress distributions and stress density. Polat (2019) analyzed the continuous contact problem of a homogeneous layer of constant thickness, perfectly bonded to a rigid support on its lower surface and loaded with a rigid stamp, using the finite element method (FEM). He also examined the contact length and contact stress between the rigid block and the homogeneous layer. Çömez et al. (2020) in their work, they investigated the problem of frictional sliding double contact, including an advancing contact region between a rigid cylindrical block and a stepped sheet and a receding contact region between the stepped sheet and a homogeneous sheet bonded to a homogeneous half-plane. Liu et al. (2016) studied the axisymmetric pair contact problems of a functionally graded plate with a rigid cylindrical block and a rigid spherical block loaded. The numerical results analyzed that the stiffness ratio and gradient index greatly influence the contact area and contact pressure. Yan and Mi (2019) analyzed in detail the frictionless contact problem of an elastic structure consisting of an elastic layer and an elastic half-plane loaded with two rigid punches having circular and parabolic profiles. Apatay et al. (2010) analyzed subsurface contact stresses caused by the frictional rigid punch effect in functionally graded coatings. The effects of punch width, punch position, friction coefficient, and material parameters on the stress distributions throughout the coating depth are investigated. Chidlow and Teodorescu (2013) investigated the frictionless two-dimensional contact problem of an inhomogeneous material loaded with a rigid punch. The study investigates the effects of material homogeneity and coating thickness on the cylindrical block. It was stated that the thickness and mechanical properties of the layer significantly affect the maximum stress. Çömez (2013) studied the contact problem in a functionally graded layer supported by the Winkler foundation using linear elasticity theory. The researcher analyzed the effects of material inhomogeneity, the Winkler Foundation's inhomogeneity, and the punch's size on contact stress, contact distance, and normal stresses. Adıyaman et al. (2015) analyzed the split contact problem for a punch resting on two quadrants and an elastic plane loaded with a distributed load using analytical and finite element methods. Contact lengths and contact stresses are solved for different loadings for both solutions. As a consequence of the study, it is analyzed that the values acquired by the finite element method are close to the values obtained by the analytical method. Su et al. (2015) investigated the two-dimensional wear contact problem of a piezoelectric half-plane loaded with a cylindrical punch using analytical methods. As a consequence of the study, they observed that the piezoelectric effect causes the coupling of normal contact pressure and tangential tension, which can significantly affect wear contact damage. Fu et al. (2024) investigated the elastic vibration analysis of the two-dimensional moving contact problem in a functionally graded layer with arbitrarily varying thermoelastic properties. In their study, they stated that increases in friction coefficient and motion speed can cause a decrease in the elastic jolt limit, and the elastic jolt limit can be improved significantly by adjusting the shear modulus and yield stress distribution gradients appropriately. Polat and Kaya (2022) analyzed the contact problem in two functionally graded layers loaded with two rigid blocks, the upper and lower surfaces of which are metal and ceramic, using the finite element method. In this study, the effects of different properties of functionally graded layers on the normal stresses between layers and between rigid blocks and the upper surface of the layer are investigated. In addition, the normal and shear stresses are investigated along the depth at the separation point under the influence of the different properties of the layers. It is noticed in the literature that the solution of this study is not found analytically and positive results are obtained in a short time with the finite element method. Kaya and Polat (2023) carried out the contact analysis of the functionally graded layer resting on the elastic two quadrants using the finite element method. In the functionally graded (FG) layer, the change in material properties along the depth is functionally defined. The changes in the FG layer initial separation distances and contact stresses and stress under the block were investigated for different values of the stiffness parameters β (Elasticity), different values of the load (P) on the block, and different block width values. İf for (FG) layer the change parameter β is very close to zero, the layer will exhibit homogeneous behavior. Analysis was also performed with the values where the FG layer showed homogeneous behavior and was added to the solution part.

2. Definition of the problem

The variation functions of a functionally graded plate located between two semi-infinite elastic planes and loaded with a rigid block are as follows.

$$\mu_2(y) = \mu_0 e^{\beta y},\ \rho_2(y) = \rho_0 e^{\gamma y} \tag{1}$$

μ and ρ state the shear modulus and density. The layer extends in the range (-∞, +∞). This system assumes the block is rigid and the contact stresses transfer only compressive stresses. Therefore, separation occurs between the elastic layers and the (FG) plane when the critical load is exceeded. The problem assumes that all surfaces are frictionless and the thickness in the z-axis direction is unity. The geometry of the problem is shown in Fig. 1.

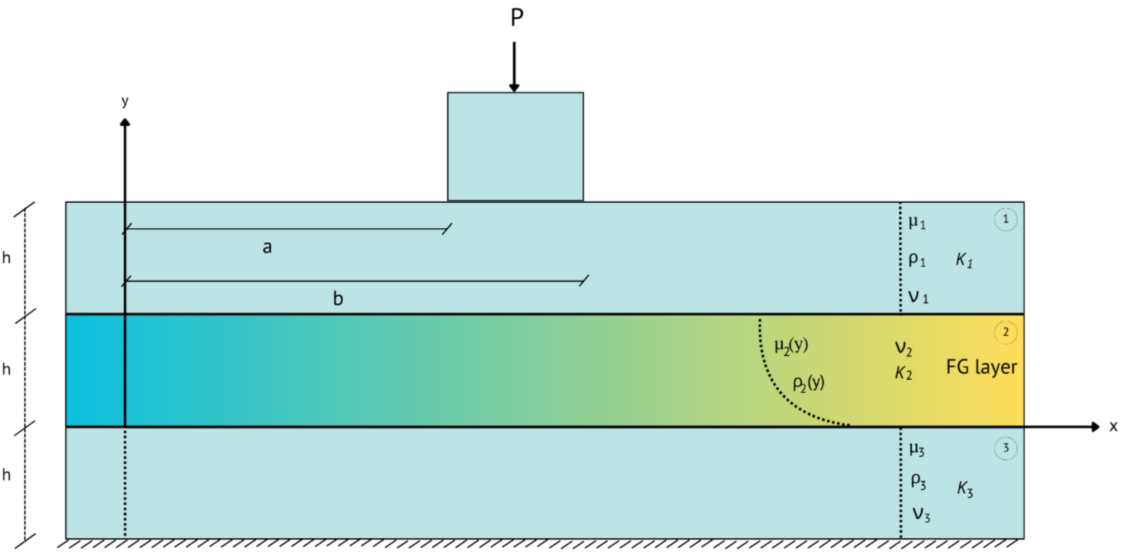

Fig. 1. Geometry of the problem loaded with a block

2.1. Analysis with finite element method

With the development of technology, analytical solutions consisting of long and complex expressions have been replaced by solution methods that can provide effective results quickly. SEM, which seeks a solution by simplifying a complex engineering problem, has become a frequently preferred method in recent years. This method relies on the basis that the solution can be divided into many finite parts. The problem is simplified. Although creating many meshes is important in approaching the complete solution, it can be seen as a disadvantage due to the increase in solution time. The use of SEM-based computer programs is quite common today. The finite element model and analysis of this solvable problem includes the ANSYS (2019) package program. All operations related to blocks and homogeneous planes were done with standard ANSYS menus. The FG layer's material storage and finite element division process was done with a program-specific macro. With the development, the code starts by defining the problem code, such as geometry and material properties, with the *set command. Depending on the simple geometry of the problem, a two-dimensional (2D) aeronautical geometric model is used for FG sheets and homogeneous elastic wings and is divided into sections with RECTNG cuts. The material properties of homogeneous elastic semi-infinite planes and blocks are selected as linear, elastic-isotropic. Defining the element type is important to obtain correct results when solving the problem. In this study, 8-node PLANE183 was used as the element type for static and 2-dimensional flight problems. Each node of this element has degrees of freedom in x and y accuracy. This element has no rotational freedom. ANSYS models of the problem are given in Figs. 2, 3, 4, and 5.

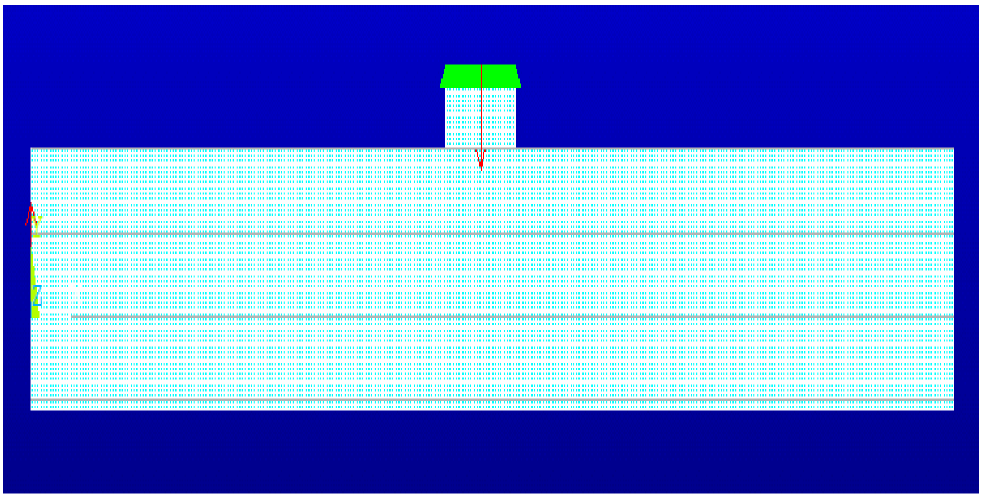

Fig. 2. Finite element model of the problem loaded with block

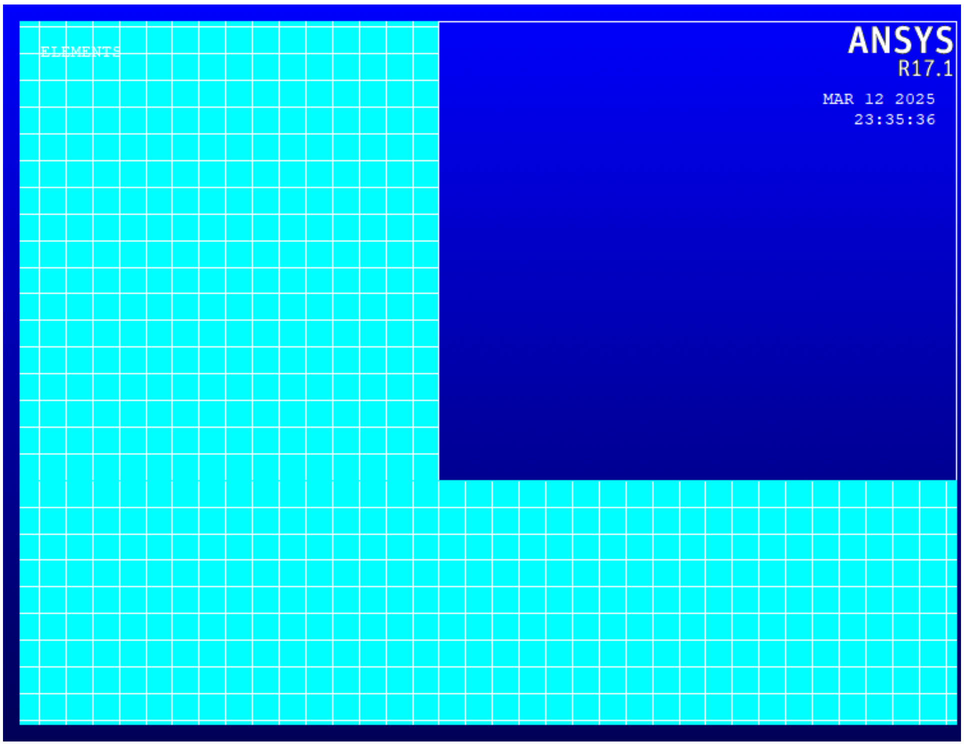

Fig. 3. Free quadrilateral mesh

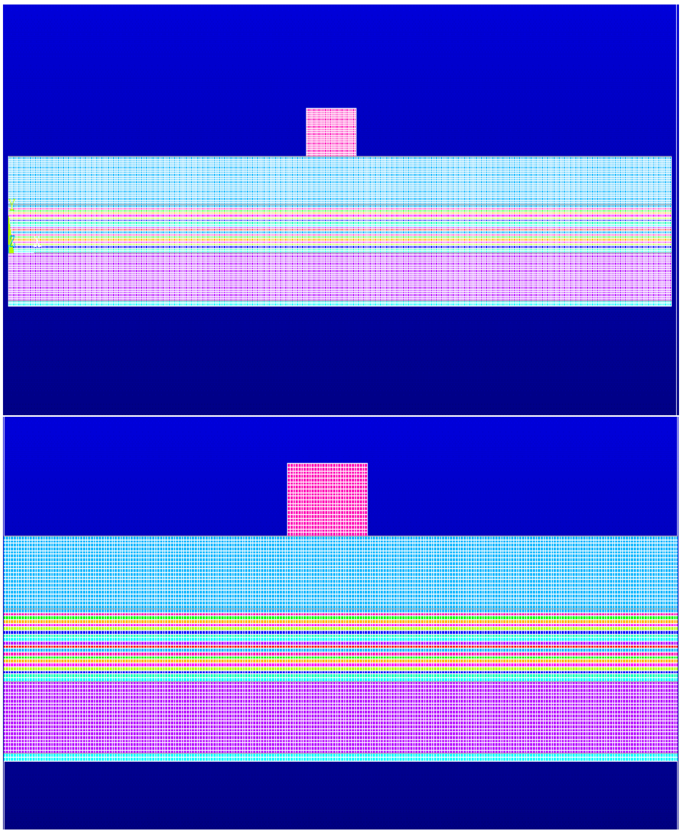

Fig. 4. Assignment of material of the problem loaded with block

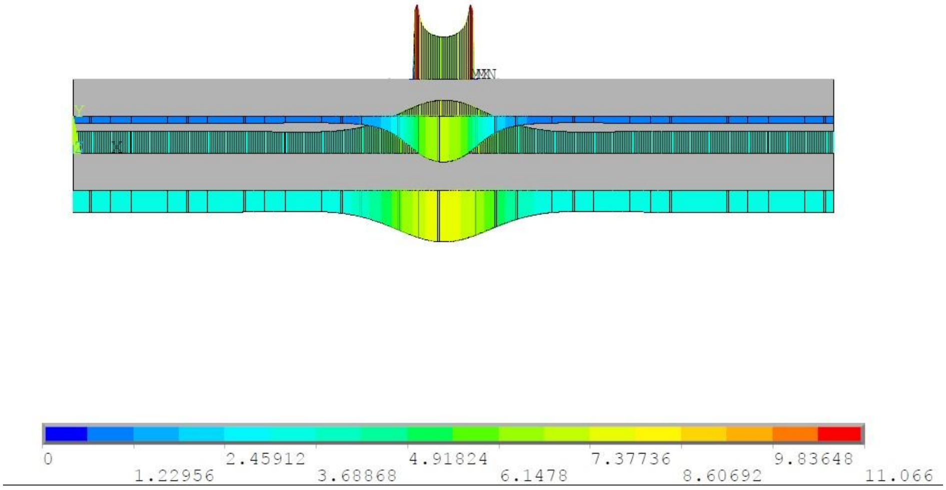

Fig. 5. ANSYS display of the status in contact with continuous contact

At this stage the recorded material is selected according to the program where only the layers graded in the factory and macro are changed exponentially to create the network.The macro used to program the material properties according to exponential change is as follows.

```
!!Material Top
*set, E_t, 100000
*set, nu_t, 0.25
*set,dens_t,1
*set,B,1.3864
*set,A,0.00001
*set,G,-0.6931
*create, mat_fgm_pol
/nopr
y_coord = arg1
E_fgm=E_t*EXP(B*y_coord) !!B=Beta
nu_fgm=nu_t*EXP(A*y_coord) !!A=Alfa
den_fgm=dens_t*EXP(G*y_coord) !!G=Gama
/gopr
*end !mat_fgm_pol
```
(2)

İn formula, the *create command is used to create a macro for the layer consisting of functionally graded material and sets a variable named y_coord = arg1. The mesh section has been moved on to. An additional macro has been added to mesh the FG layer. All geometry has been subjected to the Free Quadrilateral Mesh more frequently in contact areas. The macron for meshing the FG layer is as follows.

```
*do, j, 1, ele_numb_y, 1
y_coord = length_e_y*(j)
*use, mat_fgm_pol,y_coord
mp, ex, cntr,E_fgm
mp, prxy, cntr,nu_fgm
mp, dens, cntr,den_fgm
esel,r,cent,x,0,lngt_lyr
emodif, all, mat, counter
esel, all
```
(3)

In addition, surface-to-surface contact pairs are defined between the block-layer and layer-elastic plane. These pairs are divided into two contact and target elements. The contact is selected as CONTA172, and the target is selected as TARGE169 elements. Selecting more rigid elements than the contact element as the target element would be appropriate. In addition, the mathematical method that will provide the appropriate contact conditions is also decided while selecting the formulation to be used in the contact region. There are various contact algorithms in ANSYS, depending on the problem type. The Augmented Lagrangian Method, which provides fast results using the total potential energy theorem, was preferred as the contact algorithm.

3. Results and discussion

It is observed that as Bh increases, the initial separation distance between the FG layer and the upper homogeneous layer decreases and the initial separation load increases. It was also observed that as the load (P) acting on the Block increases, the initial separation distance does not change and the initial separation load decreases.The results are shown in Table 1.

It was observed that as Bh increased, the initial separation distance and initial separation load between the FG layer and the under homogeneous layer increased. It was also observed that as the load (P) acting on the Block increased, the initial separation distance did not change and the initial separation load decreased.The results are shown in Tables 2.

It was observed that as Bh increased, the initial separation distance and initial separation load between the under homogeneous layer and ground increased. It was also observed that as the load (P) acting on the Block increased, the initial separation distance did not change and the initial separation load decreased.The results are shown in Tables 3.

It was observed that as βh increases, the stresses between the FG layer and the upper homogeneous layer increase, while as βh decreases, the stresses decrease.The results are presented in Fig. 7.

It was observed that as βh increases, the stresses between the FG layer and the under homogeneous layer increase, while as βh decreases, the stresses decrease The results are presented in Fig. 8.

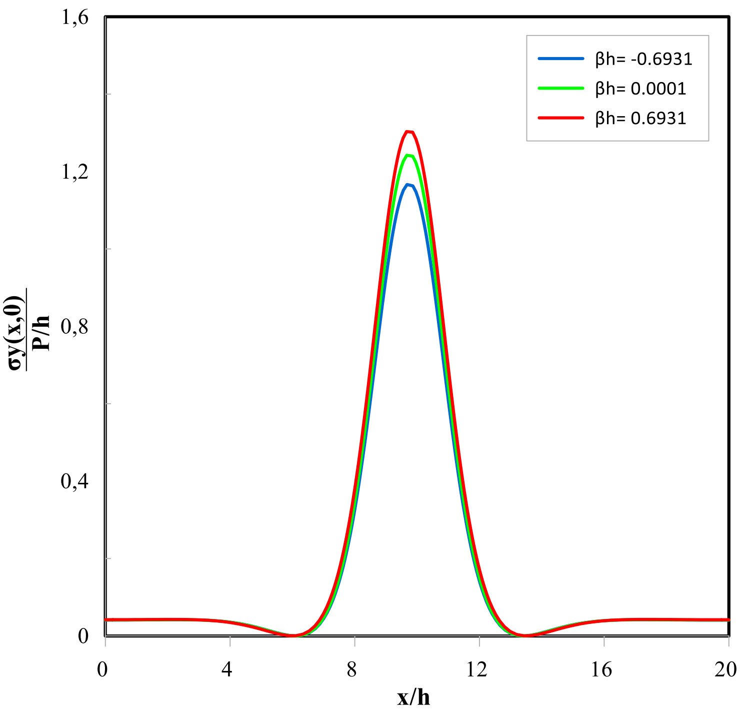

Fig. 7. Contact stress distributions between FG layer and upper homogeneous layer according to the layer stiffness parameter (βh) (a/h=9, (b-a)/h=1.5, μ0=1, K1= K 2=2, y=h, h=1, μ-h=1)

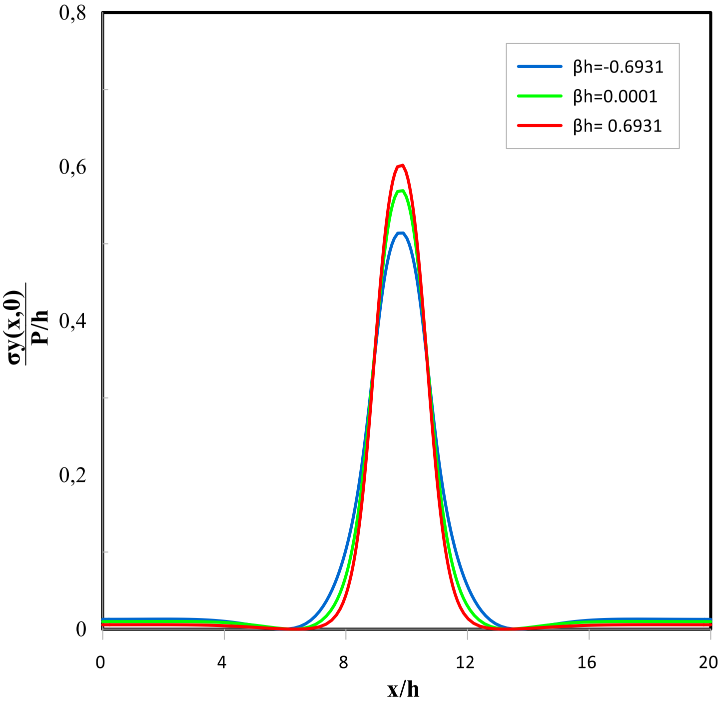

Fig. 8. Contact stress distributions between FG layer and under homogeneous layer according to the layer stiffness parameter (βh) (a/h=9, (b-a)/h=1.5, μ0=1, K2= K3=2, y=h, h=1, μ-h=1)

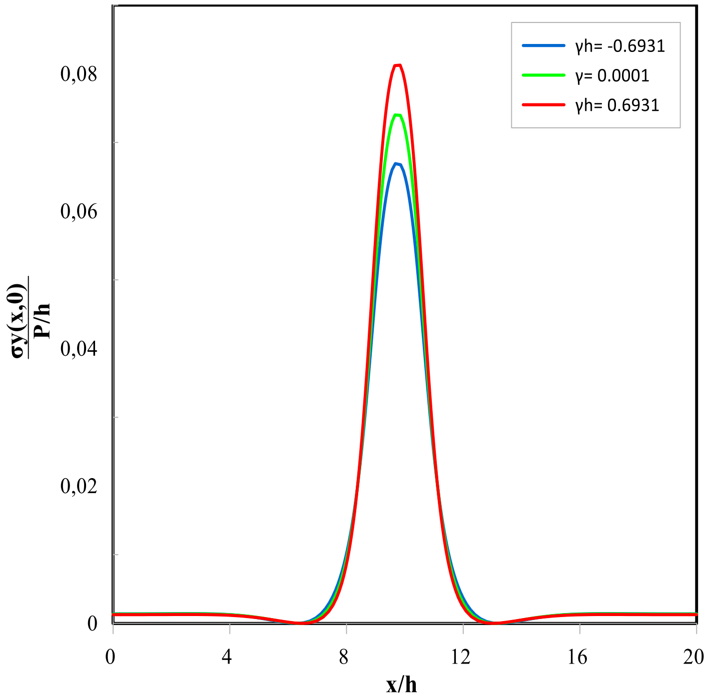

Fig. 9. Contact stress distributions between FG layer and upper homogeneous layer according to the layer stiffness parameter (γh) (a/h=9, (b-a)/h=1.5, μ0=1, K1= K2=2, y=h, h=1, μ-h=1)

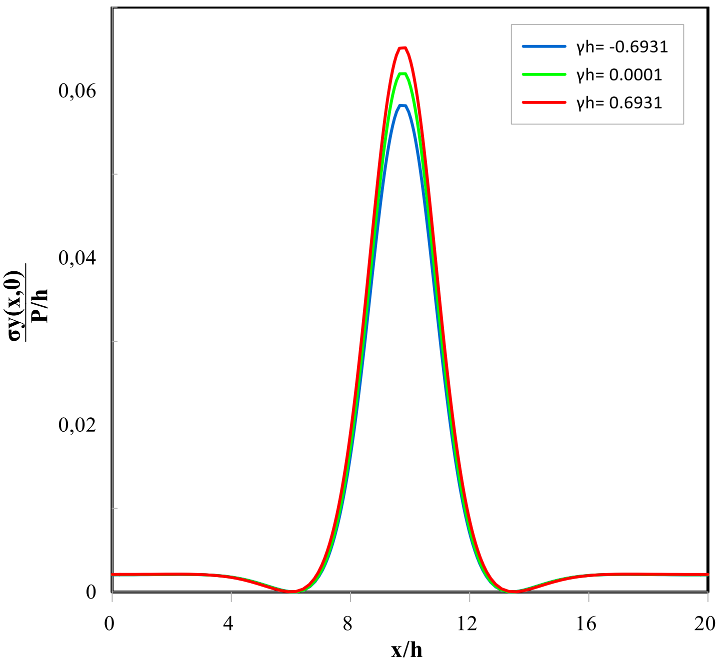

Fig. 10. Contact stress distributions between FG layer and under homogeneous layer according to the layer stiffness parameter (γh) (a/h=9, (b-a)/h=1.5, μ0=1, K2= K3=2, y=h, h=1, μ-h=1)

It was observed that the increase in the γh value led to higher stresses between the FG layer and the upper homogeneous layer, while the decrease in the γh value was associated with the decrease of these stresses. The results are presented in Fig. 9.

It was observed that the increase in the γh value led to higher stresses between the FG layer and the under homogeneous layer, while the decrease in the γh value was associated with the decrease of these stresses. The results are presented in Fig. 10.

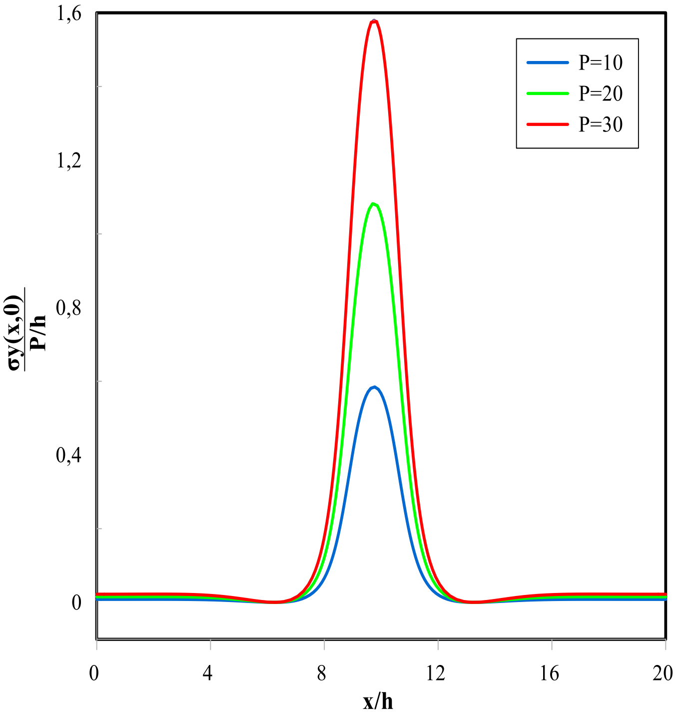

Fig. 11. Contact stress distributions between FG layer and upper homogeneous layer according to of change load(P) on the block (βh=0,693147) (a/h=9, (b-a)/h=1.5, μ0=1, K1= K2=2, y=h, h=1, μ-h=1)

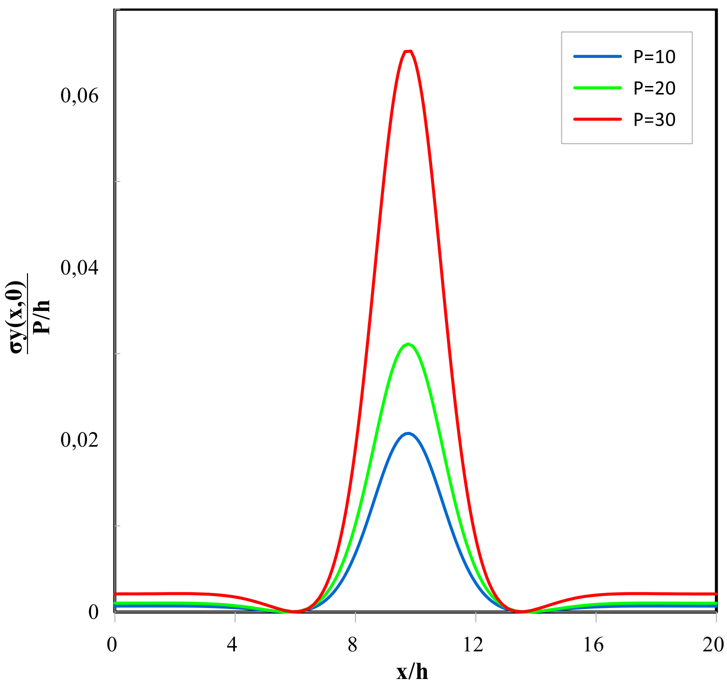

Fig. 12. Contact stress distributions between FG layer and underr homogeneous layer according to of change load(P) on the block (βh=0,693147) (a/h=9, (b-a)/h=1.5, μ0=1, K_2= K_3=2, y=h, h=1, μ-h=1)

It was observed that the increase in the load (P) applied to the block caused an increase in the contact stress values between the FG layer and the upper homogeneous layer.The results are presented in Fig. 11.

It was observed that the increase in the load (P) applied to the block caused an increase in the contact stress values between the FG layer and the under homogeneous layer. The results are presented in Fig. 12.

4. Conclusions

The aim of this study is to investigate the contact stresses in a functionally graded layer loaded with a block according to different variables such as βh, γh and load(P). These investigations have led us to the following conclusions.

- It was observed that the change in βh caused a change in the initial separation distance ($Xcr_{sağ}$) and initial separation load (λ_{cr}). It was observed that different load values did not cause a change in the initial separation distances ($Xcr_{sağ}$) but caused a change in the initial separation loads (λ_{cr}).
- It was observed that βh, γh and load(P) changes caused changes in contact stresses.

Abstract. This study investigates the performance of the geometrical nonlinear analysis of thin and thick plates under large deflections and small rotations. A parametric study was performed on rectangular plates with different boundary conditions, thicknesses and applied loadings. The numerical analysis is performed on the coupled isoparametric quadrilateral plate finite element baptized "QC4", which incorporates five degrees of freedom, deduced from the plate bending element Q4 with 3DOF/ node (W, θ_x,θ_y) and the membrane element Q4 with 2DOF/node (U, V), to engender the membrane forces induced from large deflexion. The stiffness matrices are calculated according to the Mindlin's thick plate theory and the nonlinear equilibrium equations are solved by the Newton-Raphson iterative algorithm. A MATLAB program is elaborated to compute the related stiffness matrices; the linear stiffness matrix (K_0), the large deflection stiffness matrix (K_L) and the geometric stiffness matrix ($K\sigma$). To validate the proposed approach and element; the ABAQUS software is used to validate the deflections obtained. Additionally, an experimental results of a rectangular plate subjected to a concentrated load is used to evaluate the efficiency of the formulated plate bending element"QC4". The results obtained demonstrate that the computed displacements are in strong agreement with the analytical solution and the experimental results. Moreover, validation tests confirmed the accuracy and effeciency of the QC4 element in performing the geometrical nonlinear analysis for both thin and thick plate structures.

Keywords: Quadrilateral isoparametric element; Geometrical nonlinear analysis; Thick and thin plates; Large deflections; ABAQUS software

1. Introduction

Nonlinear analysis plays a critical role in engineering, particularly in civil engineering, as it enables a precise determination of a structure's behavior. In contrast to linear analysis, which fails to provide accurate predictions, nonlinear analysis offers a more realistic representation of structural performance (Al-Nadhari et al., 2024). Numerous studies have employed various nonlinear analysis techniques to investigate the behavior of plates.Wood and Hinto(Pica et al., 1980) employ finite element analysis (FEA) based on the Mindlin plate formulation to investigate the nonlinear behavior of plates. Their study conducts a comparative evaluation of four distinct element types: linear, serendipity, Lagrangian, and Heterosis elements, under varying loading conditions. Zhang and Kim (Zhang et al., 2006) developed two displacement-based 4-node quadrilateral elements, RDKQ-NL20 and RDKQ-NL24 for nonlinear analysis of laminated composite plates. The elements are based on first-order shear deformation theory (FSDT) and von-Karman's large deflection theory, using the total Lagrangian approach.Chau-Dinh et al. (Chau-Dinh et al., 2024) presented a triangular flat shell formulation with three nodes, tailored for examining geometric nonlinearities in plates and shells. Their approach integrates Allman-type interpolation and the MITC strategy to effectively address shear locking phenomena. Rezaiee-Pajand et al. (Rezaiee-Pajand et al., 2019) introduce an advanced six-node triangular element based on a locking-free, mixed finite element methodology, designed to improve the accuracy of displacement and stress evaluations in linear as well as nonlinear structural simulations. Atnaik et al. (Patnaik et al., 2020) developed a finite element for to tackle the geometrically nonlinear analysis in plate structures, employing a fractional-order continuum framework. The two-dimensional nonlinear model, grounded in a frame-invariant and thermodynamically sound fractional theory, captures nonlocal softening effects through both Mindlin and Kirchhoff plate formulations.

In this paper, a coupled isoparametric quadrilateral plate finite element baptized "QC4", which incorporates five degrees of freedom, deduced from the plate bending element Q4 with 3DOF/ node (W, θ_x,θ_y) and the membrane element Q4 with 2DOF/node (U, V), to engender the membrane forces induced from large deflexion is used. In addition to the ABAQUS S4R element and Q4 element that developed by Patil and Kolukula(A. Patil et al., 2016) to carry out a parametric study of the plates under large deflection including the effect of boundary conditions and the effect of the thickness ratio (**Fig.1)**. The results obtained are compared with the experimental results as a reference solution and with the analytical solution.

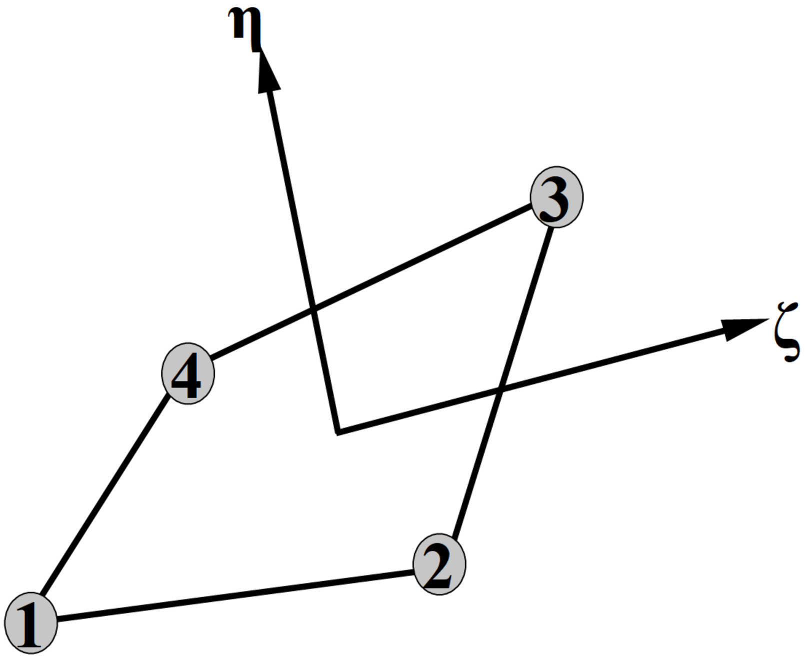

Fig. 1 Coupled isoparametric quadrilateral plate finite element "QC4"

2. Formulation of nonlinear matrices

The Green strain vector ε characterizes the primary measurement of deformation at a specific location situated a distance z from the mid-plane of a plate, as formulated in the equation below(Ganaba, 1985).

$$\{\varepsilon\} = \left\{ \begin{array}{c} \dfrac{\partial u}{\partial x} + \dfrac{1}{2}\left[\left(\dfrac{\partial u}{\partial x}\right)^2 + \left(\dfrac{\partial v}{\partial x}\right)^2 + \left(\dfrac{\partial w}{\partial x}\right)^2\right] \\ \dfrac{\partial v}{\partial y} + \dfrac{1}{2}\left[\left(\dfrac{\partial u}{\partial y}\right)^2 + \left(\dfrac{\partial v}{\partial y}\right)^2 + \left(\dfrac{\partial w}{\partial y}\right)^2\right] \\ \dfrac{\partial u}{\partial y} + \dfrac{\partial v}{\partial x} + \dfrac{\partial u}{\partial x}\dfrac{\partial u}{\partial y} + \dfrac{\partial v}{\partial x}\dfrac{\partial v}{\partial y} + \dfrac{\partial w}{\partial x}\dfrac{\partial w}{\partial y} \\ \dfrac{\partial u}{\partial z} + \dfrac{\partial w}{\partial x} + \dfrac{\partial u}{\partial x}\dfrac{\partial u}{\partial z} + \dfrac{\partial v}{\partial x}\dfrac{\partial v}{\partial z} + \dfrac{\partial w}{\partial x}\dfrac{\partial w}{\partial z} \\ \dfrac{\partial v}{\partial z} + \dfrac{\partial w}{\partial y} + \dfrac{\partial u}{\partial y}\dfrac{\partial u}{\partial z} + \dfrac{\partial v}{\partial y}\dfrac{\partial v}{\partial z} + \dfrac{\partial w}{\partial y}\dfrac{\partial w}{\partial z} \end{array} \right\} \tag{1}$$

The above equation can be written as follows:

$$\varepsilon = \begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \\ \gamma_{xz} \\ \gamma_{yz} \end{Bmatrix} = \begin{Bmatrix} \varepsilon_m \\ 0 \end{Bmatrix} + \begin{Bmatrix} z\kappa \\ \gamma_s \end{Bmatrix} + \begin{Bmatrix} \varepsilon_{NL} \\ 0 \end{Bmatrix} \tag{2}$$

Where ε_m, zκ, γ_s, and ε_{NL} denote, respectively, the linear membrane strain components, the linear bending-induced strain terms, the linear transverse shear strain measures, and the nonlinear in-plane deformation contributions as outlined in reference(Ganaba, 1985).

$$\varepsilon_m = \begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{Bmatrix} = \begin{Bmatrix} \frac{\partial u}{\partial x} \\ \frac{\partial v}{\partial y} \\ \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \end{Bmatrix}, \kappa = z \begin{Bmatrix} \frac{\partial^2 w}{\partial^2 x} \\ \frac{\partial^2 w}{\partial^2 y} \\ \frac{\theta_x}{\partial y} + \frac{\theta_y}{\partial x} \end{Bmatrix}, \text{and } \gamma_s = \begin{Bmatrix} \frac{\partial w}{\partial x} - \theta_x \\ \frac{\partial w}{\partial y} - \theta_y \end{Bmatrix}, \varepsilon_{NL} = \frac{1}{2} \begin{Bmatrix} \left(\frac{\partial w}{\partial x}\right)^2 \\ \left(\frac{\partial w}{\partial y}\right)^2 \\ \frac{\partial w}{\partial x}\frac{\partial w}{\partial y} \end{Bmatrix} \tag{3}$$

The displacement components (u, v, w) at a spatial position (x, y, z) are described as functions of the mid-surface translational displacements (u_0, v_0, w_0), along with the independent rotations θ_x and θ_y about the xz and yz planes, respectively, as formulated in the framework of Mindlin plate theory (Ganaba, 1985).

$$\begin{aligned} u &= u_0(x,y) - z\beta_x(x,y) \\ v &= v_0(x,y) - z\beta_y(x,y) \\ w &= w_0(x,y) \end{aligned} \tag{4}$$

The stiffness matrix can be obtained by using the principle of virtual work as given in reference (Ojeda et al., 2007) expressed as:

$$\int_A [\bar{B}]\{\sigma\} dA = P \tag{5}$$

the above equation can be written as:

$$[K_T]\{d\delta_i\} = \{P\} - [K_s]\{\delta_{i-1}\} \tag{6}$$

Where K_T, K_S, $d\delta_i$, and P are tangent stiffness matrix, secant stiffness matrix and nodal displacement respectively as given in references (Ganaba, 1985; Ojeda et al., 2007).

$$[K_T] = [K_0] + [K_L] + [K_\sigma]$$

$$[K_L] = \int_A [B_L]^T[D][B_{NL}]dA + \int_A [B_{NL}]^T[D][B_L]dA + \int_A [B_{NL}]^T[D][B_{NL}]dA$$

$$[K_\sigma] = \int_A [G]^T[S][G]\, dA \tag{7}$$

$$[K_0] = \int_A [B_L]^T[D][B_L]dA + \int_A [B_s]^T[D_s][B_s]dA$$

$$[K_s] = \int_A [B_L]^T[D][B_L]dA + \frac{1}{2}\int_A [B_L]^T[D][B_{NL}]dA + \int_A [B_{NL}]^T[D][B_L]dA + \frac{1}{2}\int_A [B_{NL}]^T[D][B_{NL}]dA$$

3. Applications

3.1. Clamped square plate

The clamped square plate shown in Fig.2 is analysis with the following paramaters, the parameter load $P_0 = q_0a^4/Eh^4$, the thickness ratio is taken as L/h = 100 and the Poisson's ratio v=0.316. The results obtained by the "QC4" and S4R elements are compared with the analytical solution and with those obtained by another method as presented in Table 1.

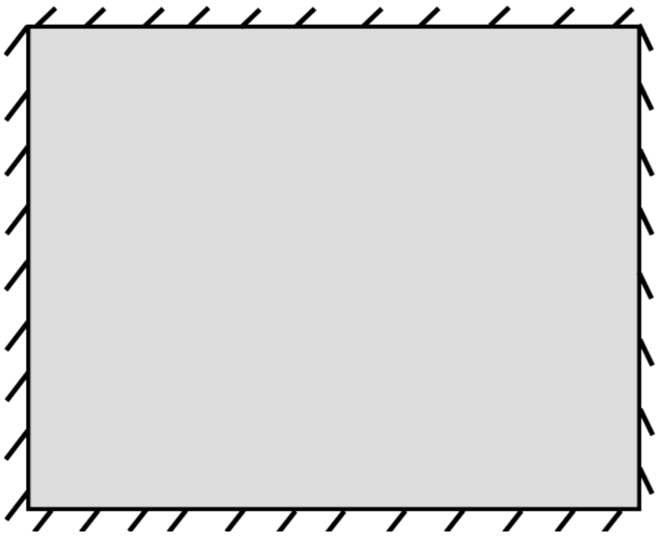

Fig.2 Clamped square plate

Table 1 Comparison of the central dimensionless deflection (w/h)

P_0	Analytical Levy(Levy et al., 1942)	"QC4"	S4R	MXFEM (Urthaler et al., 2008)	NURBSKR (Kapoor et al., 2012)
17.8	0.237	0.2356	0.2380	0.239	0.233
38.3	0.471	0.4699	0.4750	0.474	0.464
63.4	0.695	0.6957	0.7024	0.697	0.685
95	0.912	0.91273	0.9223	0.909	0.899
134.9	1.121	1.1220	1.1340	1.113	1.105
184	1.323	1.32216	1.3360	1.308	1.302
245	1.521	1.51902	1.5350	1.501	1.497
318	1.714	1.70916	1.7280	1.688	1.686
402	1.902	1.8896	1.9130	1.866	1.865

From the results shown in Table 1, it is clear that both element "QC4" and S4R provide almost similar deflections (w/h) that very cloose to the analytical Levy solution across all load levels. This confirming the effeciency of the formulate element"QC4". The "QC4" element consistently yields values nearly identical to the analytical ones, with minimal error even as the load increases, indicating strong numerical stability and precision. The S4R element, while also accurate, tends to produce slightly higher deflections at larger loads, such as at (P_0 = 402), where it predicts 1.9130 compared to 1.902 from the analytical solution and 1.8896 from "QC4" compared to the more advanced methods —MXFEM and NURBSKR—. Both "QC4" and S4R elements show better agreement with the analytical reference, with MXFEM occasionally overestimating and NURBSKR generally underestimating the response. However, the differences are minor, and both elements demonstrate high accuracy, with QC4 showing superior consistency and S4R offering slightly more sensitivity to nonlinearity.

3.2. Square plate with two clamped edges and two free edges

A square plate is subjected to concentrated load with two clamped edges and the other are free (Fig.2). The mechanical and geometrical properties of the plate are: E = 2.15×10^4 kg/mm², ν=0.3, and h= 1.98 mm. The load is applied in point N and the deflections at point A are calculated and ploted as shown in Fig.3. The results obtained from the S4R and "QC4" elements are compared with the experimental results (Kawai et al., 1969) and those found from the nonlinear theory (Kawai et al., 1969) and natural mode (Argyris et al., 1994) elements.

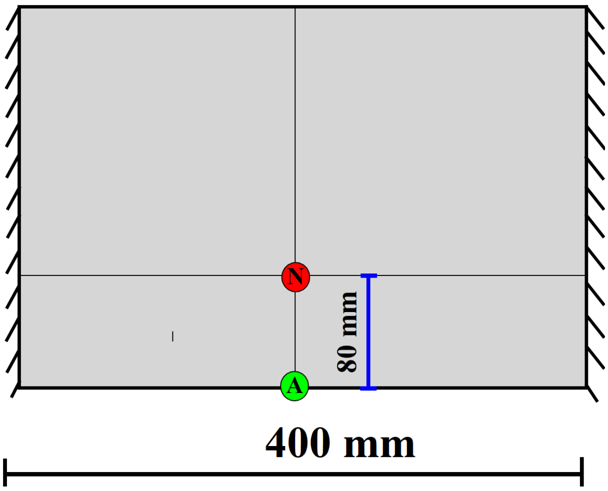

Fig. 2 Square plate with two edges clamped

The results obtained from the nonlinear analysis using "QC4" and S4R elements were compared with those derived from nonlinear theory, natural mode analysis, and experimental results are presented in (Fig. 3). Among all methods, the S4R element showed the closest agreement with the experimental and theoretical results across the entire load range, indicating its high accuracy in predicting the plate's nonlinear response. The "QC4" element, while following the general trend, consistently overestimated deflections, particularly at higher loads, showing a noticeable deviation from the reference data. The natural mode and nonlinear theory solutions remained in close proximity to the experimental values, with slightly conservative predictions. Overall, the comparison highlights that the S4R element produced results most consistent with the validated benchmarks, while the Q4 element exhibited a greater margin of error in capturing the plate's deflection under nonlinear conditions.

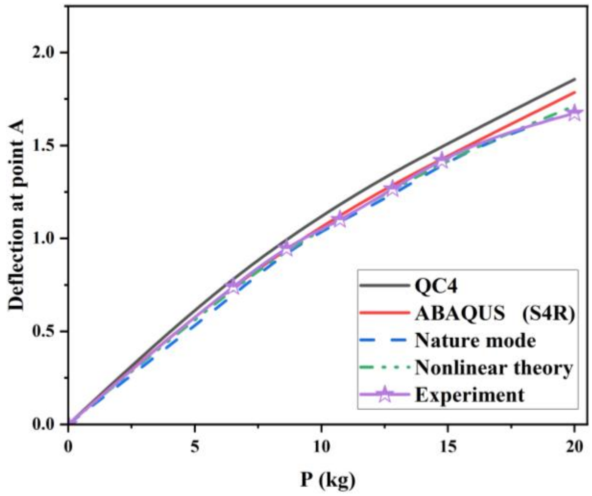

Fig.3 Comparison of the deflection at point A

3.3. Simply supported square plate

In this application, a parametric study will be conducted on the same previuos example in order to investigate the influence of boundary conditions and plate thickness on its nonlinear behavior. Initially, the existing constraints will be modified to simple supports and their impact on the plate's response. The results of this analysis are plotted in Fig. 4 and compared to the results obtained with the original constraint configuration. It is well observed that boundary conditions of a plate have a significant impact on its structural behavior, particularly in terms of stiffness and deformation. Also, clamped edges provide both translational and rotational restraints, resulting in higher stiffness and lower deflection, whereas simply supported edges allow rotation, making the plate more flexible. This reduction in constraint led to consistently higher mode or response values in the simply supported (SFSF) plate compared to the clamped-free (CFCF) case, as seen in the numerical results using both S4R and "QC4" elements. It is clear that the "QC4" element showed slightly higher values than S4R, which may be due to differences in stiffness formulation and integration schemes. Overall, the results confirm that altering boundary conditions significantly influences the plate's response, with the SFSF condition producing greater deformation and higher modal, aligning well with theoretical expectations.

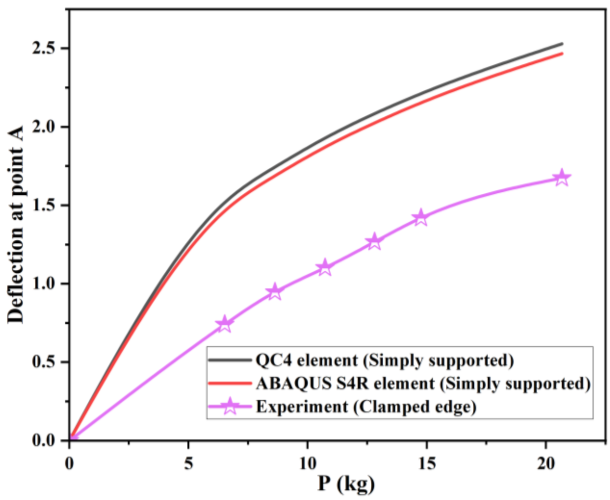

Fig. 4 Deflection of two simply supported edge

3.4. Clamped square plate

In this example, the effect of plate thickness on the nonlinear behavior of a square plate is investigated. Experimental results were obtained for a plate with a thickness of 1.98 mm (Kawai et al., 1969) and compared with numerical simulations, using "QC4" and S4R elements ith the following thickness values: 2.5 mm, 3 mm, 3.5 mm and 4 mm. Obvuiousely, as the thickness increases, the plate becomes stiffer, which leads to important reduction in nonlinearity behavior through the consistent decrease in the response values across all thicknesses and load levels as shown in (Fig. 5). This trend is observed in both QC4 and S4R element analyses, with QC4 generally predicting slightly higher values than S4R, likely due to differences in element formulation and sensitivity to bending. The reduction in response with increasing thickness indicates that thicker plates exhibit more linear behavior, as they are less sensitive to geometric nonlinearity and large deflections under the same loading conditions. The comparison with experimental data for the thinnest plate (h = 1.98 mm) confirms the validity of the numerical model and highlights how thickness plays a crucial role in controlling the degree of nonlinearity behavior in plate structures.

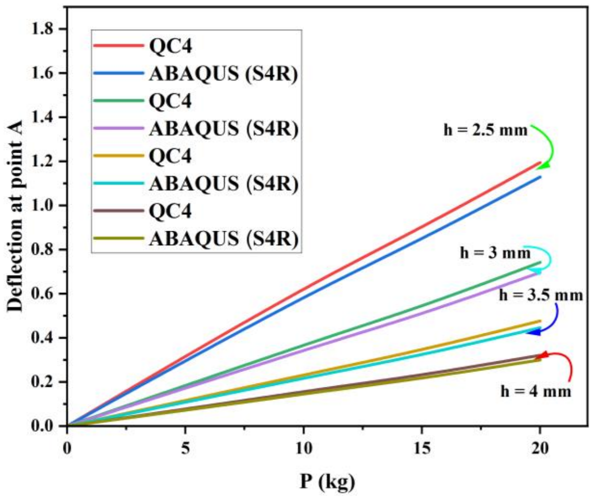

Fig. 5 Comparison of deflection at point A with different thickness

As the plate thickness increases, the displacement decreases significantly, with reductions reaching up to 81%. This highlights the stiffening effect of thickness in reducing nonlinearity behavior. In contrast, changing the boundary condition from clamped to simply supported results in an increase in displacement of up to 51%, indicating greater flexibility and enhanced nonlinear response. Fig. 6 shows the percentage increase in displacement when changing the boundary conditions. It also shows the percentage decrease in displacement as the thickness increases.

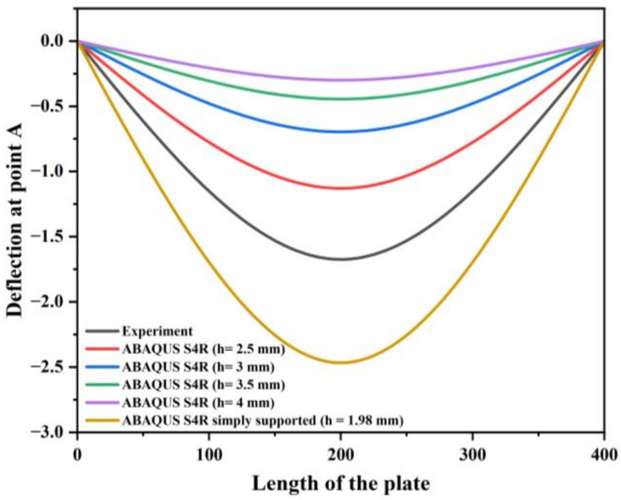

Fig. 6 Effect of the boundary condition and the thickness ratio

4. Conclusion

The nonlinear analysis of square plates using "QC4" and ABAQUS S4R elements confirm the efficiency and performance of both elements with "QC4" . It is notes that a strong alignment with analytical solutions observed with QC4, while S4R element show good agreement with experimental results, particularly at higher load levels. The parametric study highlights the significant influence of boundary conditions and plate thickness on nonlinear behavior. Clamped boundary conditions enhance stiffness and reduce deflections, while simply supported configurations increase structural flexibility and nonlinear response. Moreover, increasing plate thickness reduces deflections as thick plates exhibit more linear behavior under the same loading conditions (small deflection). These results confirm the effeciency of the formulated finite element QC4 in nonlinear analysis of plates and provide valuable engineering applications.

Geometry effects on rock fracture toughness under combined tension-shear loading

Majid R. Ayatollahi*[1], Morteza Rashidi-Moghaddam[1]

[1] *Fatigue and Fracture Lab., Centre of Excellence in Experimental Solid Mechanic and Dynamics, School of Mechanical Engineering, Iran University of Science and Technology, Narmak, 16846, Tehran, Iran*

Abstract. Fracture toughness and crack growth resistance are important material properties which describe the critical states of stresses or energy near the crack tip required for the initiation of brittle fracture. Fracture toughness can be used to determine the critical applied load required for the initiation of crack growth under static loading in cracked components and structures and can be employed as a useful tool to solve various rock engineering problems such as rock excavation, tunneling, rock cutting processes, hydraulic fracturing, rock blasting and rock slope stability analysis. The conventional fracture criteria like the maximum tangential stress (MTS) criterion and the minimum strain energy density (SED) criterion sometimes underestimate or overestimate the experimentally obtained fracture toughness in rocks particularly under combined tension-shear (or mixed mode I and II) loading conditions. In addition, the conventional fracture criteria assume that fracture resistance is not influenced by the geometry and loading conditions. In this paper, an improved approach is suggested for predicting mode I, mode II and mixed mode I/II fracture behavior of rocks using the averaged strain energy density (ASED) criterion. The Generalized ASED (GASED) criterion takes into account the effect of T-stress in addition to the singular terms of stresses/strains of William's series expansion in order to provide more accurate estimates for fracture toughness of rocks. The experimental results obtained from fracture tests performed on a British limestone using the Brazilian disk (BD) and Semi-circular bend (SCB) specimens are used to show the validity of the GASED criterion.

Keywords: Rock fracture mechanics; Tension-shear fracture; Limestone; Geometry effects; Strain energy density criterion

1. Introduction

Rock burst and rock fragmentation are considered as a process of crack initiation and propagation in rock masses. Fracture toughness and crack growth resistance are important material properties which describe the critical states of stresses or energy near the crack tip required for the initiation of brittle fracture (Ba et al., 2021 and Mehraban et al, 2023). Fracture toughness can be used to determine the critical applied load required for the initiation of crack growth under static loading in cracked components and structures and can be employed as a useful tool to solve various rock engineering problems such as rock excavation, tunneling, rock cutting processes, hydraulic fracturing, rock blasting and rock slope stability analysis. Because of the wide applications of fracture toughness in rock engineering; its determination is an important subject for engineers and researchers.

Several researchers have suggested a wide range of specimens for determination of the fracture toughness in rocks. Among these specimens, the centrally cracked Brazilian disk (BD) specimen subjected to diametral compressive load and the edge cracked semi-circular bend (SCB) specimen subjected to three-point bending (see Fig. 1) have been recognized as favorite test specimens for investigating mode I, mode II and mixed mode I/II fracture behavior in rock materials (Khan & Al-Shayea, 2000, Chang et al., 2002, Akbardoost et.al 2014).

Previous studies have shown that the conventional fracture criteria like the maximum tangential stress (MTS) criterion and the minimum strain energy density (SED) criterion sometimes underestimate or overestimate the experimentally obtained mixed mode I/II fracture toughness in rocks. In addition, the conventional fracture criteria assume that the mode I fracture resistance (K_{If}^{I}) is not influenced by the geometry and loading conditions. In this paper, an improved approach is suggested for predicting mode I, mode II and mixed mode I/II fracture behavior of rocks using the averaged strain energy density (ASED) criterion. The Generalized ASED (GASED) criterion takes into account the effect of T-stress in addition to the singular terms of stresses/strains of William's series expansion in order to provide more accurate estimates for fracture toughness of rocks.

a b

Fig. 1. The edge cracked semi-circular bend (SCB) specimen subjected to three-point bending (a) and the centrally cracked Brazilian disk (BD) specimen subjected to diametral compressive load (b)

2. Fracture model

Lazzarin & Zambardi (2001) suggested the averaged strain energy density (ASED) criterion which uses the values of strain energy density averaged in a localized damage zone of radius r_c (called control volume) to estimate the fracture load for cracked and notched specimens. They determined the ASED values directly from finite element analysis.

As an alternative approach, one can calculate the strain energy density using the equations of stresses/strains written based on the well-known Williams' series expansions. The GASED criterion accounts for the effect of *T*-stress as a key parameter in calculating the strain energy density factor around the crack tip. Based on this approach, a general equation for mixed mode fracture is obtained

$$K_{Ic}^2 = [K_{If}^2 + \frac{9-8\upsilon}{5-8\upsilon} K_{IIf}^2 + \frac{16(8-20\nu)}{15\pi(5-8\nu)} K_{If} K_{eff}(B\alpha) + \frac{4-4\upsilon}{2(5-8\upsilon)} K_{eff}^2 (B\alpha)^2] \tag{1}$$

where K_{Ic} is called mode-I fracture toughness, which should be obtained experimentally using a cracked specimen in which the *T*-stress is zero or negligible. K_{If} and K_{IIf} are the critical stress intensity factor and T_f is the critical T-stress corresponding to the fracture load. The dimensionless parameters B and α are defined as

$$B = \frac{T_f\sqrt{\pi a}}{K_{eff}} = \frac{T_f\sqrt{\pi a}}{\sqrt{K_{If}^2 + K_{IIf}^2}}, \quad \alpha = \sqrt{\frac{2r_c}{a}} \tag{2}$$

For pure mode-I loading, when $K_{IIf} = 0$, Eq. (1) is simplified to

$$K_{Ic} = K_{If}^I \sqrt{[1 + \frac{16(8-20\nu)}{15\pi(5-8\nu)}(B\alpha) + \frac{4-4\upsilon}{2(5-8\upsilon)}(B\alpha)^2]} \tag{3}$$

For pure mode-II loading, when $K_{If} = 0$, Eq. (1) is simplified to

$$K_{Ic}^2 = K_{IIf}^2 [\frac{9-8\upsilon}{5-8\nu} + \frac{4-4\upsilon}{2(5-8\upsilon)}(B\alpha)^2] \tag{4}$$

3. Results

The theoretical predictions of the mode I fracture resistance based on the GASED criterion together with the experimental data reported by Akbardoost et al (2014) for a British limestone are plotted in Fig. 2. The proposed modified criteria provide very good estimates of the mode I fracture resistance for this wide range of data. A comparison between the mode I fracture resistance predicted using the GASED criterion (Eq. (3)) and the test data shows that the GASED criterion provides very good estimates for the experimental results reported for the British limestone.

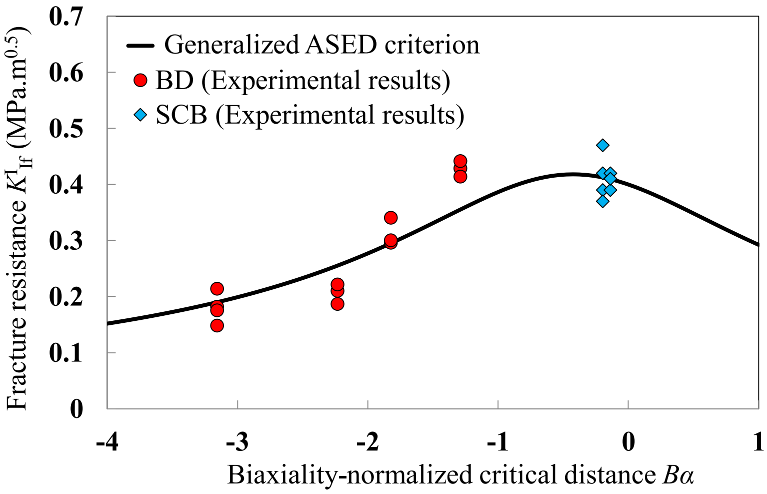

Fig. 2. Variation of mode I fracture resistance versus Bα for the British limestone extracted from the test performed by Akbardoost et al, (2014) on BD and SCB specimens

Mixed mode fracture tests were also performed on a British limestone using BD and SCB specimens by Akbardoost and his co-researchers (2014). The GASED criterion based on the critical stress intensity factors K_{If} and K_{IIf} together with the T-stress (Eq.(1)) was then used for fracture load predications in both specimens. It is seen from Figs. 3 and 4 that the GASED criterion provides significantly better predictions for the experimental results compared to the conventional ASED criterion. The improved predictions of generalized ASED criterion suggests that the increase and decrease in fracture toughness of the rock samples tested by the BD and SCB specimens were mainly due to the effect of T-stress which is ignored in the conventional criterion.

It is finally noted that the geometry dependency of fracture resistance under mixed mode loading is an important issue because engineers have to correlate the experimental results which are obtained in the laboratory conditions to practical problems where a crack is found in the field rock masses. For this purpose, the application of GASED criterion can be very useful as it considers the effects of geometry of cracked rock samples for better predictions of crack behaviour in real engineering projects related to rock mechanics.

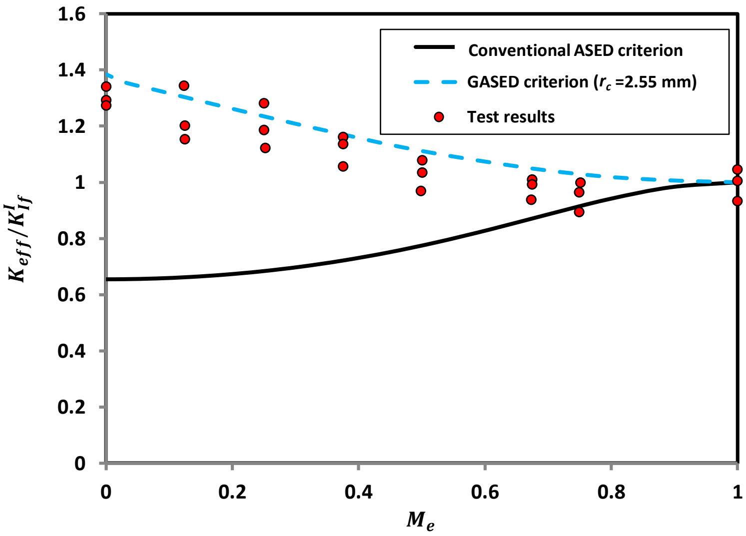

Fig. 3. Predictions of GASED criterion for mixed mode fracture toughness of a British limestone tested by Akbardoost et al, (2014) using the BD specimen

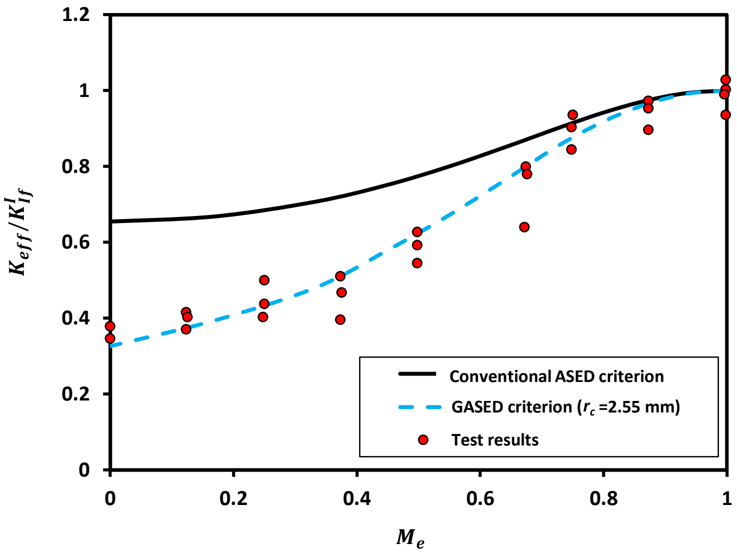

Fig. 4. Predictions of GASED criterion for mixed mode fracture toughness of a British limestone tested by Akbardoost et al, (2014) using the SCB specimen

3. Conclusions

Fracture toughness is an important parameter in rock fracture mechanics both for mode I fracture and for mixed mode I-II fracture. It was shown in this paper that the value of this parameter depends on the geometry and loading conditions in the rock samples. The effects of specimen geometry on the mixed mode fracture resistance of a British limestone were investigated using SCB and BD disk type specimens. The generalized ASED (GASED) criterion was employed to estimate the variation of the mixed mode fracture resistance with specimen geometry. The GASED criterion takes into account the effects of second term of stress field around the crack tip (*T*-stress) in addition to the conventional stress intensity factors K_{If} and K_{IIf}. It was shown that there is very good agreement between the theoretical predictions and the experimental results reported for the BD (with negative *T*-stress) and SCB (with positive *T*-stress) specimens when the modified energy-based criterion is employed.

Comparison of integrated force method and displacement method for metaheuristic optimization of civil structural systems

Ibrahim Torunoglu[1], Ayse T. Daloglu[*1]

[1] *Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye*

Abstract. In the optimization process where metaheuristic methods are used, large number of structural analysis is needed due to the nature of the methods. The most popular method used in structural analysis in civil engineering is the finite element displacement method. In the displacement method, after the global stiffness matrix is created, first the nodal displacements and then the internal forces of the elements are calculated. And these steps are repeated in each iteration, depending on the optimization method used, and naturally requires longer time for the analysis. Especially in structural systems with large number of elements, reducing analysis times can be an advantageous. In order to benefit from this advantage, choosing different structural analysis methods appears as an alternative. In this context, the performance of metaheuristic optimization methods combined with Integrated Force Method for structural analysis have been investigated. In the Integrated Force Method, first the internal forces of the elements and then the displacements of the nodes are calculated. Displacement method and Integrated Force Method are compared in terms of section optimization based on Harmony Search Algorithm and Teaching Learning Based Optimization. The obtained data show that the CPU times spent in the optimization processes using Integrated Force Method are shorter than the times spent in the case of Displacement Method.

Keywords: Finite Element Analysis; Integrated Force Method; Displacement Method; Metaheuristic Optimization

1. Introduction

From a structural engineering perspective, structural design can be considered as two stages. The first stage can be described as structural analysis and the second stage as structural design. Both stages are intertwined with each other. Pre-design is needed to perform structural analyses, and structural analysis results are needed to perform design.

In parallel with the ever-increasing vital needs of mankind, the developing engineering science has developed and continues to develop new methods for the structural analysis of increasingly complex physical models. Analytical methods, which began to be inadequate in solving complex structural models, began to give way to numerical methods as of the second half of the 20th century with the development of computer technology. The leading numerical method is the finite element method. The finite element method is divided into two separate methods. The first of these is the finite element displacement method, which is actively used in the analysis of today's engineering models, and the second is the finite element force method, which has remained in the background compared to the first. In both methods, the structural model, which is a continuum, is addressed by discretizing it into finite parts, and is analyzed under external loads by taking into account the equilibrium, boundary and compatibility conditions. The fundamental difference between the two methods is the assumption of unknowns. In the displacement method, the main unknowns are the displacements and rotations at the nodes. The internal forces occurring in the discrete elements are obtained with secondary calculations. In the force method, the main unknowns are the internal forces occurring in the elements (axial, shear, moment etc.). In this case, the displacements and rotations occurring at the nodes of the discrete elements are obtained by secondary calculations.

Increasing construction costs on a global scale, decrease in raw materials, and aesthetic concerns due to architectural reasons force the selection of cross sections to be minimized. However, earthquakes and wind loads, which have a significant effect especially on steel structures, force the designer to increase the section. The most important design criterions that comes out of this are; aesthetics, cost, sufficient strength, rigidity and ductility. Considering the factors that force the cross section selection in the minimum and maximum direction, reaching the optimum has become inevitable. This type of cross section optimization can be done manually by trial and

[*] Corresponding author, E-mail: aysed@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_363

golden light publishing

error and in a limited number of times. With the development of computer technology, cross section optimizations have now reached programmable levels simultaneously with structural analysis and design. Structural engineers have to design structures with minimum weight in order to choose the optimum one among the applicable designs (Artar, 2015). Considering steel structure optimization only in terms of bearing capacity and servisibilty constraints is insufficient in practice. Secondary constraints are regulations, specifications, standards, manufacturability and usable material section types that may vary from country to country. In this case, a very wide solution space appears for the optimization of steel structures. In this case, optimization methods that use mathematical programming techniques may not be reliable in terms of optimal convergence in such solution spaces (Hasançebi & Saka, 2010). Naturally, meta-heuristic methods have begun to be used to obtain optimum solutions in such wide solution spaces (Artar & Daloğlu, 2018). In case meta-heuristic methods are preferred, sometimes hundreds or even tens of thousands of structural analyzes need to be performed even on the smallest structural models. This circumstance results in a time constraint for the designer. In order to compare the length of the central processing unit (CPU) operating time in the case of using metaheuristic methods in the structural analysis and dimensioning process, the finite element displacement method (DM) and the finite element integrated force method (IFM) were compared. Harmony Search Algorithm (HSA) and Teaching-Learning Based Optimization (TLBO) methods were preferred as optimization techniques.

2. Integrated force method

The integrated force method was first proposed by Patnaik (1973). IFM, as in the finite element displacement method (DM), is based on the discretization of the continuum of the structural model into finite parts. Unlike DM, the force equilibriums on the nodes are taken into account. It consists of the solution of the linear equation system obtained by creating the equilibrium equations of the internal forces (moment, shear, axial, etc.) and external loads belonging to the elements which connected at the nodes. The "mxn" dimensional "B" matrix shown in Equation (1) represents the equilibrium matrix. The "nx1" dimensional "F" vector represents the internal forces belonging to the elements, and the "mx1" dimensional "P" vector represents the external forces acting on the nodes. The "m" value in the equation represents the total number of equilibrium equations, and "n" represents the number of unknown internal forces. If "m=n", the system is defined as statically determined, and if "m<n", it is defined as statically undetermined (Patnaik, 1973).

$$[B]_{mxn}|F|_{nx1}=|P|_{mx1} \tag{1}$$

Instead of creating the equilibrium equations for each node one by one, calculating the local equilibrium matrices of the elements provides convenience in terms of numerical operations (Topçu, 2017). By calculating the local equilibrium matrix "$\hat{B}$" separately for each element, the global equilibrium matrix "B_e" of the element and the global equilibrium matrix "B" of the system can be calculated with the help of the transformation matrix. For example, in Fig. 1, the local end forces at the ends "i" and "j" of a plane truss "k."th element are shown, and in Fig. 2, the global end forces at the ends "i" and "j" are shown.

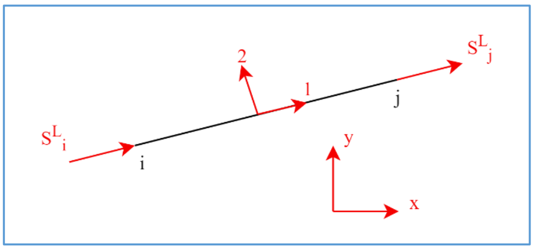

Fig. 1. Local internal forces of a plane truss element

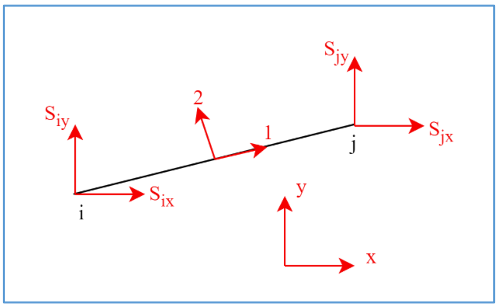

Fig. 2. Global internal forces of a plane truss element

The steps of calculating the local and global equilibrium matrices of the "k."th element in Fig. 1 and Fig. 2 are shown in eq. (2). In plane truss elements, only the axial internal force "F" occurs. The local and global end forces of the truss element can be expressed in matrix form in terms of the axial internal force.

$$S_j^L = F_k \Rightarrow \underbrace{\begin{vmatrix} \hat{S}_i^L \\ \hat{S}_j^L \end{vmatrix}}_{\hat{S}} = \underbrace{\begin{vmatrix} -1 \\ 1 \end{vmatrix}}_{\hat{B}} F_k$$

$$\underbrace{\begin{vmatrix} S_{ix} \\ S_{iy} \\ S_{jx} \\ S_{jy} \end{vmatrix}}_{S} = \underbrace{\begin{bmatrix} c & 0 \\ s & 0 \\ 0 & c \\ 0 & s \end{bmatrix}}_{T^T} \underbrace{\begin{vmatrix} \hat{S}_i^L \\ \hat{S}_j^L \end{vmatrix}}_{\hat{S}} \quad \text{(T; transformation matrix)}$$

$$\underbrace{\begin{vmatrix} S_{ix} \\ S_{iy} \\ S_{jx} \\ S_{jy} \end{vmatrix}}_{S} = \underbrace{\begin{bmatrix} c & 0 \\ s & 0 \\ 0 & c \\ 0 & s \end{bmatrix}}_{T^T} \underbrace{\begin{vmatrix} -1 \\ 1 \end{vmatrix}}_{\hat{B}} F_k \tag{2}$$

$$\underbrace{\begin{vmatrix} S_{ix} \\ S_{iy} \\ S_{jx} \\ S_{jy} \end{vmatrix}}_{S} = \underbrace{\begin{vmatrix} -c \\ -s \\ c \\ s \end{vmatrix}}_{B_e} F_k$$

In case the structural system is statically determined (m=n), eq. (1) can be solved by direct methods. In case the structural system is statically undetermined (n>m), (r=n-m) additional equations are needed. "r" represents the degree of hyperstaticity of the system. Additional equations are obtained by equating the work of the internal and external forces (eq. (3)). In eq. (3), "β" and "U" vectors represent the deformation vector of the elements and displacement vector of the nodes, respectively.

$$\frac{1}{2}\left|F^T\right|\left|\beta\right| = \frac{1}{2}\left|P^T\right|\left|U\right| \tag{3}$$

If the expression in eq. (1) is substituted into eq. (3), the expression in eq. (4) is obtained (Deformation-Displacement Relationship, DDR). Thus, with the help of eq. (4), "n" number of deformations are expressed with "m" number of displacements.

$$\left|\beta\right| = \left[B\right]^T \left|U\right| \tag{4}$$

If the displacements are expressed in terms of deformations, eq. (5) is obtained. In this expression, the matrix "C" is the "rxn" dimensional compatibility condition (CC). CC can be obtained by the SVD method.

$$\left[C\right]\left|\beta\right| = \left|0\right| \tag{5}$$

If the deformation expression in eq. (5) is expressed in terms of internal forces for each element and written in matrix form, eq. (6) which expressing the Force-Deformation Relationship (FDR) is obtained.

$$\beta_k = \underbrace{\frac{l}{AE}}_{G_k} F_k \Rightarrow \begin{vmatrix} \beta_1 \\ \beta_2 \\ \vdots \\ \beta_n \end{vmatrix} = \underbrace{\begin{bmatrix} G_1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & G_n \end{bmatrix}}_{G} \begin{vmatrix} F_1 \\ F_2 \\ \vdots \\ F_n \end{vmatrix} \tag{6}$$

The "G" matrix expressed in eq. (6) is the concatenated flexibility matrix of the structure. If eq. (6) is substituted into eq. (5), eq. (7) is obtained. Eq. (7) has the dimension "rxn" and the unknown vector is expressed in terms of internal forces. In this case, eq. (1) and (7) can be combined into a single equation system.

$$\left[C\right]\left[G\right]\left|F\right| = \left|0\right| \tag{7}$$

$$\begin{bmatrix} & \left[B\right] & \\ \left[C\right] & & \left[G\right] \end{bmatrix} \left|F\right| = \begin{vmatrix} P \\ 0 \end{vmatrix} \Leftrightarrow \quad \left[S\right]\left|F\right| = \left|P\right|^* \tag{8}$$

The coefficient matrix "S" in eq (8) is "nxn" dimension and the internal forces "F" can be obtained by direct methods. Nodal displacements are calculated with the help of eq. (9).

$$|U| = [J][G]|F| \tag{9}$$

The "J" matrix witch expressed in eq. (9) is;

$$[J] = m\,rows\,of\left[[S]^{-1}\right]^{T} \tag{10}$$

3. Optimization techniques used in this study

In this study TLBO and HSA methods are used to compare the integrated force method and the displacement method in aspect of CPU time. Before giving theoretical information about the methods to be used, the objective function and penalty coefficients used in almost every structural optimization process will be briefly stated.

Considering that the main purpose of structural optimization is to reduce the structural weight, it is inevitable to adopt the structural weight as the objective function.The objective function to be minimized for these methods is expressed in eq. (11).

$$\min.W = \sum_{k=1}^{ng} A_k \sum_{i=1}^{nk} \rho_i L_i \tag{11}$$

The penalty coefficient calculation method used for element cross sections and node displacements is taken into account as shown in eq. (12). The expression "C" is the penalty coefficient of the entire system, which includes the sum of the element and node penalty coefficients.

$$c_j = \frac{\sigma_j - \sigma_{u/l}}{\sigma_{u/l}},\ c_i = \frac{\delta_i - \delta_{u/l}}{\delta_{u/l}},\ C = \sum_{j=1}^{m} c_j + \sum_{i=1}^{n} c_i \tag{12}$$

The penalized objective function expresses the circumstance where the objective function is increased by the penalty coefficient. The expression "ε" in eq. (13) is the positive valued penalty multiplier and is taken into account as "2" in the current study.

$$\psi(x) = W(x)(1+C)^{\varepsilon} \tag{13}$$

3.1. Teaching learning based optimization

Like many metaheuristic optimization methods, TLBO is also a population-based optimization method and consists of populations of candidate solution sets to obtain the optimum solution (Rao et al., 2011). TLBO method is based on the principle that a good teacher will positively affect the grades (design variables) of students in the class (solution set). Similarly, the interaction of students with each other (information exchange) will positively affect their grades (Rao et al., 2011).

The TLBO method consists of two stages. The first stage is the teacher, and the second stage is the student stage (Rao et al., 2011). At the teacher stage, the student with the best level of knowledge (the individual with the best objective function) in the class (population) increases the average knowledge of the class by transferring his knowledge to the whole class (Rao et al., 2011). In the second stage, each student interacts with other students, exchanges information with each other and increases their knowledge levels (Rao et al., 2011).

Since TLBO is a population-based optimization method, firstly each student in the population is created with randomly selected values from the solution space. As can be seen from the relation in eq. (14), each student represents a solution set and the number of elements of the set (X^i) is equal to the number of design variables (D).

$$\begin{gathered} X^i = \left[x_1^i\ x_2^i\ x_3^i\ \ldots x_j^i\right] \\ i \in (1,2,3,\ldots NP) \\ j \in (1,2,3,\ldots D) \end{gathered} \tag{14}$$

The students of the class ($X^{1,2,\ldots,NP}$) and their current knowledge levels ($\psi(x^{1,2,\ldots,NP})$) are shown in eq. (15).

$$\text{class} = \begin{bmatrix} x_1^1 & x_2^1 & \cdots & x_D^1 \\ x_1^2 & x_2^2 & \cdots & x_D^2 \\ \vdots & \vdots & \ddots & \vdots \\ x_1^{NP} & x_2^{NP} & \cdots & x_D^{NP} \end{bmatrix} \begin{matrix} \rightarrow \psi(x^1) \\ \rightarrow \psi(x^2) \\ \rightarrow \quad \vdots \\ \rightarrow \psi(x^{NP}) \end{matrix} \tag{15}$$

In the teacher phase, the class average and the student with the best knowledge level (the student with the best objective function) are determined. Each student is allowed to communicate with the teacher using the eq. (16).

$$X^{new,i} = X^i + r(X_{teacher} - T_f X_{mean}) \tag{16}$$

The parameter "r" expressed in eq. (16) is a row vector consisting of random numbers ranging from 0 to 1, and its length is equal to the number of design variables. "T_f" is the teaching coefficient and is considered as one of the randomly selected values of 1 or 2. At the end of the teacher phase, it is checked whether the obtained $\psi(x^{new,i})$ value of i.th student is a more appropriate solution than the $\psi(x^i)$ value. If the new calculated value is more suitable than the old one, $\psi(x^{new,i})$ replaces $\psi(x^i)$. Similarly, the solution vector $X^{new,i}$ replaces the solution vector X^i.

In the student phase, each student in the population must exchange information with other students at least once (Rao et al., 2011). In this case, the i.th student selected from the population interacts with the k.th student (i≠k). Using eq. (17), each student is enabled to interact with other students.

$$\begin{aligned} \psi(X^i) < \psi(X^k) \Rightarrow X^{new,i} = X^i + r(X^i - X^k) \\ \psi(X^i) > \psi(X^k) \Rightarrow X^{new,i} = X^i - r(X^i - X^k) \end{aligned} \tag{17}$$

Similarly, if the new calculated value is more suitable than the old one, $\psi(x^{new,i})$ replaces $\psi(x^i)$. Similarly, the solution vector $X^{new,i}$ replaces the solution vector X^i.

Deb's heuristic constraint handling method (Deb, 2000) is used to compare the objective functions calculated at the teacher and student stages with the old objective function (Rao et al., 2011). This comparison takes into account the following 3 rules:

- If a solution (objective function) is a feasible solution (penalty coefficient C=0) and the other solution is an infeasible solution (penalty coefficient C>0), the feasible solution is preferred.
- If both solutions are feasible (penalty coefficient C=0), the solution with the most feasible objective function value is preferred.
- If neither solution is a feasible solution (penalty coefficient C>0), the solution with the lowest penalty coefficient is preferred.

At the end of the accepted iteration (T_{max}), the student who gives the most appropriate objective function is accepted as the solution set and the process is terminated.

3.2. Harmony search algorithm

HSA can be defined as an optimization method obtained by developing a better harmony finding method in musical performance (Geem et al., 2001). Musical harmony is an aesthetic combination of sounds coming out of instruments (design variable) (Geem et al., 2001). In HSA method, each of the solution sets is called a harmony. In eq. (18), i.th harmony (X^i) and design variables are seen.

$$\begin{aligned} & X^i = \left[x_1^i \; x_2^i \; x_3^i \; \ldots x_j^i \right] \\ & i \in \left(1,2,3,\ldots \text{HMS}\right) \\ & j \in \left(1,2,3,\ldots \text{D}\right) \end{aligned} \tag{18}$$

In order to make melodies aesthetic, each musical instrument tries to find the most aesthetic melody by producing different sounds with different notes. The notes in the melody are either taken from the note pool or the sounds in the existing harmonies are used. The sounds in the existing harmonies are subjected to pitch if necessary (Lee & Geem, 2004). Firstly, a certain number of harmonies come together to create the harmony memory (HM) (Eq. (19)) and the aesthetic performance of each melody is calculated (objective function).

$$\text{HM} = \begin{bmatrix} x_1^1 & x_2^1 & \cdots & x_D^1 \\ x_1^2 & x_2^2 & \cdots & x_D^2 \\ \vdots & \vdots & \ddots & \vdots \\ x_1^{HMS} & x_2^{HMS} & \cdots & x_D^{HMS} \end{bmatrix} \tag{19}$$

In the second stage, a new harmony is created (Eq. (20)).

$$X^{new} = \left[x_1^{new}, x_2^{new}, \ldots, x_D^{new} \right] \tag{20}$$

The calculation of the design variable of the new harmony depends on three different possibilities. In the first possibility, a random “rand-1” value between 0 and 1 is selected. The condition that the “rand-1” value is greater or less than the Harmony Memory Consideration Ratio (HMCR) is examined (Eq. (21)). If “rand-1” is greater than HMRC, the design variable is selected randomly from the solution space. In the second possibility, if the “rand-1” value is less than or equal to HMRC, the design variable is selected randomly from the melodies in the relevant column in the current HM.

$$x_j^{new} \leftarrow \begin{cases} x_j^{new} \in \left\{ x_j^1, x_j^2, \ldots x_j^{HMS} \right\} \Rightarrow \text{rand1} \le \text{HMCR} \\ x_j^{new} \in X \Rightarrow \text{rand1} \ge \text{HMCR} \end{cases} \tag{21}$$

In the third possibility, the “rand-2” value randomly selected between 0 and 1 is compared with the pitch adjustment ratio (PAR). If “rand-2” is greater than the PAR value, no change is made to the X_j^{new} value. Otherwise, the pitch adjustment is made to the newly selected design variable as specified in eq. (22). It is rounded to the nearest notes. The amount of rounding is measured by the bandwidth coefficient “b_w”.

$$x_j^{new} \leftarrow \begin{cases} = x_j^{new} + b_w * u(-1,1) \Rightarrow \text{random} \le \text{HMCR} \\ = x_j^{new} \Rightarrow \text{random} \ge \text{PAR} \end{cases} \tag{22}$$

The value of u(-1,1) shown in eq (22) represents the random number chosen between -1 and 1. The larger the selected bandwidth, the more the notes ahead or behind are rounded. The aesthetic performance of the newly formed melody is calculated $\psi(x^{new})$ and replaced with the melody with the worst performance in the HM. The calculation step mentioned above is repeated for a predetermined number of iterations.

4. Benchmark studies

In cross-section optimizations using metaheuristic methods, cross-section checks are performed for structural elements after each structural analysis. In addition, if necessary, displacement constraints at nodal points are checked. In such optimizations, while the structural geometry remains constant, element cross-sections can change at each stage. In case of using the finite element Displacement Method (DM), local and global stiffness matrices of the bar elements are calculated and the global stiffness matrix of the system is created at each structural analysis stage. In case of using the Integrated Force Method (IFM), the only expression that needs to be recalculated is the concatenated flexibility matrix seen in eq. (8). The “B” and “C” matrices depend on the structural system geometry and are independent of the element cross-section. For this reason, it is not necessary to calculate them repeatedly at each analysis stage. In order to compare the performance of both analysis methods, examples obtained from the literature containing metaheuristic methods were used. The selected examples belong to plane truss systems. HSA, TLBO, DM and IFM codes are prepared in Python programming language using object-oriented programming (OOP).

4.1. 10 bar plane truss

The plane truss system with 6 nodes and 10 bar elements defined in the X-Z plane is shown in
Fig. 3. The elasticity modulus of the material is 10000 ksi and the density of the material is 0.1 lb/in^3. The allowable stress limit for all elements is ±25 ksi, and the displacement limit for the nodes is considered to be ±2 in. Each of the elements will be sized independently. There are a total of 10 design dariables. A force of 100 kips acts on the nodes 2 and 4 in the direction seen in the figure. The structure will be optimized for both continuous and discrete variable sections, and the sections to be used for the discrete value design are shown in Table 1. Continued

4.2. 15 bar plane truss

The plane truss system with 8 nodes consisting of 15 bar elements defined in the X-Z plane is shown in Fig. 4. The elasticity modulus of the material is 200000 MPa and the density of the material is 7860 kg/m^3. The allowable stress limit for all elements is ±120 MPa and the displacement limit for the nodes is considered to be ±10 mm. Each of the elements will be sized independently and there are 15 design variables in total. A force of 35 kN acts on the nodes 4, 6 and 8 in the direction seen in the figure. The truss system will be optimized for discrete variable sections. The sections to be used in the design are shown in Table 4.

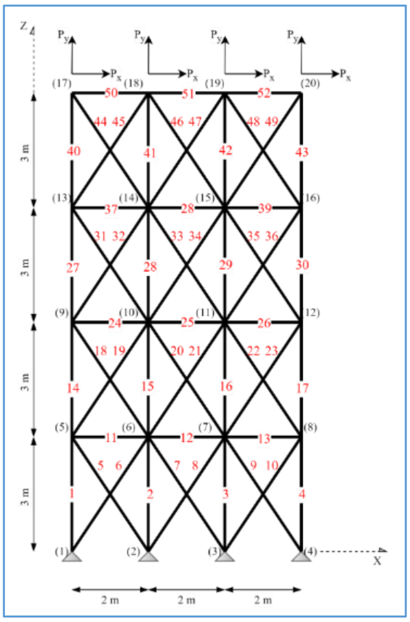

Fig. 5. 52 bar plane truss model

4.3.52 bar plane truss

The plane truss system with 20 nodes consisting of 52 bar elements defined in the X-Z plane is shown in Fig. 5. The elasticity modulus of the material is 207000 MPa and the material density is 7860 kg/m^3. The allowable stress limit for all elements is ±180 MPa, and there is no displacement limit for nodes. It will be sized in groups and there are 12 design variables in total. The nodes numbered 17, 18, 19 and 20 are subject to a force of 100 kN in the X direction and 200 kN in the Z direction. The carrier system will be optimized for discrete variable sections. The sections to be used for the discrete value design are shown in Table 6.

Tablo 8. Continued

4.4.18 bar plane truss

The plane truss system with 11 nodes consisting of 18 rod elements defined in the X-Z plane is shown in Fig. 6. The elasticity modulus of the material is 10000 ksi, and the material density is 0.1 lb/in^3. The allowable stress limit for all elements is ±20 ksi, and there is no displacement limit for the nodes. In addition to the given stress limit, Euler buckling stress $\left(\sigma_b^i = -4EA_i/L_i^2\right)$ will be taken into account for rod elements under compression. The system will be dimensioned in groups and there are 4 design variables in total. A force of -20 kips acts in the Z direction as seen in the figure from the nodes 1, 2, 4, 6 and 8. The system will be optimized for continuously variable cross-sections.

5. Results and discussion

Under the headings 4.1, 4.2, 4.3 and 4.4, plane truss models were examined by considering continuous and discrete design variables. When the obtained results were compared with the benchmark studies, it was concluded that the prepared structural analysis and optimization codes provided sufficiently accurate data.

In terms of optimization data input parameters, the required user data input parameters for the TLBO method are the population number and the iteration number. The required parameters in the HSA method are the harmony number, iteration number, HMCR and PAR values. The TLBO method offers simplicity in terms of user data input. In the HSA method, it should be taken into account that the HMCR and PAR parameters may vary depending on the structural model. Since there is no single acceptance for these values, it is necessary to check and verify them over different values even in the same structural model.

When the data obtained in terms of analysis times are compared, it is determined that structural analysis performed with IFM are 6-8 times faster than DM. The reason for this circumstances is that, as mentioned before, in fixed geometry section optimizations, when IFM is used, the only expression that changes is the concatenated flexibility matrix. It should be noted that the analysis times obtained in this study may vary from computer to computer depending on the hardware performance. Even in such a case, it will not change the fact that the CPU time rates of both analysis methods are at the same levels.

6. Conclusion

In this study, IFM and DM were compared in terms of CPU time under iterative structural analysis. Since the most intensive use of iterative analysis is metaheuristic optimization methods, two metaheuristic optimization methods were selected and cross section optimizations were performed on plane truss models. The results obtained were compared with the results in the literature. As a result of the comparisons made, it was concluded that the expected goals were achieved and IFM was more efficient in terms of CPU times compared to DM in iterative processes.

It should be noted that the obtained results are valid for fixed geometry plane truss systems. Because, it should not be forgotten that in case of geometry optimizations, the equilibrium and compatibility matrices must be recalculated at each stage.

Abstract: With the rapid advancement of technology, Structural Health Monitoring (SHM) has increasingly embraced innovative computer vision techniques, offering real-time, non-contact monitoring that significantly enhances structural integrity assessment. These methods provide efficient and cost-effective alternatives to traditional techniques, making them highly attractive for practical applications. This study aims to determine the most effective computer vision-based SHM method by comparing four optical flow algorithms—Lucas-Kanade, Farnebäck, Horn-Schunck, and Phase-based—in terms of accuracy, computational efficiency, and adaptability to varying structural conditions. Optical flow algorithms analyze pixel intensity changes between successive images to detect structural movements. Lucas-Kanade calculates displacements by tracking distinct image points, while Farnebäck estimates dense optical flow capable of capturing complex movements. Horn-Schunck incorporates a smoothness constraint, enhancing robustness against noise, whereas the Phase-based method identifies movements through phase differences derived from Fourier transforms. Displacement graphs generated from laboratory videos capturing structural vibrations were analyzed using these algorithms. Subsequently, the Fast Fourier Transform (FFT), a powerful technique converting time-domain signals into frequency-domain data, was applied to these displacement signals to accurately determine structural vibration characteristics and modal parameters. By evaluating the accuracy of anomaly detection and robustness of each method, this research provides valuable insights into their respective strengths and limitations, thereby contributing to developing reliable, scalable, and economically feasible SHM systems to enhance critical infrastructure safety and sustainability.

Keywords: Structural health monitoring (SHM); Computer vision-based methods; Optical flow algorithm; Lucas-Kanade; Farnebäck; Horn-Schunck; Phase-based

1. Introduction

With the rapid advancement of technology, Structural Health Monitoring (SHM) has increasingly incorporated innovative techniques to ensure the long-term performance, safety, and integrity of engineering structures. Traditional SHM methods typically rely on contact-based sensors such as accelerometers, displacement transducers, and strain gauges. However, in recent years, interest in non-contact measurement techniques has grown due to the challenges and costs associated with implementing these conventional sensors (Cha et al., 2017; Feng & Feng, 2018). Among non-contact approaches, computer vision-based techniques offer significant advantages as they do not impose additional loads on the structure during measurement and are capable of providing remote and real-time data (Lydon et al., 2019; Yang et al., 2020). These methods can effectively detect structural vibrations, deformations, and displacements using camera systems and image processing algorithms.
The primary objective of this study is to comprehensively evaluate the performance of computer vision-based SHM methods in terms of accuracy and computational efficiency, and to identify the most suitable technique for SHM applications. To this end, four optical flow algorithms that are widely used in the literature and have demonstrated success in various applications were examined: Lucas-Kanade (Lucas & Kanade, 1981; Baker & Matthews, 2004), Farnebäck (Farnebäck, 2003), Horn-Schunck (Horn & Schunck, 1981), and Phase-based methods (Fleet & Jepson, 1990; Gautama & Van Hulle, 2002).

Optical flow algorithms aim to precisely determine movements and displacements in the two-dimensional image plane by analyzing the temporal variations in pixel intensities between successive image frames (Barron et al., 1994; Sun et al., 2014). The Lucas-Kanade algorithm tracks motion by computing optical flow vectors at salient points in the image, offering advantages such as fast computation and high accuracy, particularly with high-

https://doi.org/10.31462/icearc2025_ce_sme_386

resolution imagery (Bouguet, 2001; Brox & Malik, 2011). The Farnebäck algorithm, based on polynomial expansion, estimates dense optical flow and is particularly effective at capturing small, complex, and continuous motions in the images (Farnebäck, 2003). The Horn-Schunck algorithm incorporates a smoothness constraint into the optical flow estimation process, which enhances consistency and reliability in noisy environments. As such, it yields effective results even with low-quality images (Horn & Schunck, 1981; Pérez et al., 2013). Phase-based methods, on the other hand, analyze phase variations in the Fourier domain of images, making them especially advantageous for detecting fine and small-amplitude movements at the micrometer scale (Fleet & Jepson, 1990; Wadhwa et al., 2013).

In this study, the effectiveness of the four different computer vision-based methods was evaluated through experimental tests conducted on a steel structure model in a laboratory environment. During the experiments, structural vibrations were induced by applying controlled impacts from below, and the entire process was recorded in video format using a fixed camera. The recorded videos were then processed using a custom-developed graphical user interface (GUI)-based analysis software. This software, designed with a user-friendly interface, enables the application of the Lucas-Kanade, Farnebäck, Horn-Schunck, and Phase-based optical flow algorithms and performs displacement analysis within the user-defined regions of interest (ROIs) on the structure for each method. Time-series displacement graphs representing the vibrational motions of the structure were generated for each algorithm, and the frequency content of these signals was analyzed using the Fast Fourier Transform (FFT) method. FFT is a powerful mathematical tool that transforms time-domain vibration signals into the frequency domain, allowing for the precise determination of modal parameters such as natural frequencies and mode shapes (Antoni & Randall, 2006).Through this integrated methodological approach, each optical flow algorithm's capability to accurately and consistently detect structural vibrations was comparatively assessed in terms of both temporal resolution and frequency-domain performance. The findings derived from these analyses will contribute to the development of scalable, reliable, and cost-effective SHM systems by enabling more effective utilization of computer vision techniques for the safety and sustainability of critical infrastructure.

2.Theory

Optical flow is a technique that enables the quantitative estimation of pixel displacements over time between consecutive frames in an image sequence. This approach is widely employed in applications such as analyzing the dynamics of moving objects and monitoring structural vibrations. Its fundamental assumptions include brightness constancy and the continuity of motion across neighboring pixels (Lucas & Kanade, 1981). Brightness constancy is mathematically expressed as

$$I(x,t) = I(x+\delta x, t+\delta t) \tag{1}$$

where I denotes the image intensity, x the spatial coordinate (or pixel location), t the time (frame index), δx the small spatial displacement vector, and δt the corresponding time increment. The optical flow constraint equation obtained through the Taylor series expansion of the above equation is as follows:

$$\nabla I(x,t) \cdot u + I_t(x,t) = 0 \tag{2}$$

were, ∇I denotes the spatial gradient of the image intensity, I_t denotes the temporal gradient, and $u = (u_x, u_y)$ is the optical flow vector. Since it is a single equation with two unknowns, the Lucas-Kanade method minimizes this error using the least squares approach:

$$E(u) = \sum_{(x,y)\in W} (\nabla I \cdot u + I_t)^2 \;\; \Rightarrow \;\; Au = b$$
$$A = \sum \begin{pmatrix} {I_x}^2 & I_x I_y \\ I_x I_y & {I_y}^2 \end{pmatrix}, \quad b = -\sum \begin{pmatrix} I_x I_t \\ I_y I_t \end{pmatrix} \tag{3}$$

In the implemented code, the parameter *winSize* = (25,25) defines a 25×25 pixel region, while *maxLevel=2* enables a two-level image pyramid (half and quarter resolutions), allowing for coarse-to-fine motion estimation. Consequently, for each primitive ROI, optical flow is estimated at feature points using the Lucas-Kanade (LK) method. New feature points are re-detected every 20 frames, and the iteration continues until either 20 iterations are completed or the update falls below 0.03 pixels. These settings provide a well-balanced trade-off between computational efficiency and accuracy.

In the Farnebäck method, each local image patch is modeled as a second-order polynomial surface

$$f(x) \approx x^T A x + b^T x + c \tag{4}$$

where $x = (x,y)^T$ denotes the spatial coordinate within the patch, A is a symmetric $2x2$ matrix of quadratic coefficients, b is a $2x1$ vector of linear coefficients, c and is a constant term. When this polynomial approximation is computed independently in two consecutive frames—yielding (A_1, b_1, c_1) and (A_2, b_2, c_2)—the inter-frame displacement d that best aligns the two surfaces can be obtained in closed form as

$$d = -\frac{1}{2}(A_1 + A_2)^{-1}(b_2 - b_1) \tag{5}$$

This analytic solution allows Farnebäck's algorithm to compute a dense flow field efficiently by directly estimating the sub-pixel shift of each patch (Farnebäck, 2003).

The Horn–Schunck method enforces both the brightness constancy constraint and the smoothness of the flow by minimizing a global energy function (Horn & Schunck, 1981). The energy function is given by

$$E(u,v) = \iint (I_x u + I_y v + I_t)^2 + \alpha^2(\|\nabla u\|^2 + \|\nabla v\|^2)\ dx\,dy \tag{6}$$

Here, α serves to balance data fidelity and flow smoothness. The iterative update derived from the associated Euler–Lagrange equations is:

$$u^{(n+1)} = \bar{u}^{(n)} - \frac{I_x \left(I_x \bar{u}^{(n)} + I_y \bar{v}^{(n)} + I_t\right)}{a^2 + {I_x}^2 + {I_y}^2}$$

$$v^{(n+1)} = \bar{v}^{(n)} - \frac{I_y (I_x \bar{u}^{(n)} + I_y \bar{v}^{(n)} + I_t)}{a^2 + {I_x}^2 + {I_y}^2} \tag{7}$$

where, $\bar{u}$ and $\bar{v}$ represent local averages from the previous iteration, computed using a kernel. In the implemented code, the parameters define the regularization weight, the number of iterations, and the convergence threshold, respectively. Initially, image noise is reduced using a Gaussian blur, followed by the computation of image gradients using simple difference kernels. Due to its global formulation, the estimated flow is smooth and robust across the entire frame, although it may smooth out sharp motion boundaries.

Phase correlation leverages the Fourier-shift theorem: a pure translation between two images manifests as a linear phase difference in the frequency domain (Kuglin & Hines, 1975). Concretely, given two windows f and g, one computes

$$F = \mathcal{F}\{f\},\quad G = \mathcal{F}\{g\},\quad R = \frac{F\bar{G}}{|F\bar{G}|},\quad r = \mathcal{F}^{-1}\{R\} \tag{8}$$

where the peak of the cross-correlation r gives the sub-pixel shift $(\Delta x, \Delta y)$. In OpenCV this is wrapped by *cv2.phaseCorrelate(prev, curr)*, which returns *(dx,dy)* directly along with a confidence *response*. Converting the images to *float32* format enhances numerical precision. The Phase-based method is robust against illumination changes and, since it provides a single displacement vector per ROI, it serves as a strong complement to gradient-based methods.

3. Methodology

The application developed in this study performs video-based optical-flow analysis and enables a comparative assessment of four algorithms—Lucas–Kanade, Farnebäck, Horn–Schunck, and Phase-based optical flow. Implemented in Python, it relies chiefly on the OpenCV, NumPy, SciPy, Pillow (PIL), Matplotlib, and Tkinter libraries. Consequently, users can (i) select a video file, (ii) define regions of interest (ROIs), (iii) determine a scale factor, and (iv) detect motion using the aforementioned optical-flow methods.

A graphical user interface (GUI) was created with Tkinter and organized into multiple function-specific frames. Within the main window, separate menu items provide core controls (play, pause, rewind, fast-forward), file handling, method selection, ROI selection, scale-factor computation, and visualisation of analysis results. When a user initiates a task, the interface switches to the relevant frame (e.g., the ROI-selection or analysis panel), ensuring that all operations remain distinct yet mutually compatible.

Video processing begins with OpenCV's *VideoCapture*, which retrieves the frame count, frames-per-second (FPS), and other basic parameters of the selected file. Each frame is resized to suit the display area with Pillow and rendered in a Tkinter Label. During playback, a slider supplies real-time feedback on the frame index, FPS, and elapsed duration.

Optical-flow analysis is conducted on the user-defined ROIs. With the Lucas–Kanade method, corner points are detected in the first frame and their subsequent positions are tracked via *calcOpticalFlowPyrLK*, after which the mean displacement vector is computed for each ROI. Farnebäck produces dense motion fields, whereas Horn–Schunck calculates spatial and temporal derivatives (using Gaussian blurring and Sobel kernels) and iteratively refines the flow field. In the Phase-based approach, consecutive frames undergo a Fourier transform to extract phase components; phase differences are unwrapped, and mean gradient values (obtained with a Sobel filter) yield the motion information. Employing multiple algorithms in this manner facilitates a rigorous comparison of their accuracy and suitability for diverse motion scenarios.

ROI selection and scale-factor estimation are fully interactive. Users delineate arbitrary regions with the mouse; these ROIs are highlighted on a Tkinter Canvas and previewed as thumbnails in real time. For scale calibration, two points are marked, the corresponding pixel distance and true physical distance are entered, and the pixel-to-length conversion factor is calculated automatically. This factor is subsequently applied to convert optical-flow displacements into meaningful physical units.

The analysis routine executes in a background thread, preventing the GUI from becoming unresponsive. A progress bar continuously displays the elapsed time and percentage completion. For every frame, x- and y-direction displacements within each ROI are aggregated, and average motion vectors are recorded. The resulting time-series data are visualised with Matplotlib; dominant frequency components are identified via a fast Fourier transform (FFT) and annotated on the plots. All graphs can be exported in PNG or PDF format. Figure 1 illustrates the application's flowchart, detailing the sequence of operations and interactions among key modules.

In conclusion, the methodological framework integrates multiple optical-flow algorithms with an intuitive interface, providing a comprehensive platform for video-based motion analysis, interactive ROI selection, and scale calibration. The application enables detailed examination of motion data in both the time and frequency domains, supports direct comparison of algorithmic performance, and yields physically interpretable results through precise unit conversion.

4. Experimental study

The experimental studies were conducted at the Earthquake and Structural Health Monitoring Laboratory of Karadeniz Technical University, utilizing a previously developed high-speed video monitoring system designed for structural health monitoring and modal parameter identification (Hacıefendioğlu et al., 2024). The portable and non-contact monitoring system comprises a CoaXPress VICTOREM high-speed industrial camera, a DVR Express Core 2 CoaXPress recording device for data storage, and a computer (Table 1). Powered by mains electricity and supported by a portable generator for field applications, the system enables the acquisition of high-resolution images and their analysis using customized software tools. The system components are connected via HDMI and USB cables, while a single CoaXPress cable is used for both power supply and data transmission (Fig. 2). The recording device supports up to four cameras simultaneously; however, an increase in the number of cameras leads to larger data sizes and reduced recording durations. Provided that the system capacity is not exceeded, there is no need to adjust the frame rate (FPS).

The test model is a rectangular steel bar with a length of 550 mm, a width of 4.42 mm, and a thickness of 3.2 mm. To ensure accurate displacement measurements based on optical flow, six square tracking points were placed at equal intervals along the length of the model. This configuration enabled the precise detection of time-dependent vibration modes and facilitated highly accurate frequency analysis.

During the experiment, the model was clamped to a rigid concrete block using a vise, leaving a 5 cm support distance at one end. The distance between the camera and the test specimen was set to 8.5 meters. This setup allowed the entire model to be captured within a single frame using one camera, thereby minimizing potential measurement errors. After configuring the camera settings, an impulsive load was applied to the lower part of the concrete block to initiate experimental vibration, ensuring that the block itself remained stationary. Video recordings were conducted at a resolution of 1552×1544 pixels, for a duration of 2 minutes, and at a frame rate of 80 FPS. This experimental setup contributed to the reduction of measurement errors, while the stable lighting conditions in the laboratory ensured consistent image quality throughout the analysis. Fig. 3 illustrates the spatial configuration of the camera and the model.

5. Results and discussion

In this section, the outcomes obtained from the code developed in a GUI-based environment are presented. All analyses were performed on a Lenovo Ideapad L340-15IRH Gaming laptop equipped with an Intel® Core™ i5-9300H processor, 8 GB of RAM, and a 250 GB SSD. In prior work, computer vision and optical flow methods were employed to compare experimental and numerical results in structural vibration analysis; the observed agreement validated the chosen algorithms (Hacıefendioğlu et al., 2024). Consequently, here we compare only the displacement and frequency data derived from our four optical flow algorithms via code execution.

Frequency analyses were conducted by applying the Fast Fourier Transform (FFT) to each displacement time series. During the experimental phase, videos were recorded at 80 FPS to capture the full model dimensions, resulting in only the primary (fundamental) frequency component appearing in the spectrum. Table 2 summarizes the computation times and fundamental frequencies for each optical flow method, facilitating direct comparison. Displacements along the X and Y axes are shown in Fig. 4, 6, 8, and 10. and the corresponding frequency spectra in Fig. 5, 7, 9, and 11. Since no significant Y-axis vibrations were detected, the analyses focus exclusively on the X-component. The fundamental vibration frequency was consistently observed at 10.16 Hz for all methods.

In terms of computation time, the Phase-based algorithm completed analysis in 2.28 s, making it the fastest; Lucas–Kanade (2.32 s) and Farnebäck (2.40 s) exhibited similar performance. The Horn–Schunck method required 4.53 s, representing the highest computational load and potentially limiting its applicability in real-time scenarios. The Lucas–Kanade method (Figs. 4 and 5) produced sharp, high-amplitude vibration peaks along the X-axis and low-amplitude noise on the Y-axis. FFT analysis revealed a dominant frequency of 10.16 Hz in both components. Corner-based feature tracking successfully balanced high frequency resolution with modest processing times.

The Farnebäck algorithm (Figs. 6 and 7) generated lower-amplitude vibrations by averaging dense flow vectors. Its FFT spectrum also indicated secondary frequency components around 30.55 Hz in the Y-axis, while maintaining a computation time comparable to Lucas–Kanade and offering broader flow-field coherence.

The Horn–Schunck approach (Figs. 8 and 9) yielded a smooth displacement profile through iterative averaging but exhibited a dominant 10.16 Hz peak on the X-axis and a 37.66 Hz secondary component on the Y-axis. However, its 4.53 s processing time may constrain its use in time-critical applications.

Table 2. Comparison of computation time and fundamental frequency for optical flow methods

Method	Computation Time (s)	Fundamental Frequency (Hz)
Lucas-Kanade	2.32	10.16
Farnebäck	2.40	10.16
Horn–Schunck	4.53	10.16
Phase-based	2.28	10.16

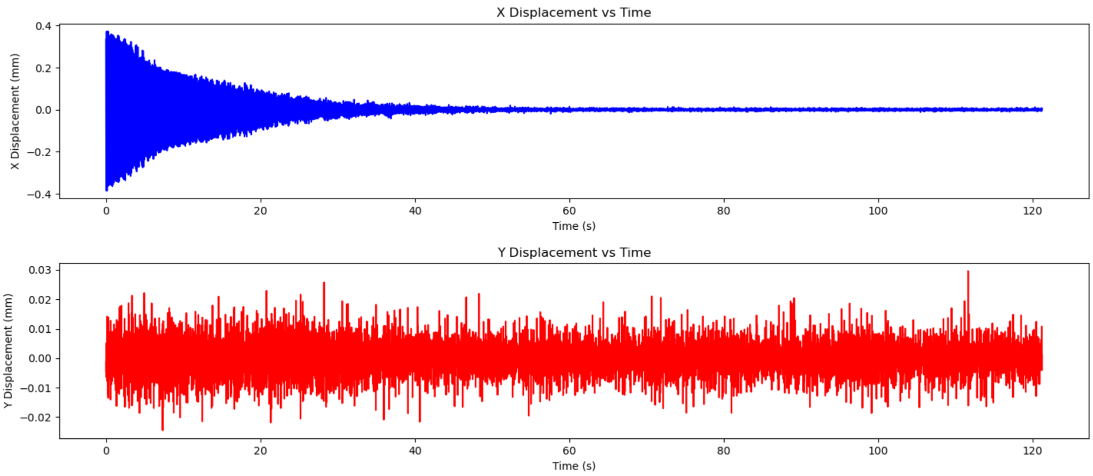

Fig. 4. X- and Y-axis displacement time series obtained using the Lucas–Kanade optical flow method

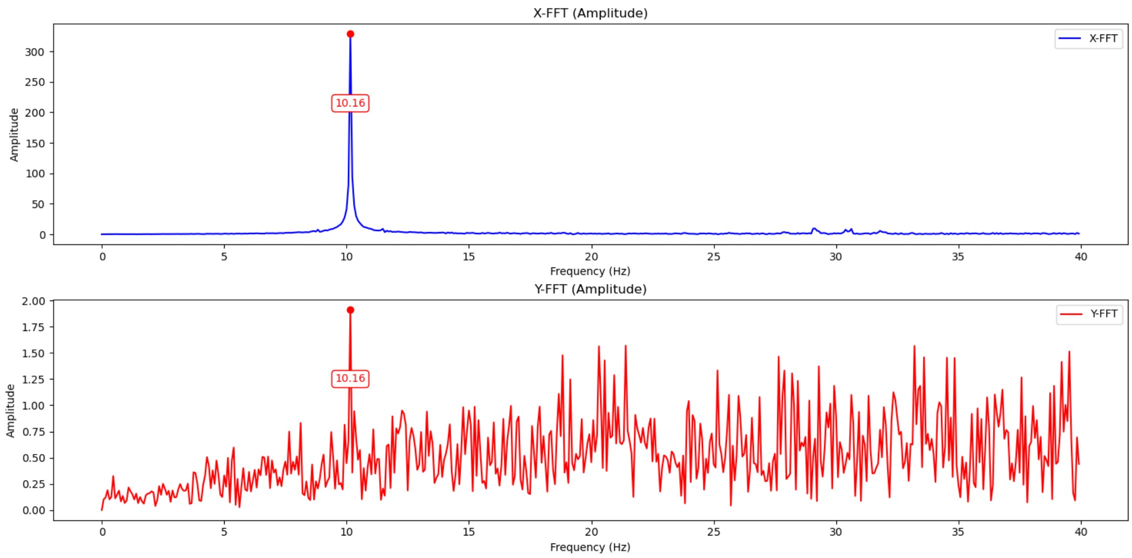

Fig. 5. Frequency spectra obtained using the Lucas–Kanade optical flow method

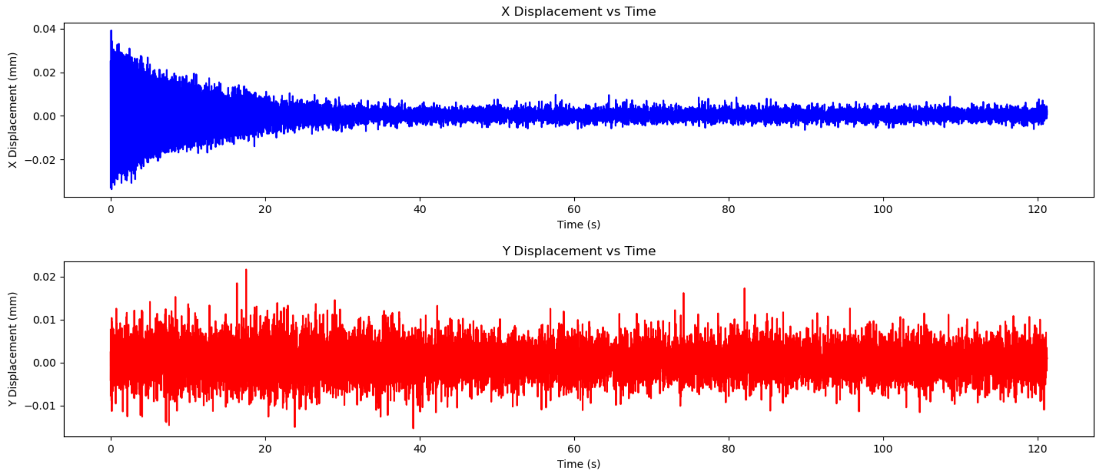

Fig. 6. X- and Y-axis displacement time series obtained using the Farnebäck optical flow method

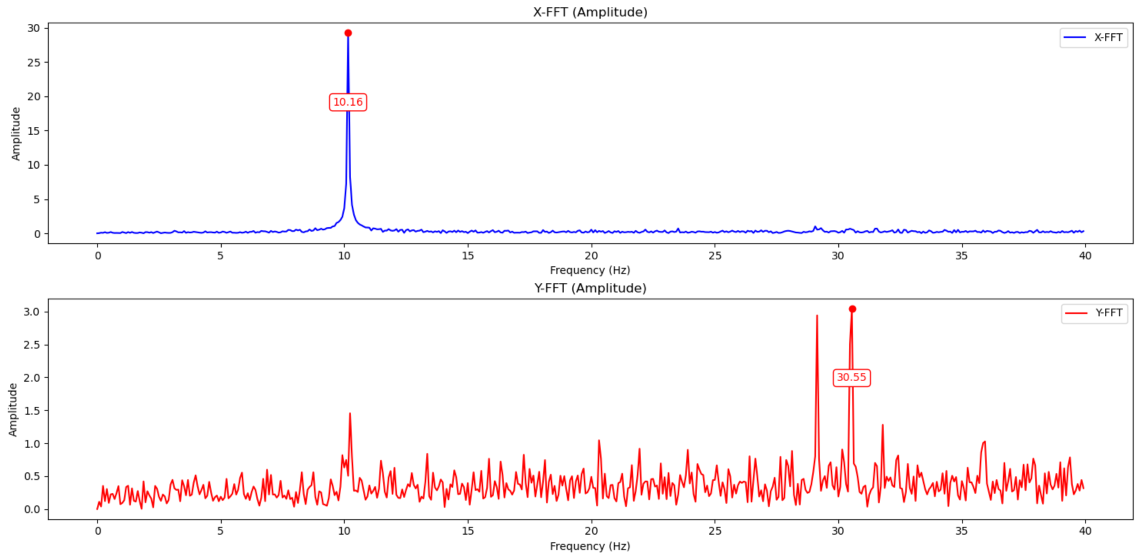

Fig. 7. Frequency spectra obtained using the Farnebäck optical flow method

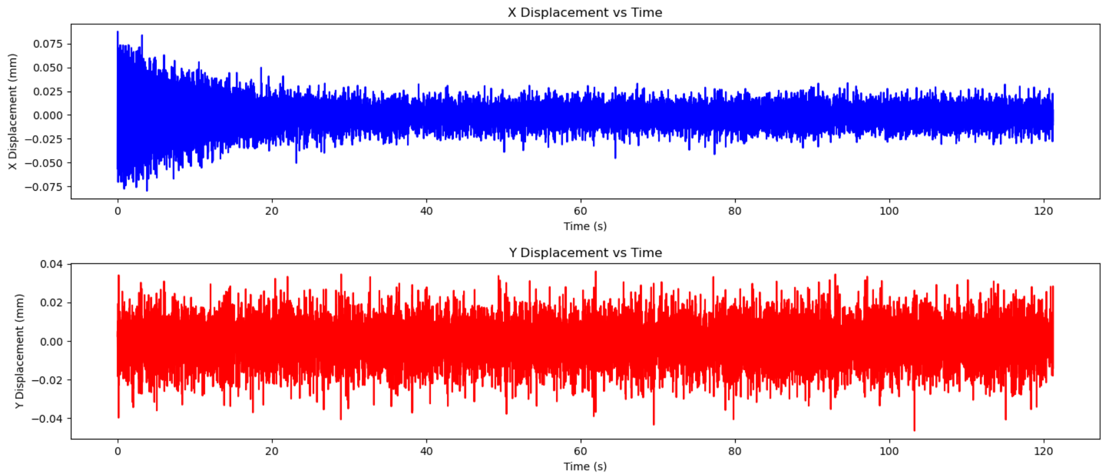

Fig. 8. X- and Y-axis displacement time series obtained using the Horn–Schunck optical flow method

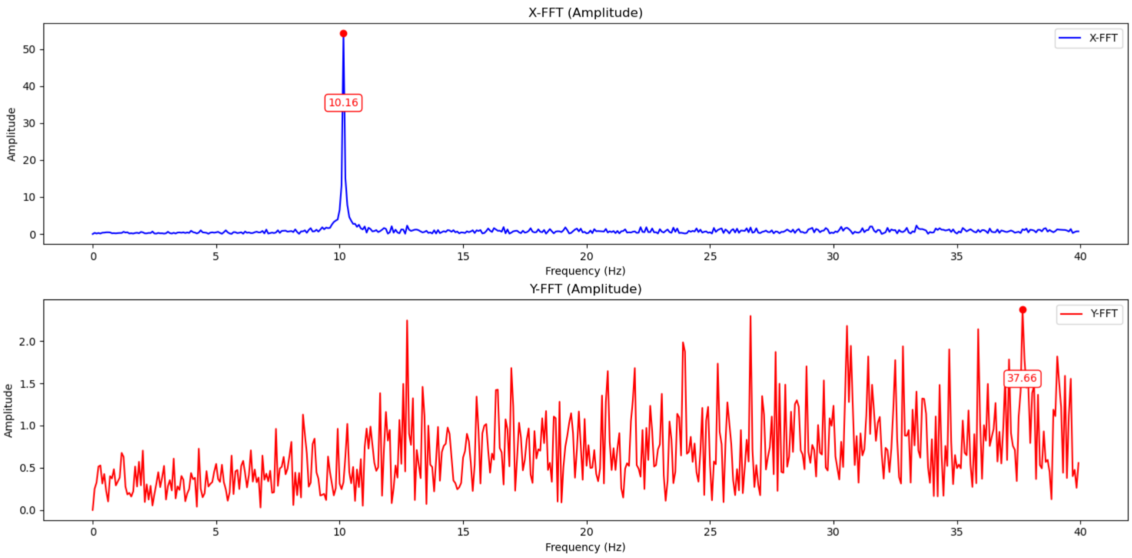

Fig. 9. Frequency spectra obtained using the Horn–Schunck optical flow method

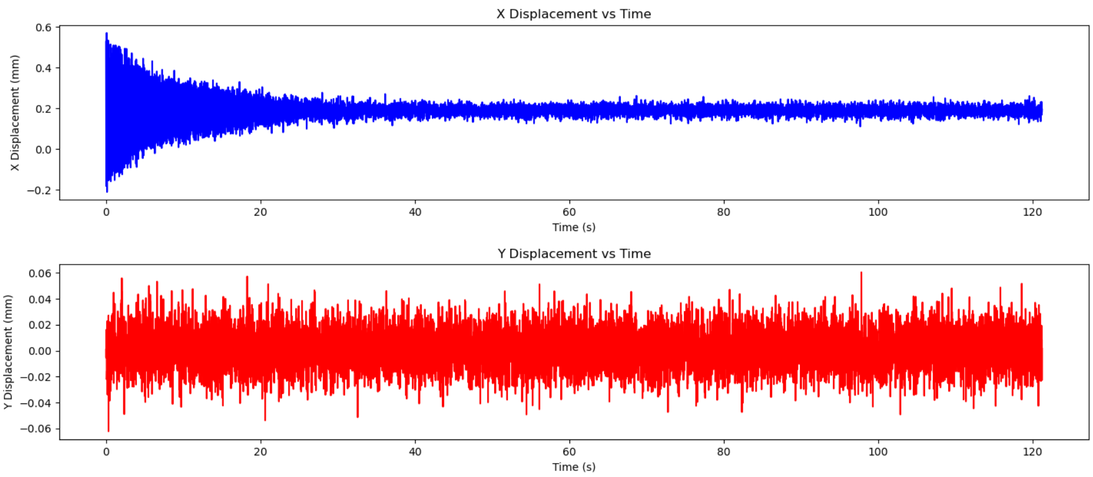

Fig. 10. X- and Y-axis displacement time series obtained using the Phase-based optical flow method

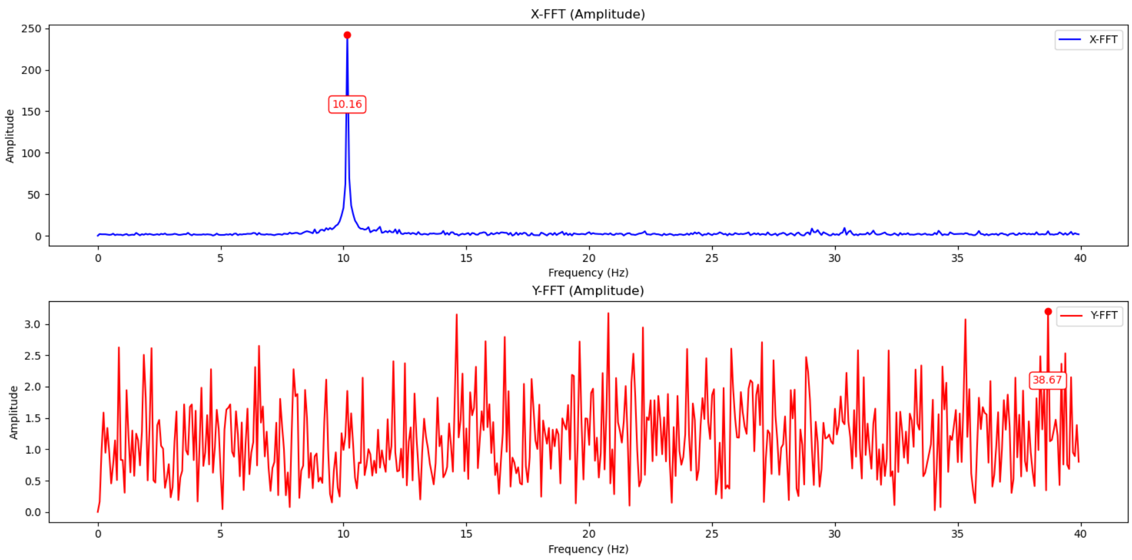

Fig. 11. Frequency spectra obtained using the Phase-based optical flow method

The Phase-based algorithm (Figs. 10 and 11) employed Fourier-domain phase correlation to capture robust, singular peaks at 10.16 Hz in both X and Y components. Its 2.28 s execution time makes it particularly attractive for applications demanding both speed and spectral accuracy.

According to the present study, the Phase-based and Lucas–Kanade methods achieved an optimal balance of speed and spectral clarity; Farnebäck provided enhanced flow-field integrity; and Horn–Schunck offered iterative smoothness. Depending on specific application requirements, the Phase-based approach is recommended for high-speed analyses; Lucas–Kanade for precise frequency studies; Farnebäck for detailed flow-map generation; and Horn–Schunck for scenarios requiring uniform displacement profiling.

6. Conclusion

In this study, a Python-based GUI application was developed to apply four optical flow algorithms to high-speed video for non-contact structural vibration analysis, featuring interactive ROI selection, scale calibration, and FFT-based frequency extraction. Benchmarking on 80 FPS data revealed that the phase-based and Lucas–Kanade methods achieve the optimal balance of speed and spectral accuracy; Farnebäck provides enhanced spatial coherence at a modest runtime increase; and Horn–Schunck yields the smoothest displacement profiles with a longer processing time. This versatile platform establishes an efficient foundation for camera-based SHM, with future work aimed at validating video-derived measurements against traditional sensors, optimizing the GUI for field use, and extending the methodology to more complex structural scenarios.

Abstract. Gaining Carbon composites are popularity in Civil construction applications due to their excellent strength-to-weight ratio and environmental compatibility. These materials are widely utilized to reinforce, retrofit, and rehabilitate concrete structures , and other civil structures, enhancing Building strength and overall quality of life. However, the long-term performance and durability of carbon composites against machining settings remain inadequately understood, especially at the microscopic level. The microscopic degradation of carbon composites in civil structures is a complex issue influenced by factors such as mechanical properties, environmental conditions, and manufacturing parameters. understanding the damage mechanisms is essential for ensuring the reliability and safety of articulations throughout their intended lifespan. Consequently, there is an urgent need for a comprehensive investigation into the microscopic degradation of carbon composites in civil applications. This research aims to fill this critical knowledge gap by thoroughly examining the microscopic degradation processes, particularly focusing on delamination. By utilizing advanced analytical techniques like scanning electron microscopy, we intend to reveal the morphological and mechanical changes occurring at the microscale, including delamination and decohesion. Furthermore, this study will assess the impact of various mechanical and environmental factors on the degradation behavior of carbon composites, offering valuable insights into their long-term performance in civil applications.

Keywords: Carbon; C-orthocryl; Delamination; Drilling; SEM; CFRP

1. Introduction

Because of their remarkable strength-to-weight ratio, corrosion resistance, and versatility when mixed with several matrices, carbon fiber reinforced polymer (CFRP) composites have drawn great interest in several application areas. Recent studies offer several angles on both the inherent qualities of carbon composites and the many techniques for its integration into sophisticated engineering uses. focusing on civil engineering, we combine developments in carbon-c orthocryl resin research in this paper, manufacturing processes, functional applications such reinforce, repair, and rehabilitate concrete buildings, and innovative material improvements using nanotechnology, carbon composites are being used more and more in civil engineering for structural strengthening and repair. Important processes to reduce bond deterioration were found by(Borrie, Al-saadi, Zhao, Singh Raman, & Bai, 2021), who also offered an in-depth analysis on bonded carbon-composite/steel systems. This is absolutely vital for the lifetime of strengthened structures.

Alongside this,(Pawlak, Górny, Dopierała, & Paczos, 2022) and(J. Wang, Su, & Gao, 2025) looked at pragmatic uses of composites advancements in fortifying both new and retrofitted buildings. Researches on the repair and rehabilitation of masonry structures (Fagone & Ranocchiai, 2017) and steel components (Kalavagunta, Naganathan, & Mustapha, 2014) underline even more the function of carbon composites in prolonging service lives and satisfying more load requirements. These findings highlight that carbon-epoxy is absolutely necessary for modern civil engineering infrastructure since its lifetime and fatigue resistance (Alam, Mamalis, Robert, Floreani, & Ó Brádaigh, 2019). In fields including fire safety improvements, composites have also developed into multifunctional materials. (Dagdag & Kim, 2024) also combined developments in via unique flame-retardant techniques, hence extending the application possibility of these composites in safety-critical settings. Particularly in the aerospace and automotive industries, where accuracy and low damage are vital, developments in manufacturing technology and processing techniques have greatly affected CFRP's use. Described by (Z. Wang et

https://doi.org/10.31462/icearc2025_ce_sme_387

al., 2023) and (Zheng, Wu, Yu, Wang, & Ma, 2024), laser processing methods offer non-contact, high-quality machining options that address typical problems including delamination
and burr generation. (Ge, J., Zhang, J., Xu, M., Wu, M., Yao, Z., Fu, G., & Sun, 2025) also underlined smart machining techniques such as data-driven prediction and optimization, therefore demonstrating the changing power of combining machine learning with conventional production methods. essential for aerospace component manufacture and other high-value industrial applications, these methods allow improved surface quality and higher production. Recent research on material improvement has concentrated on adding nanoparticles to raise the interfacial characteristics of carbon composites. (Luo et al., 2024) examined how the inclusion of metal nanomaterial's, silicon-based, and carbon-based nanoparticles can greatly increase mechanical characteristics, impact resistance, and fiber-matrix adhesion. at the same time, (Liu, Du, & Liu, 2023) offered a methodical summary of microscopic characterization techniques—including SEM, TEM, and AFM—that are absolutely vital for interpreting the intricate interfacial interactions in these nano modified composites. these developments open the door for next-generation composites with customized qualities for particular uses by improving the structural integrity at the micro-scale.

Long-term performance and safety are still much dependent on inspection and quality assurance of carbon composites components. presented by (B. Wang et al., 2022), ultrasonic testing methods allow thorough flaw detection and offer a foundation for smart nondestructive evaluation tools. ultrasonic wave propagation in CFRP composites exposes vital information on internal delamination and other damage types, hence enabling a strong framework for maintenance plans and lifecycle management. tool geometry has also been highlighted as a key factor where traditional twist drills may produce too much thrust, causing more delamination in comparison to specially designed tools like tapered drill-reamers or drills with optimized point angles (Su, Wang, Yuan, & Cheng, 2015)(Feito, Diaz-Álvarez, López-Puente, & Miguelez, 2016)(Kamaruzaman, Hassan, & Razali, 2022). though with differing success as various mechanisms like chip evacuation and heat buildup become important during drilling operations, these sophisticated geometries aid to lower the critical axial force, hence controlling the beginning of delamination (Zhang, Hu, Wang, Wang, & Luo, 2024). creative drilling techniques including ultrasonic vibration-assisted drilling have also been presented as hopeful ways to further lower mechanical loads and thermal consequences supporting delamination. by encouraging a decrease in chip adhesion and local heating, these methods improve the integrity of the drilled holes. our research is founded on the application of the SEM to examine the various degradation facies of the samples. we aim to identify the several degradations and their influence on the life of the material examined by means of several micrographs at suitable magnifications.

2. Materials and methodes

The fabrication of carbon- c-orthocryl plate to reinforce concrete beams such as the one used prevesiouly by (Abdel-Jaber, Al-Nsour, Almahameed, & Ashteyat, 2025) Fig.1 even when finishing the molding process the final plates requires a machining for assembly purpose, we used in this study were conducted based on 2*2 twill weave carbon fiber Weave 245gr/m , and for the matrix we used a special c-orthocryl resin designated for carbon fiber tissue and with hardener (112P33), one unidirectional plate 100*50 cm were made by infusion molding under
0.8 Bar pressure Fig.2, 8 layers of the fabrics the obtained thickness of the laminates was h=3 mm , the laminates were cured at room temperature for 24 hours, then at 60 c° ,For 6 hours.

Fig. 1. Carbon reinforeced beams (Abdel-Jaber et al., 2025)

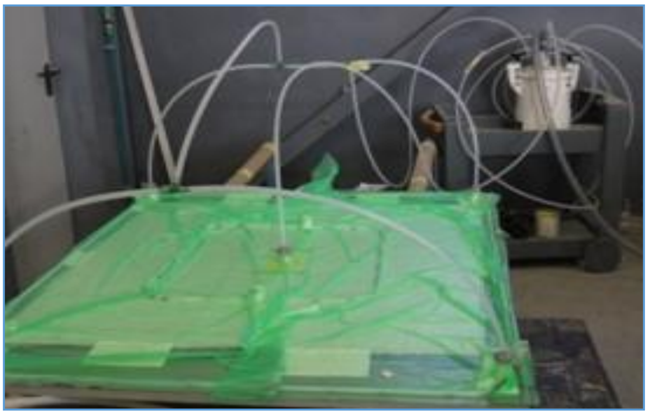

Fig. 2. Infusion moulding

2.1. Protocol

After polymerization, the plates were cut into parallelepipedic specimens of 220x30x2 mm3 and drilling process is conducted usig HSS twist drill-bit with a constant speed and feed rate v=900 rpm delamination happens at the entrance, exit, and even inside the hole Fig.3 , making the drilling process more prone to several kinds of defects (Quan & Sun, 2010). The major defects is directly related to the cutting tool's initial impact against the fiber-matrix interface causes delamination to start at the hole entrance. At the exit, however, the sudden loss of support causes fiber pull-out and crack propagation, therefore causing major damage(Hamamoto, Hirogaki, Aoyama, Fujiwara, & Taketani, 2023)(Shyha, Soo, Aspinwall, & Bradley, 2011) , Table 1 summurazie material used charactersitics .

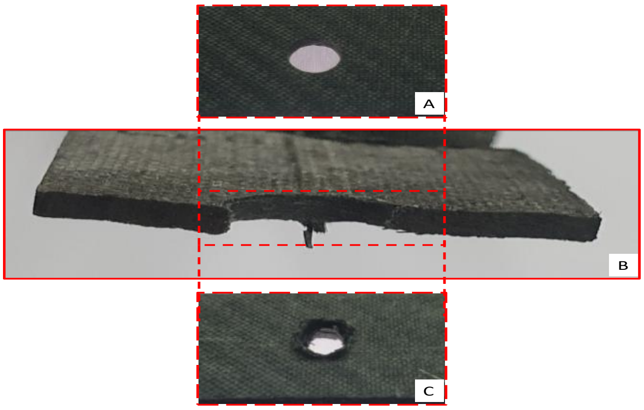

Figure 3 : Drilled specimen A: entry of the hole (peel-up) ,B: inside hole , C: exit of the hole (push-down)

Table 1. Material characteristics

Fiber	weaving	Surface density [g/m^2]	Mass fraction [%]	Supplier
Carbon	taffeta	300	35	Otto bock Germany
Resin	Layer	Weight [g]	Dimensions [mm^3]	
Epoxy c-orthocryl	3	12	220x30x2	

2.2 Microscopy

For absolute understanding of delamination when drilling this composite SEM analysis with assistance (Machine MEB), specimens were cut carefully from the drilled area of all holes with an HSS twist drill to ensure minimum marks were generated during the cutting process for a clear imaging surface. or image acquisition, a Quanta 250 In Fig. 4, SEM images were acquired in black scattered electron, the SEM images were treated using TrackerLab, the images were converted to grayscale, and the ellipse mask was applied to the region of interest.

We cut the control specimen in the longitudinal, transverse and frontal directions, Fig. 5. this cutting allows us to know the internal structure of the material and to detect possible moulding defects and fiber-resin compatibility.

Fig.4 SEM electronic mecroscopic Quanta 250

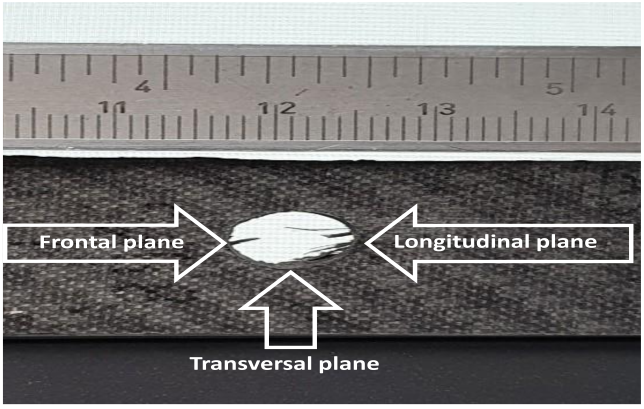

Fig.5 Different Plane according to the cross-sectional planes of the drilled hole

3. Results and discussion

3.1 Delamination in the different planes

3.1.1.Frontale plane

The obtained SEM images illustrate the different damages occuring in carbon-c-orthocryl composite in multiple locations during the drilling, highlighting intralaminar delamination and matrix tearing occurrences.Fig.6 magnified at 160x, displays considerable intralaminar delamination on the fracture surface inside hole.

The differences between separate laminates is apparent, marked by the visibility of aligned fiber bundles and the disruption of matrix homogeneity. the delamination seems to align with the fiber direction, indicating that the matrix distribution between the plies or inside the matrix was weakened under drilling process .the significant fiber pull-out and the existence of the hole fibers suggest that fracture propagation was mainly observed along the weak interlaminar planes, which is characteristic of multilayer composites subjected to out-of-plane or interlaminar loading. furthermore, matrix tearing occurs at various regions surrounding the fiber bundles.

These zones display a damaged and fractured appearance, indicating that the resin matrix failed to keep its cohesiveness during the crack propagation. the c-orthocryl resin brittle characteristics are indicated by the act of the fracture direction caused by the drill bit. Fig.7 taken at a lower magnification (56x), presents a wider perspective of the composite structure at the level of the hole entry. larger-scale delamination at the this , characterized by the separations and damages aligned with the fiber orientation. This macro-level damage corresponds with standard intralaminar delamination failure modes, where crack propagation is influenced by the anisotropic characteristics of the composite (Kamaruzaman et al., 2022) confirmed this is related to thrust force applied during the drilling , also the matrix regions exhibit increased degradation, characterized by matrix cracking and longitudinal tearing, understanding that the brittle fracture characteristic of the matrix under stress. the smooth portions between fiber-resin areas shows a good cohesion between the plies, while Fig.8 displays delamination ant the exit it appears noticeable , indicating the separation of the bottom nost layers, collectively these SEM pictures illustrate the initiation and propagation of intralaminar delamination along weak planes inside the composite, by matrix tearing, which acts as a mechanism for energy distribution but ultimately results in a catastrophic loss of structural integrity when drilling.

The observations align with failure scenarios in fiber-reinforced composites under high-stress or impact loading circumstances, where matrix-dominated failures against fiber failure.

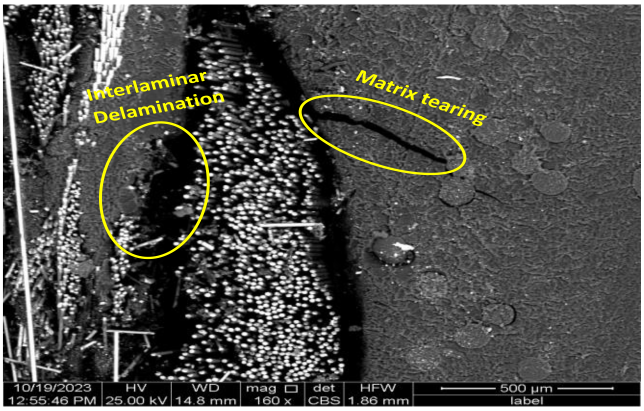

Figure 6 : SEM Image for frontal plane inside hole at 160X

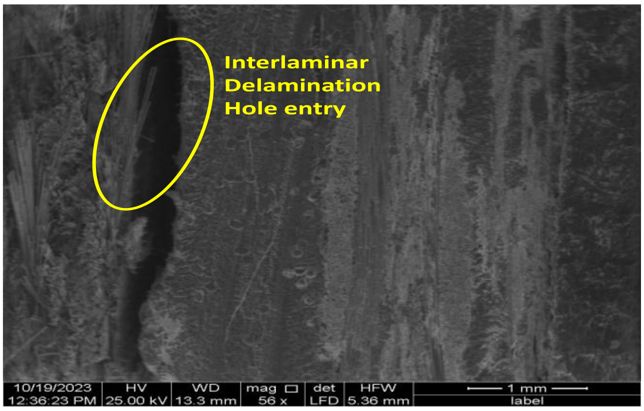

Figure 7 : SEM Image for frontal plane hole entry at 56 X

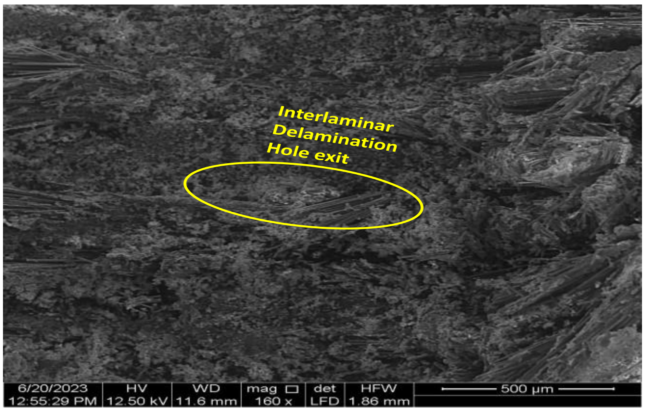

Figure 8 : SEM Image for frontal plane hole exit at 160 X

3.1.2 Longitudinal plane

The longitudinal plane micrographs shows an intralaminar delamination as a critical damage in carbon- c orthocryl composite throughout all the images. an intermediate stage of delamination, where several fiber layers are separated but still partially connected by broken fibers inside hole, is shown in Fig. 9 (120×).

While Fig. 11 taken at a higher magnification (300×) offers a detailed view of the crack network and exposed fibers at the exit of the hole, emphasizing the microstructural roughness caused by progressive damage, Fig. 9 (60×) shows the large scale of intralaminar delamination and the general fiber tearing morphology at the level inside hole .large fractures between inside fiber layers in Fig.9 and Fig.11 point to separation inside the laminate rather than complete interfacial fiber-matrix debonding. when the matrix toughness is too poor to resist fracture beginning and propagation under mechanical stress, a common feature is the separation seeming to propagate along the weak matrix-rich interlaminar regions.

The widespread, random voids point to slow delamination, due to the beginning with matrix microcracking and accelerating under greater thrust force (Sobri et al., 2020) explained this due to stress concentration generated by the drill bit . Fig.9, which shows a lesser magnification, clearly shows a weakened overall integrity of the laminate as it exposes multiple delamination planes producing a broken look. Fig.8 and Fig.10 reveal fiber ripping where bundles of fibers are damaged and pushed out at the hole exit. the fibers suggest they were under significant shear stress before collapse since they are ragged rather than smooth fiber breakage. this suggests that the fiber-matrix contact initially resisted debonding, directly transferring weight to the fibers until they tore rather than causing brittle fracture.the broken fibers in Fig.9, which project unevenly from the delaminated areas, underline that the load-bearing ability of the fibers contributed to the fracture resistance up to the point of failure.Fig.11 also shows some fibre ends exposed along the fracture paths, therefore supporting the idea of fibre rupture occurring parallel to matrix cracking and delamination.

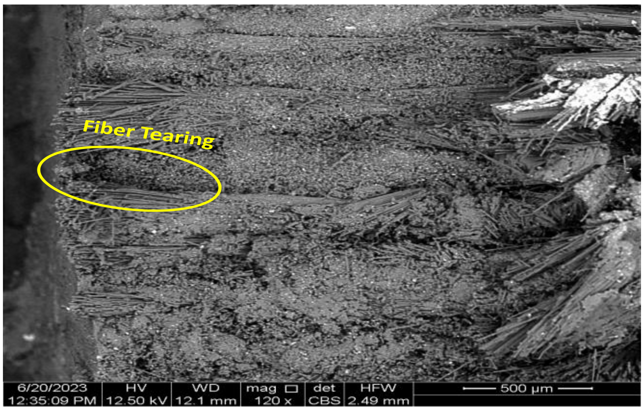

Figure 9 : SEM Image for Longitidunal plane inside hole at 120 X

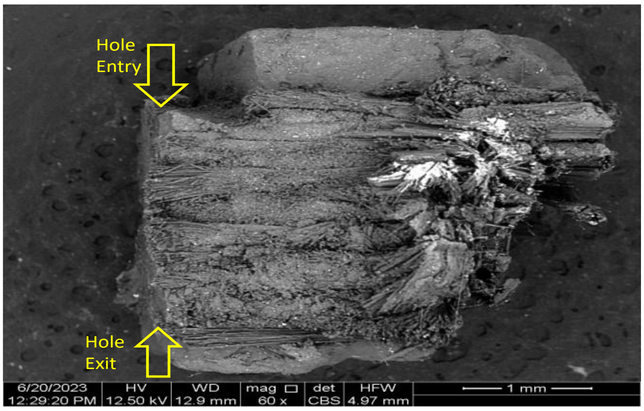

Figure 10 : SEM Image for Longitidunal plane at 60 X

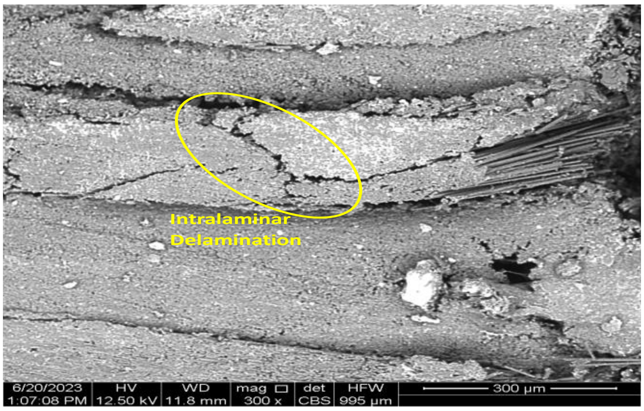

Figure 11 : SEM imagefor Longitudinal Plane hole exit at 300 X

3.1.3 Tranversal plane

Clear signs of translaminar delamination are seen in Fig. 12 and Fig. 13 at the hole enry and inside hole, unlike intralaminar delamination, which follows the plane between layers, on anther hand translaminar delamination cuts through both the matrix and the fiber bundles, usually perpendicular or at angles to the principal laminate planes and drilling direction. With delamination planes comprise across the thickness of the composite, several fiber bundles seem to have been displaced and split under 80× magnification in Fig. 12 the sharp boundaries between fiber-rich and matrix-rich regions imply that the fracture ran over the whole composite structure, cutting through the fiber and matrix phases both. where fiber bundles exhibit obvious symptoms of vertical cracking across their thickness, Fig. 13 (200× magnification) offers a closer view of the broken cross-section.

This translaminar cracking suggests that the crack energy was significant enough to fracture not only the matrix but also enter into the fiber tows, hence fostering deep-seated delamination routes, Fig.13 and Fig.14 show clear matrix decohesion. especially around the damaged fiber bundles at the interface inside and at the hole exit , notable voids and rough matrix surface areas are seen in Fig. 14 (200x magnification).

This structure shows matrix cracking and decohesion a failure mode in which excessive stress concentration or bad adhesion causes the c-orthocryl resin separates from the supporting fibers. (Haldar, Herráez, Naya, González, & Lopes, 2019) highlighted this during the fiber pull-up the due to energy dissipation generated by the drilling while (Bullegas, Pinho, & Pimenta, 2016) on the other hand demonstrated that the traslaminar delamination at pull-out in thin ply composites occurs crucially when the drill bit exit the last ply, fairly flat matrix surfaces and fiber imprints left behind verify that adhesive failure at the fiber-matrix contact have place. moreover, places where the matrix seems to have cracked or separated from fibers show the low energy absorption capacity of the matrix under drilling stress, leading to the beginning of decohesion.

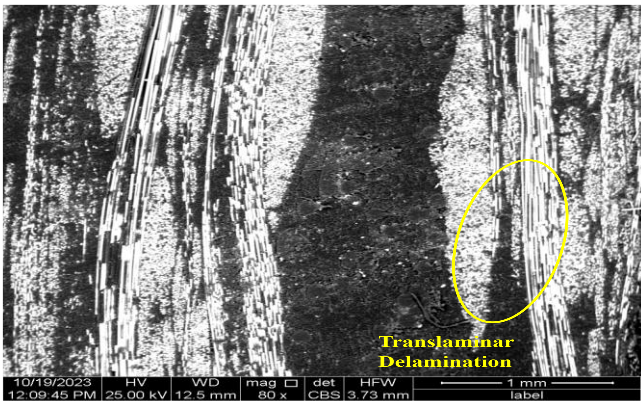

Figure 12 : SEM image for tranversal plane hole entry at 80 X

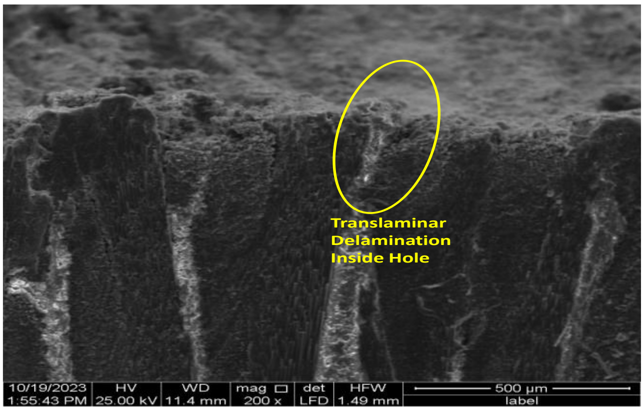

Figure 13 : SEM image for tranversal plane inside hole at 200 X

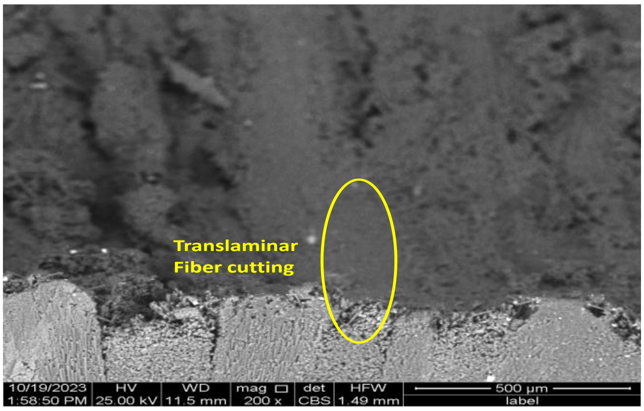

Figure 14 : SEM image for tranversal plane hole exit at 200 X

4. Conclusions

Drilling-related stresses mostly produce microdamages observed in the SEM analysis of the carbon-C-orthocryl composite across the frontale, longitudinal, and transversal planes.

- On the frontale plane Large interlaminar delamination in line with fiber orientations and significant matrix tearing in the frontale plane reveal the carbon-c orthocryl composite sensitivity to the drilling operation inside the hole and a the exit, straining the brittle matrix due to drilling induced thrust and shear force.
- the longitudinal plane micrographs draw attention to intralaminar delamination even more, so implying that inadequate matrix toughness generated slow but wide damage spread by means of progressive fiber tearing and matrix cracking.
- In the transverse plane, translaminar delamination predominated; cracks spreading across matrix regions and fiber bundles indicated that the fracture energy from drilling operation was sufficient to permeate both phases of the material. Moreover, the results indicate that matrix-dominated failures via matrix tearing, decohesion, and fiber ripping are quite significant for the overall drop in structural integrity during drilling operations in carbon-c-orthocryl composites.

Acknowledgments

We would like to express our gratitude to our colleagues (Dr. Menail Younes , Dr. Bouhafara Djaber) for their assistance and dedication in the preparation of the test plates and the SEM microscopy. It is important to note that the material utilized in this study was not funded by the University of Annaba. We would also like to express our gratitude to the individuals responsible for the operation and the manipulators of the SEM at the ENSMM (Ecole Nationale Supérieure des Mines et Métallurgie d'Annaba).

Measurement of residual stiffness of cracked segmental girder using multi-reference impact testing

Arka Mandal[1], J. M. Chandra Kishen[*1]

[1] *Indian Institute of Science, Department of Civil Engineering, 560012 Bangalore, India*

Abstract. Cracking is one of the most observed defects in reinforced concrete structures. This is due to the low tensile strength of concrete. Many of the infrastructures such as bridges, viaducts, etc suffer from severe cracking at the construction stages itself due to accidental loadings. In this work, the residual stiffness of a cracked segment of a metro viaduct under construction is determined using the dynamical characteristics through multi-reference impact testing. Cracked and uncracked segments are subjected to impact loading using an instrumented hammer. Accelerometers are mounted on these segments to measure their vibration parameters. The time histories are converted into frequency domain to determine their natural frequency. Important conclusions regarding the factor of safety and the effect of cracks on the stiffness parameters are obtained which are used to classify the cracks as structural or non-structural.

Keywords: Impact testing; Stiffness; Structural health monitoring; Natural frequency

1. Introduction

Cracking in concrete structures is the most unwanted and unavoidable feature that might cause some undesirable effects on the serviceability of the structure. Agents like fatigue, creep and corrosion adversely affect the structure in such a way as the design loads of the structures that they are fully capable of bearing without any sign of distress, can cause observable deterioration (Larosche, 2009). Under such weakening mechanisms, the load resisting stiffness reduces, which implies the lowering of the load bearing capacity. Another source of cracking is the work progress loads, where the structure is not yet ready for service (Mandal et al., 2023). Under this category most of the cracks occur and since these cracks are during the early stages of the construction, repair must be done quickly to continue with the further work without compromising the safety (Buitrago et al., 2020).

Therefore, these structures need to be monitored quite regularly and thus the methods adopted must be very feasible and efficient at the same time. Among the several techniques available like acoustic emission testing, ultrasonic testing and impact based vibration testing, the last one is supposedly the most versatile one.

The conventional nondestructive methods need a long term evaluation period which may not be available or be feasible for the regular monitoring of important structures like bridges, flyovers, etc. This issue is not faced in the case of vibration based techniques, as the structural condition is interpreted in terms of the stiffness calculated from the measured vibration response to an excitation (Saidin et al., 2023). Evaluating the structural stiffness form the natural frequency is one of the efficient yet effective methods for experimental modal analysis (Ewins, 2000). However, there are cracks that do not affect structural stiffness significantly, and such cracks are termed as the non-structural cracks, while the cracks that affect stiffness are known as the structural cracks (Kwak et al., 2006). Classifying these cracks are of utmost importance as spending a lot of time in excessive retrofitting which is not at all efficient for the development and consumes resources as well. These cracks usually do not form due to service loads, but due to early age shrinkage, exothermal concrete hydration or due to accidental loads during the construction stage (Qu et al., 2024). The fundamental operational principle by assessing the structure in the Fourier domain is explained in the upcoming section.

2. Basics of operational modal analysis

To understand the basics of the working principle of the impulse hammer test, a single degree of freedom system is considered with m, c and k representing the mass, damping and stiffness respectively with zero initial conditions.

$$m\ddot{x} + c\dot{x} + kx = f(t), x(0) = 0, \dot{x}(0) = 0 \tag{1}$$

[*] Corresponding author, E-mail: chandrak@iisc.ac.in

https://doi.org/10.31462/icearc2025_ce_sme_396

The response to the applied force *f(t)* is evaluated by the Duhamel's principle as:

$$x(t) = \int_0^t h(t-\tau)f(\tau)d\tau = \int_{-\infty}^{\infty} h(t-\tau)f(\tau)d\tau, f(\tau) = 0\ \forall\ \tau < 0, h(t-\tau) = 0\ \forall\ \tau > t \tag{2}$$

Where, *h(t)* is the impulse response function and the system is considered to be causal so there is no response until the force *f(t)* is applied. The response x(t) is in the time domain, Fourier transform of which will change the domain from time to frequency as:

$$X(\omega) = \int_{-\infty}^{\infty} x(t)e^{-i\omega t}dt \leftrightarrow x(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} X(\omega)e^{i\omega t}d\,\omega \tag{3}$$

Where, *X(ω)* is the Fourier domain response of the same quantity *x(t)* and similarly two more Fourier pairs are constructed as:

$$H(\omega) = \int_{-\infty}^{\infty} h(t)e^{-i\omega t}dt \tag{4}$$

$$F(\omega) = \int_{-\infty}^{\infty} f(t)e^{-i\omega t}dt \tag{5}$$

From the convolution operation of the Duhamel's integral given in Equation 2, the Fourier equivalent operation becomes:

$$X(\omega) = H(\omega)F(\omega) \tag{6}$$

To find the value of the transfer function *H(ω)* in Equation 6, the governing differential equation of motion in Equation 1 is converted into the Fourier domain with the following components:

$$\dot{x}(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} i\omega X(\omega)e^{i\omega t}\,d\omega \tag{7}$$

$$\ddot{x}(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} -\omega^2 X(\omega)e^{i\omega t}\,d\omega \tag{8}$$

Finally, the governing equation of motion becomes:

$$\int_{-\infty}^{\infty} [(-m\omega^2 + i\omega c + k)X(\omega) - F(\omega)]e^{i\omega t}d\omega = 0 \tag{9}$$

Since the integral is zero for all values of *ω*, the integrand must me zero, with the exponential part as non-zero as usual. The expression for the transfer function *H(ω)* in Equation 6 becomes:

$$X(\omega) = \left[\frac{1}{-m\omega^2 + i\omega c + k}\right]F(\omega) \tag{10}$$

As discussed earlier, for the impact hammer test, basically the structure is excited using a sledge hammer, which basically implies that the forcing function *f(t)* is an impulse, but here just for simplicity the magnitude is assumed to be unity. The forcing function becomes:

$$\int_{\infty}^{\infty} \delta(t)e^{-i\omega t}dt = 1, f(t) = \delta(t) \tag{11}$$

where, *δ(t)* is the Dirac's delta operator. Therefore, the final expression for the displacement function becomes:

$$X(\omega) = H(\omega) = \frac{1}{-m\omega^2 + i\omega c + k} \tag{12}$$

The amplitude of the complex function H(ω) is given as:

$$|H(\omega)| = \left|\frac{1}{-m\omega^2 + i\omega c + k}\right| = \frac{1}{|-m\omega^2 + i\omega c + k|} = \frac{1}{\sqrt{(k - m\omega^2)^2 + (\omega c)^2}} \tag{13}$$

This expression of the amplitude of the complex transfer function *H(ω)* plays the pivotal role in the entire operational modal analysis subject. As it can be seen in Equation 13, the denominator under the root contains sum of two squared quantities, and for the *H(ω)* to be maximum, the quantity under the root has to be minimum. The second term cannot be zero but the first one can. The value of the frequency *ω* at which the first bracket term of Equation 13 goes to zero is the natural frequency of the structure. This is why the responses in the time domain is measured and then the peak of the Fourier transform is computed. One point to observe is that, the accelerations are measured using accelerometers instead of the displacement and their Fourier transforms are computed. This can be explained as, we know for a single degree of freedom system with zero initial conditions, the impulse response has the form:

$$x(t) = e^{-\eta\omega t}\,sin(\omega_d t), \omega_d = \omega\sqrt{1-\eta^2}, \eta = \frac{c}{2\sqrt{km}} \tag{14}$$

Double differentiating x(t) with respect to time gives:

$$\ddot{x}(t) = e^{-\eta\omega t}sin\left(\omega_d t - \tan^{-1}\left(\frac{2\eta\omega\omega_d}{(\eta\omega)^2 - (\omega_d)^2}\right)\right)\left[\sqrt{(-\omega_d^2 + \eta^2\omega^2)^2 + (2\eta\omega\omega_d)^2}\right] \tag{15}$$

Equation 15 reveals that, the displacement and the acceleration both have the same frequency, but the amplitudes and phases are different, which does not alter the position of the maxima of their respective transfer functions. Now it is understood that the location of the peak of frequency spectrum of the acceleration response gives the natural frequency of vibration. In reality most of the structures continuous systems which are approximated as multi degree of freedom systems. In such cases, there will be multiple spikes, but the peak will represent the first mode of vibration, which is the frequency of primary interest.

The acceleration response is measured using accelerometers which are usually accompanied with bandpass filter which sets a lower and upper bounds for the frequencies captured by the data acquisition system, which is why most of the times the zero frequency measurements are neglected as it may be erroneous, or else the zero value would have given the static stiffness, evident from Equation 12.

3. Methodology implemented

To classify the cracks as non-structural and structural, the first intuitive idea is to check for the loss of stiffness due to the formation of cracks. As mentioned in the preceding section, most of the real-life structures are continuous in nature with complicated geometries. Therefore, for this section, the discussion shall include a cantilever beam with a notch at some strategic location so as to check its effect. The governing differential equation of a beam in terms of its length *L*, density *ρ*, area of cross section *A* and flexural rigidity *EI*, is given as:

$$\frac{\partial^4 v}{\partial x^4} + \frac{\rho A}{EI} \cdot \frac{\partial^2 v}{\partial t^2} = 0 \tag{16}$$

where, *v(x,t)* is the deflection at abscissae *x* at a time instant *t*. This equation is derived from the Lagrangian *H* of the elemental strips of the beam given as:

$$H = \frac{1}{2}\int_0^L \left[\rho A \left(\frac{\partial v}{\partial t}\right)^2 - EI\left(\frac{\partial^2 v}{\partial x^2}\right)^2\right] dx \tag{17}$$

Equation 17 reveals that, the origin of the governing differential Equation 16 is dependent upon the deflection of the individual elemental strips. This gives an idea that, for the strips whose effective deflection is zero or negligible, the effect on the differential equation would not be significant and hence the natural frequency will not be affected (Gillich & Praisach, 2014). The general solution to Equation 16 is assumed to have the variable separable form:

$$v(x,t) = \phi(x)e^{i\omega t} \tag{18}$$

The new form of the governing equation after substitution becomes an eigen value problem as:

$$\frac{d^4\phi(x)}{dx^4} - \lambda\phi(x) = 0, \lambda^4 = \left(\frac{\omega^2 \rho A}{EI}\right) \tag{19}$$

The mode shape function *ϕ(x)* has the general solution as:

$$\phi(x) = c_1 \sin(\lambda x) + c_2 \cos(\lambda x) + c_3 \sinh(\lambda x) + c_4 \cosh(\lambda x) \tag{20}$$

where, the constants c_1, c_2, c_3 and c_4 depends upon the boundary conditions, and for a cantilever beam they are:

$$\phi(x)|_{x=0} = \left.\frac{d\phi(x)}{dx}\right|_{x=0} = \left.\frac{d^2\phi(x)}{dx^2}\right|_{x=L} = \left.\frac{d^3\phi(x)}{dx^3}\right|_{x=L} = 0 \tag{21}$$

The null space solution of Equation 20 evaluates to:

$$\cos(\lambda L)\cosh(\lambda L) + 1 = 0 \tag{22}$$

The solutions to the above trigonometric equation for the first three modes are:

$$\lambda_1 L = 1.875,\ \ \lambda_2 L = 4.694,\ \ \lambda_3 L = 7.855$$

and the natural frequency *f* in cycles per second for the mode number *n* is given by:

$$f_n = \frac{(\lambda_n L)^2}{2\pi L^2}\sqrt{\frac{EI}{\rho A}} \tag{23}$$

The mode shape for number n is given as:

$$\phi_n(x) = c_2\left[\cos(\lambda_n x) - \cosh(\lambda_n x) + \frac{\sin(\lambda_n L) - \sinh(\lambda_n L)}{\cos(\lambda_n L) + \cosh(\lambda_n L)}\{\sin(\lambda_n x) - \sinh(\lambda_n x)\}\right] \tag{24}$$

For the second mode, there exists a node where the mode shape function of Equation 24 goes to zero at *x = 0.783L*. Since it is a node, then there is no displacement and hence a notch should not affect much. To check this, a model is constructed in ABAQUS with the following specifications and appropriate units as given in Table 1.

Table 1. Specifications of the beam modelled in ABAQUS.

Length	Width	Depth	Modulus of Elasticity	Density	Poisson's ratio
mm	mm	mm	N/mm^2	tonne/mm^3	

500	50	20	210×10^3	7.8×10^{-9}	0.28

Theoretically, the value of the natural frequency for the first mode of vibration is 67 *Hz*, and the ABAQUS model with tetrahedral elements with the beam modelled as a deformable solid with one face encased gave 67.21 *Hz*.

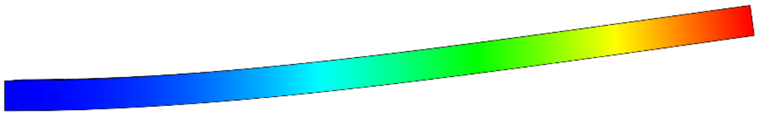

Fig. 1. Deformed shape of uncracked cantilever beam

Fig. 1 shows the deformed shape of the beam and for a later case to study the effect of a notch at the node, which in this case is starts at an abscissa of 391.5 *mm* and ends at 392.5 *mm*. The height of the notch is 15 *mm* and it produced a natural frequency of 66.92 *Hz*.

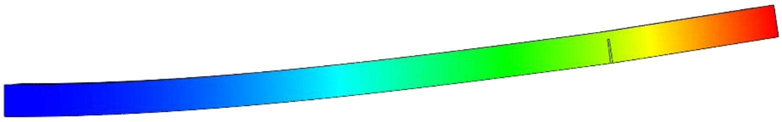

Fig. 2. Introduction of a notch at the node of mode number 1

The notch in this case is introduced by reducing the area of cross section by the area of the notch. The percentage loss of stiffness assuming that the change in mass is neglected, is *0.88%* roughly. Now, a notch of exactly same dimension is placed at a distance of 70 *mm* from the encased fixed boundary. Now the deformed beam is shown in Fig. 3.

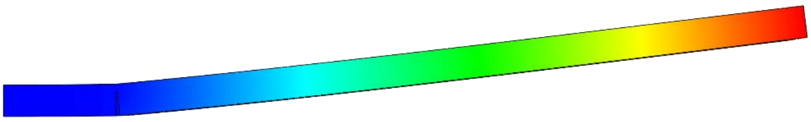

Fig. 3. Notch near the fixed end

Due to the introduction of this notch, there is a drastic loss of the natural frequency. The new natural frequency is 37.018 *Hz*, which means there is a loss

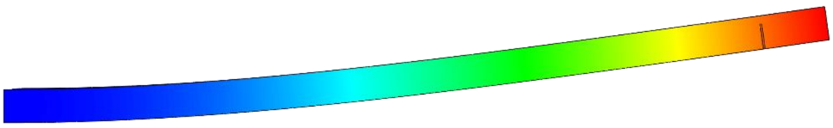

Fig. 4. Notch near the free end

Another notched case is considered where the notch is placed very close to the free end is shown in Fig 4., at a distance of 40 *mm* from the free end, so as to ensure that the notch at the mode one has the least effect. The natural frequency for this case is very close to the discussed case, but is lower. The natural frequency is 66.54 *Hz*. This shows that the node is the safest point in the cantilever beam, since the natural frequency of interest is the first one. Since the node is for the second mode, the natural frequency of vibration was about 419 *Hz*, exactly same as that of the uncracked beam. With this idea, a box girder was assessed using the vibration test.

4. Instrumentation and test program

A concrete box girder segment was reported to have some observable cracks near the joint between the flange and the web. Usually, cracks in these locations are not structural because they are in the compression side of the beam, and this is concept is kept in mind while designing the beam for loads acting downwards, like the gravity load. When these girders are lifted and placed on the bearings of the columns, sometimes due to some eccentricity or due to fast pulling of the crane shaft, there might be a vertical force acting on the joint that might cause tensile stresses in the zone which is expected to resist compressive loads. Under static cases, these cracks are dormant, but these types of girders are used for the metro system, they carry heavy and fast moving trains. Under the action of the wheel loads, there might be stress reversals, that may allow the crack to extend. Therefore, to check for the activeness of the cracks, dynamic tests are the most ideal ones.

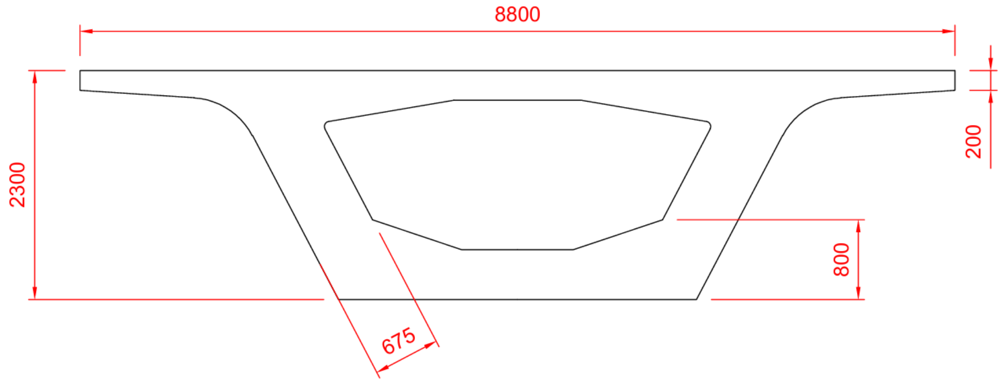

Fig. 5. Geometry of the box girder segment of length 3000 *mm* (All dimensions in *mm*)

An instrumented hammer was utilized to set the structure into vibration and accelerometers were placed on the cantilever flanges, so as to measure the vibrations (Kishen et al., 2013). Two accelerometers were utilized for this study, so as to ensure that the crack has not propagated, by the Maxwell-Betti's theorem.

First the hammer was struck near accelerometer one, and the responses of both the accelerometers were recorded, then the hammer was hit near the accelerometer two and the responses were recorded. If there were a significant amount of crack, there will be a difference in the cross responses of the two accelerometers (Raghavendrachar & Aktan, 1992). A 64-channel data acquisition system manufactured by M/s DEWETRON was used to capture the data continuously from the pair of accelerometers. First the acquisition was turned on and after that the hammer was hit and the data was recorded till the acceleration decayed significantly. An input from the hammer is shown in Fig. 6.

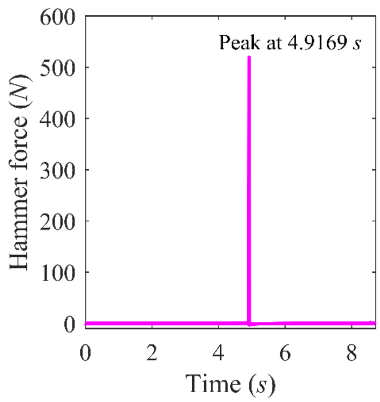

Fig. 6. Impulse input to the system when hammer is struck near accelerometer one

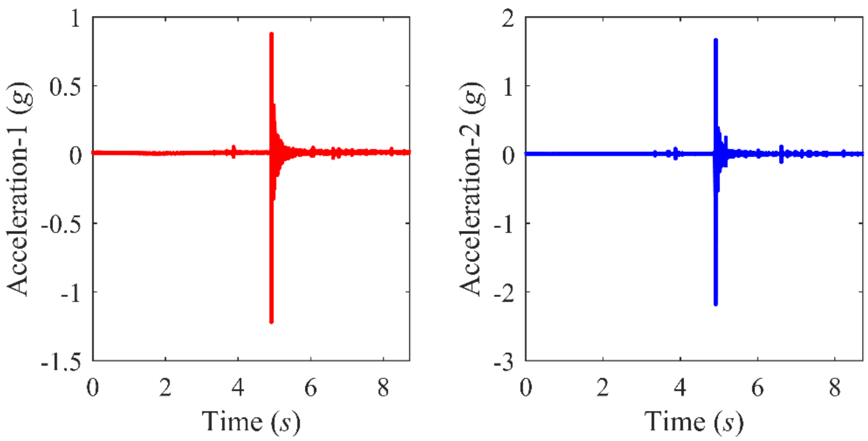

Fig. 7. Accelerometer responses to the excitation by the hammer strike near accelerometer one

Fig. 7 shows the responses of the accelerometers when the hammer is struck near the accelerometer one. Similarly, this process is further repeated once again near the accelerometer two, but sufficient time was given each time in between tests so that residual vibrations are decayed. Every time the accelerometers were calibrated using the calibrator and the surfaces on which they are supposed to be mounted by silicon grease were finely sanded so as to ensure adequate contact. The hammer tip made of rubber used for all the tests were the stiffest available and was calibrated using the hung mass technique so as to get the conversion factors from millivolts to Newtons. Also, the vibrations prior to the hammer strike were minimized so as to minimize the errors.

5. Results and discussions

The natural frequency was obtained by the Fast Fourier Transform (FFT) technique using MATLAB. The FFT was applied on the last few seconds of the signal after hammer hit, as this constituted the free vibration of the structure. The key step while computing the FFT is the sampling frequency. As per the Nyquist-Shannon sampling theorem, the sampling frequency must be at least twice the highest frequency present in the signal, and for this case it was taken care of by generating the frequency spectrum till the value which is half of the actual data acquisition frequency. The results for the hit shown in Fig. 6 are shown in Fig. 8.

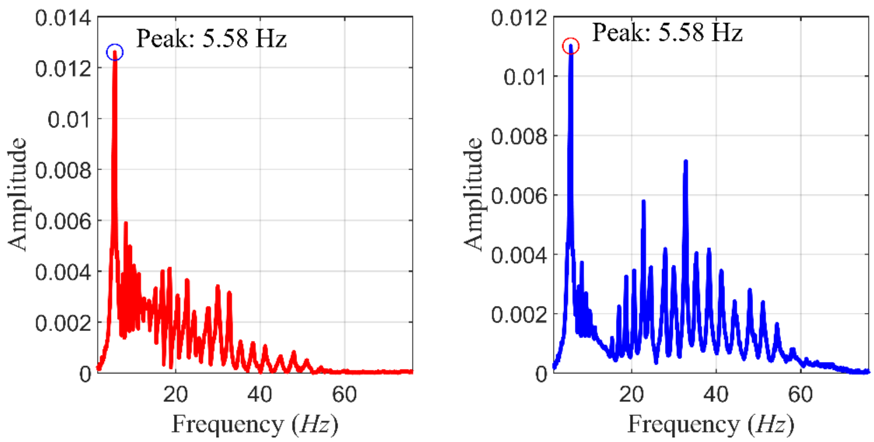

Fig. 8. Acceleration spectra in Fourier domain when hammer is struck near accelerometer one

The first observable feature is that the frequencies are same for both the accelerometers indicating that there are not enough micro-cracks that might contribute to damping and essentially lower the recorded frequency. However, to ensure that the stiffness is intact, the responses have to be considered when the hammer was struck near the second accelerometer.

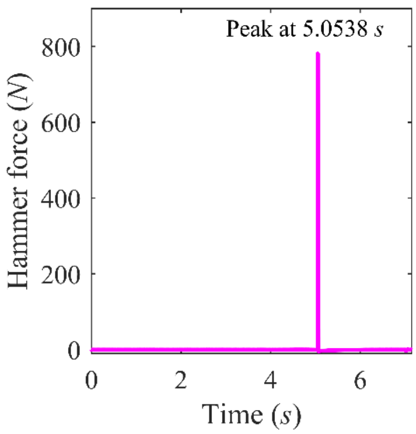

Fig. 9. Impulse input to the system when hammer is struck near accelerometer two

Due to the input of Fig. 9, the time domain responses of the accelerometers are shown in Fig. 10. The natural frequencies are obtained using the FFT technique, and the results are shown in Fig. 11.

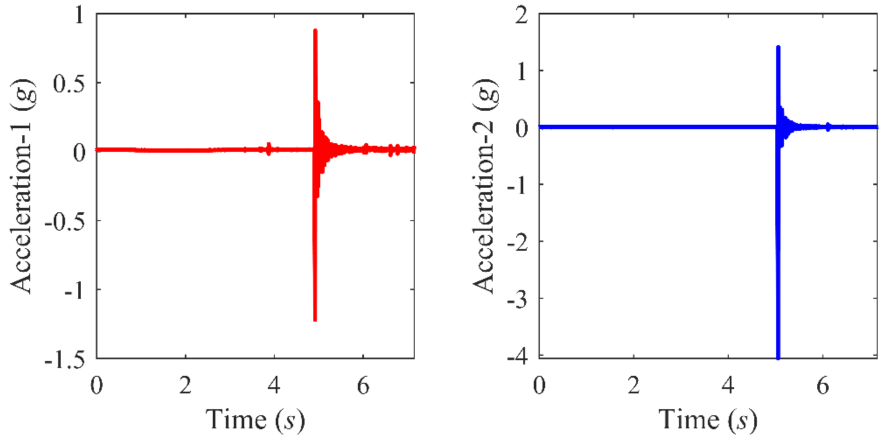

Fig. 10. Accelerometer responses to the excitation by the hammer strike near accelerometer two

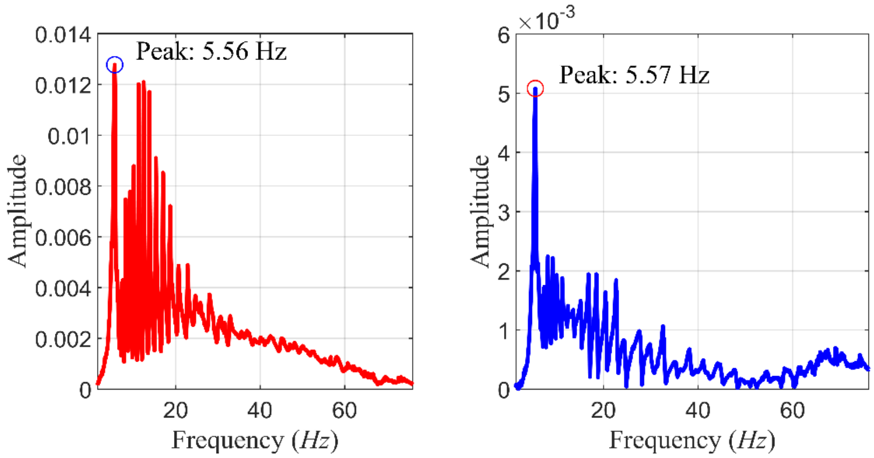

Fig. 11. Acceleration spectra in Fourier domain when hammer is struck near accelerometer two

The frequency is nearabout the same for the alternate cases, which ensures the reliability of the readings. To check whether the crack is really dormant, a model was prepared in ABAQUS with the specified geometry as shown in Fig. 5. The mode shapes indicate that the region of interest is always within the nodal zone.

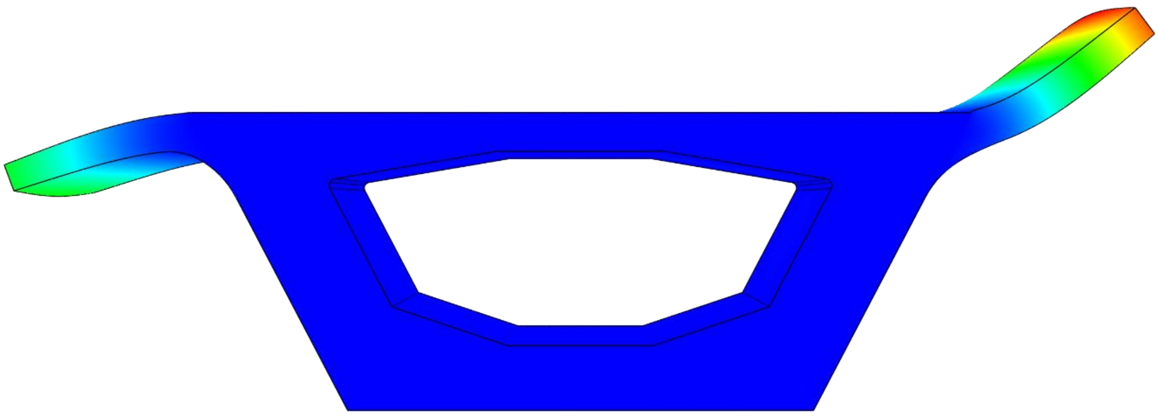

Fig.12. First mode shape of the girder

In fact, this remains in the nodal zone even for the second mode as shown in Fig. 13.

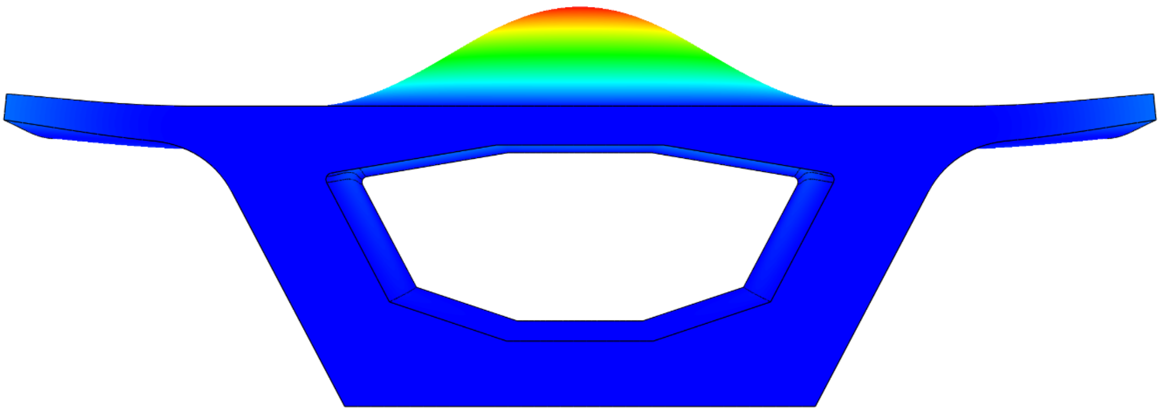

Fig. 13. Second mode shape of the girder

This natural frequency computed from the numerical model in ABAQUS was 5.73 *Hz*, which is very close to the obtained frequencies from the FFT of the time domain signals obtained. Therefore, it can be concluded that the cracks occurring in the nodal regions do not impose a sever threat to the structure, but still there is a reduction in the natural frequency. This loss can however be regained easily with minimal retrofits, and moreover all these types of girders used for metro will have railway tracks laid on them. Those steel tracks will enhance the stiffness to a huge extent and ultimately after the construction the differences would not be evident.

6. Conclusions

The results as obtained from the vibration test using the impact hammer, show that the cracks caused in the region of joint of the cantilever flanges with the web of the girder do not impose a serious issue to the structure. Even though they are dormant, due to corrosion of the reinforcements, or due to fatigue action, these cracks may propagate so it is better to take at least the minimum prescribed or the necessary retrofits. In this study, there was indeed a change in the natural frequency, but was not significant so the crack can be classified as a non-structural one.

In fact, if test reports are available for the intact girders, and if any crack appears in the future, the vibration tests on the affected segment can be used to classify the cracks as structural or non-structural based on the percentage change in the natural frequency of vibration and also the importance of the structure.

- The vibration tests are capable of assessing the structure within a very short span of time, and that too with adequate reliability.
- For this study, two accelerometers were used in order to check the modal reciprocity which is also a very good test regarding the increase in damping due to presence of micro-cracks, that may not be evident from the change in the natural frequency.
- The natural frequency obtained from the tests were very close to the one obtained from the numerical model, thus showing that the crack in the joint in between the flange and the web is an inactive zone.

As a future scope, these preliminary conclusions need to be investigated further by involving the transfer matrix approach to estimate the actual modal mass and the modal stiffness. Also, to reinforce this idea, modal acceptance criteria on more number of tests will be imposed so as to minimize the chances of instrumentation and experimental errors.

Automated structural crack detection using a deep learning-based YOLO algorithm and robotic dog

Ayşecan Bostan*[1], Kemal Hacıefendioğlu[1]

[1] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. This study aims to automatically detect cracks in structural elements using the YOLO object detection algorithm, based on Deep Learning techniques, integrated with robotic dog technology. This approach seeks to enhance both the accuracy and efficiency of structural health monitoring processes. The study begins with the selection of appropriate datasets via the Roboflow platform, where a dataset consisting of 2,600 annotated crack images was utilized for model training. Training was conducted in the Google Colab environment, resulting in the development of an object detection model. Additionally, a segmentation model was created using the same dataset to ensure more precise crack boundary delineation. The performance of the trained models was evaluated through real-time tests using images captured by cameras mounted on the Unitree Go2 Edu Plus robotic dog. These tests were conducted on a reinforced concrete frame with induced cracks at the Structural Health Monitoring Laboratory of Karadeniz Technical University. The images were processed in real-time using YOLO models, enabling immediate crack detection. The findings demonstrate that the robotic system, combined with the YOLO algorithm, effectively detects cracks in real-time with high accuracy. This study highlights the potential of integrating Deep Learning and robotic technologies for structural health monitoring, offering a reliable and efficient solution for damage assessment in civil engineering applications. The results validate the proposed approach as a practical and dependable method for automated structural crack monitoring.

Keywords: Crack detection; Robotic dog; YOLO models; Deep Learning; Object detection

1. Introduction

Earthquakes are natural disasters that cause extensive physical destruction and significant loss of life on a large scale. In the aftermath of such catastrophic events, the rapid and reliable assessment of the structural integrity of buildings is of critical importance. Traditional damage detection methods primarily rely on manual inspections, which are often time-consuming, labor-intensive, and susceptible to human error. These limitations underline the necessity of developing innovative and automated approaches that can deliver fast and accurate evaluations of structural conditions (Qayoumi et al., 2025; Jia & Ye, 2023).

Recent advancements in robotics and artificial intelligence (AI) offer promising opportunities to revolutionize post-disaster structural assessments (Zhai et al., 2024; Ye et al., 2022). In this context, the primary aim of this study is to develop an integrated system that utilizes robotic technologies and deep learning-based methods for the rapid and automated detection of structural damages. The project involves the integration of the Unitree Go2 robotic dog platform with the YOLOv8 deep learning model to enable real-time detection of cracks, deformations, and other structural damages on building surfaces.

The robotic dog is designed to move safely and efficiently even in challenging terrain conditions. It is equipped with advanced sensors and reinforced with artificial intelligence algorithms, allowing it to autonomously explore and inspect areas that are difficult or dangerous for human access. Through the use of a deep learning model capable of processing environmental images, the system can accurately identify and classify structural damages without the need for human intervention (Morfidis et al., 2023; Ilmak et al., 2024).

Another significant feature of the developed system is its ability to process data in real time, providing operators with instant information and comprehensive reporting during inspections. This capability ensures that critical decisions can be made rapidly, which is particularly vital in the immediate aftermath of earthquakes when timely interventions can save lives and prevent further structural failures.

By combining robotic mobility, advanced sensing technologies, and AI-driven damage detection, this study aims to offer a fast, reliable, and efficient solution for post-earthquake structural assessments. The proposed system

https://doi.org/10.31462/icearc2025_ce_sme_419

represents a significant step forward in enhancing the effectiveness of disaster response efforts and minimizing the risks associated with manual inspection methods.

2. Materials and methods

The following section provides a comprehensive overview of the key components utilized in the study, including the robotic dog platform, the YOLO algorithm, the dataset employed for training and testing, and the testing model. These elements are essential for understanding the methodology and the process of damage detection that forms the basis of this research.

2.1. Unitree Go2 Robotic Dog

The Unitree Go2 is a next-generation robotic dog model developed by the Chinese robotics company, Unitree Robotics. It features a quadrupedal structure resembling that of a cat or dog. The Go2 builds upon the experience gained from previous models such as the A1, Go1, and AlienGo. Designed for both industrial and individual use cases, it offers advanced performance, agility, and enhanced artificial intelligence (AI) capabilities.

One of the most prominent features of the Go2 is its advanced mobility. Thanks to its quadrupedal design, it is capable of maintaining balance even in rugged terrains. The robot can easily navigate difficult environments, including stairs and obstacles, making it versatile in various scenarios. Compared to earlier models, the Go2's maximum speed has been increased, and its acceleration has been significantly improved, enhancing its overall performance.

In terms of artificial intelligence and sensing capabilities, the Go2 is equipped with a range of sensors, including depth cameras and LiDAR, enabling it to perceive its surroundings in three dimensions. The robot can perform functions such as object recognition, obstacle detection, and path planning with high accuracy. The combination of a powerful processor and AI algorithms further boosts the robot's ability to process data in real-time, enhancing its responsiveness to environmental changes.

Additionally, the durability and portability of the Go2 are noteworthy. Constructed with lightweight yet robust materials, its body is resistant to impacts and falls, ensuring longevity even in challenging environments. The robot's rechargeable battery allows for extended periods of continuous operation, and different battery options may be available depending on the application. Furthermore, its foldable or easily portable design makes it convenient to transport from one location to another, offering practicality for various use cases. The Unitree Go2 robot dog and its equipment are shown in Fig. 1.

Fig. 1. Unitree Go2 robotic dog and equipment

2.2.YOLO (You Only Look Once) algorithm

YOLO (You Only Look Once) is a computer vision model introduced by Joseph Redmon, Santosh Divvala, Ross Girshick, and Ali Farhadi at the CVPR conference in 2016, where it gained significant attention. Winning OpenCV's "People's Choice" awards, YOLO is a single-stage detector that performs object detection and classification through a single network pass (Nelson, 2025).

Among single-stage detection models, YOLO remains one of the most well-known and widely used frameworks. However, it is not the only example of such models; for instance, MobileNetSSDv2 is another popular single-stage detector. Nonetheless, YOLO often demonstrates superior performance compared to other models in terms of both speed and accuracy.

YOLO models approach the object detection task through a single-shot regression method that predicts the bounding boxes of objects directly. This approach provides high processing speed and a compact network structure. These characteristics make YOLO not only an efficient tool for accelerating the training process but also highly suitable for deployment on edge devices with limited computational resources.

An example illustrating the working principle of YOLO is presented in Fig. 2 below. The visual representation clearly demonstrates the process of detecting and classifying objects by identifying their bounding boxes.

Thanks to these advantages, YOLO has become a highly preferred model in a wide variety of practical applications. Its ability to balance accuracy and speed has led to its widespread adoption across both academic research and industry sectors. Furthermore, the model's efficiency in resource-constrained environments makes it a practical choice for real-world deployments where computational power may be limited.

YOLO models appeal to a wide range of developers due to their ability to be trained on a single GPU. Machine learning practitioners can deploy these models at a low cost, either on edge devices or in cloud environments. The speed offered by YOLO is particularly advantageous in scenarios that require real-time object detection.

Before the emergence of YOLO, R-CNNs were commonly used for object detection; however, their slow processing speeds made them unsuitable for real-time applications. In contrast, YOLO greatly facilitates rapid inference tasks in applications such as vehicle detection, animal recognition, and security surveillance, where fast and accurate detection is critical.

YOLOv8 represents a state-of-the-art advancement in computer vision, developed by Ultralytics, the organization behind the widely adopted YOLOv5 model. Designed to address a variety of tasks—including object detection, image classification, and instance segmentation—YOLOv8 combines cutting-edge performance with developer accessibility through an intuitive command-line interface (CLI) and a well-structured python package. This dual interface approach significantly lowers the barrier to entry for both novice and experienced practitioners, promoting widespread adoption across research and industry.

A major innovation distinguishing YOLOv8 from its predecessors is its anchor-free architecture. Unlike traditional models that rely on predefined anchor boxes to estimate object locations, YOLOv8 directly predicts object centers. This design shift results in enhanced localization accuracy, reduced computational complexity, and improved inference speed, making the model particularly well-suited for real-time applications on both high-performance and resource-constrained devices.

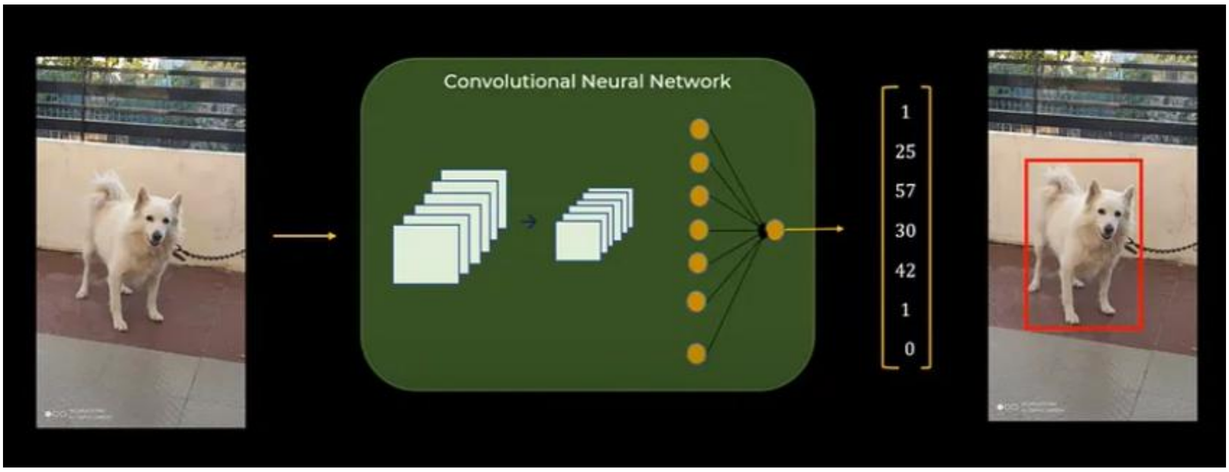

Fig. 2. General working mechanism of YOLO (Kumar, 2022)

Table 1. YOLOv8 detection models comparison (Ultralytics, 2025)

Model	Size (pixels)	mAPval (50-95)	Speed CPU (ms)	Speed T4 GPU (ms)	Params (M)	FLOPs (B)
YOLOv8n	640	37.3	-	-	3.2	8.7
YOLOv8s	640	44.9	-	-	11.2	28.6
YOLOv8m	640	50.2	-	-	25.9	78.9
YOLOv8l	640	52.9	-	-	43.7	165.2
YOLOv8x	640	53.9	-	-	68.2	257.8

In this study, the YOLOv8n model, whose features are presented in Table 1, has been selected. YOLOv8n operates with a 640x640 pixel input size and achieves a mAP (50-95) value of 37.3%. The model has only 3.2 million parameters (M) and 8.7 billion FLOPs (floating point operations). Due to its lightweight structure and low computational cost, it is particularly suitable for resource-constrained systems.

2.3. Characteristics of the dataset used

The dataset used in this study was obtained from the Roboflow platform. Roboflow is a comprehensive platform that provides all the necessary tools for creating, developing, and deploying computer vision models. The platform offers flexible usage by enabling integration at any step of the pipeline through APIs and SDKs. Additionally, it provides end-to-end interface support to automate the image processing workflow from start to finish.

Roboflow Annotate is an online annotation tool specifically designed for labeling images in tasks such as object detection, classification, and segmentation. This tool facilitates the accurate and rapid annotation of images, streamlining the dataset preparation process. These features significantly enhance the quality of the dataset used in this study, making a substantial contribution to the computer vision model development process. A visual taken from the Roboflow homepage is presented in Fig. 3.

The dataset used in this study consists of a total of 3,255 crack images. All these images have been carefully labed to precisely indicate the locations of the cracks. The dataset is divided into three groups for model training and evaluation: "training," "validation," and "test."

- Training Group: The largest group used for model training, consisting of 2,658 annotated images.
- Validation Group: This group, containing 300 annotated images, is used to evaluate the accuracy of the model during the training process.
- Test Group: This group, consisting of 297 annotated images, is reserved to independently assess the model’s performance.

The meticulous preparation of this dataset significantly contributes to achieving high accuracy and reliability during the model training and evaluation processes. The labeling process ensured that the data was processed in a clear and consistent manner, positively impacting the model’s performance.

Example excerpts from the image and label files in the dataset are presented in Fig. 4 and 5 below. These excerpts provide a clearer visual understanding of the dataset structure and the annotation format used.

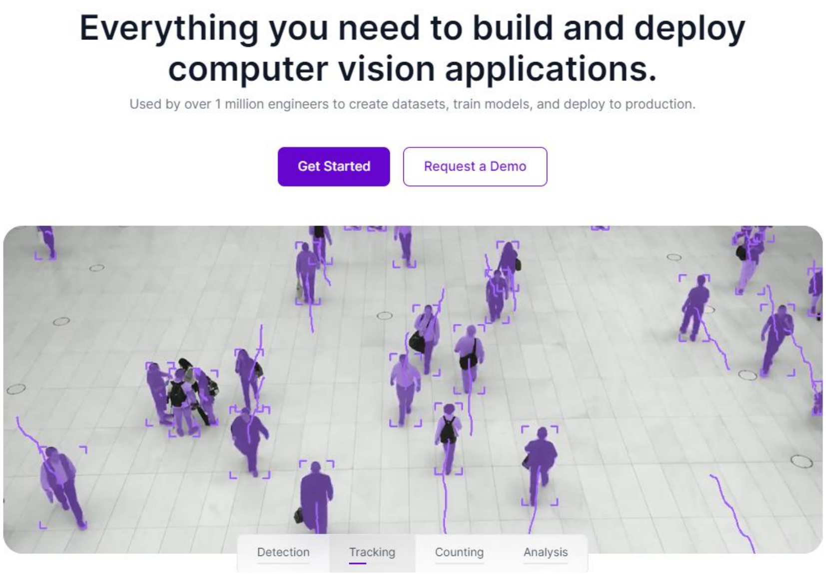

Fig. 3. Roboflow homepage (Roboflow, 2025)

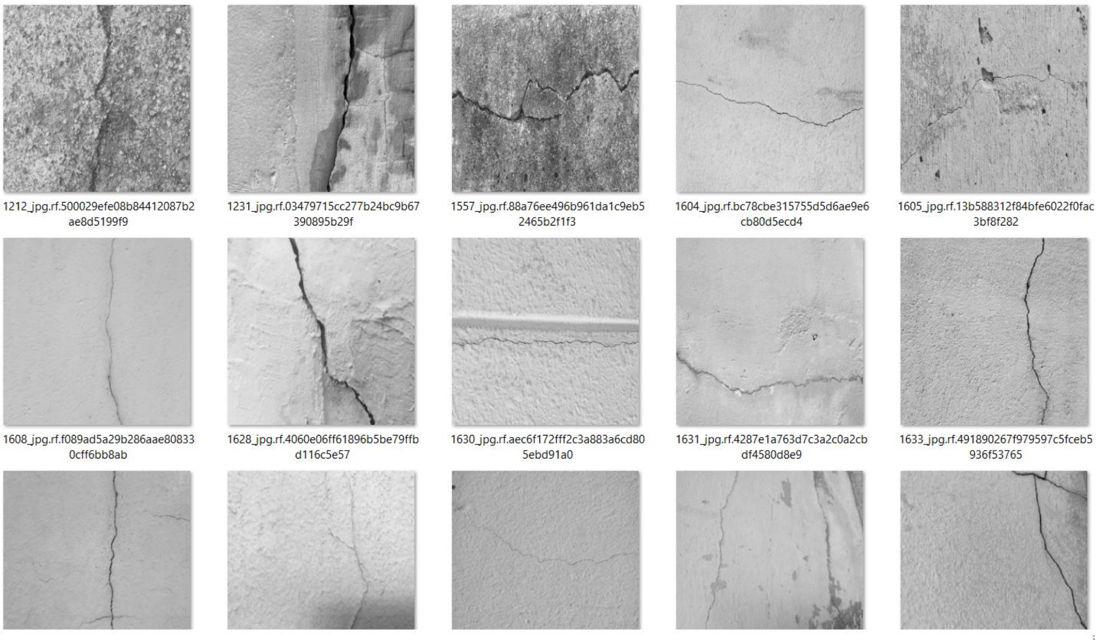

Fig. 4. Sample images from the dataset

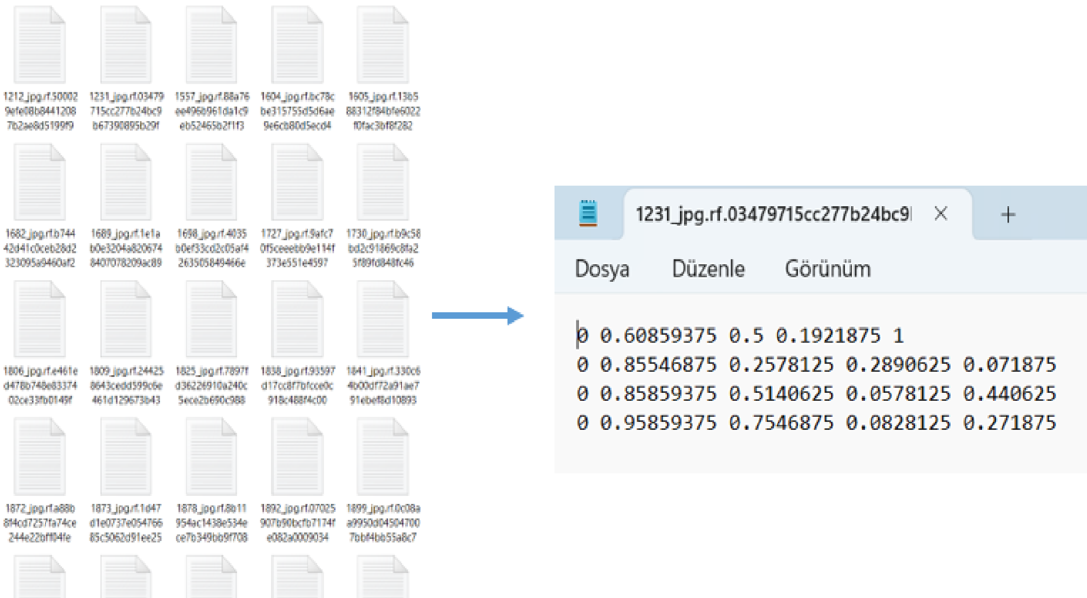

Fig. 5. Label files

The text file presented in Figure 5 is an annotation file in YOLO format, used to provide training data for an object detection model. Such files contain annotations that are essential for enabling the model to acquire object detection capabilities. Each line in the file represents an object and provides the following information: the class ID, the center coordinates of the bounding box, and the width and height of the box. All these values are normalized with respect to the dimensions of the corresponding image. This format helps the model learn the locations and sizes of objects within the images. Once the training process is completed, the model can detect and correctly classify similar objects in new data. The YOLO annotation structure plays a critical role in developing fast and efficient object detection models.

The object detection results for the first two lines provide detailed information about the identified objects, including their class, position, and bounding box dimensions in normalized coordinates. In Line 1, the object is assigned a Class ID of 0, with the center of its bounding box located at 60.86% of the image width and 50% of the image height. The bounding box spans 19.22% of the image width and covers the full height of the image, indicating a vertically elongated object occupying a significant portion of the image's vertical axis. In Line 2, another object with the same Class ID (0) is detected, with its bounding box center positioned at 85.55% of the image width and 25.78% of the image height. The corresponding bounding box dimensions are 28.91% of the image width and 7.19% of the image height, suggesting a more compact and horizontally wider object. Lines 3 and 4 follow the same format, representing additional detected objects using normalized center coordinates and relative dimensions.

2.4. Training process and code block used

The code block required to initiate the training process was obtained from the official page of the "Ultralytics YOLOv8" application and is presented in Fig. 6. Various modifications were made to the code to align it with the specific requirements of the project, and subsequently, the training process was initiated. The training was configured to run for a total of 100 epochs and took approximately 2.293 hours to complete. Throughout the training phase, the model parameters were optimized with the aim of achieving high accuracy. This stage played a critical role in enhancing the overall performance of the model and ensuring successful results in real-world applications.

The command shown in Fig. 7 is a terminal or Python code line used to train a YOLOv8 model on a dataset. Below is an explanation of each part of the command:

- !yolo detect train: Used to train the YOLOv8 model for an object detection task. This command indicates that the model will be run in training mode.
- data=/content/drive/MyDrive/object_detection2/config.yaml: The path to the configuration file of the dataset to be used for training. This file includes the dataset path, number of classes, and other relevant settings.
- model=yolov8n.pt: The pre-trained weight file of the YOLOv8 model to be used for training. (yolov8n.pt refers to the "nano" version of YOLOv8, which is lightweight and fast.)
- epochs=100: Indicates that the model will be trained for 100 epochs. An epoch means the entire training dataset is passed through the model once.
- imgsz=640: The resolution to which the images will be resized during training. Here, all images are resized to 640x640 pixels.
- workers=8: The number of CPU cores to be used for data loading. More workers can speed up the data loading process.
- batch=8: The number of images to be processed in each iteration during training. Larger batch sizes require more memory.
- device=0: Specifies which device will be used for the training process. (0: training will be performed on GPU. If training is to be performed on CPU, this should be set as device=cpu.)
- name=yolov8_crack_detection2: The name under which the trained model file will be saved. This will also be the name of the folder where training output files are stored.

Fig. 8. Training

As illustrated in Fig. 8, the training process was successfully completed, and the resulting data were analyzed to assess the model's performance in terms of both accuracy and speed. The YOLOv8 model was trained over a total of 100 epochs, with the entire training phase taking approximately 2.293 hours. Thanks to the carefully prepared dataset and the selection of appropriate hyperparameters, the model was able to learn efficiently and achieve a high level of generalization. Upon completion of the training, two optimized weight files were generated: *last.pt*, representing the model's weights at the end of the training, and *best.pt*, corresponding to the model's best performance during training. Both files were designed to be lightweight, each with a file size of just 6.3 MB, making them suitable for real-time applications.

The model's performance was rigorously evaluated using a validation dataset. It achieved a precision of 84.6%, indicating its ability to correctly classify detected objects, and a recall of 82.6%, reflecting its effectiveness in identifying all relevant objects. The mean Average Precision at a 50% Intersection over Union (mAP@50) was recorded at 86.7%, demonstrating the model's strong object detection capability. Furthermore, the model achieved a mAP@50-95 score of 61.3%, which assesses overall accuracy across a broader range of IoU thresholds, confirming its robustness in more complex evaluation settings.

In addition to accuracy, the model also performed efficiently in terms of speed. During validation, the average preprocessing time per image was measured at 1.1 milliseconds, the inference time at 4.3 milliseconds, and the post-processing time at 6.1 milliseconds. These results highlight the model's suitability for real-time detection tasks where both high accuracy and low latency are critical.

These results show that the YOLOv8 model can perform object detection tasks with high accuracy and sensitivity. A mAP@50 value of 86.7% proves that the model achieved a strong learning capacity during training and could effectively detect objects in the dataset. Additionally, the lightweight optimized weight files and fast processing times indicate that the model is also suitable for deployment in environments with limited computational resources.

2.5. Training and validation results

The figure shown in Fig. 9 illustrates the losses and performance metrics obtained during the training process of the YOLOv8 model. Each of these graphs is used to understand how the model progresses throughout the training and how its performance changes during validation. A detailed interpretation of the graphs is presented below:

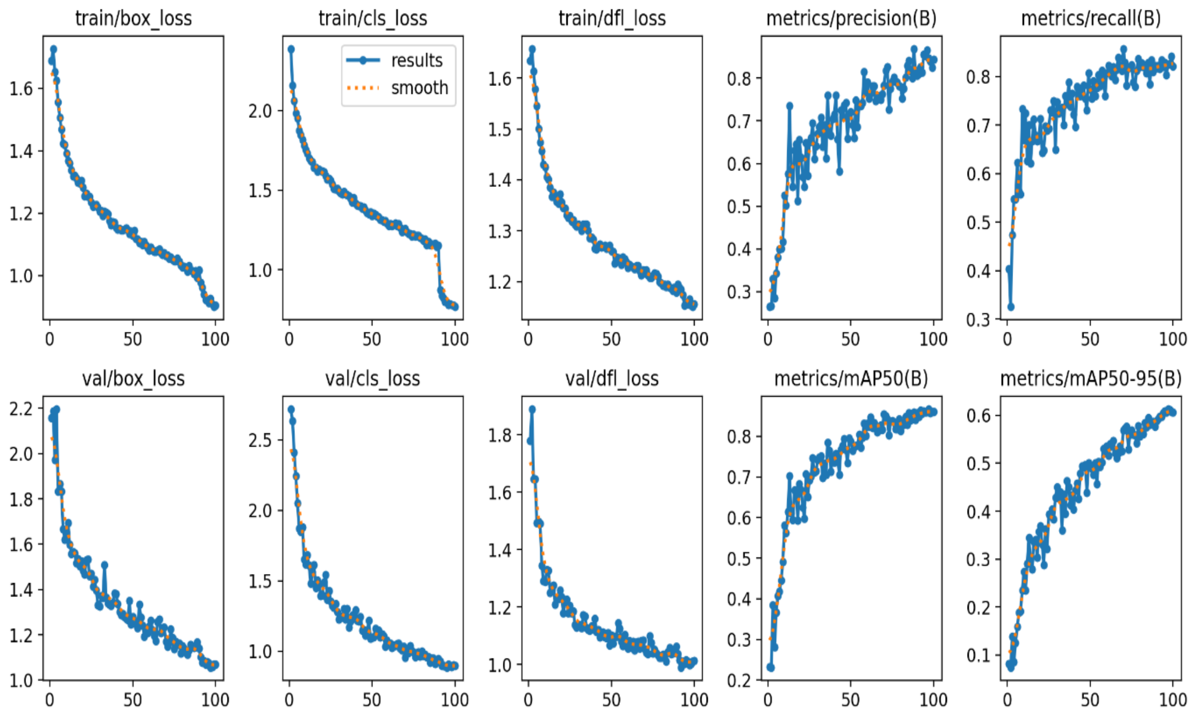

Fig. 9. Results

The evaluation of the training process included a detailed analysis of loss functions and performance metrics, which provided insights into the model's learning behavior and accuracy. The training losses, including box loss (*train/box_loss*), classification loss (*train/cls_loss*), and distribution focal loss (*train/dfl_loss*), consistently decreased over time. The reduction in box loss indicates that the model increasingly improved its accuracy in predicting bounding box locations. Similarly, the decrease in classification loss reflects enhanced accuracy in object classification, while the declining distribution focal loss shows progress in the precise localization of bounding boxes. Correspondingly, the validation losses—*val/box_loss*, *val/cls_loss*, and *val/dfl_loss*—also demonstrated a parallel downward trend. This consistency between training and validation losses suggests that the model achieved generalizable performance without significant overfitting.

In terms of performance metrics, the model showed continuous improvement across all key indicators. Precision steadily increased with each epoch, eventually reaching approximately 85%, indicating a high rate of correctly classified detected objects. Recall also showed a gradual upward trend, achieving around 82%, which confirms the model's ability to detect most objects present in the dataset. The mean Average Precision at an IoU threshold of 50% (*mAP@50*) reached about 86%, reflecting strong object detection accuracy. Moreover, the more comprehensive *mAP@50-95* metric, which evaluates performance across multiple IoU thresholds, achieved a value of approximately 61%. This result highlights the model's robustness and effectiveness in varying detection scenarios, confirming its suitability for practical applications in real-world environments.

Throughout the training process, a consistent reduction in both training and validation losses was observed, indicating that the model successfully learned the underlying distributions of the training data. The continuous improvement in performance metrics (precision, recall, and mAP) suggests that the model progressively became better at making predictions. Moreover, the parallel decrease in training and validation losses confirms that the model has strong generalization capabilities and that overfitting did not occur.

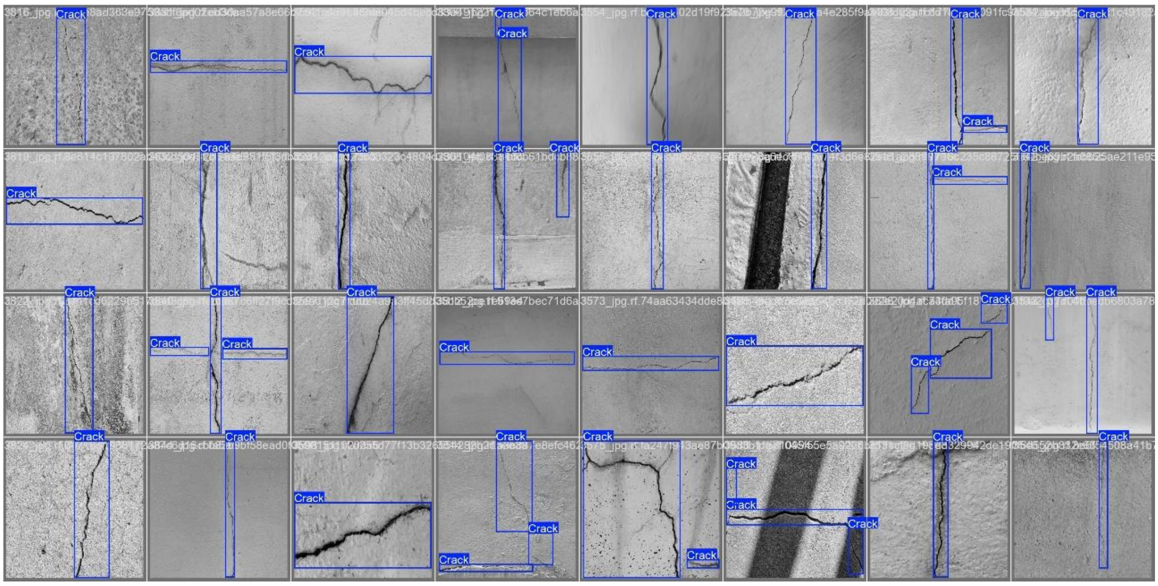

Fig. 10. Validation data set

The image presented in Fig. 10 shows the crack detection results performed by the model on the validation dataset. In the image, each detected crack is labeled with blue bounding boxes, indicating that the model has accurately identified each crack area. Such images are highly useful for evaluating how well the model has performed during training and for assessing its accuracy in object detection tasks.

Each blue bounding box represents a crack that the model has correctly detected. Observing that the objects in the image are correctly classified and the bounding boxes are properly placed demonstrates that the model operates with high accuracy and successfully performs the object detection task. Furthermore, the presence of cracks of different sizes and at various locations within the image reflects the model's ability to effectively detect various types of cracks. These kinds of outputs confirm that the model has processed the examples encountered during training correctly and has developed a strong generalization capability.

3. Testing process and analysis results

In this study, a YOLOv8 crack detection model was developed, and a comprehensive testing process was conducted to evaluate the model's accuracy. To assess the model's applicability, a successful connection was established between the robot and the YOLOv8 model, allowing the monitoring of the model's performance through this integration. The testing environment was set at the Structural Health Monitoring Laboratory of Karadeniz Technical University, where real-world measurements were conducted to assess the model's success under practical conditions. The use of a reinforced concrete steel frame structure for testing was deemed an appropriate choice to achieve highly accurate results in crack detection tasks.

The technical specifications of the tested reinforced concrete model in Fig. 11. were carefully defined. The concrete strength class was set at C25/30, a standard that ensures sufficient strength and durability of the material. The steel reinforcement strength was selected as B420C, guaranteeing high structural resilience. The physical dimensions of the reinforced concrete model were also an important criterion: the model measured 550 × 1700 × 300 mm (width × length × height) with a total height of 1850 mm (Çolakoğlu et al., 2024). These dimensions provided sufficient structural elements and an adequate testing area, enabling the development of a model suitable for crack detection studies.

This well-structured model increased the diversity of the data used during the training phase and allowed for broader testing of the model's capabilities.Tests conducted on the structure aimed to determine the effectiveness of the YOLOv8 model in crack detection. During these tests, the model's accuracy was compared against real-time data, and the results showed that the model performed with high accuracy not only in the training environment but also in real-world applications. This process demonstrated that the YOLOv8 model is a reliable and effective tool for crack detection in reinforced concrete structures. Moreover, integrating the model with robot technology proved to be an important innovation in the field of structural health monitoring.

The measurement process was meticulously carried out, and all stages were carefully monitored. The activated robot dog, as shown in Fig. 12, was remotely controlled via a remote control, enabling it to reach every point within the testing area. The camera mounted on the robot recorded real-time images and transmitted them to the computer screen, allowing for a detailed inspection of the entire reinforced concrete model through these images. Each surface of the model was observed via the camera footage, and potential cracks were carefully identified.

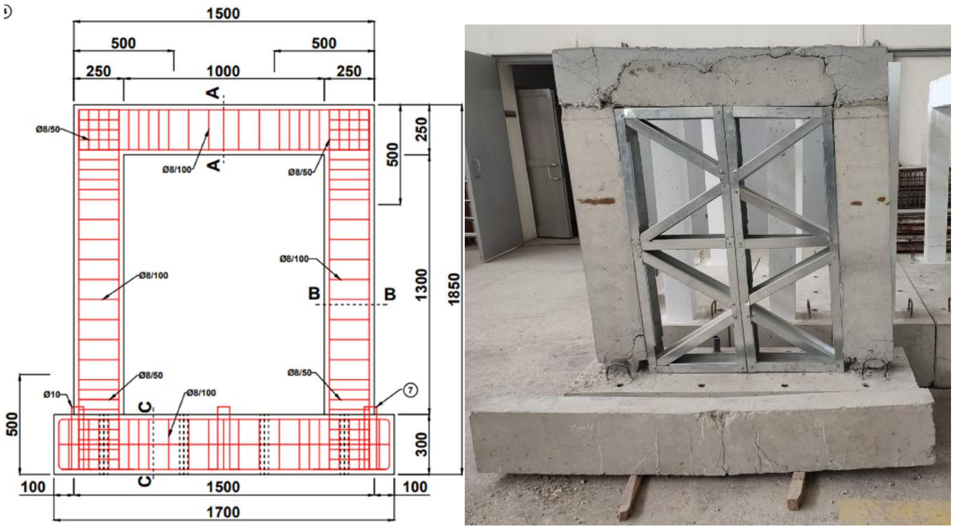

Fig. 11. Test model

Fig. 12. Images of the measurement process

A portion of the Python code that establishes the connection between the YOLOv8 model and the Unitree Go2 robot dog, enabling real-time analysis of the images captured by the robot's onboard camera, is presented in Fig. 13. This code processes the images obtained from the robot's camera, allowing the model to accurately detect cracks and simultaneously evaluate these detections with the model.

The Python script ensures that the images captured by the camera are converted into a format suitable for the model, allows the YOLOv8 model to make predictions on these images, and displays the results in real time on the screen. In this way, the system provides instant crack detection results to the user.

Additionally, the code is designed to operate in synchronization with the robot dog's movements. The images captured from different angles are accurately analyzed, and classification results are generated for each frame. This structure plays a crucial role in both testing the model's accuracy and enhancing the robot dog's effectiveness in field applications.

```python
import imutils
import cv2
import time
import random
import numpy as np
import sys
from ultralytics import YOLO
from unitree_sdk2py.core.channel import ChannelFactoryInitialize
from unitree_sdk2py.go2.video.video_client import VideoClient

# Predefined variables
confidence_score = 0.5
text_color_b = (0, 0, 0)  # Black
text_color_w = (255, 255, 255)  # White
background_color = (0, 255, 0)
font = cv2.FONT_HERSHEY_SIMPLEX

# Load YOLO model
model = YOLO("/home/kemalheo/Desktop/YOLO/models/yolov8n_büyük_veri_setli.pt")  # Model path
labels = model.names
colors = [[random.randint(0, 255) for _ in range(3)] for _ in labels]

# Initialize Unitree Go2 video client
if len(sys.argv) > 1:
    ChannelFactoryInitialize(0, sys.argv[1])
else:
    ChannelFactoryInitialize(0)

client = VideoClient()  # Create a video client
client.SetTimeout(3.0)
client.Init()
```

Fig. 13. A portion of the Python code

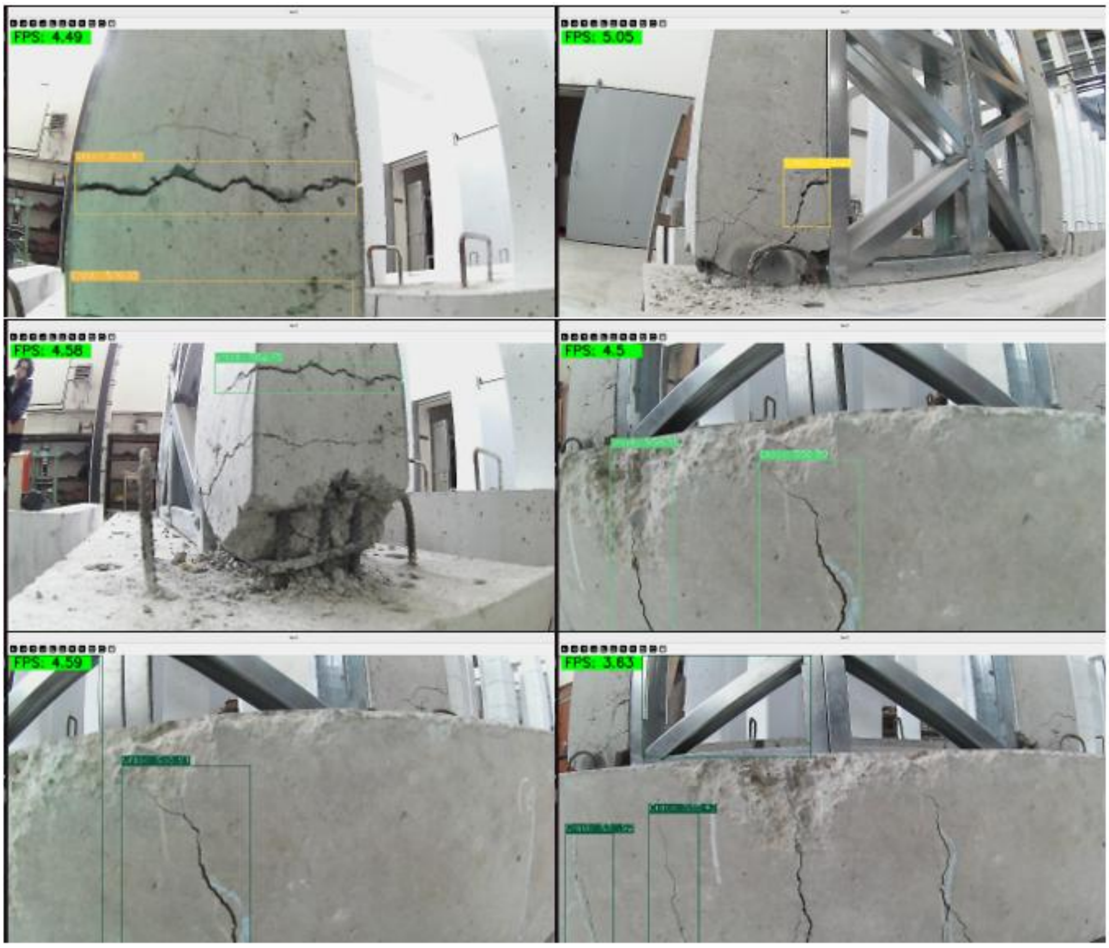

Fig. 14. Analysis results

During the testing phase, the YOLOv8-based crack detection model achieved highly successful results, particularly in accurately identifying and classifying cracks in structural elements. Analyses conducted on the captured images demonstrated that the model precisely detected cracks and accurately assigned them to the correct categories.

As shown in Fig. 14, the bounding boxes generated by the model were accurately placed over the regions containing cracks, and the locations of these cracks were determined with high precision. This level of accuracy indicates that the developed YOLOv8 model is capable of effectively detecting various types of cracks, including both micro-cracks and more visible structural damages. Moreover, the model's ability to maintain high detection performance across cracks of different sizes and locations highlights its robustness and versatility under varying conditions.

The results obtained during the tests confirmed that the model performs reliably not only on training datasets but also under real-world application conditions. Comprehensive measurements and evaluations demonstrated that the YOLOv8 model can be effectively utilized in the field of Structural Health Monitoring (SHM), offering significant advantages for on-site inspections.

Additionally, during this process, the integration between the robot dog's image processing capabilities and the YOLOv8 model was successfully achieved, enabling real-time crack detection. Through the analysis of images captured from multiple angles, the system exhibited considerable potential for advanced applications such as large-scale area scanning and automated defect detection.

In conclusion, this study successfully validated the reliability and efficiency of the developed YOLOv8 crack detection model under both laboratory and real-world conditions, confirming its applicability for critical structural health monitoring tasks.

4. Conclusions

In this study, a robust and efficient crack detection system was developed by integrating a state-of-the-art YOLOv8 deep learning model with the Unitree Go2 quadruped robot, aiming to enable autonomous, real-time structural inspection. The primary goal was to evaluate the feasibility and effectiveness of combining advanced object detection algorithms with mobile robotic platforms to facilitate the automated monitoring of structural integrity, particularly for reinforced concrete systems. The system was extensively tested in a controlled experimental environment at the Structural Health Monitoring Laboratory of Karadeniz Technical University. These tests were designed to simulate realistic inspection scenarios and assess the model's performance under practical conditions, including variable lighting, surface textures, and crack orientations.

Performance evaluation of the model revealed promising results. The normalized confusion matrix showed that the YOLOv8 model achieved a high crack detection accuracy of 89%, while demonstrating perfect classification (100%) for background regions. Although 11% of crack instances were incorrectly classified as background, the overall performance highlights the model's strong generalization capability and ability to reliably distinguish structural anomalies from non-defective areas. Moreover, the F1-Confidence Curve analysis indicated that the model achieved its peak F1-score of 0.84 at a confidence threshold of 0.531. This suggests that fine-tuning the confidence threshold can further optimize the model's detection performance, especially in safety-critical applications where false negatives must be minimized.

For the experimental validation, a full-scale reinforced concrete frame specimen was prepared using C25/30 concrete and B420C steel reinforcement. The specimen had dimensions of 550 mm × 1700 mm × 300 mm and a total height of 1850 mm, providing a realistic and sufficiently large surface for evaluating the model's ability to detect various types and sizes of cracks. The Unitree Go2 robot, equipped with a high-resolution onboard camera, was remotely navigated around the test specimen. As it moved, the robot continuously captured images of the concrete surface, which were processed in real time by the YOLOv8 model. This enabled the system to autonomously detect and localize cracks from different angles and distances, showcasing its adaptability to varying viewpoints.

Visual inspection results, supported by representative examples such as those presented in Fig. 10 and 14, confirmed the system's high localization accuracy. The model successfully identified and outlined crack regions with precise bounding boxes, even in complex surface conditions. This demonstrates the system's capability to perform detailed and reliable inspections without the need for manual intervention. The seamless integration of the YOLOv8 model with the Unitree Go2 robot resulted in a fully automated inspection workflow, capable of navigating, capturing, and analyzing structural data in real time.

In conclusion, the developed robotic inspection system has proven to be accurate, reliable, and efficient for detecting surface cracks in reinforced concrete structures. Its performance indicates strong potential for deployment in real-world Structural Health Monitoring (SHM) applications, particularly in scenarios where manual inspection is difficult, hazardous, or time-consuming. Future research will focus on improving the model's classification accuracy through advanced data augmentation, expanding the training dataset, and evaluating its performance across diverse structural materials and environmental conditions. Additionally, incorporating 3D mapping and path-planning algorithms may further enhance the robot's autonomy and inspection coverage in complex environments.

Abstract. The post-fire evaluation of structural damage in bridge elements has become increasingly critical within the context of modern infrastructure safety and resilience planning. The numerical evaluation of bridge fire exposure is generally relied heavily on Computational Fluid Dynamics (CFD) simulations, most notably the Fire Dynamics Simulator (FDS), to model flame propagation, smoke behavior, and thermal responses of structural elements. Among the key outputs of FDS, the Adiabatic Surface Temperature (AST) serves as a crucial thermal metric, providing surface-level temperature data essential for assessing instantaneous heat transfer and predicting post-fire conditions of exposed structural components. While FDS-based simulations offer crucial insights, their computational complexity and runtime constraints limit their practicality for real-time decision-making or iterative design workflows. To address this limitation, the present study proposes the use of Dynamic Spatio-Temporal Models (DSTMs) that integrate Recurrent Neural Networks (RNNs) for temporal modeling with Graph Convolutional Networks (GCNs) for spatial learning. A hybrid RNN-GCN architecture was developed and trained on FDS-generated bridge fire data from multiple vehicle fire scenarios initiating on suspension bridge deck. The model captures the evolution of fire exposure across time and its spatial propagation along the suspension bridge tower, predicting the damage condition of the tower at different heights. The proposed hybrid model demonstrated strong predictive performance, achieving a test accuracy of 88.6%, precision of 87%, and a ROC AUC score of 0.94, indicating high reliability in distinguishing between intact and damaged structural states. These results confirm the model's ability to generalize across varying fire intensities and spatial configurations. The integration of DSTMs into the structural fire engineering domain represents a significant shift from static simulations toward more adaptive and computationally efficient forecasting frameworks. By enabling rapid assessments of fire-induced damage, the approach supports enhanced operational readiness, real-time monitoring, and more resilient bridge design and management strategies.

Keywords: Computational fluid dynamics; Fire dynamics dimulator; Adiabatic surface temperature; Recurrent neural networks; Graph convolutional networks

1. Introduction

Fire presents a critical hazard to the structural integrity of bridges, with high-intensity fire incidents possessing the potential to cause significant structural damage or even total collapse. Vehicle fires occurring on bridge decks, ranging from standard passenger vehicles to heavy fuel tankers, can rapidly elevate temperatures in structural elements, severely compromising their mechanical properties (Mostofi et al., 2024). Notably, steel components such as cables and towers exhibit substantial strength degradation at elevated temperatures; empirical studies indicate that steel loses more than 50% of its tensile strength at approximately 500 °C (Q. Li et al., 2022), thereby rendering intense fire events particularly catastrophic for suspension bridges.

Assessment methodologies for bridge fire predominantly rely on physics-based simulation tools such as the Fire Dynamics Simulator (FDS) in conjunction with post-incident inspection protocols to quantify and evaluate fire-induced damage (Mostofi & Altunişik, 2024a). While these approaches provide valuable insights, they are time consuming and lack real-time predictive capabilities. As the frequency and intensity of fire incidents escalate, particularly in urban bridge environments, there is an urgent demand for the development and implementation of intelligent, predictive tools capable of delivering real-time evaluations during fire events. Recent advancements in

machine learning (ML) have significantly transformed bridge fire evaluation (Franchini et al., 2024). Conventional numerical techniques, although informative, are often limited by high computational costs. ML techniques offer an alternative by learning patterns from simulation data.

Dynamic Spatio-Temporal Models (DSTMs), a class of advanced machine learning frameworks, constitute an advanced class of deep learning architectures engineered to extract and learn underlying patterns that evolve simultaneously over both spatial and temporal dimensions. Unlike conventional neural networks that might treat data as independent (ignoring temporal order or spatial relations), DSTMs incorporate sequential time dependencies and spatial interconnections directly into their architecture. This dual capability renders them particularly effective for modeling complex systems such as critical infrastructure subjected to evolving loads, including fire events. Two of the key building blocks in DSTMs are recurrent neural networks (RNNs) and graph convolutional networks (GCNs), which can be combined into hybrid frameworks. These architectures can be integrated into hybrid spatio-temporal frameworks to provide comprehensive modeling of time-evolving systems with spatial heterogeneity.

- RNNs, including advanced variants such as Long Short-Term Memory (LSTM) networks and Gated Recurrent Units (GRUs), are adept at capturing long-range temporal dependencies within sequential data (Liu et al., 2023). These models maintain a dynamic internal state that evolves at each time step, allowing the network to encode both short-term fluctuations and long-term trends. Empirical evaluations have consistently demonstrated the efficacy of RNN-based architecture in long-horizon forecasting tasks, particularly where continuous monitoring data are available over extended periods. However, a vanilla RNN does not inherently understand spatial relationships among multiple input locations.
- GCNs are designed to model data defined on graphs, capturing spatial relationships in complex systems. In infrastructure modeling, each node in the graph may represent a physical element, while edges denote mechanical, physical, or communicative relationships. GCNs perform convolution-like operations that allow each node to update its feature representation by aggregating the states of its neighboring nodes. This approach enables the network to learn how spatially distributed phenomena—such as heat conduction, load redistribution, or structural degradation—propagate through interconnected elements. As a result, GCNs are particularly effective for modeling systems where spatial dependencies are critical to behavior prediction (X. Li et al., 2023). They overcome the limitations of traditional 1D Convolutional Neural Networks (CNNs) and RNNs, which often fail to adequately capture structural spatial dependencies in complex physical systems.
- By combining GCNs with temporal models like RNNs, one can capture both space and time dynamics. In such configurations, the GCN component is responsible for encoding the spatial state of the system at each discrete time step, effectively transforming the graph-based sensor or structural data into an enriched feature vector. This vector is then passed to an RNN layer, which propagates the information temporally, allowing the model to forecast future states of the system. prior studies in other domains have found that combining graph convolution with recurrent units significantly improves forecasting in complex, time-dependent systems. This dual-capability model structure is ideally suited for forecasting the evolution of fire-induced damage in large-scale structures such as suspension bridges.

The recent application of deep learning models has significantly advanced the damage assessment of structures. Techniques such as Bi-GRUs have been successfully integrated with attention mechanisms to capture dynamic dependencies across time (Dibiantara et al., 2025), while graph-based methods like GNNs and Graph Attention Networks (GATs) capture inter-sensor spatial correlations, significantly improving sensitivity to distributed damage patterns (Dang et al., 2022; Dang & Pham, 2023). Hybrid architectures, such as CLG-BHM and MPCA-biGRU-AM, show that combining temporal and spatial learning components enhances robustness in damage detection, even in the presence of sensor noise or missing data (Dang & Pham, 2023; Dibiantara et al., 2025). These frameworks are also capable of reducing detection delays and outperforming conventional CNN-based approaches in modeling long-range dependencies. By moving beyond purely temporal or spatial representations, spatio-temporal models support comprehensive understanding of damage propagation mechanisms, thereby offering new capabilities for digital twins, probabilistic assessment, and real-time structural integrity forecasting. Despite these advancements, relatively few studies have applied spatio-temporal deep learning specifically to bridge fire scenarios.

Numerical fire evaluation of bridges generally relies on coupled physics simulations: a fire model, using Computational fluid dynamics (CFD) such as Fire Dynamic Simulator (FDS) to provide thermal loads, and a structural model computes the response of the bridge to those loads. While accurate, this process is computationally intensive and impractical for real-time assessment. As an alternative, DSTMs offer a data-driven solution by learning from simulation outputs and directly mapping fire exposure patterns to structural damage predictions.

This study explores the use of DSTMs in the context of structural fire engineering, with a specific emphasis on suspension bridges. These models are uniquely designed to capture both spatial and temporal dependencies within dynamic systems, offering substantial advantages over static approaches. In particular, this research focuses on a hybrid Recurrent Neural Network–Graph Convolutional Network (RNN-GCN) architecture, which combines sequence modeling and graph-based learning to assimilate complex fire simulation data for predictive damage assessment. The study applied this hybrid framework to diverse vehicular fire scenarios, each representing varying fire sizes and intensities, to evaluate their impact on suspension bridge tower. The RNN component effectively captures the time evolution of thermal exposure, while the GCN component models the spatial relationships between structural nodes, allowing the architecture to forecast localized damage over time. The primary objective is to replace computationally intensive coupled physics simulations with a trained data-driven surrogate model capable of rapid and accurate post-fire assessment. To this end, a high-fidelity bridge fire dataset was synthetically generated using PyroSim (*PyroSim | Thunderhead Engineering*, n.d.), a graphical interface for the Fire Dynamics Simulator (FDS), simulating detailed thermal load distributions resulting from multiple vehicle fire scenarios on the Bosphorus Suspension Bridge.

Three distinct vehicle types were considered to represent varying fire intensities and durations: a standard passenger sedan, a full-sized passenger bus, and a large fuel-carrying truck. Each vehicle was positioned on lane 1 of the Bosphorus Bridge to simulate real-world urban fire risks and their localized thermal impact. The developed dataset was subsequently used as inputs to train a hybrid RNN-GCN model. Readings from temperature sensors were used as node-level features, representing localized thermal states at different heights of the bridge tower. Spatial relationships between these nodes were defined using the devices that recorded the adiabatic surface temperature (AST) as the edge column. AST defines the theoretical temperature a surface attains when exposed to convective and radiative heat transfer without conductive energy dissipation. AST provides a more accurate assessment of the thermal load on a structure, making it an important parameter for evaluating fire-induced damage (Mostofi & Altunişik, 2024b). The RNN component modeled the temporal evolution of fire exposure using sequential temperature data, while the GCN component captured spatial dependencies via graph convolutions at each time step. Once trained, the hybrid RNN-GCN model predicted damage condition at various heights of the tower. The developed DSTM can rapidly predict fire-induced damage – far faster than running detailed simulations – and can incorporate real-time data, making it valuable for both design assessment (e.g. evaluating many what-if scenarios of vehicle fires on a bridge) and active fire incident management.

2. Materials and methods

This study employed a hybrid RNN-GCN deep learning framework for predicting fire-induced damage conditions in a suspension bridge structure. The dataset employed in this study was synthetically generated using PyroSim and consists of fire simulation data representing various vehicle fire scenarios on the Bosphorus Suspension Bridge. The dataset comprised a total of 113,949 records, each corresponding to time-dependent thermal measurements from various points along the bridge tower. The data included seven key columns: Time, AST device, AST Value, Vehicle, Gas temperature device, Temp Value, and Damage Condition.

The input data was restructured to match the requirements of a spatio-temporal learning framework. Each temperature sensor reading was treated as a node feature, encoding the localized thermal condition of a specific point along the bridge tower. The AST device field defined graph edges and constructed the spatial topology GCN processing. Temporal modeling was enabled by organizing data into rolling windows with clearly defined durations for training, validation, and testing. Each window contained a time-series of node features representing thermal evolution under fire exposure, mapped to corresponding damage states.

The RNN component was constructed using a multi-layer recurrent network, which processes time-series thermal features from thermocouple sensors. The input features were first reshaped to include a sequence dimension and passed through two stacked RNN layers. The spatial learning component comprises a single-layer GCN implemented using the GCNConv function from the PyTorch Geometric library. It took the temporally processed features and performed graph convolutions using the bridge's spatial connectivity matrix (edge_index), defined by the AST device. The GCN propagates node features across adjacent nodes, effectively modeling the thermal interdependence among spatial regions of the bridge.

To prevent overfitting and enhance model generalization, a dropout layer of 0.3 was introduced between the RNN and GCN layers. The final output was passed through a ReLU activation followed by a log_softmax layer, producing class probability distributions over the target categories (Intact/Safe and Damaged). The model parameters, including input_dim, hidden_dim, and output_dim, were tuned for optimal classification performance. The training was conducted using a cross-entropy loss function. The training was executed over 500 epochs, with an early stopping patience of 25 epochs to prevent unnecessary computation once the validation performance plateaued. Data was processed using a batch size of 32, and training was conducted across multiple rolling time windows. Each rolling window included defined training, validation, and test masks, supporting spatio-temporal generalization. For each window, input data were preprocessed into PyTorch Geometric Data objects containing node features (x), edge indices (edge_index), and target labels (y), and were passed into customized DataLoaders. Model weights were updated for each window to improve generalizability across different phases of the fire.

At the start and end of the training block, timestamps, memory usage, and GPU statistics were recorded to compute elapsed wall-clock time, CPU user and system time, change in memory usage. These profiling results offer insights into the computational cost of deploying such deep models in real-time bridge monitoring systems.

3. Results and Discussion

The proposed model was trained using a dynamic spatio-temporal learning approach and evaluated across several performance metrics. The performance of the proposed model was evaluated using five standard classification metrics: accuracy, precision, recall, F1 score, and ROC-AUC. These metrics provide a comprehensive view of model behavior in correctly identifying damaged and intact structural states. Accuracy measures the overall correctness of the predictions by calculating the ratio of correctly predicted instances to the total instances evaluated. Precision assesses the model's ability to correctly identify only the relevant class (e.g., correctly labeling damage where damage exists). Recall (or sensitivity) quantifies the model's capability to capture all relevant cases, such as detecting all actual damaged regions. F1 Score provides a harmonic means of precision and recall, offering a balanced measure that accounts for both false positives and false negatives. ROC-AUC (Receiver Operating Characteristic – Area Under Curve) is used to evaluate the model's ability to distinguish between the two classes (intact vs. damaged).

During training, convergence was observed at Epoch 162, where the model achieved a training loss of 0.0533 and a corresponding training accuracy of 96.06%. On the validation set, the model attained a validation loss of 0.1586 and a validation accuracy of 86.93%, indicating good generalization to unseen temporal-spatial patterns in the bridge fire simulation data. The resulst yielded on the independent test set are shown in Table 1. The confusin matrix presented in Fig. 1 further interpret the classification behavior of the model.

Table 1. Performance evaluation of the model

Test loss	Test accuracy	Precision	Recall	F1 Score	AUC
0.18	88.6%	0.87	0.60	0.63	0.94

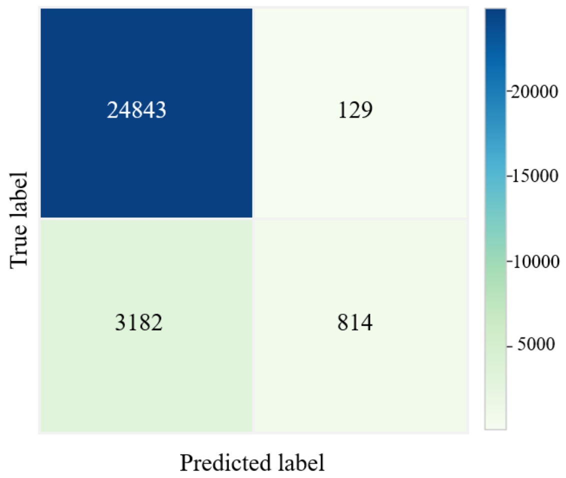

Fig. 1. The confusin matrix

From Fig. 1, it is clear that the model performs very well in predicting intact regions, correctly identifying 24,843 out of 24,972 intact cases (true negatives), with only 129 false positives. However, performance on the damaged class is more constrained, correctly identifying 814 out of 3,996 damaged nodes (true positives) but misclassifying 3,182 as intact (false negatives). Given that the dataset includes time-sequenced thermal exposures and spatial connectivity, the model's design is particularly suited to identify patterns that manifest over time and space. The high test accuracy and strong AUC confirm that the model effectively exploits both sequential temperature trends and structural adjacency patterns. This proves the suitability of hybrid architectures in capturing complex thermo-mechanical behaviors in real-world fire scenarios.

4. Conclusions

Structural fires represent a critical threat to steel components of bridges. Conventional fire evaluation techniques, primarily based on coupled physics simulations and post-event inspections, are often computationally intensive, time-consuming, and unsuitable for real-time deployment. This research addressed the need for rapid, and scalable alternatives by proposing a hybrid Recurrent Neural Network–Graph Convolutional Network (RNN-GCN) model tailored for dynamic spatio-temporal prediction of fire-induced damage in suspension bridge structures.

The primary objective of the study was to develop a data-driven surrogate capable of learning from simulation-derived thermal exposure profiles and accurately predicting post-fire condition of steel tower of suspension bridges. To achieve this, a novel methodology was adopted, integrating RNNs to model the temporal evolution of fire exposure and GCNs to capture spatial dependencies among temperature measurement nodes distributed along the vertical axis of a suspension bridge tower. The dataset used for model training and evaluation was derived from high-fidelity PyroSim-generated fire scenarios involving three vehicle types positioned on lane 1 of the simulated bridge.

The results demonstrate that the RNN-GCN model achieved high classification accuracy (88.6%), indicating excellent discriminative capability. The relatively moderate recall and F1 score, however, reveal an area for improvement in detecting damaged state.

Future research should focus on incorporating real-time sensor data from full-scale fire experiments or in-service bridge monitoring systems to enhance model realism and adaptability. Moreover, the architecture could be expanded to integrate attention mechanisms, temporal convolutions, or Transformer-based modules for improved temporal reasoning. Finally, embedding the model within a decision-support dashboard could facilitate real-time structural health evaluations for infrastructure stakeholders, contributing to safer and more resilient urban transportation systems.

Solving structural optimization problems using marathon runner algorithm

Kamil E. Arslan[1], Ali Mortazavi[*1]

[1] *Izmir Democracy University, Department of Civil Engineering, Izmir, Turkey*

Abstract. The structural optimization process aims to enhance performance of the structural system while minimizing weight and/or cost, considering some additional constraints to find feasible solutions. In this study, the recently developed optimization technique, the so-called Marathon Runner Algorithm (MRA) which is a metaheuristic approach inspired by endurance strategies, is tested on solving structural optimization problems. This method uses a special concept called region point to consider all data collected by the by the population in each step and by this approach, it prevents to waste any acquired data during the optimization process. This behavior helps the algorithm to search the domain more precisely while decreasing the likelihood of trapping into local minima. Also, this method models there, individual interactions between competitors in the real computation to perform a precise local search in each iteration. So, the MRA applies both exploration and exploitation search behavior in each iteration. The algorithm's performance is evaluated using a predefined performance index, considering factors such as convergence speed, solution accuracy, and computational efficiency. The results demonstrate that MRA offers superior solution accuracy and robustness, efficiently handling various problem complexities while maintaining stability. Overall, the MRA proves to be a promising optimization method, striking a balance between exploration and exploitation, making it a proper optimization technique for handling structural optimization problems.

Keywords: Marathon runner algorithm; Structural optimization; Metaheuristic techniques; Performance index; Engineering design

1. Introduction

In today's world, along with the rapid advancement of technology and constraints of natural resources, there is a growing demand for the construction of structures providing design requirements that are suitable for the conditions of the region where they are located all while minimizing costs. This advancement, leads to Structural optimization problems (Talatahari et al., 2013). Most of the time solutions of Structural optimization involve complex problems. Methods utilized in solutions to these optimization problems are generally categorized as deterministic and non-deterministic approaches. Deterministic methods operate within mathematical limitations such as gradient information of the objective function. These methods have rapid convergence. Gradient based deterministic methods may limit deterministic methods in many engineering problems. Moreover, these methods are very dependent on the starting point. Therefore, it may be insufficient to reach the optimum global solution in complex design spaces (Mortazavi, 2019).

Due to these reasons and the development of computer technologies, non-deterministic methods have come to the fore in solving structural optimization problems. Metaheuristic approaches are important subsets of non-deterministic methods. Thus, in the last decades metaheuristic approaches have been among methods widely explored and effectively employed. These approaches are easier to implement, and global searching capacity is better than deterministic methods. When examining the searching strategy of metaheuristic approaches, their search strategies often yield efficient solutions for complex optimization problems. These algorithms generally include randomness to reach a global solution and aim to balance various exploration and exploitation mechanisms in the search process (Gandomi et al., 2011). Metaheuristic approaches inspired by natural phenomena can be examined under four main headings: (i) Physical System and Simulation-based Algorithms, (ii) Swarm and Colony Algorithms, (iii) Evolutionary Algorithms and (iv) Human-based Algorithms. These categories and representative examples are examined below.

Physical System and Simulation-based Algorithms: These algorithms are inspired by physical and chemical processes in nature. (HTS) models the heat transfer mechanism in different environments (Patel & Savsani, 2015).

[*] Corresponding author, E-mail: ali.mortazavi@idu.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_485

Water Wave Optimization (WWO) mimics the water waves behavior (Zheng, 2015). The Ion Motion Algorithm (IMO) simulates the movement of ions such as anions and cations according to their energy in a physical space, aiming to reach more stable (lower energy) states (Javidy et al., 2015). and golden ratio optimization method (GROM) which based on principle of the golden ratio, is known as aesthetic ratio and found in growing plants and animals (Nematollahi et al., 2019).

Swarm and Colony Algorithms: Swarm and Colony Algorithms are inspired by the collective behavior of living organisms and communities in nature. Particle swarm optimizer (PSO) mimics the collective movement of swarms, such as bird or fish swarms (Kennedy & Eberhart, 1995). Butterfly Optimization Algorithm (BOA) models of Butterfly's food search mechanism (Arora & Singh, 2019). Drosophila food-Search Optimization (DSO) that simulates insects' food search mechanism (Das & Singh, 2014). Firefly Algorithm (FA) mimics fireflies' light emission behavior (Yang, 2009). Symbiotic organisms search (SOS) mimics symbiotic collaboration relationship of organisms (Cheng & Prayogo, 2014). Virus optimization algorithm (VOA) inspired by the mechanisms by which viruses spread and multiply in host cells (Liang & Cuevas Juarez, 2016).

Evolutionary Algorithms: Evolutionary Algorithms are inspired by natural evolution process such as natural selection, mutation and crossover. Genetic algorithm (GA), a search strategy that models the mechanisms of genetic evolution (Holland, 1984).

Human-based Algorithms: These algorithms are inspired by the way humans solve problems, learn, collaborate, and develop strategies. Teaching and Learning Based Optimization (TLBO) models the knowledge teach and learn process in the classroom (Rao et al., 2011). Tabu search (TS) algorithm limits the feasible neighborhood candidates by involving them in a list (Glover, 1989) and ship rescue optimization (SRO) mimics the ship maneuvering motion in operation of ship rescue process (Chu et al., 2024).

2. Materials and methods

2.1. Marathon Runner Algorithm (MRA)

Marathon Runner Algorithm (MRA), including in the literature as a next generation metaheuristic algorithm inspired by human behavior. The difference between MRA and conventional elitist algorithms is that MRA employs a guidance strategy based on the quality of the entire population, instead of Being guided only by the position of the best solution.

The development of the Marathon Runner Algorithm was inspired by the competitive behavior of marathon runners. These behaviors are modeled as two main components, namely ambitious movement and associated movement. The most distinctive difference between Marathon Runner Algorithm and conventional elitist algorithms is: Instead of the concept of 'best individual' utilized by elitist algorithms, MRA uses a weighted guide point known as the 'vision point (VP)'. Vision Point represents a weighted average considering the entire population. The directions of each agent are determined by the population's Vision Point. Thanks to the Vision Point (VP) approach, the algorithm reduces the risk of getting trapped in local minimum and protects the diversity of the population throughout the optimization process.

In Marathon Runner Algorithm the population is updated through three vectors. These vectors are the Distance Desired to be Decreased (DDD) vector, which represents the effort to reduce the distance between each agent's solution and its nearest agent. The second one is the Distance Desired to be Increased (DDI) vector, which represents the effort to increase that distance, and the last one is vision point (VP) vector. Also, if the relevant agent is in a bad situation according to VP, there will be an attractive effect; otherwise, the opposite is the case, there will be a repulsion effect. In both cases, the sign function (sgn) is utilized to determine the direction of the effect. Considering all these characteristics, the MRA exhibits a well-balanced structure that incorporates both exploration and exploitation capabilities.

$$X^W = \sum_{i=1}^{n} \bar{c}_i^{\,w} X_i \tag{1}$$

In which, X^W is weighted agent, X_i is i^{th} agent, $\bar{c}_i^{\,w}$ weighted coefficient of the i^{th} agent, calculated as:

$$\bar{c}_i^{\,w} = (\hat{c}_i^{\,w} / \sum_{i=1}^{n} \hat{c}_i^{\,w}) \tag{2}$$

$$\hat{c}_i^{\,w} = \frac{max_{1\le k\le n}(f(X_k)) - f(X_i)}{max_{1\le k\le n}(f(X_k)) - min_{1\le k\le n}(f(X_k)) + \varepsilon}, i = 1,2,\ldots,n \tag{3}$$

n is population size, $f(X_i)$ objective function value of the i^{th} agent and $f(X_k)$ is objective function value of k^{th} agent, $max(f(X_k)) - min(f(X_k))$: maximum and minimum objective function values of agents, a small positive number (e.g., 0.0001) to avoid division by zero condition.

$${}^{t+1}X_i = {}^{t}X_i + r_1 \odot ({}^{t}X_{i-1} - {}^{t}X_i) + r_2 \odot ({}^{t}X_i - {}^{t}X_{i+1}) + 2.\alpha.r_3 \odot ({}^{t}X^{w} - {}^{t}X_i) \tag{4}$$

where

$$\alpha = sgn(f({}^{t}X_i) - f(X^w)) \tag{5}$$

where ${}^{t}X_i$ is represents the i^{th} agent at the t^{th} iteration (current candidate solution), ${}^{t+1}X_i$ is denotes i^{th} agent at the $t+1^{th}$ iteration, ${}^{t}X^{w}$ is represents weighted agent at the t^{th} iteration, ${}^{t}X_{i-1}$ is refers to $i-1^{th}$ agent at the t^{th} iteration (better candidate), ${}^{t}X_{i+1}$ is represents the $i+1^{th}$ agent at the t^{th} iteration (worst candidate), r_1, r_2 and r_3 are uniform random values in the range [0,1], $\odot$ is Hadamard (elementwise) product, sgn(.): Sign function and returns +1, if the X^w is in the better location than current agent (${}^{t}X_i$), and otherwise it returns -1.

2.2. Structural optimization

In the structural design process, reducing the costs while remaining design constraints is the crucial point. Therefore, one of the crucial factors is minimizing total weight of structural components. Violation of constraints is significant to obtain feasible and practical design. Incorporating constraints violations into the objective function through a penalty mechanism is a common approach in literature. Total weight of structure represents objective function for feasible solutions to providing all constraints. Penalized objective function increase with violation ratio for Solutions with constraint violation. This process provides applicable solutions and leads to the optimum solution. In this study, analysis performed on 25 bar spatial truss and 72 bar spatial truss systems which are extensively cited in the literature. Minimizing the total weight process in this article is formulated below.

$$minimize\ W = \sum_{i=1}^{nm} \rho_i\, L_i A_i \tag{6}$$

In which ρ is the density of materials, L is length of each member, A is the cross-section area of each member and nm is the number of the members of the truss structures. The constraints that integrate the penalized objective function must be normalized and normalized stress and displacement constraints given as below:

$$g_i\,(x) = \frac{\sigma_i(x)}{\sigma_a} - 1\ \leq 0\ \ i = 1,2, \dots, nm \tag{7}$$

$$g_j\,(x) = \frac{\delta_j(x)}{\delta_a} - 1\ \leq 0\ \ j = 1, 2, 3, \dots, nd \tag{8}$$

In this formulation, ${g_i}^{\sigma}$ represents the normalized stress constraint, with σ_i is calculated stress for i^{th} structural member, σ_a is allowable stress limit. Meanwhile, ${g_j}^{\delta}$ denotes normalized displacement constraints, δ_j is calculated displacement in j^{th} node of system, δ_a is allowable displacement limit and "nd" is the number of nodes whose displacement is restricted. Penalty function is given as below,

$$C = \sum_{i=1}^{m} c_i\ ,\ \begin{cases} c_i = g_i(x) & ,if\ g(x)_i > 0 \\ c_i = 0\ , & otherwise \end{cases} \tag{9}$$

where, m represents number of constraints, c_i is the value of each constraint and this term can be calculated as,

The formulation of the penalized objective function is as follows:

if $C = 0$ then

$$F_i = \sum_{i=1}^{nm} W_i \tag{10}$$

if $C > 0$ then

$$F_i = (1 + \varepsilon_1 . C)^{\varepsilon_2} \sum_{i=1}^{nm} W_i \tag{11}$$

where, F_i is objective function value of each agent, ε_1 is a constant parameter and its value is 1, ε_2 is a constant parameter and its value is 2, C represents the sum of the constraints and W_i denotes sum of the weight of each agent in population.

3. Results and discussion

3.1. Numerical examples

In the current section, two benchmark problems are solved to evaluate the performance of the MRA algorithm on the handling the structural optimization problems. In this regard, A 25-bar and A 72-bar spatial truss systems are selected.

3.1.1. 25 Bar spatial truss system

25 Bar spatial truss system has 25 elements and 10 node numbers. Size, geometry, axes and node numbers of structure are shown in Fig. 1. Material properties, discrete cross-sectional areas and constraints of structure represent in Table 1. The node numbers to which each element is connected and the group numbers of the elements used in the grouping process for reaching the optimum solution are shown in Table 2. Load information about the 25-Bar spatial truss system defined in Table 3. Furthermore, this system has 18 degrees of freedom. Also, elements of this structure are divided into 8 groups. Thus, population dimension is defined as 8 in solution process.

Table 1. Material properties and constraints data of the 25-bar space truss system

Property (Unit)	Value
E, modulus of elasticity (ksi)	10^4
ρ, material density (lb/in^3)	0.1
Discrete area set for design variables (in^2)	0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 1.1, 1.2, 1.3, 1.4, 1.5, 1.6, 1.7, 1.8, 1.9, 2.0, 2.1, 2.2, 2.3, 2.4, 2.5, 2.6, 2.8, 3.0, 3.2, 3.4
Constraints data

3.1.2. 72 Bar spatial truss system

72 Bar spatial truss system has 72 elements and 18 degrees of freedom. This system's size, shape geometry, axes and node numbers of structure represent in Fig. 2. This system is a structure frequently studied in literature. Material properties, discrete cross-sectional areas and constraints of 72 Bar spatial truss system denoted in Table 4. The group numbers of the elements used in the grouping process for reaching the optimum solution are shown

in Table 5. Load information and cases are indicated in Table 6. Also, this structure's elements are divided into 16 groups. Therefore, population dimension is defined as 16 in solution process.

4. Conclusions

In this study, the performance of a recently developed optimization technique, the Marathon Runner Algorithm (MRA), a metaheuristic approach inspired by endurance strategies, is evaluated for solving structural optimization problems with discrete variables. The algorithm is applied to weight minimization problems in two structures: a 25-bar spatial truss and a 72-bar spatial truss. The results obtained can be summarized as follows:

- The numerical results obtained for the selected problems indicate that the algorithm performs well in terms of accuracy.
- Statistical tests (measured by standard deviation) show that the MRA demonstrates a high level of stability in handling the selected problems.
- The number of required objective function evaluations (OFEs) suggests that the MRA demands comparatively lower computational cost to find the optimal solution.
- These improvements can be attributed to the Marathon Runner Algorithm's use of weighted agents, unlike many other metaheuristic algorithms that rely solely on the best agent during the population update phase.

By utilizing all stored information within the population, the weighted agent preventing data loss makes a better application of the gathered information and increases the efficiency of the search process.

According to these conclusions, generally, MRA shows promising optimization algorithm for structural optimization problems. Based on this fact, in the future works, it is planned to utilize Marathon Runner Algorithm on more complicated structural engineering problems.

Abstract. Geometrically nonlinear analysis of composite beams composed of transversely-isotropic layers is performed via the mixed finite element method under the influence of distributed forces along its length in this study. The classical beam stress-free surface conditions are satisfied on the three-dimensional constitutive equations of a transversely-isotropic body based on Von Kármán nonlinear strains. The virtual work theorem and the first variation of the Hellinger-Reissner functional are employed to derive the nonlinear equations of the mixed finite element formulation. The two-noded mixed finite elements have twenty-four degrees of freedom in total such as three displacements, three section rotations, three forces, two bending moments, and one torsional moment at each node. The finite element mesh convergence analysis is performed both for the mixed finite elements and the 3D brick finite elements (ANSYS SOLID186 elements). Quite satisfactory geometrically nonlinear displacements of composite beams having transversely isotropic layers are obtained via the two-noded mixed finite elements by using lesser degrees of freedom compared to the results of ANSYS SOLID186 elements. As benchmark examples, the moderately large deflections of composite beams subjected to the distributed forces are investigated and the results are compared to the linear deflections as the span ratio decreases and/or the thickness of stiffener increases.

Keywords: Geometrically nonlinear analysis; Composite beams; Transversely-isotropic material; Mixed finite elements

1. Introduction

Laminated composite structures are widely used in engineering due to their high strength, stiffness, and lightweight properties. These structures consist of fiber-reinforced layers, typically transversely isotropic, allowing engineers to optimize performance by adjusting fiber type, orientation, and matrix composition. Compared to metals, laminated composites offer superior weight reduction and mechanical efficiency, making them ideal for aerospace, automotive, and marine applications (Hwu, 2024).

A specialized type, sandwich structures, consists of stiff outer facings and a lightweight core (foam, honeycomb, or corrugated materials), enhancing impact resistance and reducing weight. Their excellent mechanical properties make them crucial in strength-sensitive applications (Sandeep & Srinivasa, 2020).

Composite structures exhibit nonlinear behavior under increased loading. Initially, load-displacement remains linear, but beyond a critical threshold, nonlinearity emerges due to material effects (plasticity, damage, matrix cracking) and geometric effects (large deformations altering stiffness). Understanding these nonlinearities enables the design of more efficient and durable structures (Drosopoulos & Stavroulakis, 2022).

Sayyad and Ghugal (2017) reviewed bending, buckling, and vibration analyses of laminated and sandwich beams, emphasizing the need for further nonlinear studies. Their study focused on equivalent single-layer, layerwise, and zig-zag theories, as well as exact elasticity solutions. They examined various analytical and numerical methods based on classical and refined beam theories. While linear analysis is well-explored (Baziyar Hamzehkhani et al., 2024; Ma, 2020; Pietro et al., 2019; Sorrenti et al., 2025; Yan et al., 2018), nonlinear analysis remains underdeveloped.

Given its crucial role in predicting structural behavior under large deformations, this study focuses on geometrically nonlinear analysis. The following section reviews recent research conducted over the past five years on this topic. Ascione and Gherlone (2020) developed a nonlinear formulation using Refined Zigzag Theory (RZT) to analyze the buckling and nonlinear static response of multilayered composite and sandwich beams with

https://doi.org/10.31462/icearc2025_ce_sme_497

geometric imperfections. Their numerical simulations examined three sandwich beams with different core materials and slenderness ratios under simply supported and cantilever boundary conditions. The analysis employed C_0-beam finite elements based on RZT and Timoshenko Beam Theory (TBT), with initial imperfections approximated using quadratic Lagrange polynomials. The results from RZT and TBT were validated against high-fidelity commercial software, such as Abaqus and Nastran.

Wei et al. (2020) introduced an extended high-order sandwich panel theory (EHSAPT) to evaluate the static response of sandwich panels while incorporating both geometrical and material nonlinearities. Geometrical nonlinearity was accounted for using Green–Lagrange strain expressions for the face sheets and core, while material nonlinearity was modeled through a piecewise function derived from experimental stress–strain data fitted with a polynomial approach. The governing equations were solved using the Ritz method, demonstrating the model's effectiveness in capturing the stress stiffening effect in geometric nonlinear analysis.

Wei and Wu (2023) developed a theoretical framework for analyzing the transient response of elastoplastic sandwich beams subjected to underwater blasts. They introduced two fully coupled fluid-structure interaction (FSI) models to study blast wave propagation, energy dissipation, and optimal sandwich structure design for enhanced blast resistance. Using nonlinear dynamic high-order sandwich panel theory (EHSAPT), they modified the governing equation by incorporating a rarefaction-wave-related term into the structural damping matrix. This reformulated the underwater blast analysis as a dynamic response problem under incident and reflected waves in a vacuum. Additionally, they derived a simplified governing equation to obtain an analytical solution for the impulse transferred to the structure, considering displacement and core rigidity assumptions.

Chen and Chen (2024) formulated finite element models based on higher-order refined zigzag theory (HRZT) to investigate the linear static bending, geometric nonlinearity, and buckling behavior of sandwich composite beams. HRZT extends RZT by incorporating higher-order terms related to average shear strain and zigzag-induced rotation. For linear static bending, both C_0 and C_1 finite elements were formulated, with an additional node introduced in the C_0 element to reduce shear locking. In the geometric nonlinear analysis, a two-node C_0 element was used to evaluate the bending response under lateral loading and buckling behavior. Numerical results were validated against 2D exact solutions, analytical solutions from HRZT, and commercial software models. Comparisons were also made with various beam theories, including first-order shear deformation theory (FSDT), higher-order shear deformation theory (HSDT), RZT, and other higher-order zigzag theories.

In this study, the moderately large deflections of composite beams having transversely-isotropic layers are investigated via the geometrically nonlinear mixed finite element formulation. The constitutive equations are derived via satisfying the classical beam stress-free surface conditions on the three-dimensional constitutive equations of transversely-isotropic bodies considering Von Kármán nonlinear strains. The nonlinear equations of the mixed finite element formulation are based on the first variation of the Hellinger-Reissner functional. The two-noded mixed finite elements have twelve degrees of freedom at each node.

2. Mathematical formulation

The constitutive relations of a transversely-isotropic body are given in Jones (2018) based on the Hooke's law as $\boldsymbol{\sigma} = \mathbf{E}\boldsymbol{\varepsilon}$, where $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$ are the three-dimensional stress and strain vectors, respectively and $\mathbf{E}$ is the elasticity matrix. The constitutive relations of layered composite beams which are derived via satisfying the classical beam stress-free surface conditions on the three-dimensional constitutive relations are given in Aribas et al. (2019) as,

$$\begin{Bmatrix} \sigma_x \\ \tau_{zx} \\ \tau_{xy} \end{Bmatrix}_L = \boldsymbol{\beta}_L \begin{Bmatrix} \varepsilon_x \\ \gamma_{zx} \\ \gamma_{xy} \end{Bmatrix}_L \tag{1}$$

where the subscript L is the layer partition and $\boldsymbol{\beta}_L$ is a 3×3 matrix. The displacement field of the layered beam is stated as,

$$\begin{aligned} u_x^* &= u_x + z\,\Omega_y - y\,\Omega_z \\ u_y^* &= u_y - z\,\Omega_x \\ u_z^* &= u_z + y\,\Omega_x \end{aligned} \tag{2}$$

where, u_x, u_y, u_z and $\Omega_x, \Omega_y, \Omega_z$ are the displacements and the rotations on the beam axis, respectively. Von Kármán nonlinear strains are obtained based on the displacement field as,

$$
\begin{aligned}
\varepsilon_x^* &= u_{x,x}^* + \tfrac{1}{2}\left[\left(u_{x,x}^*\right)^2 + \left(u_{y,x}^*\right)^2 + \left(u_{z,x}^*\right)^2\right] \\
\varepsilon_{xy}^* &= \tfrac{1}{2}\left[u_{x,y}^* + u_{y,x}^* + u_{x,x}^*\, u_{x,y}^* + u_{y,x}^* u_{y,y}^* + u_{z,x}^* u_{z,y}^*\right] \\
\varepsilon_{zx}^* &= \tfrac{1}{2}\left[u_{x,z}^* + u_{z,x}^* + u_{x,x}^*\, u_{x,z}^* + u_{y,x}^*\, u_{y,z}^* + u_{z,x}^* u_{z,z}^*\right]
\end{aligned}
\tag{3}
$$

where, the partial derivations are denoted by the commas in the subscripts. The forces F_x, F_y, F_z and the moments M_x, M_y, M_z are obtained via the integration of stresses through the thickness (Aribas et al., 2022). Finally, the explicit form of the equilibrium equations is,

$$
\begin{aligned}
&-F_{x,x} - \left(F_x\, u_{x,x}\right)_{,x} - \left(M_y \Omega_{y,x}\right)_{,x} - \left(M_z \Omega_{z,x}\right)_{,x} + \left(T_y \Omega_z\right)_{,x} - \left(T_z \Omega_y\right)_{,x} - q_x = 0 \\
&-T_{y,x} - \left(T_x\, u_{y,x}\right)_{,x} + \left(M_y \Omega_{x,x}\right)_{,x} + \left(T_z \Omega_x\right)_{,x} - q_y = 0 \\
&-T_{z,x} - \left(T_x\, u_{z,x}\right)_{,x} + \left(M_z \Omega_{x,x}\right)_{,x} - \left(T_y \Omega_x\right)_{,x} - q_z = 0 \\
&-M_{x,x} + \left(M_y u_{y,x}\right)_{,x} + \left(M_z u_{z,x}\right)_{,x} + T_y u_{z,x} - T_z u_{y,x} - M_{x,x} - m_x = 0 \\
&-M_{y,x} + T_z - \left(M_y u_{x,x}\right)_{,x} - \left(M_x \Omega_z\right)_{,x} + T_z u_{x,x} - M_x \Omega_{z,x} - m_y = 0 \\
&-M_{z,x} - T_y - \left(M_z u_{x,x}\right)_{,x} - T_y u_{x,x} + M_x \Omega_{y,x} + \left(M_x \Omega_y\right)_{,x} - m_z = 0
\end{aligned}
\tag{4}
$$

where, the external distributed forces and moments are q_x, q_y, q_z and m_x, m_y, m_z, respectively. Based on the field equations and boundary conditions $-\mathbf{u} + \hat{\mathbf{u}} = \mathbf{0}$, $-\mathbf{\Omega} + \hat{\mathbf{\Omega}} = \mathbf{0}$, $\mathbf{F} - \hat{\mathbf{F}} = \mathbf{0}$ and $\mathbf{M} - \hat{\mathbf{M}} = \mathbf{0}$ where, the displacement, cross-sectional rotation, force and moment vectors are given by $\mathbf{u}(u_x, u_y, u_z)$, $\mathbf{\Omega}(\Omega_x, \Omega_y, \Omega_z)$, $\mathbf{F}(F_x, F_y, F_z)$ and $\mathbf{M}(M_x, M_y, M_z)$, respectively, and the terms with a hat are the known boundary values, the first variation of Hellinger-Reissner functional (Aksoylar, 2010) is derived via,

$$
\delta \Pi_{HR} = \int_V \left(\boldsymbol{\varepsilon}^{\mathrm{u}} - \boldsymbol{\varepsilon}^{\sigma}\right)^T \delta\boldsymbol{\sigma}^{\sigma} \mathrm{d}V + \int_V \left(\left(\boldsymbol{\sigma}^{\sigma}\right)^T \delta\boldsymbol{\varepsilon}^{\mathrm{u}} - \mathbf{q}^T \delta\mathbf{u}\right) \mathrm{d}V - \int_\Gamma \hat{\mathbf{t}}^T \delta\mathbf{u}\, \mathrm{d}\Gamma = 0 \tag{5}
$$

where, $\hat{\mathbf{t}}$ is the traction vector at the boundary Γ, the components in terms of the forces and displacements are denoted by the superscripts σ and ε, respectively. The variational equations in the mixed form are,

$$
\begin{aligned}
&\int_L \left[u_{x,x} + \tfrac{1}{2}u_{x,x}^2 + \tfrac{1}{2}u_{y,x}^2 + \tfrac{1}{2}u_{z,x}^2\right]\delta F_x\, \mathrm{d}x + \int_L \left[-C_{11}F_x - C_{12}F_y - C_{14}M_x - C_{15}M_y\right]\delta F_x\, \mathrm{d}x - \int_L \delta u_x q_x \mathrm{d}x \\
&+\int_L \left[\left(u_{y,x} - \Omega_z\right) - u_{x,x}\Omega_z + u_{z,x}\Omega_x\right]\delta F_y\, \mathrm{d}x + \int_L \left[-C_{12}F_x - C_{22}F_y - C_{24}M_x - C_{25}M_y\right]\delta F_y\, \mathrm{d}x - \int_L \delta u_y q_y \mathrm{d}x \\
&+\int_L \left[\left(u_{z,x} + \Omega_y\right) + u_{x,x}\Omega_y - u_{y,x}\Omega_x\right]\delta F_z\, \mathrm{d}x + \int_L \left[-C_{33}F_z\right]\delta F_z\, \mathrm{d}x + \int_L \left[\Omega_{x,x} + \Omega_{y,x}\Omega_z\right]\delta M_x\, \mathrm{d}x - \int_L \delta u_z q_z \mathrm{d}x \\
&+\int_L \left[-C_{14}F_x - C_{24}F_y - C_{44}M_x - C_{45}M_y\right]\delta M_x\, \mathrm{d}x + \int_L \left[\Omega_{y,x} + u_{x,x}\Omega_{y,x} - u_{y,x}\Omega_{x,x}\right]\delta M_y\, \mathrm{d}x - \int_L \delta\Omega_x m_x \mathrm{d}x \\
&+\int_L \left[-C_{15}F_x - C_{25}F_y - C_{45}M_x - C_{55}M_y\right]\delta M_y\, \mathrm{d}x + \int_L \left[\Omega_{z,x} + u_{x,x}\Omega_{z,x} - u_{z,x}\Omega_{x,x}\right]\delta M_z\, \mathrm{d}x - \int_L \delta\Omega_y m_y \mathrm{d}x \\
&+\int_L \left[-C_{66}M_z\right]\delta M_z\, \mathrm{d}x - \int_L \delta\Omega_z m_z \mathrm{d}x + \int_L \left[F_x + F_x\, u_{x,x} + M_y \Omega_{y,x} + M_z \Omega_{z,x} - F_y\Omega_z + F_z\Omega_y\right]\delta u_{x,x}\mathrm{d}x \\
&+\int_L \left[F_y + F_x\, u_{y,x} - M_y \Omega_{x,x} - F_z\Omega_x\right]\delta u_{y,x}\mathrm{d}x + \int_L \left[F_z + F_x\, u_{z,x} - M_z \Omega_{x,x} + F_y\Omega_x\right]\delta u_{z,x}\mathrm{d}x \\
&+\int_L \left[F_y u_{z,x} - F_z u_{y,x}\right]\delta\Omega_x \mathrm{d}x + \int_L \left[M_x - M_y u_{y,x} - M_z u_{z,x}\right]\delta\Omega_{x,x}\mathrm{d}x + \int_L \left[F_z + F_z u_{x,x}\right]\delta\Omega_y \mathrm{d}x \\
&+\int_L \left[M_y + M_y u_{x,x} + M_x\Omega_z\right]\delta\Omega_{y,x}\mathrm{d}x + \int_L \left[-F_y - F_y u_{x,x} + M_x\Omega_{y,x}\right]\delta\Omega_z \mathrm{d}x + \int_L \left[M_z + M_z u_{x,x}\right]\delta\Omega_{z,x}\mathrm{d}x \\
&-\Big\langle \left(\left(u_x - \hat{u}_x\right), F_x\right) + \left(\left(u_y - \hat{u}_y\right), F_y\right) + \left(\left(u_z - \hat{u}_z\right), F_z\right) + \left(\left(\Omega_x - \hat{\Omega}_x\right), M_x\right) + \left(\left(\Omega_y - \hat{\Omega}_y\right), M_y\right) \\
&+\left(\left(\Omega_z - \hat{\Omega}_z\right), M_z\right)\Big\rangle_{\varepsilon} - \Big\langle \left(\hat{F}_x, u_x\right) + \left(\hat{F}_y, u_y\right) + \left(\hat{F}_z, u_z\right) + \left(\hat{M}_x, \Omega_x\right) + \left(\hat{M}_y, \Omega_y\right) + \left(\hat{M}_z, \Omega_z\right)\Big\rangle_{\sigma}
\end{aligned}
\tag{6}
$$

where, $C_{11}, C_{12}, C_{14}, C_{15}, C_{22}, C_{24}, C_{25}, C_{33}, C_{44}, C_{45}, C_{55}, C_{66}$ are the components of the compliance matrix which is given in Aribas et al. (2024). The nonlinear equations are linearized (Basar & Krätzig, 2013; Doğruoğlu & Omurtag, 2000) and the functional is obtained. The two-noded mixed finite element formulation has twelve degrees of freedom at each node as three displacements, three rotations, one axial force, two shear forces, one torsional moment, and two bending moments (Aribas et al., 2024; Eratli et al., 2016; Omurtag & Aköz, 1992). The Newton-Raphson algorithm is employed for the iterative solution approach (Aksoylar, 2010).

3. Numerical examples

3.1. Convergence analysis

In this example, a finite element mesh convergence analysis is performed for the geometrically nonlinear deformations of a cantilever sandwich beam subjected to the distributed loading along its length via the mixed finite elements (MFEs) and SOLID186 brick finite elements of ANSYS. The length of the cantilever sandwich beam is L = 4m. The width and total thickness of the sandwich cross-section are w = 0.3m and h = 0.03m, respectively. The stiffeners have equal thicknesses, and the total thickness of the stiffeners is h_s = 0.05m. The core is made of Kevlar 49-Epoxy and its elasticity moduli are E_x = 76GPa, $E_y = E_z$ = 5.56GPa, Poisson's ratios are $\nu_{xy} = \nu_{xz} = 0.34$, $\nu_{yz} = 0.718$, and the shear moduli are $G_{xy} = G_{zx}$ = 2.3GPa, G_{yz} = 1.618GPa, respectively. The stiffeners are made of Boron Epoxy and its elasticity moduli are E_x = 241.5GPa, $E_y = E_z$ = 18.89GPa, Poisson's ratios are $\nu_{xy} = \nu_{xz} = 0.24$, $\nu_{yz} = 0.25$, and the shear moduli are $G_{xy} = G_{zx}$ = 5.18GPa, G_{yz} = 3.45GPa, respectively. The cantilever sandwich beam is subjected to the uniformly distributed load q_z = 184N/m along its length (Fig. 1). First, the displacement at the tip u_z of the cantilever sandwich beam is obtained via 10, 20, 30, 40 and 50 mixed finite elements (corresponding to 132, 252, 372, 492, 612 degrees of freedom, respectively) and the results are given in Table 1. It is obtained that 132 DOFs provide quite satisfactory convergence for the mixed finite elements. Next, the displacement at the tip u_z of the sandwich beam is obtained via SOLID186 brick finite elements with 801 – 775341 DOFs (Table 2). The percentage difference of the results with respect to the result of 775341 DOFs becomes less than 1% for the 15210 DOFs. The percentage difference of the results of MFEs having 132 DOFs with respect to the results of SOLID186 elements having 15210 DOFs is -0.93%.

3.2. Parametric analysis

In this example, a parametric analysis is performed for the geometrically nonlinear deformations of a sandwich beam subjected to uniformly distributed loads along its length as the span ratio and/or the ratio of total thickness of stiffeners to cross-section decreases. The length of the sandwich beam is set to L = 4m, 6m and 8m, respectively while keeping the width and total thickness of the cross-section constant as w = 0.3m and h = 0.03m, respectively. The stiffeners have equal thickness and the ratio of total thickness of stiffeners to cross-section is set to λ_h = 0.100, 0.133 and 0.167, respectively. The core is made of Kevlar 49-Epoxy and the stiffeners are made of Boron Epoxy. The material properties of Kevlar 49-Epoxy and Boron Epoxy are given in Section 3.1. First, the displacement at the tip of a cantilever sandwich beam related to the increase in the magnitude of the distributed load q_z is given in Table 3 for each case. The percentage differences of the tip displacements obtained via the geometrically nonlinear analysis with respect to the linear analysis are illustrated in Fig. 2. Next, the midspan displacements of a sandwich beam having pinned support at both ends are obtained via the linear and geometrically nonlinear analyses for L = 4m (Table 4). Similarly, the percentage differences of the midspan displacements obtained via the geometrically nonlinear analysis with respect to the linear analysis are illustrated in Fig. 3.

* u_z and $\bar{u}_z$: Displacements of linear and geometrically nonlinear analyses, respectively.

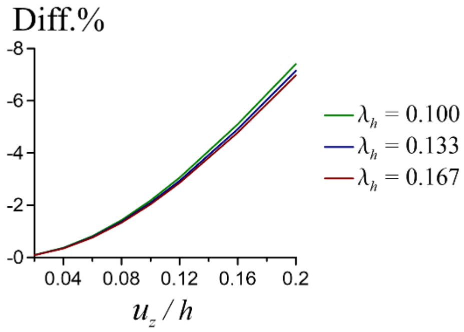

Fig. 3. The percentage differences of geometrically nonlinear midspan displacements to linear results

It is obtained that the absolute percentage differences of geometrically nonlinear tip displacements with respect to the linear displacements increase more as the span ratio of the cantilever sandwich beam decreases (Fig. 2). Similarly, the absolute percentage differences increase as the ratio of total thicknesses of stiffeners to cross-section decreases. It is more obvious as the span ratio decreases, for example, the percentage differences are -0.9197%, -0.9198% and -0.9200% for λ_h = 0.167, 0.133 and 0.100, respectively in the case of u_z / h =10 and L = 4m. However, the influence of the geometrically nonlinear deformation becomes greater within the scope of the pinned boundary conditions compared to the cantilever boundary conditions (Fig. 3). The percentage differences become -6.97%, -7.15% and -7.41% as u_z / h increases to 0.2 for λ_h = 0.167, 0.133 and 0.100, respectively in the case of L = 4m.

4. Conclusions

This study presents a geometrically nonlinear analysis of sandwich beams composed of transversely-isotropic layers, using the mixed finite element method under distributed loading along the beam's length. The analysis is grounded in satisfying the classical beam stress-free surface conditions on the three-dimensional constitutive equations specific to transversely isotropic materials, and it incorporates Von Kármán-type nonlinear strain assumptions. To derive the nonlinear governing equations, the virtual work principle and the first variation of the Hellinger-Reissner functional are applied. The two-noded mixed finite elements having twelve degrees of freedom at each node are used in this study. The convergence analyses show that the mixed FEM achieves accurate geometrically nonlinear displacement results while using fewer degrees of freedom than the high-resolution ANSYS 3D model, demonstrating the efficiency and robustness of the proposed approach. The study concludes that:

- Geometric nonlinearity becomes more significant as the span ratio decreases, leading to greater differences between nonlinear and linear tip displacements in cantilever sandwich beams.
- These percentage differences also increase as the thickness of stiffeners decreases, highlighting the sensitivity of beam behavior to cross-sectional composition.
- The effect of geometric nonlinearity is more pronounced under pinned boundary conditions than under cantilever conditions.
- For pinned beams, the nonlinear effects become greater with increasing u_z / h ratio, reaching differences over 7% in some cases, emphasizing the need for nonlinear analysis in such configurations.

Postfire response of GFRP-reinforced concrete beams with cement-based and intumescent paint fireproofing systems

Mohammed Al Dawood[1] , Salem Khalaf[1] , Farid Abed[*1]

[1] *American University of Sharjah, Department of Civil Engineering, Sharjah, United Arab Emirates*

Abstract. The fire safety considerations for Glass Fiber Reinforced Polymer (GFRP) bars, an alternative to traditional steel reinforcement in concrete structures, are being increasingly studied. This research addresses a critical gap by examining the postfire response of GFRP-reinforced concrete (RC) beams coated with different fireproofing systems. A total of six beams were tested, including two control beams without fire exposure, two fire-exposed beams without insulation, and two fire-exposed beams coated with either a cement-based mortar (Sikacrete 213F) or intumescent paint. The fire tests were conducted for a duration of 3 hours and followed the ASTM E119 fire curve. Post-fire flexural tests were performed to evaluate residual structural capacity. The results reveal significant differences in thermal and mechanical performance among the fireproofing systems. The Sikacrete-coated beam exhibited significant thermal resistance, maintaining lower internal temperatures and minimal surface damage compared to the intumescent paint-coated beam. Furthermore, the residual flexural capacity of the Sikacrete-coated beam was 147% higher than that of the intumescent paint-coated beam.

Keywords: Fire performance; GFRP-reinforced beams; Cement-based fireproofing; Intumescent paint; Flexural capacity

1. Introduction

Fiber reinforced polymers (FRP) are increasingly recognized as sustainable alternatives to conventional steel reinforcement, gaining widespread acceptance in modern construction. FRP materials commonly incorporate fibers such as basalt, carbon, and glass, with glass fiber reinforced polymer (GFRP) rebars emerging prominently due to their advantageous characteristics that include enhanced corrosion resistance, long-term durability, and high tensile strength. These features make GFRP particularly suitable for applications in aggressive environments, including hydraulic infrastructure like offshore structures and bridge decks (Al-Thairy et al., 2020). However, concerns regarding the deterioration of mechanical properties and the bond strength between GFRP bars and concrete at elevated temperatures have limited their adoption in fire-prone structural applications (Gooranorimi et al., 2018). To address these concerns, protective coatings such as cement-based mortars (e.g., Sikacrete 213F) or intumescent paints have been proposed to mitigate heat damage and preserve structural integrity (El-Kurdi et al., 2024). With the increasing interest in utilizing GFRP in various structural applications, it is essential to experimentally evaluate not only their thermal performance during fire but also their residual structural performance following fire exposure, to get keen insights on how GFRP reinforced concrete beams behave after cooling following fire exposure.

Abed et al. (2023) investigated the performance of GFRP bars under elevated temperatures up to 150°C. The results revealed a linear degradation in elastic modulus, with up to 87% strength loss occurring at 150°C—exceeding the glass transition temperature of the resin. These findings emphasize the susceptibility of GFRP bars to thermal damage even before reaching their decomposition.

Several authors also examined the postfire response of FRP reinforced concrete beams. Gooranorimi et al. (2018) exposed two simply-supported concrete slab strips that were reinforced with GFRP bars to fire for 2 hours. During fire exposure, the slabs were subjected to a sustained service load applied as a point load at midspan. The authors mentioned that the maximum recorded temperature was 1000˚C. However, the maximum recorded temperature on the internal bars was 115˚C. After exposure, the slabs were cooled for 24 hours and then tested using a three-point bending test. Results showed that, because the temperature of the bars only reached its approximate glass transitioning temperature, the beams exhibited load capacities greater than the theoretically calculated capacities and the load capacity of the control slab. The authors emphasized the need for high concrete

[*] Corresponding author, E-mail: fabed@aus.edu

https://doi.org/10.31462/icearc2025_ce_sme_517

covers to help insulate the GFRP bars from increased fire temperature, since the decomposition temperature is crucial for the flexural capacity of the bars.

Jafarzadeh and Nematzadeh (2022) studied concrete beams (150×200 mm cross-section, 1200 mm span) reinforced with two longitudinal GFRP bars. The beams were exposed to high temperatures in a furnace to simulate fire damage, and three target exposure levels of 200 °C, 400 °C, and 600 °C were applied to different beams. The flexural capacity of the beams was then evaluated and compared using four-point bending tests after cooling. The maximum temperature readings for the GFRP bars were approximately 200˚C and 400˚C for the beams exposed to 400˚C and 600˚C maximum temperatures, respectively. Results show that the flexural capacity of the beams that were exposed to a maximum temperature of 600˚C decreased by approximately 70% of the flexural capacity of the beams that were exposed to a maximum temperature of 400˚C. The authors attribute this decrease to the decompisiton temperature that the GFRP bars experienced (~400 °C). Additionally, the 400˚C exposed beams experienced an improved flexural capacity, approximately 14% more than the control beam, aligning with the results obtained by Gooranorimi et-al (2017). The authors essentially attribute this increase to the post-curing of the GFRP resin and enhanced bond conditions from microcrack resin infiltration, which improves its postfire performance, in opposite of the study performed by Abed et al. (2023).

Other authors verify the weakness of FRP reinforced concrete structures when temperatures exceed 600˚C Ghazal Aswad et al. (2025) evaluated the flexural performance of BFRP-reinforced beams exposed to temperatures up to 700°C. The study reported that BFRP beams retained around 34% of their capacity at 700°C, suggesting a vulnerability similar to GFRP at elevated temperatures.

These results underscore the necessity of effective fireproofing systems for FRP-reinforced concrete members. Khalaf et al. (2024) investigated the post-fire performance of GFRP-RC columns when insulating the columns and found that while non-insulated columns exhibited significant thermal degradation, insulated specimens—particularly those coated with cement-based systems like Sikacrete 213F—retained up to 60% of their axial capacity. This aligns with the findings in this study, where Sikacrete coating preserved the flexural performance of GFRP beams post-fire exposure

This paper aims to evaluate the post-fire flexural performance of 2.5-meter GFRP-reinforced concrete beams that were previously exposed to fire in a large-scale furnace following ASTM E119 standards. The main investigated parameter is the type of fireproofing system used: a cement-based mortar (Sikacrete 213F) and a single-component intumescent paint. By comparing the residual structural capacities of the beams, the study seeks to identify the more effective protection strategy for preserving the mechanical integrity of GFRP-RC members after fire exposure. This research addresses a critical gap in current ACI design provisions by providing experimental data on the behavior of fire-exposed GFRP-reinforced beams under flexural loading.

2. Materials and methods

2.1. Test matrix

All beams are 2.5 meters in length and share identical cross-section and reinforcement details. B1 and B2 were not exposed to fire to serve as control beams for the fire exposed beams. The other beams were exposed, as shown in Table 1. Additionally, B5 and B6 were coated with different fireproofing systems, namely Sikacrete 213F and intumescent paint, to evaluate their impact on the post-fire flexural performance of the beams.

Table 1. Test matrix

Beam ID	Fire Exposure	Coating
B1	Not exposed	None
B2	Not exposed	None
B3	Exposed	None
B4	Exposed	None
B5	Exposed	Intumescent pain
B6	Exposed	Sikacrete 213F

2.2. Beam fabrication

The GFRP-reinforced beams were designed to fail in flexure according to the guidelines provided in ACI 440.11-22 (2022). In compliance with the ACI 318-19 (2019) building code, which mandates a minimum concrete clear cover of 40 mm for protection against environmental exposure, a 40 mm cover was used. The beam dimensions were set at 300 mm in width and 400 mm in depth. The beams were reinforced with four 13 mm bottom GFRP bars and two 13 mm top GFRP bars. To ensure flexural failure during testing, 12 mm GFRP stirrups were placed at 150 mm intervals along the entire beam length. The typical dimensions and reinforcement details of the beams are displayed in Fig. 1. Prior to casting, *k*-type thermocouples were strategically positioned within the formwork—at the top and bottom reinforcement layers and around the stirrups. These thermocouples were used to monitor and record the temperature readings at the reinforcement, to provide explanation for the behavior of failure. After placement, the beams were cast and cured for 6 months before the fire test.

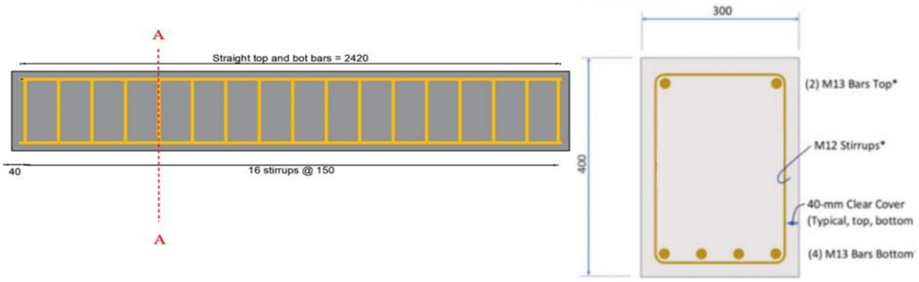

Fig. 1. Beam cross-sections

2.3. Material properties

In addition to casting the beams, a total of three cylinders, three cubes, and three prisms were cast to evaluate the compressive and flexural strength of the concrete. The cube tests yielded an average compressive strength of 47.623 MPa, while the cylinders recorded an average of 40.157 MPa. Flexural strength, determined from the prisms, averaged 5.278 MPa. The reinforcement used consisted of sand-coated M13 GFRP bars, which have a glass transition temperature of 110°C and a matrix decomposition range between 280°C and 445°C (Yousef et al., 2021). These bars possess an ultimate tensile strength of 850 MPa and a modulus of elasticity of 52 GPa.

For fire protection, two fireproofing systems were applied. Intumescent paint, known for expanding significantly under heat while maintaining low density, was applied in five layers to beam B5. This expansion forms an insulating char layer that restricts oxygen access and slows heat transfer to the underlying material (Khaneghagi et al., 2018). Sikacrete 213F, a high-performance, cement-based fire-resistant mortar, was also used as a protective layer. This non-shrink dry-mix mortar contains phyllosilicate and provides a compressive strength of 2.0 MPa with a thermal conductivity of 0.23 W/m·K at 10°C. Notably, Sikacrete offers up to four hours of fire resistance, making it well-suited for applications demanding strong thermal protection.

2.4. Fire and flexural testing

All beams underwent fire exposure in a large-scale furnace (5m x 4x x 2.5m) for a duration of 180 minutes. The furnace temperature was controlled to follow the ASTM E119-20 (2020) standard fire curve throughout the test. Thermocouples, connected to the laboratory data acquisition system, recorded temperature readings at 30-second intervals. With an operating range spanning from -270°C to 1260°C, the thermocouples provided accurate and consistent monitoring of temperature variations within the furnace. Essentially, the beams were not subjected to any mechanical loading during the fire exposure.

After cooling, the four fire-exposed beams (B3–B6) were tested alongside the two unexposed control beams (B1 and B2) using a three-point bending setup to evaluate their flexural performance. Each beam was simply supported at both ends, and a single concentrated load was applied at mid-span through the loading cell at a constant rate of 2 mm/min, as illustrated in Fig. 2. Testing continued until failure, which was identified by a substantial reduction in the beam's load-carrying capacity.

Fig. 2. Test setup

3. Results and discussions

3.1. GFRP temperatures

The maximum temperatures experienced by the GFRP bars for all of the fire exposed beams are presented in Table 2. It is shown that for B3 and B4, the maximum temperatures were the same, considering both beams were not insulated. B5 had a maximum GFRP temperature reading of 455 ˚C, indicating a minor but not sufficient decrease from the uninsulated beams. All three mentioned beams exceeded the typical decomposition temperature of GFRP bars. On the other hand, B6 had a maximum GFRP temperature of 147˚C, slightly higher than the typical glass transitioning temperature of 110˚C. Based on these results, Sikacrete 213F successfully insultated the GFRP bars from attaining temperature values up to decomposition temperature, whereas intumescent paint failed in doing so.

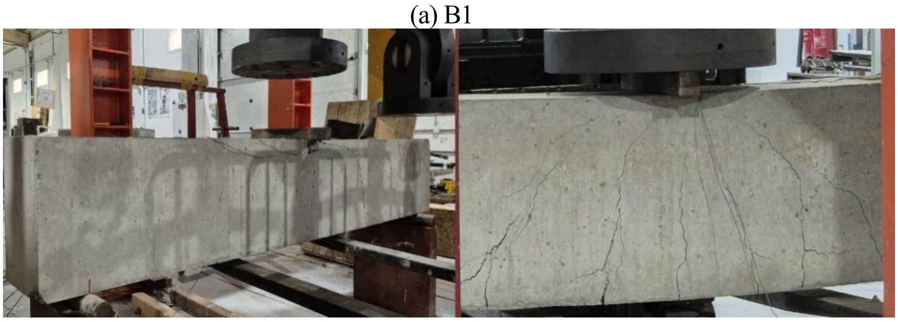
Table 2. Temperature readings for GFRP bottom bars

Beam ID	GFRP bottom bars temperature
B3	510˚C
B4	510˚C
B5	455˚C
B6	147˚C

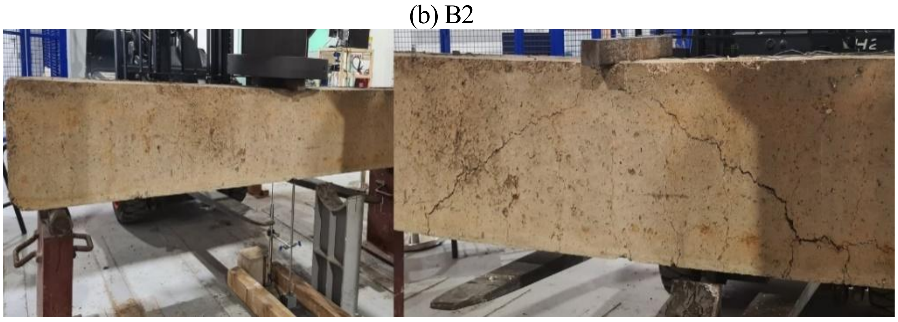
3.2. Flexural test results

The post-fire flexural behavior of the beams varied significantly depending on their exposure conditions and fireproofing systems applied. The failure mode of all six beams are displayed in Fig. 3. The control beams, B1 and B2, which were not exposed to fire, exhibited classic flexural cracking patterns with vertical cracks forming near mid-span. In contrast, beams B3 and B4, which were exposed to fire without any insulation, experienced severe surface spalling and discoloration. The crack patterns in these beams were irregular and more dispersed, likely caused by the degradation of the GFRP bars due to high internal temperatures.

(a) B1

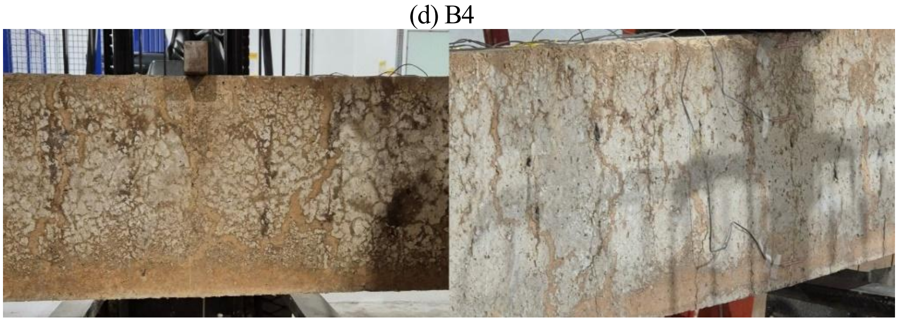


(b) B2

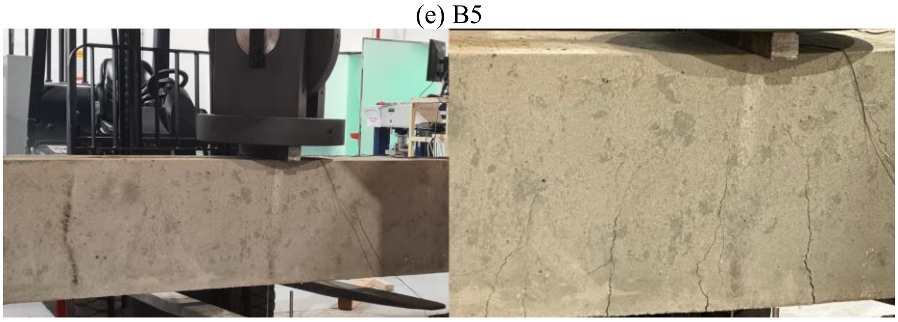


(c) B3

(d) B4



(e) B5



(f) B6

Fig. 3. All beams before and after flexural test

Beam B5, which was insulated with intumescent paint, displayed a charred surface with evidence of paint expansion, consistent with the material's response to heat. While the cracking pattern showed partial resemblance to flexural behavior, the damage suggested some thermal penetration and reduced structural performance. Beam B6, protected with Sikacrete 213F, showed the least surface damage and exhibited a well-defined flexural cracking pattern similar to the control beams.

Table 3 presents the maximum moments of each beam, as well as their residual capacities, calculated based on the average moments of B1 and B2. B3 and B4, the fire exposed beams without fire coating, have an average capacity of 50% of the control beams. This shows that the decomposition temperature experienced by the GFRP bars cause them to significantly deteriorate in strength. Additionally, B5, the beam coated with intumescent paint, retained a capacity of 44%, approximately similar to that of the uninsulated fire exposed beams. This shows that intumescent paint did not adequately provide proper insulation to the beam. On the other hand, and in alignment to the studies conducted by Gooranorimi et-al (2017) and Jafarzadeh and Nematzadeh (2022), B6, the beam exposed to fire and insulated with Sikacrete 213F, exhibited a higher maximum moment than B1 and B2, resulting in a residual capacity of 109%. As mentioned previously, the temperature of the bar was 147˚C, slightly above its typical glass transitioning temperature. In accordance with Jafarzadeh and Nematzadeh (2022), this caused the bars to undergo a process called post-curing, where additional polymer cross-linking occurred. This addition improved the bond performance of the GFRP bar, which in turn increased its moment capacity relative to its normal state.

Table 3. Maximum moment (kN-m) and residual capacity of the beams (%)

Beam ID	Moment capacity (kN-m)	Residual capacity (%)
B1	108.47	-
B2	117.30	-
B3	66.624	59
B4	45.73	40
B5	50.2	44
B6	123.92	109

4. Conclusions

This study presents the post-fire performance of four beams, two of which were coated with two different fireproofing systems : intumescent paint and Sikacrete 213F. The results of this study are as follows:

- Beams without insulation (B3 and B4) experienced significant thermal degradation, with GFRP bar temperatures exceeding 500 °C, resulting in a residual flexural capacity averaging only 50% of the unexposed control beams and a significantly less stiffness.
- The beam protected with intumescent paint (B5) exhibited similar performance to the uninsulated fire-exposed beams, with a GFRP bar temperature of 455 °C and a residual capacity of 44%. This indicates that the intumescent paint was ineffective in preventing thermal degradation of the reinforcement.
- In contrast, the beam insulated with Sikacrete 213F (B6) maintained a GFRP bar temperature well below the decomposition threshold (147 °C), resulting in minimal thermal damage. This beam exceeded the flexural capacity of the unexposed control beams, achieving a residual capacity of 109%.
- The enhanced performance of the Sikacrete coated beam is attributed to the post-curing effect, where thermal exposure near the glass transition temperature led to additional polymer cross-linking within the GFRP bars, hence improving their mechanical properties.

Abstract: This study presents a mixed finite element formulation for analyzing the behavior of functionally graded beams (FGBs) resting on an elastic foundation using the Higher-Order Shear Deformation Theory (HSDT). Functionally graded materials (FGMs) are characterized by continuous variations in material properties, enabling superior performance under complex loading conditions. The formulation is based on the Hellinger-Reissner variational principle, which incorporates both displacement and stress components as primary variables, ensuring improved accuracy and convergence. The functionally graded beam is modeled using a mixed approach that combines the displacement field and stress components as primary variables, ensuring higher accuracy and convergence rates. The elastic foundation is represented using Winkler and a two-parameter Pasternak model to account for shear interactions and foundation stiffness. The formulation is validated through benchmark problems, comparing results with existing solutions in the literature by utilizing different shear functions. Also, outcomes are obtained for various values of material gradation factor. Moreover, numeric studies are conducted to investigate the effects of length to thickness ratio, boundary conditions, foundation stiffness, and geometric parameters on the flexural responses of the FG beam. The results demonstrate the efficiency and accuracy of the mixed finite element formulation in capturing the complex interactions between the FGM beam and the elastic foundation. This study provides a robust tool for the design and analysis of FGBs in advanced engineering applications.

Keywords: Mixed finite element formulation; Hellinger-reissner principle, HSDT; Elastic foundation; Functionally Graded Beams

1. Introduction

Functionally graded materials (FGMs) are innovative materials increasingly utilized across industries such as aerospace, nuclear, automotive, civil, biomechanical, mechanical, electronic, chemical, and shipbuilding. Since their emergence in the 1980s, FGMs have been extensively researched, developed, and successfully applied in various industrial sectors. These materials exhibit microscopic inhomogeneity and spatial variation in composition, typically consisting of a blend of two distinct materials, such as ceramics and metals. Several studies have been performed to analyze the mechanical responses of FG structures. Abdelaziz et al. (Abdelaziz et al., 2011) proposed a novel high-order shear deformation theory with only four unknowns for analyzing the static response of functionally graded sandwich plates, deriving variationally consistent governing equations and validating its accuracy through comparisons with existing theories. Şimşek et al. (Şimşek & Kocatürk, 2009) examined the free and forced vibration behavior of a functionally graded Euler–Bernoulli beam subjected to a moving harmonic load. Turan and Hacıoğlu (2023) proposed a higher-order finite element model based on the Higher-Order Shear Deformation Theory (HSDT) for the static and free vibration analysis of Functionally Graded Beams (FGBs). They utilized five-node elements with 16 degrees of freedom to effectively capture transverse shear effects and prevent shear locking. Kafkas (2023) examined the influence of different homogenization techniques—particularly the power-law distribution—on the bending response of FGBs. The study used classical and refined beam theories combined with analytical methods to evaluate the effects of gradation on structural behavior. Wang et al. (2023) developed a model for axially graded microbeams based on the reformulated strain gradient elasticity theory. Using this approach, they analyzed both static bending and wave propagation, addressing material inhomogeneity and size effects inherent in micro-scale structures. Ghazwani (2023) introduced an enriched finite element formulation for porous functionally graded beams resting on elastic foundations. The study applied the First-Order Shear Deformation Theory (FSDT) and employed a polynomial shape function within a finite element framework for

https://doi.org/10.31462/icearc2025_ce_sme_531

the static bending analysis. Hadji, Plevris, and Madan (2023) carried out a comprehensive study on the static and free vibration behavior of porous FGBs using a newly proposed HSDT. Their method incorporated variable porosity models and micromechanical considerations, providing enhanced accuracy for sandwich and layered beam structures. In another recent published by Ozman and Ozhan (2025), researchers employed the Euler–Bernoulli beam theory and verified their finite element simulations with experimental data obtained from 3D-printed FGB specimens, confirming the robustness of theoretical predictions. Li et al. (2025) proposed a force-based beam finite element model grounded in a modified HSDT, enhancing the accuracy of static analysis for FGBs by considering true transverse shear stress distribution. Eshaghi et al. (2025) explored various Scientific Machine Learning approaches, including Physics-Informed Neural Networks (PINNs), for analyzing functionally graded porous beams, demonstrating the potential of data-driven methods in structural analysis. Tran-Duc et al. (2025) developed a multiscale patch scheme for studying the system-level characteristics of heterogeneous FGBs in 3D, enhancing the predictive capabilities of computational models. Adiyaman (2024) proposed a higher-order shear deformation theory (HSDT) for the free vibration analysis of porous 2D FGBs. The study utilized a two-node finite element model with eight degrees of freedom, effectively capturing shear effects without the need for shear correction factors. Material properties were described by an exponential function, incorporating porosity effects, and the results were validated through convergence analysis. Mesbah et al. (2024) developed a new quasi-3D finite element model based on an accurate shear and normal deformation beam theory to evaluate the free vibration and stability behaviors of thick FGBs. The model employed a hyperbolic warping function for transverse shear deformation and stress, ensuring traction-free boundary conditions without shear correction factors. Comparative studies demonstrated the model's effectiveness in capturing the mechanical behavior of FGBs. Wu et al. (2023) presented a nonlinear free vibration analysis of FGBs using a mixed finite element method and a comparative artificial neural network. The study addressed the nonlinearities in FGBs and compared the results obtained from the finite element method with those predicted by the artificial neural network, demonstrating the potential of machine learning techniques in structural analysis. Huang et al. (2024) applied the differential quadrature method to investigate the free vibrations of bi-directional FGBs. The study considered various boundary conditions and material gradation profiles, providing insights into the dynamic characteristics of FGBs under different loading and boundary scenarios

When reviewing the literature, various types of analyses and beam theories for functionally graded beams can be found. In this study, however, the static behavior of functionally graded beams will be investigated using a mixed finite element method. The inclusion of higher-order shear theory and the effects of Winkler and Pasternak soil interactions make this study unique.

2. Formulation

Let us consider a functionally graded beam shown in Figure 1a, which is subjected to loading in the xz-plane. The centroidal axis of the beam lies along the x-axis, and the cross-section is defined with respect to the yz-axes. The material distribution equation of the functionally graded beam is given in the Numerical Examples section. Under a distributed load p(x) acting along the z-direction, the axial and transverse displacement fields of the beam can be defined according to the Higher-Order Beam Theory as follows:

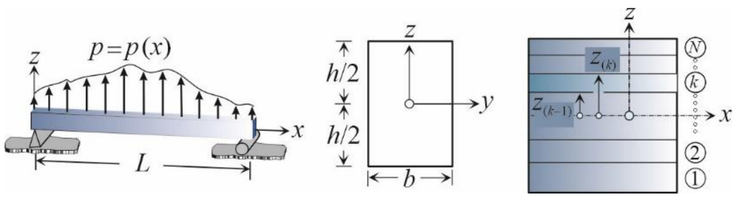

Fig. 1. Functionally graded beam a) Beam axes b) Cross-section dimensions c) Lamination

2.1. Field equations and formulation

$$\begin{aligned} u^* &= -z\, w_{,x} + f(z)\theta_x \\ w^* &= w \end{aligned} \tag{1}$$

w(x) is the transverse displacement along the x-axis, q(x) defines the rotation of the cross-section about the y-axis, and f(z) is the shear function, which in this study is taken as Reddy's shear function:

$$f(z) = z\left(1 - \frac{4z^2}{3h^2}\right) \tag{2}$$

Here, h denotes the beam height (see Figure 1b). The strain components throughout the beam cross-section, based on the displacement field given above, are expressed as:

$$\varepsilon_{xx} = u^*_{,x} = -zw_{,xx} + f\theta_{x,x}$$
$$\gamma_{xz} = u^*_{,z} + w^*_{,x} = f'\theta_x \tag{3}$$

The strain measures in Equation (3) can be expressed as follows:

$$\kappa_0 = -w_{,xx}$$
$$\kappa_1 = \theta_{x,x} \tag{4}$$
$$\varepsilon_s = \theta_x$$

The strain-stress relationship in the k-th layer of the laminated composite beam, as shown in Figure 1c, can be written using Hooke's Law as:

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{xz} \end{Bmatrix}^{(k)} = \begin{bmatrix} \bar{Q}_{11} & 0 \\ 0 & \bar{Q}_{55} \end{bmatrix}^{(k)} \begin{Bmatrix} \varepsilon_{xx} \\ \gamma_{xz} \end{Bmatrix}^{(k)} \tag{5}$$

The first variation of the functional for the elastic system according to the Hellinger-Reissner principle is given by:

$$\delta\Pi_{HR} = \int_V \left(\boldsymbol{\varepsilon}^{\mathbf{u}} - \boldsymbol{\varepsilon}^{\sigma}\right)^T \delta\boldsymbol{\sigma}^{\sigma}\mathrm{d}V + \int_V \left(\left(\boldsymbol{\sigma}^{\sigma}\right)^T \delta\boldsymbol{\varepsilon}^{\mathbf{u}} - \mathbf{q}^T\delta\mathbf{u}\right)\mathrm{d}V - \int_\Gamma \hat{\mathbf{t}}^T\delta\mathbf{u}\mathrm{d}\Gamma = 0 \tag{6}$$

In this equation, the first integral corresponds to the weak form of the compatibility conditions of the strain field, while the second represents the weak form of the equilibrium equations under external loading. The last integral accounts for the work done by the boundary tractions. Here, the variation operator is denoted by δ. For beam problems, the 3D formulation in Equation (6) is reduced by integrating through the cross-section, resulting in stress components and strain measures.

$$\delta\Pi_{HR} = \int_L \left(\mathbf{e}^{\mathbf{u}} - \mathbf{e}^{\mathbf{P}}\right)^T \delta\,\mathbf{P}\,\mathrm{d}L + \int_L \left(\mathbf{P}^T\delta\,\mathbf{e}^{\mathbf{u}} - \mathbf{p}^T\delta\,\mathbf{u}\right)\mathrm{d}L - \int_\Gamma \hat{\mathbf{t}}^T\delta\mathbf{u}\mathrm{d}\Gamma = 0 \tag{7}$$

Here, the strain measures are defined kinematically by $\mathbf{e}^{\mathbf{u}T} = [\kappa_0 \quad \kappa_1 \quad \varepsilon_s]^T$, while they are also expressed in terms of stress resultants $\mathbf{P}^T = [M_{xx} \quad M^f_{xx} \quad Q_{xz}]$. The distributed load acting on the laminated composite beam is denoted by $\mathbf{p}$, where M_{xx}, M^f_{xx}, and Q_{xz} represent the bending moment, higher-order bending moment, and shear force, respectively.

$$\left(M_{xx}, M^f_{xx}, Q_{xz}\right) = b\sum_{k=1}^{N}\int_{z_{(k-1)}}^{z_{(k)}} \left(z\sigma^{(k)}_{xx},\, f(z)\sigma^{(k)}_{xx},\, (\mathrm{d}f(z)/\mathrm{d}z)\sigma^{(k)}_{xz}\right)\mathrm{d}z \tag{8}$$

Here, *b* is the beam width (see Figure 1b), and *N* is the total number of layers in the cross-section. Substituting the constitutive relations from Equation (5) into Equation (8), the relationship between strain measures and stress resultants is obtained as follows:

$$\mathbf{P} = \mathbf{E}\mathbf{e}^{\mathbf{u}} \quad or \quad \begin{Bmatrix} M_{xx} \\ M^f_{xx} \\ Q_{xz} \end{Bmatrix} = \begin{bmatrix} D_{11} & F_{11} & 0 \\ F_{11} & H_{11} & 0 \\ 0 & 0 & A^s \end{bmatrix} \begin{Bmatrix} \kappa_0 \\ \kappa_1 \\ \varepsilon_s \end{Bmatrix} \tag{9}$$

Here, the terms in the section stiffness matrix are computed as follows:

$$\left(D_{11} \quad F_{11} \quad H_{11}\right) = b\sum_{k=1}^{N}\int_{z_{(k-1)}}^{z_{(k)}} \bar{Q}^{(k)}_{11}\left(z^2 \quad zf(z) \quad f(z)^2\right)\mathrm{d}z \tag{10}$$

$$A^s = b\sum_{k=1}^{N}\int_{z_{(k-1)}}^{z_{(k)}} \bar{Q}^{(k)}_{55}\left(f'(z)\right)^2\mathrm{d}z \tag{11}$$

By defining the compliance matrix $\mathbf{S} = \mathbf{E}^{-1}$, Equation (9) is reformulated for use in Equation (7).

$$\mathbf{e}^{\mathbf{P}} = \mathbf{S}\mathbf{P} \quad or \quad \begin{Bmatrix} \kappa_0 \\ \kappa_1 \\ \varepsilon_s \end{Bmatrix} = \begin{bmatrix} D'_{11} & F'_{11} & 0 \\ F'_{11} & H'_{11} & 0 \\ 0 & 0 & A^s \end{bmatrix} \begin{Bmatrix} M_{xx} \\ M^f_{xx} \\ Q_{xz} \end{Bmatrix} \tag{12}$$

The Pasternak elastic foundation model (Kutlu & Omurtag, 2019) defines the interaction force intensity transmitted between the soil and the structure, based on the vertical displacement of the structure interacting with the soil, by the following expression:

$$p_f = K_w w - K_s w_{,xx} \tag{13}$$

Here, K_w is the Winkler foundation parameter, acting like a spring constant that relates the local settlement to the interaction force intensity. K_s is the shear parameter of the foundation, introducing a shear interaction between adjacent springs as defined in Winkler's foundation model. Considering the Pasternak foundation interaction, the beam equilibrium equations can be derived according to the Higher-Order Shear Deformation Theory (HSDT) as follows:

$$\begin{gathered} M_{xx,xx} + p - \overline{K_w} w + \overline{K_s} w_{,xx} = 0 \\ M^f_{xx,x} - Q_{xz} = 0 \end{gathered} \tag{14}$$

In Equation (14), the definitions of $\overline{K_w} = bK_w$ and $\overline{K_s} = bK_s$ enable the loading condition to be expressed as a line load along the beam axis. Ultimately, by substituting the equilibrium equations given in Equation (14) and the compatibility conditions from Equation (12) into the expression (7), and applying partial integration to the second-order derivative term related to the foundation, the stationary condition of the Hellinger-Reissner functional for a laminated composite beam resting on a Pasternak foundation and described by the Higher-Order Shear Deformation Theory (HSDT) is obtained as follows:

$$\begin{aligned} \delta\Pi_{HR} = {} & \int_L \left[w_{,x}\delta M_{xx,x} - \left(\bar{D}_{11}M_{xx} + \bar{F}_{11}M^f_{xx}\right)\delta M_{xx} \right] \mathrm{d}L \\ & + \int_L \left[\theta_{x,x} - \left(\bar{F}_{11}M_{xx} + \bar{H}_{11}M^f_{xx}\right) \right] \delta M^f_{xx}\mathrm{d}L + \int_L \left[\theta_x - \left(\bar{A}^s Q_{xz}\right) \right] \delta Q_{xz}\mathrm{d}L - \int_L \delta w p \mathrm{d}L \\ & + \int_L \left(M_{xx,x}\,\delta w_{,x} + M^f_{xx}\delta\theta_{x,x} + V_{xz}\delta\theta_x + \overline{K_w} w\delta w + \overline{K_s} w_{,x}\delta w_{,x} \right) \mathrm{d}L - \int_\Gamma \hat{\mathbf{t}}^T \delta\mathbf{u}\,\mathrm{d}\Gamma = 0 \end{aligned} \tag{15}$$

The stationary condition of the system described by Equation (15) will be used to derive the finite element system matrices. Since the highest derivative order in this expression is first-order, the beam domain will be discretized using linear elements, which involve linear shape functions possessing C0 continuity. The shape functions ensuring C0 continuity, the matrix of unknowns at the nodes, and the stress evaluation are described in detail by Bab and Kutlu (2023).

3. Numerical examples

In this study, a variety of solutions are carried out for functionally graded beams to validate the presented formulation and the generated numerical solution method. Convergence and comparison analyses are conducted, considering beams resting on elastic foundations with different thicknesses ($L/h = 5$ *and* $L/h = 20$) and subjected to sinusoidal loads. The results are obtained for simply supported boundary conditions.

All beams, which are used in this study, have same material properties. Those properties can be written as:

$$E_m = E_{al} = 70\ GPa,\ v_m = v_{Al} = 0.3,\ E_c = E_{Al_2 0_3} = 380\,GPa,\ v_c = 0.3$$

Here, $\boldsymbol{E_m}$ represents the young modulus of metalic phase and $\boldsymbol{E_c}$ denotes for ceramic one. The distribution of material property is given below as:

$$E(z) = (E_c - E_m)\left(\frac{z}{h} + 0.5\right)^n + E_m \tag{16}$$

Here, n corresponds for the exponential factor where it is used in the performed examples as $n = 0, 1, 5, 10$. Also, results of the mid-span deflection and axial stress are obtained by utiziling the following nondimensional formula (Hadji et al., 2023):

$$\bar{w} = 100\frac{E_m h^3}{q_0 L^4} w\left(\frac{L}{2}\right), \quad \overline{\sigma_x} = \frac{h}{q_0 L}\sigma_x\left(\frac{L}{2}, \frac{h}{2}\right) \tag{17}$$

Also, the results obtaine from the analysis for different slenderrness ratios and variable Ks & Kw factors for different exponential factors, and compared with the study of Sayyad and Ghugal (Sayyad & Ghugal, 2018), are given in Table 1 and Table 2.

Table 1 summarizes the results for FG beams with a slenderness ratio of $\rho = 5$. The deflection predictions exhibit remarkable accuracy, with errors consistently below 0.2% across all gradation exponents and foundation stiffness parameters. For homogeneous beams $(n = 0)$, stress (S_x) errors remain minimal (≤0.08%), validating the formulation's capability for uniform materials. However, as the exponental factor (n) increases, stress errors escalate significantly, reaching 6.43% for $n = 10$, when $K_s = 0.1$ and $K_w = 0.1$. This trend underscores the challenge of modeling stress fields in beams with steep material gradation, particularly when coupled with foundation interactions. The systematic underestimation of S_x for $n \geq 1$ suggests that the current formulation may oversimplify stress redistribution mechanisms in graded materials, especially under combined elastic foundation effects.

Table 2 focuses on slender beams (and reveals similar deflection accuracy (errors <0.21%) but highlights amplified stress magnitudes compared to Table 1. Despite the increased slenderness, stress errors for $n \geq 1$ follow comparable trends, peaking at 6.45% for $n = 10$ with active foundation parameters. Notably, introducing K_s and K_w exacerbates discrepancies in S_x, even as deflection remains unaffected. This reinforces the hypothesis that stress inaccuracies stem primarily from material gradation complexity rather than geometric factors. The persistent underestimation of stress in high n cases, regardless of ρ, points to a fundamental limitation in capturing localized stress gradients under nonlinear material-foundation coupling.

Comparing both tables, the formulation demonstrates consistent deflection accuracy across slenderness ratios, confirming its reliability in predicting global stiffness. However, stress predictions degrade sharply with increasing nn, irrespective of ρ highlighting a critical gap in modeling functionally graded materials. The amplified errors in slender beams (Table 2) suggest that geometric slenderness compounds stress prediction challenges, likely due to heightened sensitivity to shear and foundation interactions. These results emphasize the need for advanced modeling techniques—such as enriched displacement fields or adaptive meshing—to address stress inaccuracies in high-n FG beams, particularly for applications requiring precise stress analysis in aerospace or civil engineering structures.

4. Conclusion

The present work advances the analysis of functionally graded beams (FGBs) on elastic foundations through a novel mixed finite element framework grounded in the Hellinger-Reissner variational principle and Higher-Order Shear Deformation Theory (HSDT). The methodology's efficacy is emphasized by its ability to maintain deflection accuracy within negligible margins (<0.21%) for diverse material gradations and foundation interactions, solidifying its utility in scenarios demanding reliable global deformation predictions. A critical insight from this investigation is the pronounced divergence in stress fidelity as material inhomogeneity intensifies. High gradation exponents induce stress prediction discrepancies exceeding 6%, attributed to inherent complexities in resolving steep property gradients and nonlinear interactions between foundation parameters and graded material behavior.

Notably, this study pioneers a versatile computational tool that harmonizes accuracy with efficiency, leveraging the mixed formulation to bypass shear correction factors while accommodating complex foundation interactions—a significant advancement over conventional approaches. The framework's adaptability to varying boundary conditions, material distributions, and slenderness ratios positions it as a valuable asset for preliminary design phases in aerospace, civil, and mechanical engineering. By rigorously validating results against established benchmarks and integrating higher-order kinematics, the work sets a robust foundation for future extensions into dynamic, nonlinear, or multi-physical analyses of FGBs. To bridge these gaps, future efforts should explore multi-scale modeling approaches, integrating microstructural gradation effects with macroscopic beam behavior. Additionally, coupling the formulation with optimization algorithms or probabilistic frameworks could enhance predictive reliability for extreme gradation and foundation conditions. By addressing these computational and theoretical frontiers, the proposed framework can evolve into a comprehensive tool for next-generation FGB design, balancing precision with adaptability in advanced engineering systems.

Performance of Ch-SAMP-Rao algorithm on RC slab bridge superstructure CO_2 emission optimization

Hasan Tahsin Öztürk *[1], Nurcan Öztürk[1]

[1] *Karadeniz Technical University, Faculty of Technology, Department of Civil Engineering, 61830, Trabzon, Türkiye*

Abstract. In this study, Rao1, Rao2, Rao3, SAMP-Rao1, SAMP-Rao2, SAMP-Rao3, and Ch-SAMP-Rao algorithms developed using a chaotic switching strategy were used in the optimum designs of single-span reinforced concrete slab bridge superstructures with minimum CO_2 emissions. The main purpose of the study is to examine the performance of the developed Ch-SAMP-Rao algorithm compared to other Rao algorithm versions. In the developed chaotic SAMP-Rao algorithm, switching was performed between the search equations used in the SAMP-Rao1, SAMP-Rao2, and SAMP-Rao3 algorithms with chaotic maps. Thus, it was thought that these three algorithms, which show different performance in different problems, could show a more stable performance. For this purpose, a problem suite consisting of two different reinforced concrete slab bridge problems was created by considering the AASHTO-LRFD Bridge Code. There was a total of 13 design variables in the problem. These were deck thickness, main rebar diameter in the interior and edge strip, distribution rebar diameter in the interior and edge strip, shrinkage and temperature rebar diameter, concrete grade, steel rebar grade, main rebar spacing in the interior and edge strip, distribution rebar spacing in the interior and edge strip, and shrinkage and temperature rebar spacing. The findings obtained as a result of the independent simulations were evaluated with box plot graphics and the Friedman test, which is a non-parametric statistical test. The findings showed that the performance of the proposed Ch-SAMP-RAO algorithm is better than the others.

Keywords: Slab Bridge; Superstructure; Optimization, CO_2 emission; Ch-SAMP-Rao

1. Introduction

Traditional design methods in structural engineering often rely on empirical knowledge and iterative trial-and-error approaches. While these methods ensure compliance with strength and durability regulations, they typically do not prioritize cost efficiency or material optimization. In the context of diminishing natural resources and increasing environmental concerns, there is a growing need for designs that minimize both economic costs and carbon emissions. This necessity has led to the widespread adoption of optimization techniques in structural engineering, particularly metaheuristic algorithms, due to their adaptability and effectiveness in solving complex real-world problems.

Numerous studies have explored the optimization of bridge structures using various metaheuristic approaches. For instance, Rana et al. (2010) and Ahsan et al. (2012) applied the Evolutionary Operation (EVOP) algorithm to optimize the cost of post-tensioned I-girder bridges, while Ghodoosi et al. (2018) employed Genetic Algorithms (GA) to minimize maintenance costs in reinforced concrete girder bridges. Other researchers, such as Martí et al. (2015) and Bruno et al. (2016), focused on optimizing prestressed and arch bridge configurations using memetic and iterative algorithms, respectively. Multi-objective optimization has also gained attention, with studies like those by Martinez-Martin et al. (2012) and García-Segura & Yepes (2016) incorporating cost, reinforcement density, and CO_2 emissions as key objectives.

Recent advancements have introduced hybrid and improved metaheuristic techniques, such as the Enhanced Colliding Bodies Optimization (ECBO) and Water Strider Algorithm (WSA), to enhance optimization efficiency (Kaveh et al., 2022). Additionally, sustainability-driven optimizations, including those by Yepes-Bellver et al. (2022) and Martínez-Muñoz et al. (2022), have emphasized reducing carbon footprints alongside cost. Despite these developments, further research is needed to refine optimization criteria, improve computational efficiency, and integrate emerging algorithms for more sustainable and economical bridge designs.

The SAMP-Rao and Rao algorithms are noteworthy as meta-heuristics that yield effective results in real-world optimization problems. However, the efficacy of variants 1, 2, and 3 of these algorithms varies in different problem

https://doi.org/10.31462/icearc2025_ce_sme_566

types. Specifically, while Rao-1 demonstrates efficacy in low-dimensional problems with its simple and fast convergence, the more complex search mechanisms of Rao-2 and Rao-3 can yield superior results in multimodal and high-dimensional optimization problems. In a similar vein, although the adaptive parameter structure of SAMP-Rao provides flexibility in engineering problems with uncertainty, performance fluctuations can be observed in some cases due to excessive parameter sensitivity. This finding indicates that the configuration of the problem should be considered when selecting the algorithm.

This study presents a new Chaotic SAMP-Rao (Ch-SAMP-Rao) algorithm by combining the convergence equations of the SAMP-RAO algorithm using chaotic mapping reference signals. Thus, it is thought that by selecting a problem-specific signal, an algorithm with higher performance than the variants of the SAMP-Rao and Rao algorithms can be developed. For this purpose, performance tests were performed on the optimization problem of reinforced concrete slab bridge deck with the same span and two different widths. The results obtained are compared with those obtained from the variants of SAMP-Rao and Rao algorithms by various statistical tests.

The structure of this study is as follows: The first section discusses the motivation and goal of the present study. The second section describes the formulation of the optimization problem, constraints, algorithm settings, and proposed Ch-SAMP-Rao algorithm. Findings and investigations are presented in the third section. Finally, the conclusions obtained from the study are summarized in the fourth section and some suggestions for future studies are made.

2. Method

2.1. Design variables, parameters, and objective function

The optimum design of the slab bridge deck shown in Fig. 1 was performed according to the AASHTO-LRFD bridge regulation with minimum CO_2 emission (Öztürk, 2024). The design variables used were shown on the bridge cross-section in Fig. 2. The lower and upper bounds of the design variables are presented in Table 1. and the design parameters of the problem are presented in Table 2.

The objective function of the optimization problem consists of the sum of the concrete and reinforcement costs of the bridge deck. Where V_c is the volume of concrete, W_s is the total weight of reinforcement, Cs and Cc are the unit costs of steel and concrete respectively, the objective function is calculated as in Eq. 1.

$$f(x) = V_c C_c + W_s C_s \tag{1}$$

Unit emission values for concrete and steel grades are given in Table 3.

In the study, two problem cases were analyzed as design 1 and design 2. In both problems, the bridge span is fixed and is 10 m. In design 1, the bridge width is 5.60 m with two traffic lanes and in design 2, the bridge width is 9.2 m with three traffic lanes.

2.2. Constraints

The first constraint concerns the minimum thickness control of the bridge deck. The first constraint is given in Eq.2, where h_{min} is the minimum thickness calculated according to AASHTO-LRFD bridge specifications.

$$g_1(x) = \frac{h_{min}}{X_1} - 1 \leq 0 \tag{2}$$

In this study, the longitudinal strip method presented in the AASHTO-LRFD regulation is used for the design of the bridge. In order to use this method, the span length must be greater than 4600 mm. This requirement is controlled by the constraint given in Eq. 3.

$$g_2(x) = \frac{4600}{L} - 1 \leq 0 \tag{3}$$

The third and fourth constraints are related to the crack control for the interior and edge strips of the deck. In this inspection, firstly, it should be checked whether there is cracking in the tensile region of the section. For this purpose, concrete is cracked if the maximum tensile stress f_t occurring in critical sections is greater than 80% of the modulus of rupture (f_r) of the section. If the section is not cracked, no cracking check will be performed. If the section is cracked, the tensile stress in the main reinforcement must satisfy the condition $f_{ss} \leq 0.60 \cdot f_y$ for the crack to be under control. The crack control constraint in Eq. 4 is checked separately for the interior and edge strips.

$$g_{3-4}(x) = \frac{f_{ss}}{0{,}60 \cdot f_y} - 1 \leq 0 \tag{4}$$

Table 1. Upper, lower bounds and increments of design variables

Variable	Definition	Lower Bound	Upper Bound	Increment	Number of possible values
X_1	Deck thickness	300 mm	1200 mm	10 mm	91
X_2	Main rebar diameter in the interior strip	{6 8 10 12 14 16 20 25 28 32} mm			10
X_3	Main rebar diameter in the edge strip	{6 8 10 12 14 16 20 25 28 32} mm			10
X_4	Distribution rebar diameter in the interior strip	{6 8 10 12 14 16 20 25 28 32} mm			10
X_5	Distribution rebar diameter in the edge strip	{6 8 10 12 14 16 20 25 28 32} mm			10
X_6	Shrinkage and temperature rebar diameter	{6 8 10 12 14 16 20 25 28 32} mm			10
X_7	Concrete grade (fc')	{25, 30, 35, 40, 45, 50} MPa			6
X_8	Steel rebar grade (fy)	{400, 500} MPa			2
X_9	Main rebar spacing in the interior strip	50 mm	450 mm	10 mm	41
X_{10}	Main rebar spacing in the edge strip	50 mm	450 mm	10 mm	41
X_{11}	Distribution rebar spacing in the interior strip	50 mm	450 mm	10 mm	41
X_{12}	Distribution rebar spacing in the edge strip	50 mm	450 mm	10 mm	41
X_{13}	Shrinkage and temperature rebar spacing	50 mm	450 mm	10 mm	41

Table 2. Design parameters of slab bridge problem

Description and unit	**Value**
Width of traffic barriers (mm)	530
Load modifier (η)	1
Exposure factor (γ_e)	1
Wearing surface thickness (mm)	80
Impact factor	0.33
Impact factor (for fatigue)	0.15
Density of reinforced concrete (kN/m^3)	25
Density of wearing surface (kN/m^3)	22
Cross-sectional area of traffic barriers (mm^2)	0.24
Clear concrete cover for bottom of slab (mm)	25
Clear concrete cover for slab surface (mm)	60

Table 3. Unit emissions for concrete and reinforcement (Yepes et al., 2012)

Material	Unit CO_2 emission
Steel Rebar (400 MPa)	2.82 kg/kg
Steel Rebar (500 MPa)	3.02 kg/kg
Concrete (25 MPa)	224.34 kg/ m^3
Concrete (30 MPa)	224.94 kg/ m^3
Concrete (35 MPa)	265.28 kg/ m^3
Concrete (40 MPa)	265.28 kg/ m^3
Concrete (45 MPa)	265.91 kg/ m^3
Concrete (50 MPa)	265.95 kg/ m^3

The fifth and sixth constraints given in Eq. 5 are related to the crack control of the deck section. The expression in the denominator of the constraint is the maximum limit of the reinforcement spacing. Cracks are assumed to be under control if the principal reinforcement spacing in the interior and edge strips is below this maximum limit.

$$g_{5-6}(x) = \frac{s}{\frac{123000 \cdot \gamma_e}{\beta_s \cdot f_{ss}} - 2 \cdot d_c} - 1 \leq 0 \tag{5}$$

Where γ_e is the exposure factor and β_s is a factor, f_{ss} is the tensile stress in reinforcement at the service limit state, d_c is the concrete cover measured from the extreme tension fiber to the center of the closest flexural reinforcement.

The constraint given in Eq. 6 is used for deflection control where Δ_{LL+IM} is the deflection under live load and Δ_{LL+IM}^{allow} is the allowable deflection. The allowable deflection is considered as 1/800 of the span length.

$$g_7(x) = \frac{\Delta_{LL+IM}}{\Delta_{LL+IM}^{allow}} - 1 \leq 0 \tag{6}$$

For fatigue control, the condition $f_f < (\Delta F)_{TH}$ must be satisfied. Where $(\Delta F)_{TH}$ is the stress range limit for fatigue control and f_f is the stress amplitude. This condition is controlled by the constraint given in Eq. 7.

$$g_8(x) = \frac{f_f}{(\Delta F)_{TH}} - 1 \leq 0 \tag{7}$$

The moment capacity of the bridge deck must be greater than the design moment ($M_r \geq M_u$) in both the edge and interior strips. For this check, the ninth and tenth constraints for the interior and edge strips are used.

$$g_{9-10}(x) = \frac{M_u}{M_r} - 1 \leq 0 \tag{8}$$

In the constraint given in Eq. 9, where M_{cr} is the cracking moment and M_u is the design moment, the minimum reinforcement ratio limit is controlled by the eleventh and twelfth constraints in the interior and edge strips.

$$g_{11-12}(x) = \frac{\min\begin{cases}1{,}2 \cdot M_{cr} \\ 1{,}33 \cdot M_u\end{cases}}{M_r} - 1 \leq 0 \tag{9}$$

The distribution reinforcement control is realized by the thirteenth and fourteenth constraints given in Eq. 10 for the interior and edge strips. Where $A_d^{required}$ is the amount of transverse distribution reinforcement required and A_d is the amount of transverse distribution reinforcement placed in the section.

$$g_{13-14}(x) = \frac{A_d^{required}}{A_d} - 1 \leq 0 \tag{10}$$

The amount of shrinkage and temperature change reinforcement to be placed in both directions is $\text{Temp } A_s^{required}$ and the placed reinforcement $\text{Temp } A_s$, the amount of this reinforcement is controlled by the fifteenth constraint, and the spacing condition is controlled by the sixteenth constraint.

$$g_{15}(x) = \frac{\text{Temp } A_s^{required}}{\text{Temp } A_s} - 1 \leq 0 \tag{11}$$

$$g_{16}(x) = \frac{s_{TEMP}}{\min\begin{cases}3 \cdot h \\ 450 \text{ mm}\end{cases}} - 1 \leq 0 \tag{12}$$

2.3. Proposed Ch-SAMP-Rao algorithm

The difference of the Chaotic SAMP-Rao (Ch-SAMP-Rao) algorithm proposed here from the SAMP-Rao 1, SAMP-Rao 2 and SAMP-Rao 3 algorithms is presented below in Table 4. in the green colored lines. The difference between SAMP-Rao 1, SAMP-Rao 2 and SAMP-Rao 3 algorithms is the convergence equations used in the update mechanisms. The Ch-SAMP-Rao algorithm proposed in this study uses one of these three convergence equations according to a reference signal generated from chaotic maps according to the number of function evaluations.

Therefore, the algorithm uses SAMP-Rao 1, SAMP-Rao 2 and SAMP-Rao 3 convergence equations in a chaotic manner in its life cycle.

3. Results of simulation studies

3.1. Simulation environment and algorithm settings

The characteristics of the simulation environment are summarized in Table 5. The same equipment was used in all experiments to ensure a fair comparison.

In addition to the Ch-SAMP-Rao algorithm proposed in this study, Rao1, Rao2, Rao3, SAMP-Rao1, SAMP-Rao2, SAMP-Rao3 were used in the study and statistical performance comparisons were made. For the tested algorithms, the settings recommended in the literature were used as a standard procedure. The algorithms tested on the slab bridge problems investigated in this study, the reference works of the algorithms and the settings recommended in the reference works are presented in Table 6.

3.2. Optimum design of problems

Details of the optimum designs of the 5.6m wide (Design 1) and 9.2m wide (Design 2) slab bridges are presented in Table 7.

Table 7. shows that as the bridge width increases, the amount of primary reinforcement, distribution reinforcement and shrinkage and temperature change reinforcement increases. When the bridge span is constant, an increase of 64% in the width causes an increase of approximately 45% in the prime reinforcement, 47% in the distribution reinforcement, 65% in the shrinkage and temperature change reinforcement, and 91% in the amount of concrete. In this context, it is understood that the increase in the width of the bridge causes the highest proportional increase in the amount of concrete and the highest increase in the amount of distributing reinforcement among the reinforcements.

When the CO_2 emissions are compared, it is seen that while the bridge span is constant, an increase of 64% in width increases concrete emissions by 62% and reinforcement emissions by 47%. The total emission decreased by 0.59%. This is due to the increase in the volume of concrete used as a result of the increase in width.

Another finding that should be noted is that the emissions per unit deck area decreased with an increase in bridge width by 64%. As the bridge width increases, the total emission value per unit area of the bridge decreases by 3%.

Tablo 7. Optimal design details

		Design 1	Design 2
	Span (m)	10	10

	CO_2 Emission of Concrete per Slab Area (kg)	273.93	269.93
	Total CO_2 Emission per Slab Area	332.94	322.56

3.3. Statistical performance tests

In order to compare the proposed Ch-SAMP-Rao algorithm with the SAMP-Rao and Rao algorithms, three different statistical performance evaluations were performed. The first performance evaluation involves examining the mean solutions and their standard deviations of the results obtained from independent runs of the algorithms. In order to perform this evaluation, Table 8. presents the mean emission values and their standard deviations from the independent runs of the algorithms for both designs. In order to better evaluate these statistical findings visually, box-plot plots have been prepared and are presented in Fig. 3.

The algorithms in Table 8. are ranked from smallest to largest according to the average emission value. When the average emission values and standard deviations of the emissions given in Table 8. are analyzed, it is seen that the Ch-SAMP-Rao algorithm has the smallest average emission value for both problems. In addition, the proposed Ch-SAMP-Rao algorithm has the lowest standard deviation in both problems. This shows that Ch-SAMP-Rao is statistically the most successful algorithm among the competing algorithms. The algorithm with the second smallest mean in Design 1 is SAMP-Rao3, while the algorithm with the second smallest mean in Design 2 is SAMP-Rao1. This shows that the performances of Rao and SAMP-Rao algorithms are extremely sensitive to the problem.

Similarly, examination of the box-plot graphs presented in Fig. 3 shows that the Ch-SAMP-Rao algorithm achieved the lowest mean and standard deviation. Moreover, it is clear from both Table 8. and the box-plots that the SAMP-Rao algorithm variants using the sub-population separation method are more successful than the Rao variants.

The second performance comparison was performed with the Friedman Test (Friedman, 1940). With this test, the scores of the algorithms were determined and the performance ranking of the algorithms on the problems was given according to the scores. In addition, the average scores were calculated, and a ranking was also performed according to the average score. These rankings can be found in Table 9.

Table 8. Mean and standard deviation of algorithms

Design 1		Design 2	
Ch-SAMP-Rao	18644.39 (3.73 10^{-12})	Ch-SAMP-Rao	29680.79 (21.00)
SAMP-Rao3	18649.65 (14.04)	SAMP-Rao1	29755.98 (103.25)
SAMP-Rao1	18655.48 (15.39)	SAMP-Rao2	29706.06 (123.13)
Rao1	18657.79 (20.41)	SAMP-Rao3	29810.42 (130.02)
SAMP-Rao2	18666.13 (23.83)	Rao3	29811.74 (121.41)
Rao3	18930.63 (709.46)	Rao1	29870.96 (179.24)
Rao2	19259.77 (981.28)	Rao2	29889.03 (256.85)

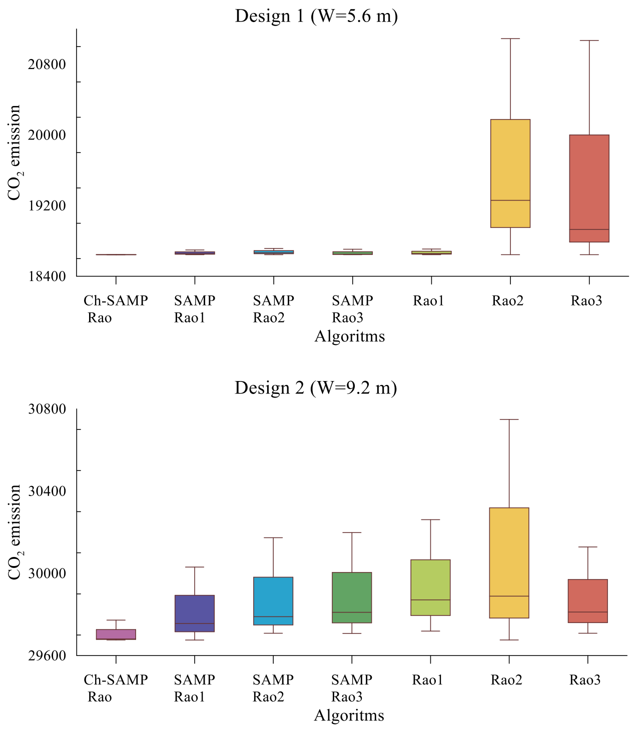

Fig. 3. Box plots of Ch-SAMP-Rao, SAMP-Rao and Rao variants for slab bridge problem

Table 9. Friedman scores of Ch-SAMP-Rao, SAMP-Rao and Rao variants for slab bridge problem

Friedman Scores and Rankings					
Design 1		Design 2		Mean Score	
Ch-SAMP-Rao	1.95	Ch-SAMP-Rao	1.43	Ch-SAMP-Rao	1.69
SAMP-Rao3	2.81	SAMP-Rao1	3.00	SAMP-Rao1	3.32
SAMP-Rao1	3.64	SAMP-Rao2	4.40	SAMP-Rao3	3.75
Rao1	3.71	Rao2	4.69	Rao1	4.39
SAMP-Rao2	4.40	SAMP-Rao3	4.69	SAMP-Rao2	4.40
Rao2	5.45	Rao3	4.71	Rao2	5.07
Rao3	6.02	Rao1	5.07	Rao3	5.37

According to the Friedman scores presented in Table 9, the proposed Ch-SAMP-Rao algorithm is ranked first in both designs. The second-ranked algorithms were SAMP-Rao3 in Design 1 and SAMP-Rao1 in Design 2. Friedman's tests further corroborate the hypothesis that SAMP-Rao algorithms may exhibit divergent performance, even when confronted with problems of a similar nature. According to the mean score, the proposed Ch-SAMP-Rao algorithm demonstrates the highest level of performance.

The third and final comparison was executed using the Wilcoxon test (Wilcoxon, 1945), which facilitates paired comparisons of the Ch-SAMP-Rao algorithm, which was ascertained to be in the leading position by the Friedman test, with other competitors. The Wilcoxon test results are presented in Table 10. The three scores assigned to each cell indicate the number of problems in which the competitor algorithm performs better, similar, or worse, respectively, compared to the Ch-SAMP-Rao algorithm.

The results of the Wilcoxon test, as presented in Table 10, indicate the superiority of the Ch-SAMP-Rao algorithm over all variants of the Samp-Rao and Rao algorithms in both problems.

In summary, the statistical evaluations indicate that the Ch-SAMP-Rao algorithm significantly outperforms the SAMP-Rao and Rao algorithm variants in the context of designing reinforced concrete slab bridges with minimal carbon dioxide emissions.

4. Conclusions

In this study, a novel metaheuristic algorithm, Chaotic SAMP-Rao (Ch-SAMP-Rao), was proposed for the optimum design of reinforced concrete slab bridges, targeting environmental sustainability and cost efficiency. The developed algorithm dynamically integrates the convergence equations of three variants of the SAMP-Rao family using chaotic maps, thereby offering a flexible and robust optimization mechanism that adapts to the structure of the problem.

Simulations were carried out on two different bridge design problems with widths of 5.6 m and 9.2 m. The performance of the proposed algorithm was compared with established variants of the Rao and SAMP-Rao algorithms from the literature. The results demonstrated that Ch-SAMP-Rao produced the lowest average CO_2 emission values in both problems and achieved the smallest standard deviations, indicating strong solution stability.

Statistical analyses using the Friedman and Wilcoxon tests further confirmed the superiority of the Ch-SAMP-Rao algorithm over its competitors. Notably, while the performance of traditional algorithms varied with problem structure, the proposed algorithm consistently exhibited high adaptability and success across different scenarios.

In conclusion, the Ch-SAMP-Rao algorithm provides an effective optimization approach for reducing environmental impacts and enhancing efficiency in structural engineering design. Future research may focus on applying the algorithm to different bridge types and infrastructure systems, testing it in multi-objective optimization scenarios, and developing hybrid enhancements to further improve computational efficiency.

Table 10. Wilcoxon test results of Ch-SAMP-Rao, SAMP-Rao and Rao variants for slab bridge problem

Ch-SAMP-Rao vs.	Design 1	Design 2
SAMP-Rao1	0 / 0 / 1	0 / 0 / 1
SAMP-Rao2	0 / 0 / 1	0 / 0 / 1
SAMP-Rao3	0 / 0 / 1	0 / 0 / 1
Rao1	0 / 0 / 1	0 / 0 / 1
Rao2	0 / 0 / 1	0 / 0 / 1
Rao3	0 / 0 / 1	0 / 0 / 1

Quality processes for bridge analysis models

Serhan Guner*[1]

[1] *University of Toledo, Department of Civil and Environmental Engineering, 2801 W. Bancroft St., MS 307, Toledo, Ohio 43606, USA*

Abstract. The design of bridges often involves the use of structural analysis models of varying degrees of complexity. Superstructure design models vary from approximate one-dimensional line girder analysis models to complex two- and three-dimensional finite element analysis models. Substructure and foundation models often consider soil-structure interaction, second-order effects, dynamic response for seismic analysis, and interaction with the superstructure. A variety of analysis methods and associated software are used to create and analyze these models and obtain the analysis output. This process can be quite complex with a large number of input parameters and significant amounts of output data. A study was recently conducted in the United States to identify and document state departments of transportation (DOT) practices related to the quality processes for bridge structural analysis models. The study documents the written and informal processes for identifying appropriately qualified staff including in-house personnel and consultants; choosing an appropriate analysis method and software; validating the analysis software; modeling a bridge structure with proper approaches and assumptions; verifying the analysis results; and reconciling discrepancies between independent models. Information was gathered through a literature review, a survey of all DOTs, and follow-up interviews with five selected agencies as case examples. The survey was completed by 51 DOTs, including 50 states and the District of Columbia, yielding an overall response rate of 100%. This paper aims to summarize the main findings and refer readers to the relevant references. In addition, commonly misunderstood concepts and processes, such as verification, validation, uncertainty, error, and calibration, are clarified.

Keywords: Bridge analysis; Consultant projects; In-house projects; Quality assurance; Quality control.

1. Introduction

The design of bridges often involves the use of structural analysis models of varying degrees of complexity. Superstructure design models vary from approximate one-dimensional line girder analysis models to sophisticated two- and three-dimensional finite element analysis models. Substructure and foundation models often consider soil-structure interaction, second-order effects, dynamic response for seismic analysis, and interaction with the superstructure. A variety of analysis methods and software can be used to create and analyze these models. This process can be quite complex with a large number of input parameters and significant amounts of output data.

The engineer must understand the limitations of the analysis method and software, possess experience in developing analysis models with proper approaches and assumptions, and correctly interpret the results. An appropriate understanding of the expected behavior of the structure is also required to assess if the predicted behavior represents the actual performance of the structure. A simple check of the program input values is not an adequate way of ensuring the accuracy and validity of these models. Quality assurance (QA) and quality control (QC) are two essential processes for the quality management of analysis models. Verification and validation (V&V) play a critical role in the QA/QC process.

A study was recently conducted in the United States to identify and document state Departments of Transportation (DOT) practices related to the quality processes for bridge structural analysis models. The study documents the written and informal processes for identifying appropriately qualified staff, including in-house personnel and consultants; choosing an appropriate analysis method and software; validating the analysis software; modeling a bridge structure with proper approaches and assumptions; verifying the analysis results; and reconciling discrepancies between independent models. In addition, the study identified gaps that could be addressed to enable state DOTs to benefit more effectively from the quality processes for bridge analysis models.

This paper aims to summarize the main findings and refer readers to the relevant references for the complete study details. In addition, commonly misunderstood concepts and processes are clarified.

2. Commonly misunderstood concepts and processes

Quality assurance and quality control are two essential aspects of quality management. While some quality assurance and quality control activities are interrelated, they are defined differently. QA activities and responsibilities cover virtually all of the quality system in one fashion or another, while QC is a subset of the QA activities (American Society for Quality, 2023) (Fig. 1). Elements in the quality system might not be specifically covered by QA/QC activities and responsibilities but may involve QA and QC (Technical Committee ISO/TC 176, 2015).

Verification and validation (V&V) are indispensable components of QA/QC processes in computational modeling of bridge structures. V&V are the processes by which evidence is gathered to determine the accuracy of the computer model for specified conditions. These accuracy results, along with uncertainty quantification, contribute to the determination of the credibility of the model for the conditions of its intended use (ASME V&V 10-2019, 2020).

While the terms verification and validation are often used interchangeably in casual conversations in bridge engineering practice, they have, in fact, quite different meanings. Stated succinctly, verification deals with 'mathematics' while validation deals with 'physics' (Patrick J. Roache, 1998). Verification assesses the numerical accuracy of a computational model regardless of the physics being modeled, while validation assesses the degree to which the computational model is an accurate representation of the physics being modeled (ASME V&V 10-2019, 2020). Verification uses comparison of computational solutions with highly accurate (analytical or numerical) benchmark solutions whereas validation compares the numerical solution with the experimental results. In verification, the relationship of the simulation to the real world is *not* an issue. In validation, the relationship between computation and the real world *is* the issue (Oberkampf, Hirsch, & Trucano, 2003). The relationships between V&V activities involved are schematically presented in Fig. 2 (Kwaśniewski, 2009).

Verification is defined as 'the process of determining that a computational model accurately represents the underlying mathematical model and its solution' (ASME V&V 10-2019, 2020). Verification has also been described as *'solving the equations right'* (Van Hees, 2013). The fundamental strategy of verification is to identify, quantify, and reduce errors in the computational model and its numerical solution (Oberkampf et al., 2003).

Validation is defined as 'the process of determining the degree to which the model is an accurate representation of corresponding physical experiments from the perspective of the intended uses of the model' (ASME V&V 10-2019, 2020). Validation has also been described as *'solving the right equations'* (Van Hees, 2013). The fundamental strategy of validation involves identifying and quantifying errors and uncertainty through comparison of simulation results with experimental data.

At this point, it is useful to define uncertainty and error. *Uncertainty* is a potential deficiency in any phase or activity of the modeling process that is due to the lack of knowledge, while *error* is a recognizable deficiency in any phase or activity of modeling and simulation that is not due to lack of knowledge (AIAAG-077-1998, 2002). The key phrase differentiating the definitions of uncertainty and error is 'lack of knowledge.' The key word in the definition of uncertainty is 'potential,' which indicates that deficiencies may or may not exist. The definition of error implies that the deficiency is identifiable upon examination (Van Hees, 2013).

One approach for determining the level of uncertainty and its effect on an analysis is to perform a sensitivity analysis (AIAAG-077-1998, 2002). *Sensitivity analysis* is the general process of discovering the effects of model input parameters on the response quantities of interest using techniques such as analysis of variance (Mason, Gunst, & Hess, 2003). When performed after the computational model is verified but before it is validated, a sensitivity analysis can provide important insight into the characteristics of that computational model (ASME V&V 10-2019, 2020).

It is also important to define calibration and put it in perspective. One simple definition of *calibration* is to employ explicit tuning or updating of model parameters associated with an engineering code to achieve improved agreement with existing validation experiments (Oberkampf, Trucano, & Hirsch, 2004; Trucano, Swiler, Igusa, Oberkampf, & Pilch, 2006). As another definition, calibration is a procedure where, through repeated calculations with modified input parameters, the engineer tries to find an 'optimal' set of input data which can provide the model's response closest to the actual experimental data (Kwasniewski & Bojanowski, 2015). The process allows the most common sources of modeling (and experimental) difficulties to be represented as simple mechanical models and calibrated so that the global response of the computational model agrees with the experimental results (ASME V&V 10-2019, 2020). Calibration of the model should be performed only after both code verification and calculation verification have been performed (ASME V&V 10-2019, 2020).

Parametric model calibration determines only the model's fitting ability, not its predictive capability. A model calibrated to experimental results may not yield accurate predictions over the range of its intended use. It is possible that, due to superimposing of errors, the engineer can get good correlation between the experimental and numerical results for a wrong model, defined by incorrect input parameters. Such a situation is often detected when the model is used for a different case with changed input conditions. Furthermore, a complex model with only some of the input parameters 'correctly' calibrated should give a response different from the experimental data due to the indeterminacy of other parameters. (Oberkampf et al., 2004).

As another important definition, *a benchmark* is a choice of information that is believed to be accurate or true for use in verification, validation, or calibration. The fundamental purpose of benchmarks is to draw specific conclusions from their comparison with calculations. In the case of verification, this purpose is to assess the mathematical accuracy of numerical solutions. For validation, this purpose is to assess the physical fidelity for a stated application of the mathematical equations solved in the code. For calibration, the purpose is to choose parameter values that improve the agreement of the code calculations with the chosen benchmarks, in the belief that such tuned accuracy improvement will increase the believed credibility of the code – a goal commonly consider to be incorrect. The choice of benchmarks must vary depending on the purpose of the comparisons (Trucano et al., 2006).

3. State of practice in the United States

To collect the most current information, an online survey was distributed to each DOT's voting member in the AASHTO Committee on Bridges and Structures. The survey included 25 questions grouped in three sections: quantities of the bridge design and evaluation projects undertaken; bridge designs completed by consultants; and bridge designs completed in-house by agencies. The survey was completed by 51 DOTs, including 50 states and the District of Columbia, giving an overall response rate of 100%. In addition, specific information was collected from five selected state DOTs—California, Colorado, Iowa, Louisiana, and New York— as case studies to expand on their quality processes related to bridge structural analysis models. The following section presents a summary of the results obtained from the survey and case studies under four headings.

3.1 Quantity of the Bridge Design and Evaluation Projects Undertaken

The survey asked respondents about the total number of bridge engineers employed by their agencies. As shown in Fig. 3, there is a large variation across the nation. The most represented range is 20 to 40 engineers as selected by 17 DOTs (33%) while the least represented range is less than 10 engineers as selected by 5 DOTs (10%).

Fig. 4 compares the responses from two questions related to the percentage of new bridge design and existing bridge analysis work assigned to consultants. The analysis of responses indicates that the average percentage of new bridge and bridge replacement designs assigned to consultants is 59% while the existing bridge analyses, including load ratings, assigned to consultants is 47%. The complete set of questions and results may be found in Guner (2024).

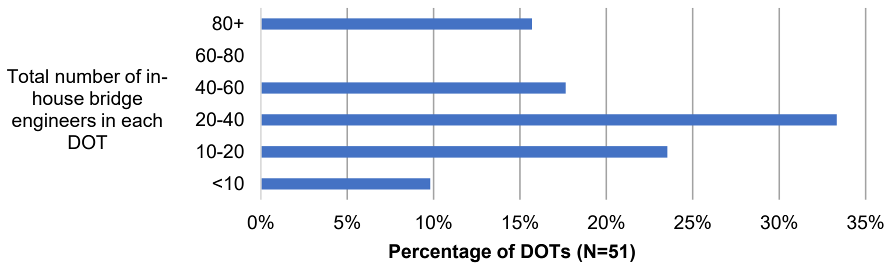

Fig. 3. Number of bridge engineers currently working in each DOT.

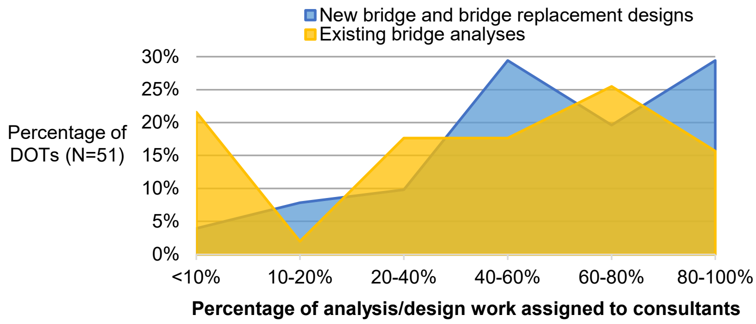

Fig. 4. Comparative DOT responses for new bridge design and existing bridge analysis assigned to consultants.

3.2 Quality processes for the bridge design projects undertaken by consultants

Three questions asked respondents about the presence of processes for certain consultant-related bridge design activities. As shown in Fig. 5, the most common written process, selected by 31 DOTs (61%), is for 'identifying appropriately qualified consultants.' This process also has the least amount of no process responses as only selected by 4 DOTs (8%). The least common written process, selected only by 8 DOTs (16%), is for 'verifying the analysis results obtained from consultants.' 6 DOTs (12%) indicated that this process may be undertaken as defined in the proposal of the consultant.

The respondents were asked how they select appropriately qualified consultants for bridge design projects. They were given three response options. The most common process, as selected by 46 DOTs (90%) is 'proposal evaluation,' while the least common process is 'interview' as selected by 18 DOTs (35%). The geographical distribution of two processes for selecting appropriately qualified consultants is presented in Fig. 6.

The survey asked a follow-up question to 36 respondents whose agencies have pre-qualification requirements, with four response options. As shown in Fig. 7, the most common requirement, selected by 30 DOTs (83%), was "minimum number of similar project experience," while the least common requirement, selected by only five DOTs (14%), was "structural engineer credentials."

The 15 DOTs (29%) which track what methods of analysis are used by their consultants were asked what methods of analysis are used for bridges analyzed by their consultants. As shown in Fig. 8, the most frequently used analysis method is "one-dimensional line girder analysis," while the least frequently used method is "nonlinear finite element method."

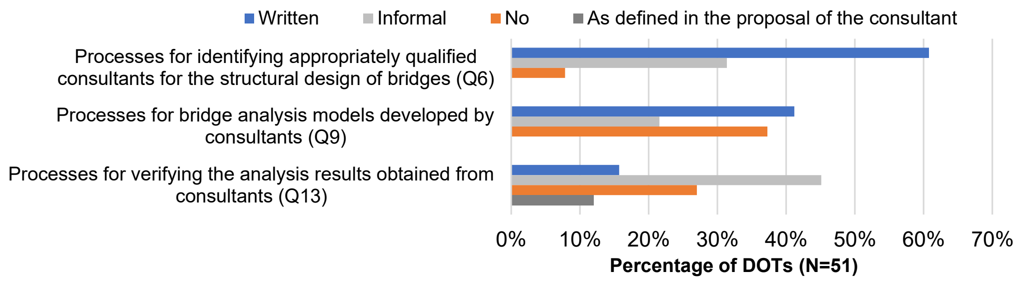

Fig. 5. Comparative DOT responses to three questions on consultant processes.

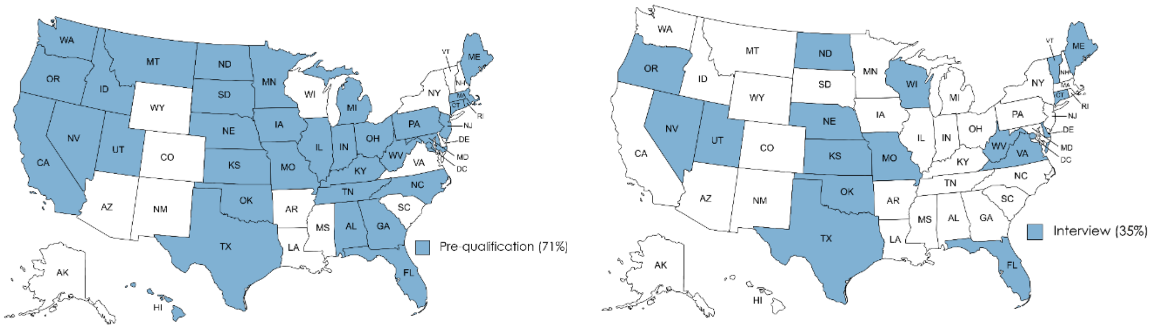

Fig. 6. DOTs with pre-qualification and interview requirements for selecting appropriately qualified consultants.

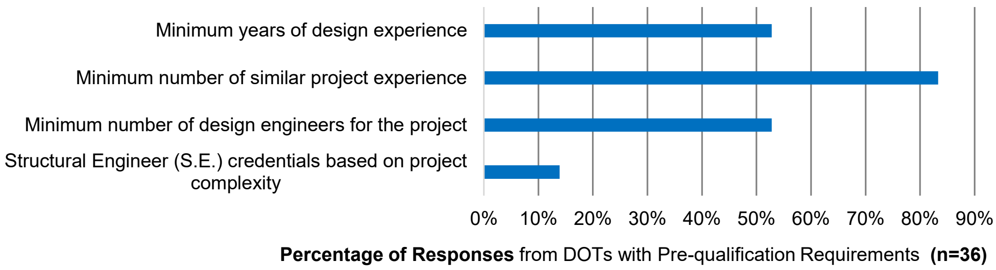

Fig. 7. DOT requirements for the pre-qualification process. Check-all-that-apply type of question.

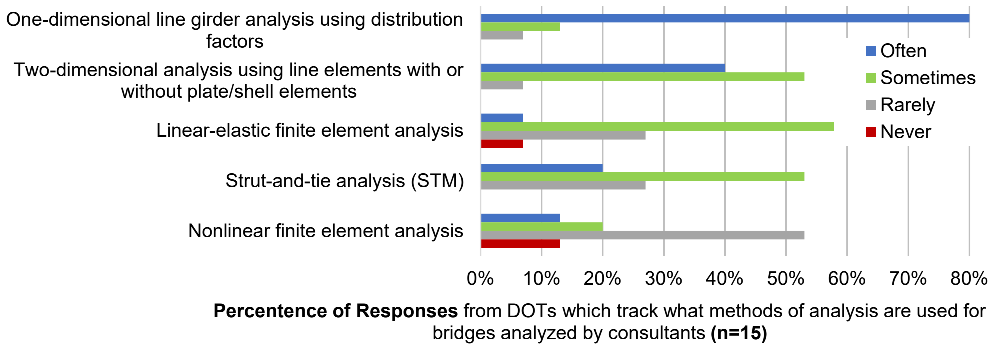

Fig. 8. Methods of analysis used for bridges analyzed by consultants.

3.3 Quantity of the bridge design projects performed in-house by agencies

The respondents were asked six questions on the presence of processes for certain in-house bridge design activities. As shown in Fig. 9, the largest number of DOTs with a written in-house process (for modeling a bridge) is 16 (31%), while the largest number of DOTs with a written consultant process (for identifying appropriately qualified consultants) is 31 (61%).

The respondents were asked what methods of analysis are used for bridges analyzed in-house by their agencies. Fig. 10 compares the percentage of responses from DOTs for the analysis methods used by consultants and DOTs for the "often" frequency. This comparison indicates that consultants use more refined analysis methods.

Fig. 11 shows the responses obtained from 7 DOTs which have written processes for validating the analysis software. The most common response for the "often" frequency, selected by five DOTs (71%), was "analysis engineer decides how to validate." The most common response option for the "sometimes" frequency, selected by four DOTs (57%), was "hiring external consultants."

The respondents were asked whether their agencies have any written or informal processes for verifying in-house analysis results. Fig. 12 shows the responses obtained from 13 DOTs which have written processes for verifying their in-house analysis results. The most common response for the "often" frequency, selected by eight DOTs (62%), was "checking of input variables." "Another team of engineers uses a different method or software" and "analysis engineer decides how to verify" were the other common responses for the "often" frequency.

The respondents were asked whether their agencies have any written or informal processes for reconciling discrepancies between independent models. Fig. 13 shows the responses obtained from eight DOTs that have written processes. The most common response for the "often" frequency was "the same team of engineers works to resolve the discrepancies," selected by five DOTs (63%), followed by "analysis engineers decide how to reconcile," selected by four DOTs (50%). The least common response was "data from field tests and sensor deployment are used," followed by "an external consultant is involved to perform independent checks."

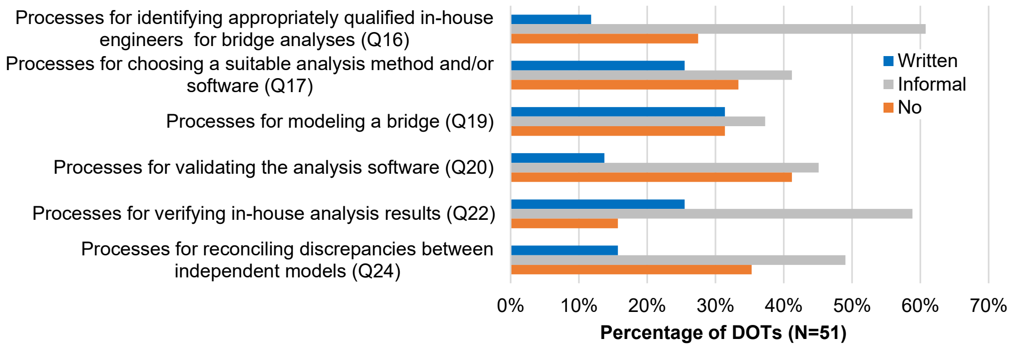

Fig. 9. Comparative DOT responses to six questions on in-house processes.

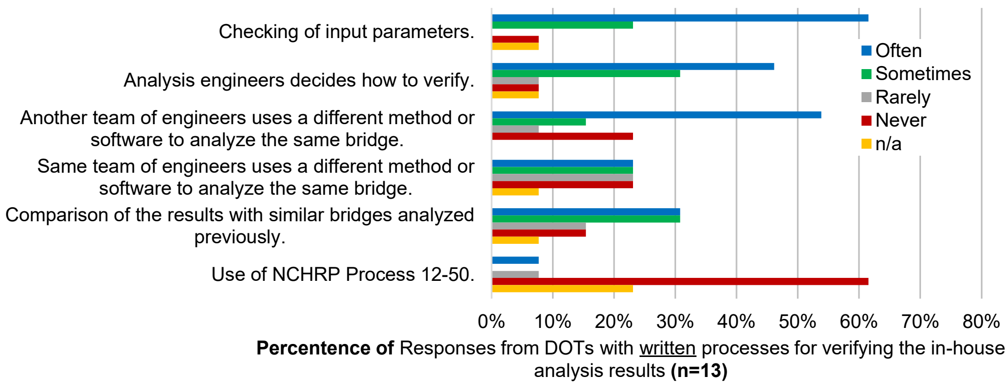

Fig. 12. Methods of verification of in-house analysis results for medium- to high complexity bridges and substructures that require 2D or 3D analysis models (DOTs with written processes).

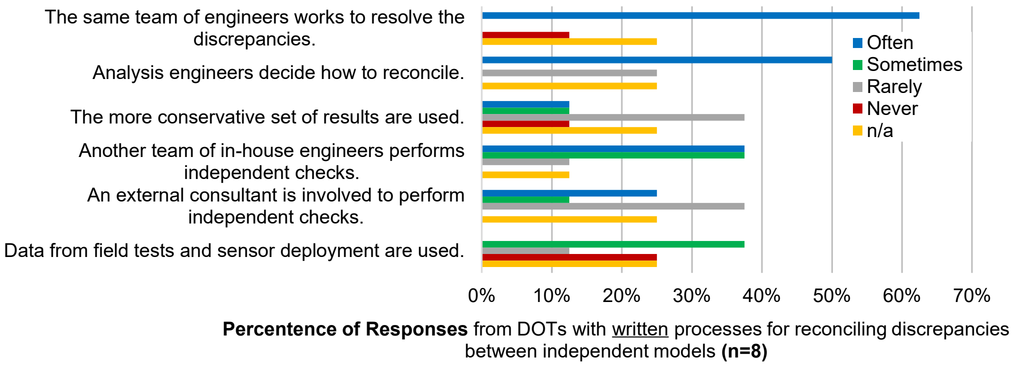

Fig. 13. Methods for reconciling discrepancies between independent models (DOTs with written processes).

3.4 Case examples

Five state DOTs were selected as case examples based on a set of criteria described in Guner (2024). The selected DOTs are as follows: California and Colorado from the West (Pacific and Mountain regions), Louisiana from the South, Iowa from the Midwest, and New York from the Northeast. Some of the findings obtained from these case studies are described below.

The case example agencies use two types of consultant selection processes: project-specific and/or statewide on-call. These agencies require consultants to either submit their QA/QC plans or follow the agency's specific QA/QC plans. As two examples, the Louisiana DOT has a well-defined evaluation and scoring criteria for consultant QA/QC plans while the New York State DOT (NYSDOT) has specific QA/QC plans that the consultants must follow.

All five case example agencies have informal processes that rely on a manager, supervisor, or unit leader to select appropriately qualified engineers based on their experience and availability. This decision also considers professional development needs, including training less experienced engineers or challenging more experienced engineers with unique or interesting projects.

All five case example agencies most frequently use 'one-dimensional line girder analysis.' While all case example agencies rely on the analysis (or design) team to select the most appropriate method(s), NYSDOT provides written guidance on when to use refined analysis methods.

All five case example agencies require a checker to independently verify the accuracy of design engineer's models, calculations, and results. For complex bridges, California DOT (Caltrans) requires project-specific design criteria, a peer review panel, and an independent check conducted by an engineer not associated with the group who has completed the original analysis. Both Caltrans and NYSDOT require the use of different software in the independent check.

To overcome the challenges with finding appropriately qualified engineers in district offices, Caltrans established the seismic and special analysis branch, which is only focused on structural modeling and analysis, while NYSDOT established the Main Office Structures group with sixty-five design staff who only perform structural analysis and final design.

For training engineering staff, Caltrans established a six-week 'bridge design academy' while NYSDOT has a 24-session 'Bridge 101' training series. Iowa DOT indicated the benefits of designer-checker pairing and a dedicated training budget for the professional development of engineering staff.

4. Conclusions

A selection from the major findings are summarized below.

- The majority of DOTs assign more than half (59%) of their new bridge and bridge replacement designs to consultants while they assign almost half (47%) of their existing bridge analyses, including load ratings, to consultants.
- The survey asked three questions on the presence of consultant quality processes. The most common written consultant process, as selected by 61% of DOTs, is 'identifying appropriately qualified consultants,' while the least common written process, selected by only 16% of DOTs, is 'verifying the analysis results obtained from consultants.' The most common 'no process' response, as selected by 37% of DOTs, is the 'bridge analysis models developed by consultants.'
- The survey asked six questions on the presence of in-house quality processes. The most common written in-house process, as selected by 31% of DOTs, is 'modeling a bridge'. The least common written process, as selected by 12% of DOTs, is 'identifying appropriately qualified in-house engineers.' This result is in sharp contrast with the consultant processes where 'identifying appropriately qualified consultants' was the most common written process. The most common 'no process' response, as selected by 41%, is 'validating the analysis software.'

- State DOTs and their consultants most frequently use the 'one-dimensional line girder analysis.' The least frequently used method is the 'nonlinear finite element method.'
- The skills acquired in undergraduate university education may not be sufficient for a competent application of the finite element and strut-and-tie methods and the interpretation of the analysis results obtained from these methods. A qualified training system with standardized requirements could be developed for bridge engineers performing these types of analyses.
- Future research could develop guidance to help state DOTs assess the effectiveness and quality of their QA/QC processes.
- Future research is suggested to develop a nationwide repository for sharing finite element and strut-and-tie models between DOTs.
- Future research could develop guidance and bridge-specific guidance on the development and verification of the finite element and strut-and-tie models.
- New training courses and seminars could be developed to cast light on commonly misunderstood concepts such as verification, validation, uncertainty, error, and calibration, and train bridge engineers on how to effectively perform these activities.

The full details of the studies conducted and the conclusions reached may be found in Guner (2024).

Seismic performance evaluation of monopole billboard regarding connection stiffness

Huseyin K. Celik[*1,2], Gokhan Sakar[2]

[1] *Izmir University of Economics, Department of Civil Engineering, 35330 Izmir, Türkiye*
[2] *Dokuz Eylul University, Department of Civil Engineering, 35390, Izmir, Türkiye*

Abstract. Billboard structures are typically constructed with a single post and a panel installed over the monopole. Due to its nature, it does not have much redundancy. The structural stability mainly depends on the stiffness of the monopole i.e., its connection behaviour significantly affects the structural performance. Furthermore, there is no direct regulation on monopole billboards and it is generally treated as a product rather than a structure. However, many papers have already highlighted the importance of the billboard's structural safety concern, but not much effort has been made about its general design principles. Therefore, to investigate the seismic behaviour of monopole billboard structures, the study is proposed by the authors. An example monopole billboard was taken and static pushover analyses were performed for the flexibility of the post foundation and post panel connection. Base shear and peak displacement were compared. Important conclusions about the behavior of monopole billboard were proposed.

Keywords: Billboard; Monopole; Semi-rigid; Pushover; Sign post

1. Introduction

Billboards are one of most common non-building type of construction. Billboards are generally designed so that highlight an information like advertising or banner. For this purpose, billboards generally constructed with a single pole which will carry a panel where illustrations will be shown around its space. Panel is generally installed at a high level, like top of a monopole. Depending on the maintain and usage condition, billboards are generally subjected lateral (seismic, wind) and vertical (dead load) loads. For construction material, steel is preferred generally due to billboards slender nature (Jones B., 1998). An illustration of structural system is given in Fig. 1.

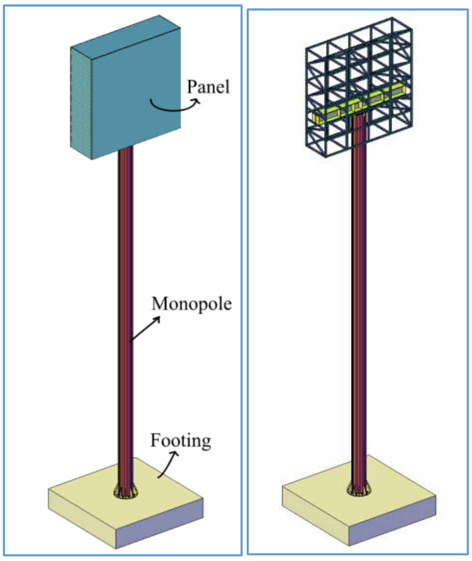

Fig. 1. Illustration of a monopole billboard or signpost and its structural system

https://doi.org/10.31462/icearc2025_ce_sme_608

Being as a monopole construction, billboards have lack of redundancy. Its stiffness solely comes from the stiffness of the pole. Due to this, structural stiffness will be strongly affected by connections. In practice, idealization of connections is assumed as being perfectly rigid or hinged as illustrated in Fig. 2. This assumption states that rigid joint cannot rotate under moment while pinned joints can freely rotate under moments. However, in reality, most of the connections behaves like semi-rigid joints, which is fall into two ideal states. Due to this, connection will behave with an initial stiffness rather than totally rigid and hence, it can result decrease in structural stiffness. Same is valid for panel connection too. Panel is carried by monopole and its stiffness is strongly affected by connection behavior (Celik and Sakar, 2022).

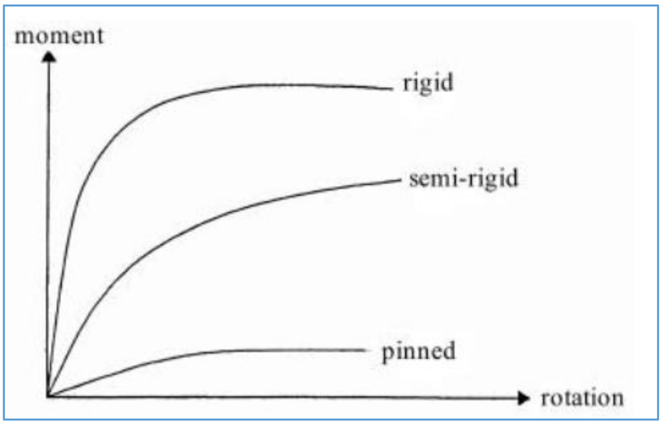

Fig. 2. Typical moment-rotation relationship of connections

Within this scope, design perspectives of monopole billboard regarding seismic actions should be examined. According to Turkish Building Seismic Design Code (2018), a building should have enough stiffness, ductility and robustness. Even if billboards differ from buildings, it's still valid for structural safety. On the other hand, there is no direct reference for design billboards.

Current seismic design regulation has some criteria to satisfy seismic safety of the building. With respect to limit state design; section of structural elements, story drifts, base shear etc. are regulated for a demand ductility. However, there is a few regulations can be highlighted in this scope. For example, Minimum Design Loads for Building and Other Structures (ASCE 7, 2022) has a mention about monopoles and its ductile demands is relatively low comparing building type construction. Due to lack of redundancy, after failing a component of structural system will lead sudden collapse of the system. Similar to this outcome, many example of sudden collapse is reported around the world, based on vulnerability of lateral loads

Current literature showed many reasons for failure of a signpost. In brief; corrosion, overloading due to wind and seismic excitation, inadequate structural detailing, accidental loads like car crash etc. leads to global collapse of a billboard. Beside the reason of it, failure mechanism in collapses is failure of base plate or foundation and buckling of the pile at base region (Herrera et al., 1995; Hosseini, 2005; Sha and Malinov, 2014; Carabollo and Ernesto, 2018; Wen and Xie, 2020).

Many studies showed that base connection is the most vulnerable component of a signpost. However, there is limited study exist about the connection behavior and impact of it on the sign post. Hence, this study presented by the authors to investigate seismic performance of monopole sign post under the effects of connection flexbility. An example sign post structure was taken and nonlinear static analysis was performed, with respect to rigid assumption and semi-rigid behavior. Base shear and peak displacement were compared and important conclusions were made.

2. Material and method

The model of the present study is given in Fig. 3. The signpost consists of a pole and panel. For the pole, circular hollow section (CHS406.4x12) was chosen. For panel truss, square hollow section (SHS40x4) was chosen. For all materials, S235 steel was selected. As joint, bolted connections were selected. For base joint, circular base plate with stiffeners were taken. For panel, a HEA300 beam was placed on the pole and connected with a plate with stiffeners. Panel components were assumed to be welded. So, only bolted connection was used in base and panel to pole joints. In total, panel height is 14 m while panel size was 3x3 m.

For global analyses, SAP2000 (2025) were used. SAP2000, a well-known structural analysis software which able to perform static and dynamic analysis of structure with regarding material and geometrical nonlinearities. However, analysis of connection is required to determine flexibilities of the connection. For this purpose, Idea Statica (2025) were used. Idea Statica is another software used in steel construction. Main purpose of the software is designing connection. The software is able to perform advanced analysis and it uses finite element method

(FEM) for modelling. The software can classify connection behavior according to Eurocode 3 (1993) or United States regulations (ASCE-AISC, 2022).

To model signpost, frame element was used. For modelling semi-rigid behavior of connection, several methods can be used. In this study, rotational sprigs were chosen. Even if the whole behavior of connection is nonlinear, only the initial stiffness was taken into account for the sake of calculation. Finally, signpost was pushed at center of the panel up to failure, with rigid assumption and semi-rigid behavior.

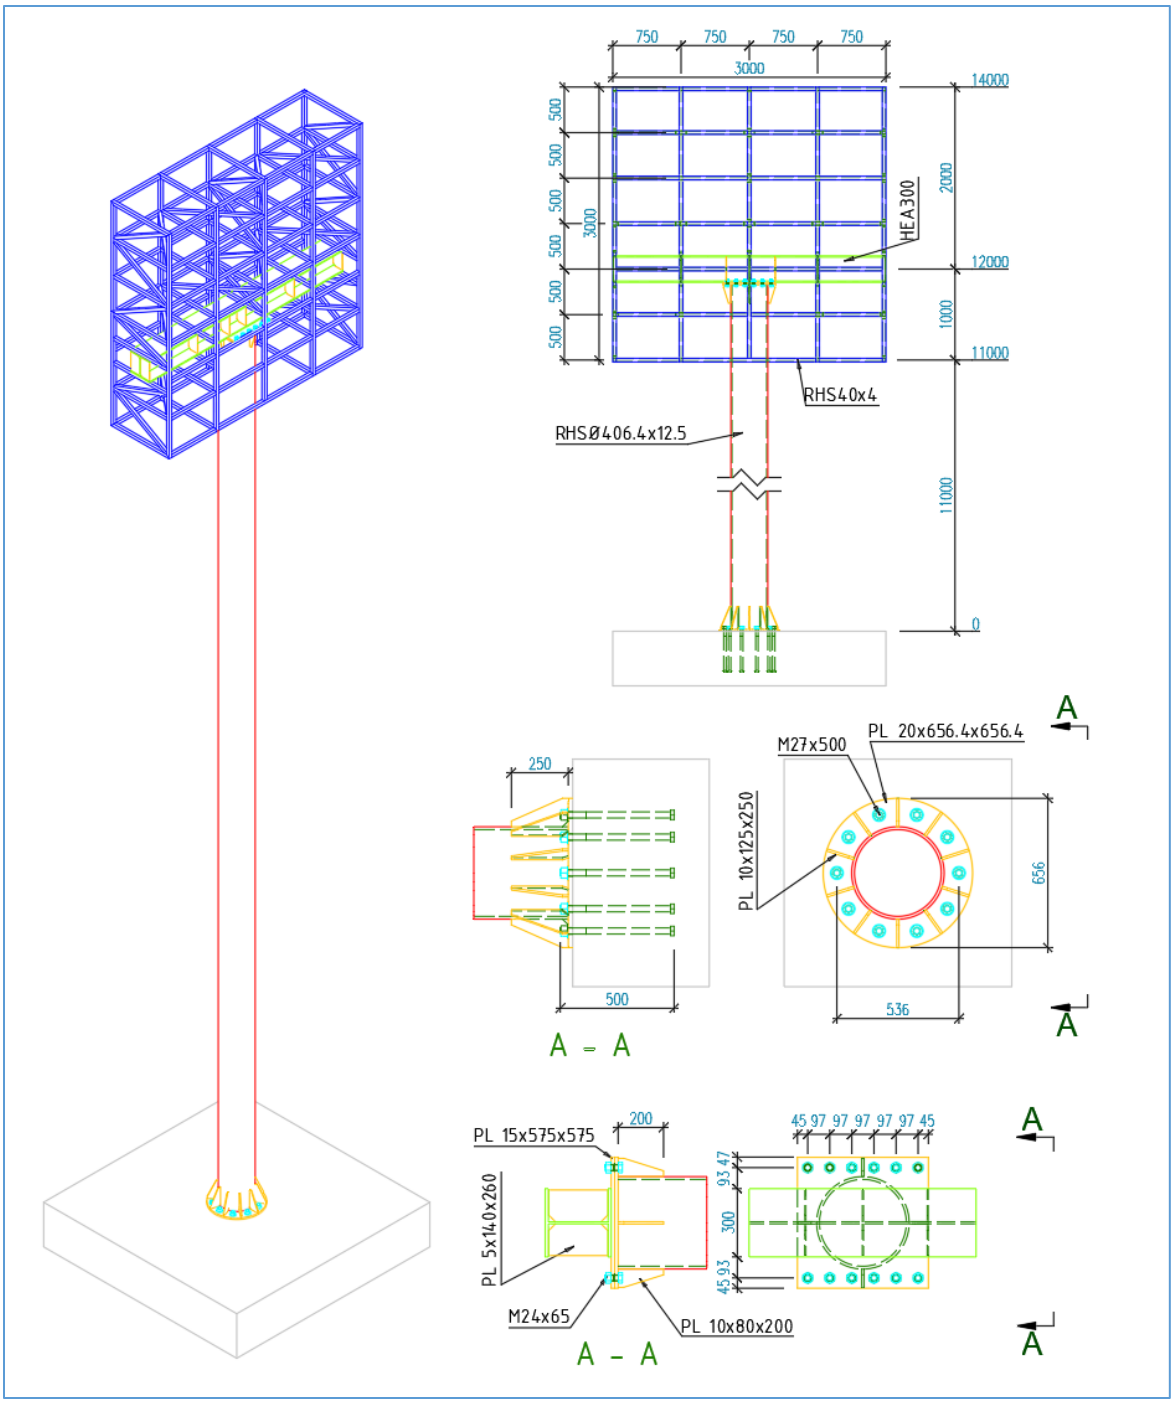

Fig. 3. Detail of the billboard

3. Analysis results

FEM analyses of two connection details showed that they fall into semi-rigid behavior, according to their initial stiffness. And, 140000 kNm/rad and 7000 kNm/rad of connection stiffness were found for base plate and seated connection, respectively. FEM models were given in Fig. 4. Moment-rotation curves of the connections were given in Fig. 5.

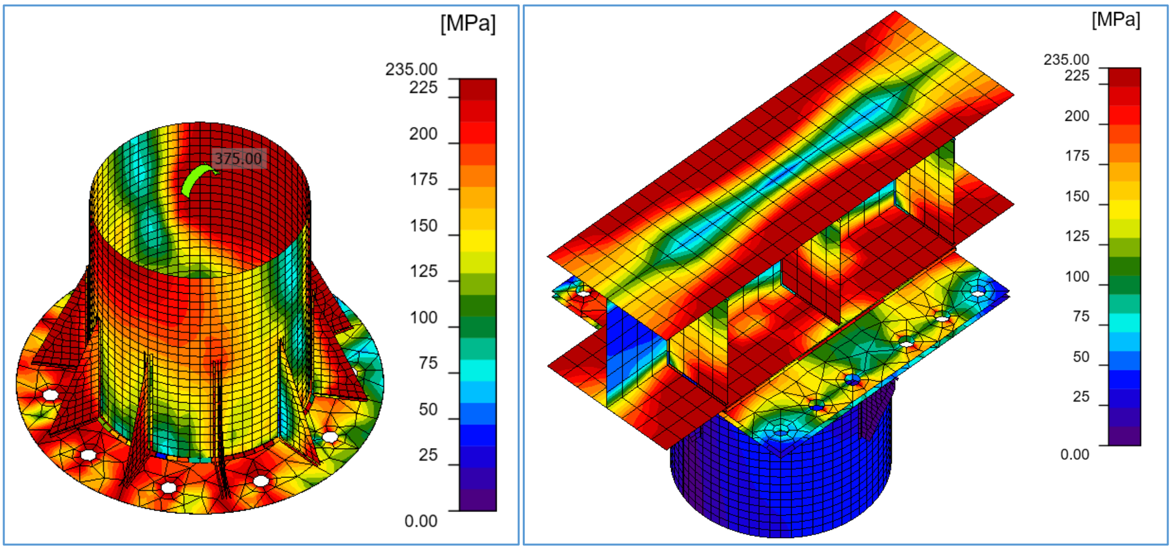

Fig. 4. FEM results of connection details

Analyses were performed in two steps. First, connections were assumed to rigid and pushover curve obtained. Then initial stiffness of the connections was adopted and second curve was obtained. Analysis model are given in Fig. 6. And, pushover curves are given in Fig 7.

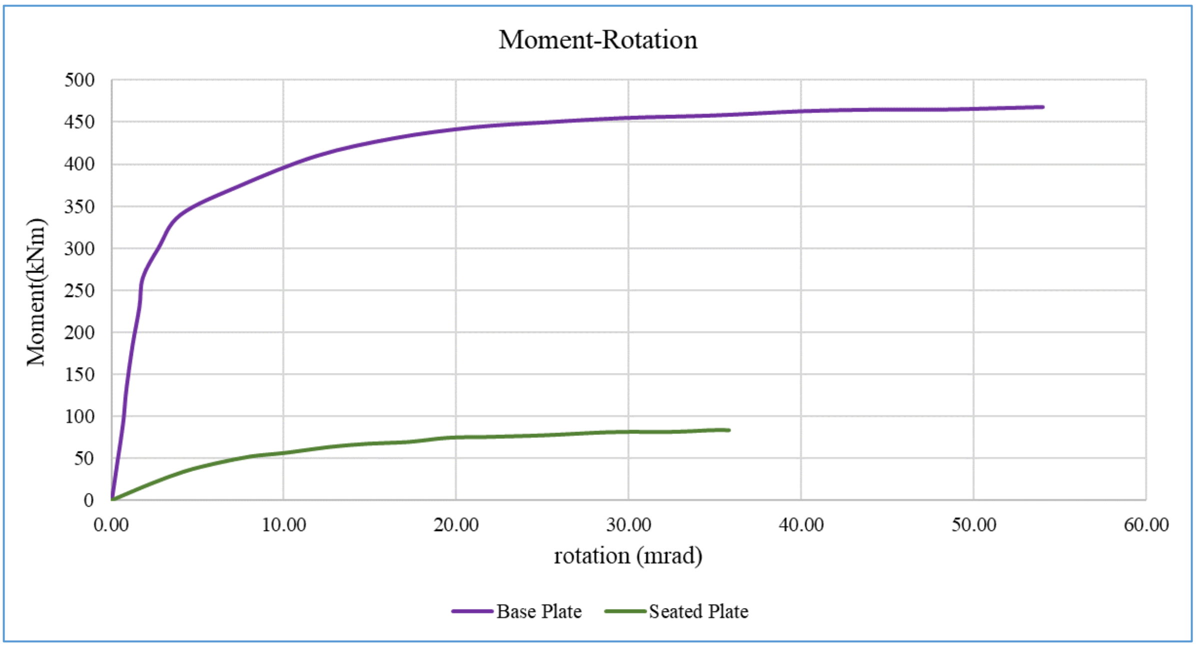

Fig. 5. Moment-rotation curves of connections

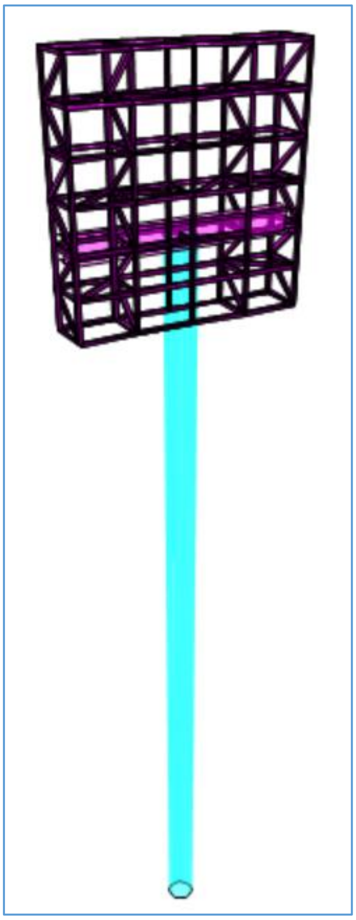

Fig. 6. Analysis model

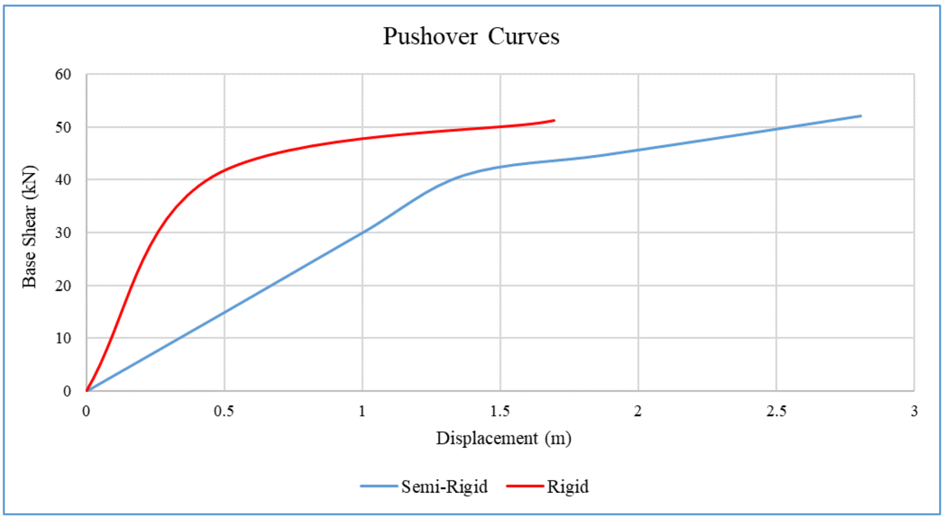

Fig. 7. Pushover curves of rigid and semi-rigid models

According to study result, base plate was found stiffer than seated joint, similar to previous studies (Celik and Sakar, 2024). For rigid assumption, signpost went strong drift after the plastic hinge formed at the bottom of the pole. After the signpost reached 10% story drift, it lost load bearing ability. For semi-rigid analysis, lateral stiffness of the pole decreased strongly due to flexible joint. Thus, drift ratio was increased under the same base shear. In contrast to this, both of the analyses went yielding at the same base shear. In both analyses, plastic hinge formed at the bottom of the pole. However, drift was affected by seated joint stiffness, rather than base shear. As a result of it, peak displacement was found higher than rigid assumption, even if the base shear was same for the both analyses.

4. Conclusions

In this study, seismic performance of monopole signpost was examined. A signpost detailed and then nonlinear static analyses were performed (pushover), with regarding connection stiffness. Models were created with frame elements while connection flexibilities were taken as rotational springs at the end of the frame. In brief:

- Connection stiffness has a strong impact on the stiffness of the structure.
- Rigid assumption may not valid; in other word, stiffness of the connection may differ from the assumption.
- Since the signposts are lack of redundancy, lateral stiffness of the monopole showed major impact of the pushover curves.
- In every case, plastic hinge was formed at the bottom of the pole. However, base shear at yielding didn't change. Further, connection stiffness mostly affects displacement of the structure.
- Semi-rigid connection reached higher displacement at same base shear; however, it should not be evaluated as higher ductility since stiffness of the pole is decreased.
- Even if the hinge formed at the bottom, seated joint stiffness mostly affect the behavior.
- Seated joint showed semi-rigid behavior at pinned limit, (similar to previous studies of the authors (Sakar and Celik, 2024).
- Connection stiffness should be taken into account in place of rigid assumption, especially for seated connection.

As a general outcome, several point should be highlighted for the design of the signpost:

- Base connection should be designed to bear plastic rotation of the pole under seismic demand.
- Flexibility of seated joint should be limited to satisfy drift ratio, since it contributes lateral displacements significantly.
- Drift limit and ductile demand may change for the place of construction. If human activities is dense at construction zone, harder limit may be taken into account for ductile design.
- Since stiffness of pole and panel is very different, stability of the panel throughout the loading should be covered with ensuring plastic rotation capacities of the seated joint.

Like stated previously, current design codes have lack of information about the design of signpost which is very slender and vulnerable for lateral loading. Thus, may be local regulation should be improvement especially region for high wind speed and high seismic hazard. Rather than an advertising product, signpost should be treated as an engineering structure.

Abstract. In this study, the analysis of the continuous contact problem of a functionally graded material is carried out by the finite element method (FEM). The problem consists of a functionally graded plate resting between two semi-infinite elastic planes and loaded by two elastic blocks. The external loads P and Q are transmitted to the plate by means of two elastic blocks. It is assumed that there is no friction on the surfaces. The finite element model of the functionally graded plate is created using the ANSYS package program and the two-dimensional analysis of the problem is carried out.

Keywords: Functionally graded material; Stress analysis; Contact pressure; Finite element method; Homogenous layer

1. Introduction

Most mechanical systems and structures have elements that rub against each other, that is, in contact. This creates the contact problem. The term contact problem examines changes in structural behavior and mechanical properties due to friction and wear within the elements. In particular, structural elements and mechanical systems often come into contact with friction. Contact problems are widely used in various areas of engineering today. Examples include foundations, railways, grain elevators, fuel tanks, cylindrical shafts and shafts. With the development of technology, a non-homogeneous, gradual or continuously changing structure is required in the materials used to meet the needs of new types of systems and elements.

The lack of a material that provides high strength and thermal resistance, especially for space vehicles, has led scientists to new research. As a result of these studies, functionally graded materials have emerged that reduce thermal stresses caused by different thermal expansion coefficients between two substances that have different physical and chemical properties and minimize the disadvantages that may arise due to physical and chemical changes between the two substances. These materials are used in space, defense, medicine, electronics, energy and many other industries. They are widely preferred due to their high thermal resistance and durability. Functionally graded materials (FGMs) are a special class of dissimilar materials whose mechanical properties vary continuously from one point to another. FGM structures, made from two materials mixed in specific volume ratios, provide a solution for situations where composite materials cannot technically react.

These materials offer additional functionality in addition to the properties of traditional materials and are often the product of advanced technologies. The historical process of functionally graded materials began with people's interest in developing and customizing materials according to their functions. Even in the early periods of human history, the selection and processing of materials for specific purposes was a common practice. However, the development and use of modern functional materials emerged with more advanced science, technology and engineering developments. The World War II era was a major turning point for the development of functionally graded materials. During the war, the demand for special materials for military applications increased. For example, research and production of materials such as microwave absorber materials for the development of radar systems and special alloys for nuclear energy applications accelerated. In the early 20th century, research on understanding and controlling the physical, chemical and mechanical properties of materials accelerated. During this period, it was discovered that some metal alloys had special properties and began to be used for industrial applications. For example, nickel-based superalloys were used in areas such as aircraft engines due to their resistance to high temperatures and pressures. In recent years, the use of functionally graded materials has become more widespread, with factors such as sustainability and energy efficiency coming to the forefront. It is often used

[*]Corresponding author, E-mail: alperpolat@munzur.edu.tr

in fields such as civil engineering to increase the durability of materials, optimize energy efficiency and reduce environmental impact.

Today, thanks to advanced research and production methods, the use of functionally graded materials is rapidly increasing. Advances in materials science and engineering have made it possible to design and produce materials with previously unimaginable properties and functions. This increases the potential for more innovative and sustainable solutions in civil engineering and other industries. The use of these materials ensures the longevity of structures and is an important tool in the construction industry to build safer, more efficient and more environmentally friendly structures. Hertz's 1882 work, which inspired many researchers, is known to be the foundation of the field of contact problems (Johnson, 1985). Weitsman performed contact analysis on the elastic plate and elastic plane to investigate the distance of the contact area formed between the elastic plate and the sheet (Weitsman, 1969). Conway investigated the frictional contact analysis of the plate loaded with cylinder blocks. In his study, he investigated the effect of friction on the contact stress and found that this effect was very small (Conway, 1971). Erdoğan and Ratwani, İn their study performed the contact analysis of the elastic layer resting on the double elastic layer. Using the analytical method, they showed that the contact area does not change with the effect of the load but depends on the distance of the load.

Taking into account different load cases, the problem was reduced to a generalized Cauchy singular integral equation and presented the numerical results (Erdogan & Ratwani, 1974). Adams investigated the contact analysis of an elastic layer under a single load, lying on an elastic semi-infinite plane and showing a constant inclination. He observed the effect of different material changes by examining the complex problem in his work according to the Fredholm integral method (Adams, 1978). In their work, Keer and Miller investigated the contact problem of curved blocks and circular plates placed on simple or indented supports at the edges (Keer & Miller, 1983). Adams and Zeid investigated the effect of a fixed elastic block on an elastic plane. In their study, the stress distribution, sliding velocities and friction coefficients along the contact surface for various material combinations were discussed using the theory of elasticity (Adams & Zeid, 1984). Geçit and Gökpınar examined the contact analysis of an elastic plate with a rigid circular block. They did not take friction into account in the contact areas, and only the compressive stress was transmitted. With a uniformly acting force, the stress distributions in the contact area for blocks of different geometries and the contact distances were investigated (Gökpınar & Geçit, 1985). Nowell and Hills investigated the frictional and frictionless analysis of elastic plates that are acted upon by cylinder blocks. In the analysis part of the study, contact stresses were analyzed with a hybrid method (Nowell & Hills, 1988). Sabin and Kaloni in their study, solved the contact problem of a rigid body rotating about a vertical axis in an elastic half-plane using the theory of elasticity by including friction (Sabin and Kaloni, 1989).

Dempsey et al. in their study, investigated the contact analysis of elastic, homogeneous and isotropic layers based on the Winkler basis. In their study, the load was applied to both the rigid block and the cylinder and the results were observed (Dempsey et al., 1990). Wozniak et al. solved the symmetrically generated contact analysis loaded by spheres or cylinders. It was assumed that this layer was filled with material properties whose structure changed under the influence. This material was modeled in the Winkler environment and the Hankel integral transform technique was used in the solution (Wóniak et al., 2002). Rekik et al. analyzed the cracking effect in a functionally graded layer connected to a homogeneous semi-infinite plane by analytical method. In this analysis, cracks were also examined by finite element method and the data were compared with analytical solutions (Rekik et al., 2010).

Ellumi and his colleagues observed the contact situation between the half-layer, whose material properties varied from place to place, and the arbitrarily shaped block under vertical loading. It was stated that the graded medium observed in this analysis was materials with different properties, which belonged to constant Poisson ratios with shear modulus varying depending on a certain function (Elloumi et al., 2010). Kaman and Cetisli investigated the crack analysis in a cylinder coated with functional grade materials. In the analysis, the tensile strength was investigated for the crack length with different values of radii with different materials by processing in the Ansys program (Kaman & Çetişli, 2011). Abhilash and Murthy analyzed the contact of a semi-infinite plane covered by a functionally classified material and loaded with a block using the finite element method. Initially, the blocks were assumed to be rigid and the results were verified using solutions available in the literature. Then, the analysis was performed by including the blocks in the process where they were elastic (Abhilash & Murthy, 2014). Adıyaman et al. performed the separation contact analysis for a block resting on a double quadrant plane and an elastic layer loaded with a distributed load using analytical and finite element methods. For both solutions, contact lengths and contact pressures were examined for different load conditions and dimensionless quantities. In the research results, it was observed that the data obtained with the finite element method were consistent with the analytical results (Adiyaman et al., 2015). Kulchytsky et al. studied the contact analysis of a half-plane loaded with a functionally graded coating loaded with a distributed load.

As a result of the study, they observed that the Poisson value of the functionally graded coating did not change, while the shear modulus changed proportionally with the height (Kulchytsky-Zhyhailo & Bajkowski, 2015). Adıyaman et al. investigated the separation contact problem between a functionally graded layer and two homogeneous quarter planes in their study. They investigated the effect of material inhomogeneity parameter on the contact pressure and separation contact length (Adıyaman et al., 2016). Öner, in his study, analytically performed continuous and discontinuous contact analysis in functionally graded pavement loaded with a rigid punch and seated on an elastic half-layer. Two different solutions were made as rigid block circular and flat. In the study, contact stresses, normal stresses and shear stresses occurring under the punch in case of continuous contact, first separation loads and first separation distances occurred between functionally graded pavement and elastic half-layer were obtained. He stated that contact stresses decreased in case of flat punch as the punch width increased, in case of circular punch as the punch radius increased, the half-contact length between the functionally graded layer and the punch increased, and the half-contact length decreased as the load ratio increased. He also observed that as the rigidity parameter (βh) value increased in case of circular punch, the contact distance between the FG layer and the punch increased, and as the ratio of the rigidity of the lower surface of the FG layer to the rigidity of the elastic half-layer increased, the half-contact length increased (Öner et al., 2022) . Polat et al. analyzed the continuous contact condition in functionally graded coating using the finite element method. The data obtained in the case where the material properties do not change from one point to another were compared with the observed data in the case where the effect of the parameters that cause the properties of the material in the functionally graded coating to change from one point to another did not change at all.

In addition, the interaction of different Poisson values in the functionally graded coating was observed in the analysis (Polat et al., 2018). In their study, Demirbaş and Çakır obtained trained models using Artificial Neural Network to determine the equivalent stress levels of one-dimensional functionally graded rectangular plates. They obtained results close to the real values with 99% efficiency of the equivalent stress prediction value in the plates and the minimum number of cycles (Demirbaş & Çakır, 2019). In his study, Polat solved the continuous and discontinuous contact situation in the functionally graded layer where the load is transferred by rigid blocks on the elastic semi-infinite plane in two ways, namely the finite element method and analytically. He examined the effect of different stiffness and density parameters of the FD layer on the distances between the blocks, different geometries of the blocks and under different loads, and compared the values found with the analytical method with the results obtained with the finite element method (Polat, 2019).

Polat et al. investigated the contact problem for a partially functionally graded layer using the finite element method. The analysis for the partial FGM layer was compared with the fully FGM layer analysis in figures and tables, and as a result, they predicted that partial FGM could be used for static problems and could have practical applications in the industry (Polat et al., 2019). Balci and Dağ performed a moving contact analysis involving functionally graded coating where loads are transferred by means of a rigid punch. They analyzed the effects of punch speed, friction coefficient, material inhomogeneity and coating thickness on contact stress distributions and stress intensity factors (Balci & Dag, 2020).

Karabulut and Çömez analyzed the contact problem in an orthotropic functionally graded layer loaded with a rigid punch using analytical and finite element methods. They observed that the separation zone increased when the load and inhomogeneity parameters increased (Karabulut & Çömez, 2023). Kaya and Polat performed the contact analysis of the functionally graded layer resting on two elastic layers using the finite element method. In the study, the effects of external load, stiffness parameter (βh), density parameter (γh) and distributed load change on the resulting stresses were investigated. They observed that when the stiffness increased, the resulting stress values increased but the contact lengths decreased. They also examined that when the radius increased, the stresses formed in the edge region of the punches increased but the stresses formed in the middle region of the punches decreased (Kaya & Polat, 2023)

2. Definition of the problem

Material properties of functionally graded layer;

$$\mu_2(y) = \mu_0 e^{\beta y},\ \rho_2(y) = \rho_0 e^{\gamma y},\ v_2(y) = v_0 e^{\alpha y} \tag{1}$$

μ is the shear modulus, ρ is the density and v is the Poisson's ratio.

The layer extends in the range (-∞, +∞). In this system, the blocks are assumed to be elastic and the contact stresses transfer only compressive stresses. Therefore, when the critical load is exceeded, separation occurs between the elastic layers and the (FG) plane. In the problem, all surfaces are assumed to be frictionless and the thickness in the z-axis direction is uniform. The geometry of the problem is shown in Fig. 1.

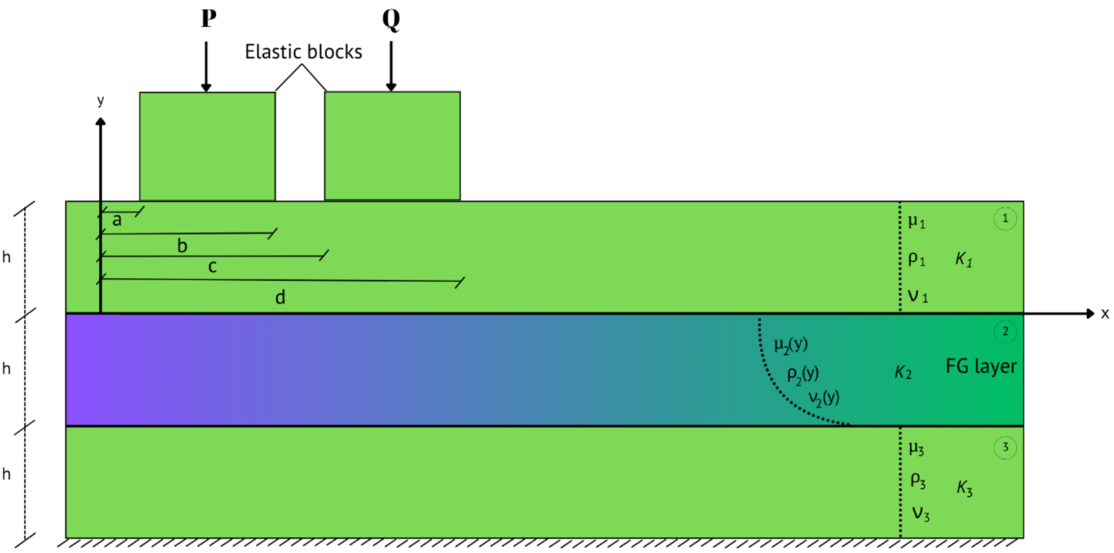

Fig. 1 Geometry of problems

2.1. Analysis with finite element method

The Finite Element Method, to put it briefly, is to solve a complex problem by simplifying it. The finite element method analyzes the behavior of each element by dividing a structure into small pieces (elements) and analyzes the entire structure by modeling it by combining the results. Thanks to this method, the behavior of complex structures can be calculated more easily and accurately. In the mesh process, instead of analyzing the problem as a single piece and as a whole, a large number of small pieces are created and a more precise solution is made with these pieces, and the problem is analyzed in more detail and with high accuracy. While the large number of these small pieces provides benefits for more accurate results in the analysis, it is a disadvantage in terms of time as it increases the solution time of the problem. The use of Finite Element Model-based computer programs has become quite widespread today.

The finite element model and analysis of this solvable problem includes the ANSYS (2019) package program. All operations related to blocks and homogeneous planes were done with standard ANSYS menus. The material storage and finite element division process of the FG layer was done with a program-specific macro. With the development, the code starts by defining the problem code such as geometry and material properties with the *set command. Depending on the simple geometry of the problem, a two-dimensional (2D) aeronautical geometric model is used for FG sheet and homogeneous elastic wings and is divided into sections with RECTNG cuts. The material properties of homogeneous elastic semi-infinite planes and blocks are selected as linear, elastic-isotropic. Defining the element type is important in terms to obtain correct results in solving the problem. In this study, 8-node PLANE183 was used as the element type for static and 2-dimensional flight problems. Each node of this element has degrees of freedom in x and y accuracy. This element has no rotational freedom. This element has no rotational freedom. ANSYS models of the problem are given in Figs. 2, 3, 4 and 5.

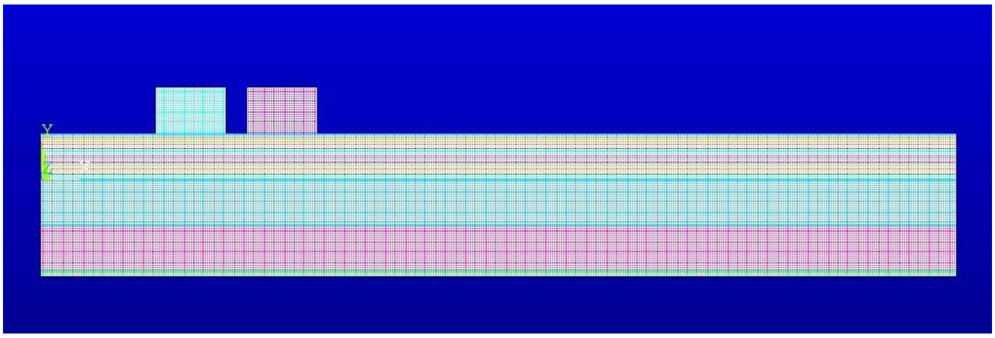

Fig. 2. Finite element model of the problem loaded with blocks

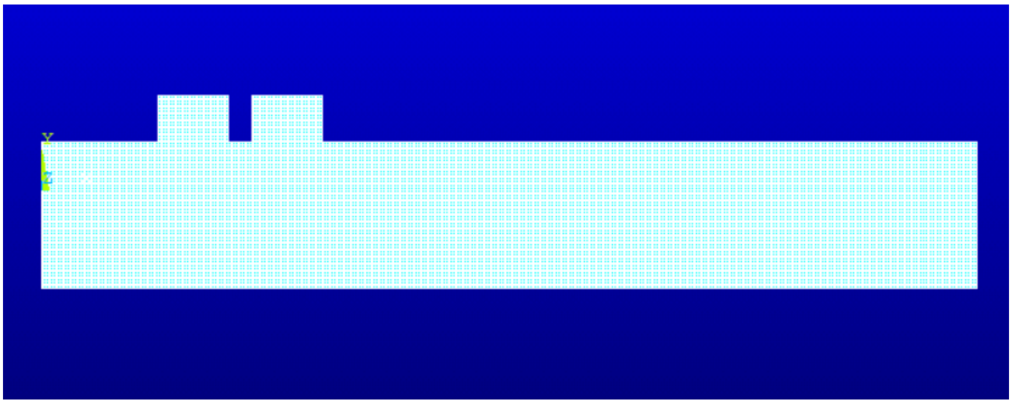

Fig. 3. Assignment of material of the problem loaded with blocks

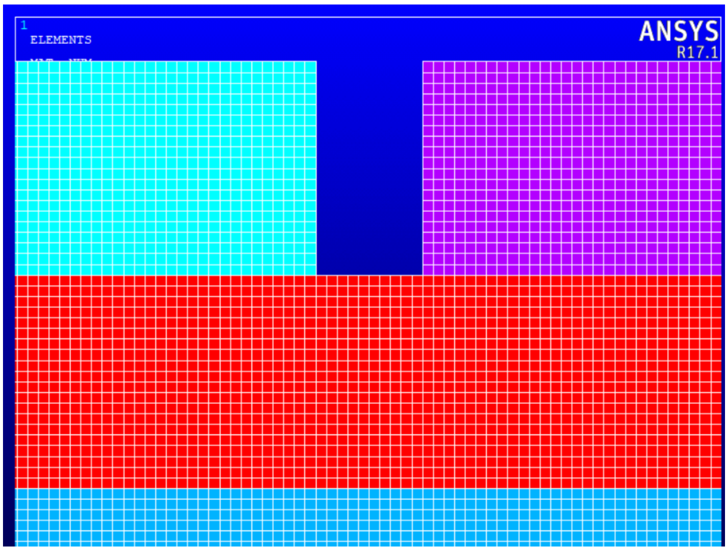

Fig. 4. Free quadrilateral mesh

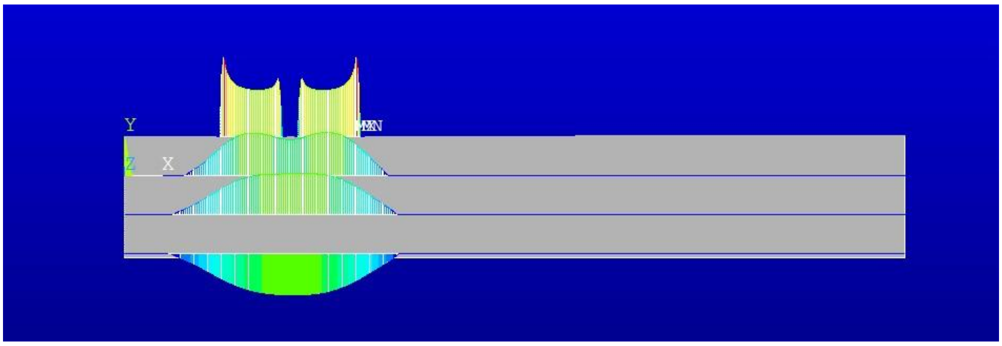

Fig. 5. ANSYS display of the status in contact with continuous contact

At this stage the recorded material is selected according to the program where only the layers graded in the factory and macro are changed exponentially to create the network.The macro used to program the material properties according to exponential change is as follows.

```
!!Material Top
*set, E_t, 100000
*set, nu_t, 0.25
*set,dens_t,1
*set,B,1.3864
*set,A,0.00001
*set,G,-0.6931
*create, mat_fgm_pol                                                    (2)
/nopr
y_coord = arg1
E_fgm=E_t*EXP(B*y_coord) !!B=Beta
nu_fgm=nu_t*EXP(A*y_coord) !!A=Alfa
den_fgm=dens_t*EXP(G*y_coord) !!G=Gama
/gopr
*end !mat_fgm_pol
```

In formula, the *create command is used to create a macro for the layer consisting of functionally graded material and sets a variable named y_coord = arg1

The mesh section has been moved on to. An additional macro has been added for meshing the FG layer. All geometry has been subjected to the Free Quadrilateral Mesh, more frequently in contact areas. The macron for meshing the FG layer is as follows.

```
*do, j, 1, ele_numb_y, 1
y_coord = length_e_y*(j)
*use, mat_fgm_pol,y_coord
mp, ex, cntr,E_fgm
mp, prxy, cntr,nu_fgm                                                   (3)
mp, dens, cntr,den_fgm
esel,r,cent,x,0,lngt_lyr
emodif, all, mat, counter
esel, all
```

In addition, surface to surface contact pairs are defined between the block-layer and layer-elastic plane. These pairs are divided into two as contact and target elements. The contact is selected as CONTA172, and the target is selected as TARGE169 elements. It would be appropriate to select more rigid elements than the contact element as the target element. In addition, while selecting the formulation to be used in the contact region, the mathematical method that will provide the appropriate contact conditions is also decided. There are various contact algorithms in ANSYS depending on the problem type. The Augmented Lagrangian Method, which provides fast results using the total potential energy theorem, was preferred as the contact algorithm.

3. Results and discussion

It was observed that the increase in the distance between the blocks (c-b) led to a decrease in the contact stress between the FG layer and the upper homogeneous layer.The results are presented in Fig. 6.

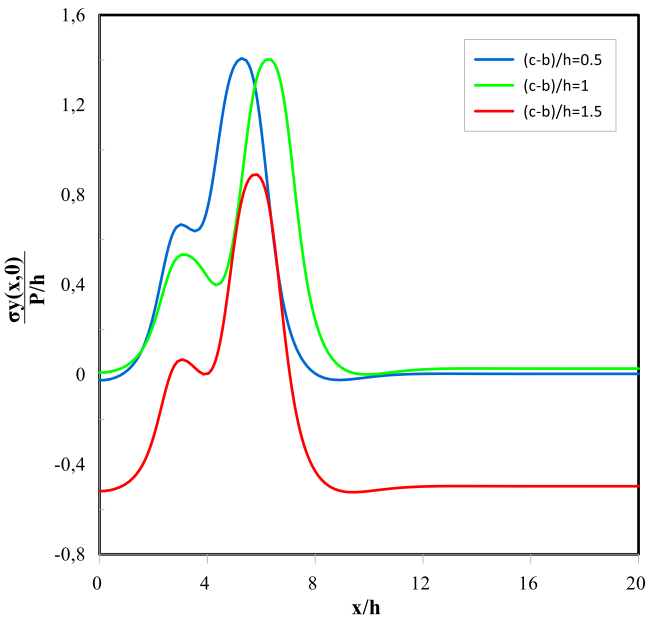

Fig. 6. Contact stress distributions between the FG layer and the upper homogeneous layer, depending on the distance between the blocks (a/h=2.5, μ0=1, K_1=K_2=2, y=h, h=1, μ-h=*1*)

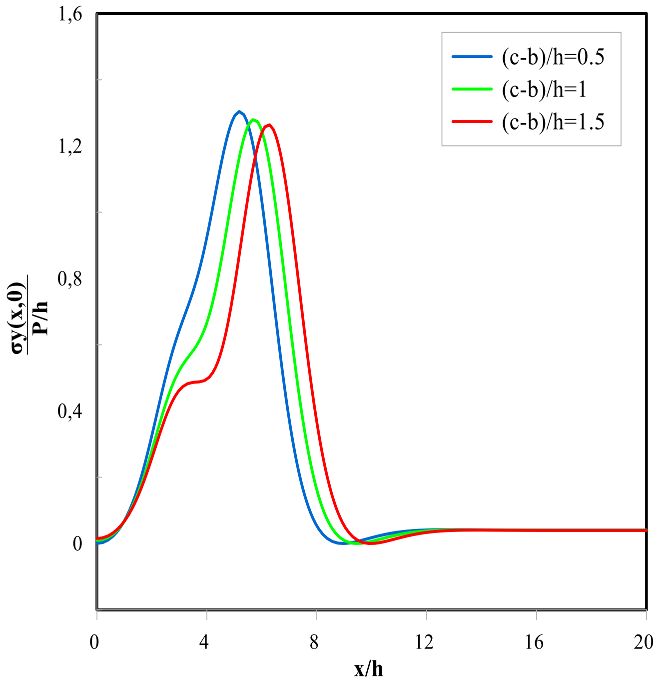

Fig. 7. Contact stress distributions between the FG layer and the under homogeneous layer, depending on the distance between the blocks (a/h=2.5, μ0=1, K_2= K_3=2, y=h, h=1, μ-h=1)

It was observed that the increase in the distance between the blocks (c-b) led to a decrease in the contact stress between the FG layer and the under homogeneous layer.The results are presented in Fig. 7.

The results showed that the increase in the load (Q) applied to the block caused an increase in the contact stress between the FG layer and the upper homogeneous layer.The results are presented in Fig. 8.

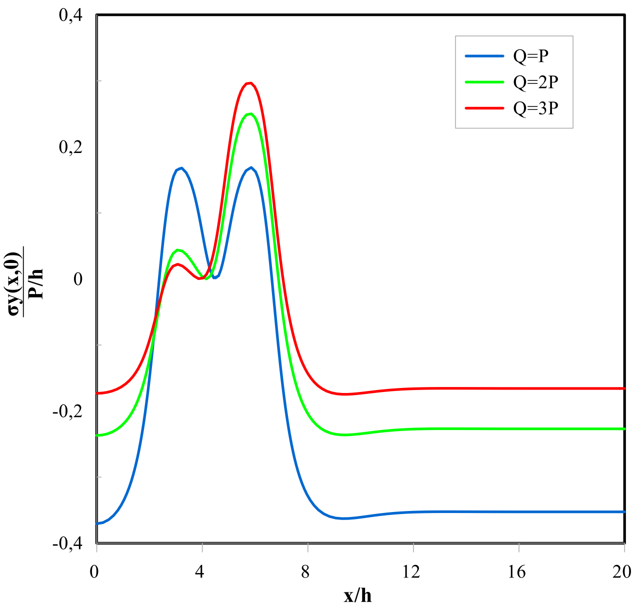

Fig. 8. Contact stress distributions between the FG layer and the upper homogeneous layer, according to the load (Q) change (a/h=2.5, (b-a)/h=1.5 μ0=1, $\kappa_1 = \kappa_2 = 2$, y=h, h=1, μ-h=1)

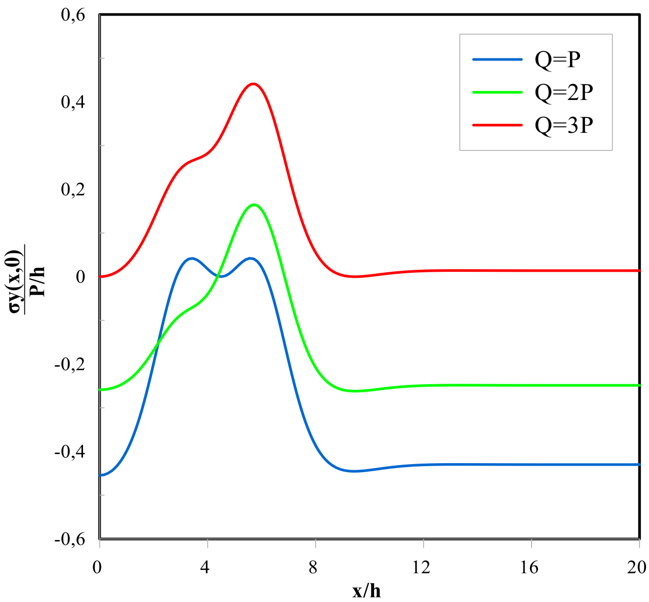

Fig. 9. Contact stress distributions between the FG layer and the under homogeneous layer, according to the load (Q) change (a/h=2.5, (b-a)/h=1.5 μ0=1, $\kappa_2 = \kappa_3 = 2$ y=h, h=1, μ-h=1)

The results showed that the increase in the load (Q) applied to the block caused an increase in the contact stress between the FG layer and the under homogeneous layer.The results are presented in Fig. 9.

It was found that the decrease in the stiffness of the blocks caused an increase in the contact stress between the FG layer and the upper homogeneous layer.The results are presented in Fig. 10.

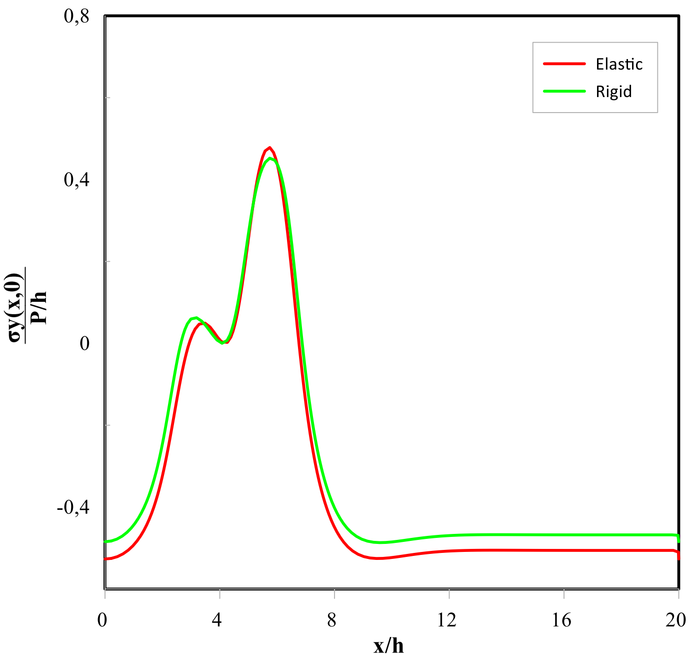

Fig. 10. Contact stress distributions between the FG layer and the upper homogeneous layer, according to the elasticity state of the blocks (a/h=2.5, μ0=1, K_1= K_2=2, y=h, h=1, μ-h=1)

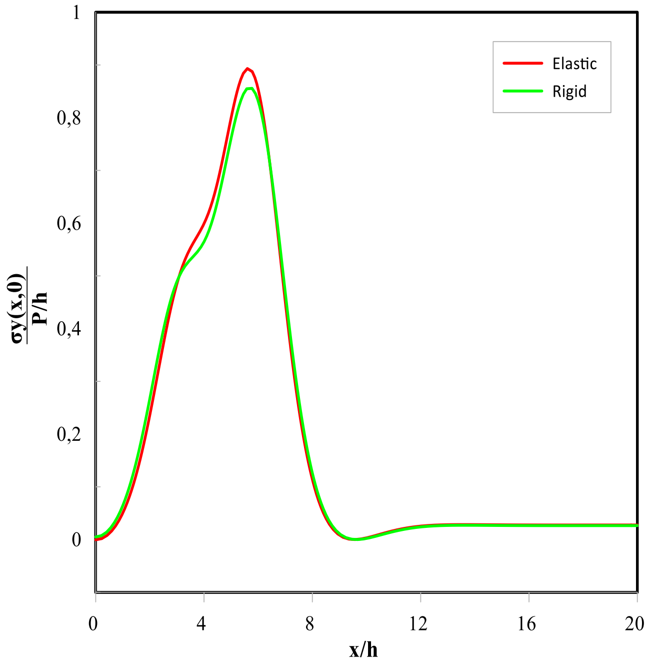

Fig. 11. Contact stress distributions between the FG layer and the under homogeneous layer, according to the elasticity state of the blocks (a/h=2.5, μ0=1, K_2= K_3=2, y=h, h=1, μ-h=1)

In the configuration where the first block is elastic and the second block is rigid, the increase in the rigidity of the upper homogeneous layer causes the first block to decrease. The results are presented in Fig. 12.

In the configuration where the first block is elastic and the second block is rigid, the increase in the rigidity of the upperr homogeneous layer causes the first block to decrease.The results are presented in Fig. 13.

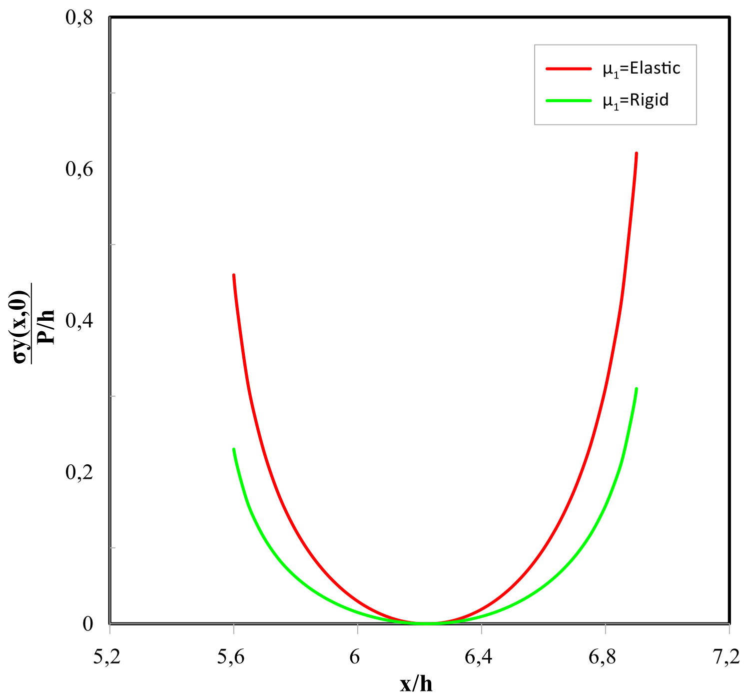

Fig. 13. According to the case where the 1st block is elastic and the 2nd block is rigid, the stress under the 2nd block (μ_1= shear stress of the upper homogeneous layer) (a/h=2.5, μ0=1, K_2= K_3=2, y=h, h=1, μ-h=1)

4. Conclusions

The aim of this study is to investigate the contact stresses in a functionally graded layered system loaded with two elastic blocks according to different variables such as the distance between the blocks and the stiffness of the blocks. These investigations led us to the following conclusions.

- t was observed that changes in different variables such as the distance between the blocks, the stiffness of the blocks, and the stiffness of the homogeneous layers lead to a change in the contact stresses.

- It was observed that the stiffness of the blocks and the stiffness of the homogeneous layers caused a change in the stresses under the blocks.

Advanced connection topology optimization in steel space frames using metaheuristic algorithms

Jay Prakash*[1], Ayşe T. Daloğlu[1]

[1] *Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye*

Abstract. This research paper elucidates an optimization process that utilizes two metaheuristic algorithm to achieve minimum weight by selecting beam-column connection types and structural sections as design variables. In connection topology optimization, connection topologies are classified into two principal categories: connection topology (1) and connection topology (2). Connection topology (1) encompasses rigid, semi-rigid (top and seat angles), and pinned connections. Conversely, connection topology (2) consists of rigid, semi-rigid (end plate with column stiffeners), and pinned connections. The design optimization incorporates the stress constraints established by the AISC-LRFD (American Institute of Steel Construction - Load and Resistance Factor Design) and considers displacement, inter-story, and geometric constraints. Initially, optimal designs for two distinct space frames drawn from existing literature are developed without factoring in the connection topology approach. Subsequently, the results are compared to those in the literature. Thereafter, the same optimization procedures are repeated for the case involving space frames with connection topology approaches. All optimization methods utilize C# version 17.10.5, designed for integration with version 22 of SAP2000-OAPI (Open Application Programming Interface) for two-way data flow. The results obtained in the study indicate that considering the arrangement of beam-column connections leads to heavier steel weights but results in more economical designs in terms of stiffness.

Keywords: Metaheuristic algorithms; Semi-rigid connection; Connection Topology Optimization; SAP2000-OAPI; AISC-LRFD

1. Introduction

Steel moment frameworks achieve their highest lateral stiffness when entire connections are firmly rigid. This situation allows designers to refine the dimensions of each beam and column to create the lightest and, in terms of material weight, the most cost-effective design. In comparison to pinned connections, rigid connections entail significantly higher costs due to the requirements for fabrication, welding, inspection, and other related processes (Alberdi, Murren, & Khandelwal, 2015). Although a fully rigid frame may produce the lightest structure, it is often not the most cost-effective design, considering the associated connection costs. For instance, Carter et al. (2000) noted that material expenses can account for just a 1/4th of the overall cost of a steel frame. In contrast, Evers and Maatje (2000) highlighted that nearly half of the expenses are linked solely to connections. Given the significant costs associated with rigid connections, more efficient designs can be achieved by concurrently adjusting member sections and the stiffness of connections, including the utilization of semi-rigid configurations.

The optimal arrangement of pinned, semi-rigid, and rigid connections, referred to as connection topology, along with effective member sizing, has the potential to produce designs that minimize costs. The incorporation of semi-rigid connections into the connection topology optimization process represents a more realistic design strategy, enhancing the practicality of steel frame optimization for engineering applications. Moreover, this approach provides engineers with the opportunity to strategically distribute frame stiffness, thereby facilitating the pursuit of more economical structural solutions.

In earlier studies, Xu (2002), Ali et al. (2009), and Degertekin and Hayalioglu (2010) explored the advantages of balancing the affordability of pinned connections with the overall lateral stiffness provided by moment and semi-rigid connections. However, some researchers, such as Hall (2006), Hagishita and Ohsaki (2008), Kripakaran et al. (2011), Tovar and Khandelwal (2013), Kaveh et al. (2017), and Rahami et al. (2017), have applied connection topology optimization techniques to two-dimensional steel frames.

This research presents the optimization of connection topology for steel space frames, employing metaheuristic methods to adjust connection types, including semi-rigid connections and member section profiles, to achieve

golden light publishing

optimum design in terms of stiffness. Two metaheuristic algorithms, Teaching-Learning-Based Optimization (TLBO) and Particle Swarm Optimization (PSO), are utilized to accomplish this.

2. Metaheuristic algorithms

2.1. Teaching-learning-based optimization (TLBO)

The TLBO algorithm was developed by Rao et al. (2011). This algorithm imitates the interactions of teaching and learning that ensue between instructors and students in a conventional classroom setting. The student with the most incredible level of knowledge in the class is chosen to act as the instructor. The class leader then shares their knowledge with the other students. These procedures offer practical strategies for optimizing steel frames. The essential elements of this innovative approach are teaching and learning. The initial step begins randomly generating values for the starting population in a matrix format during the teaching phase, as demonstrated in Eq. 1.

$$\text{Population} = \begin{bmatrix} x_1^1 & x_2^1 & \cdots & x_{ndv-1}^1 & x_{ndv}^1 \\ x_1^2 & x_2^2 & \cdots & x_{ndv-1}^2 & x_{ndv}^2 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ x_1^{ps-1} & x_2^{ps-1} & \cdots & x_{ndv-1}^{ps-1} & x_{ndv}^{ps-1} \\ x_1^{ps} & x_2^{ps} & \cdots & x_{ndv-1}^{ps} & x_{ndv}^{ps} \end{bmatrix} \begin{matrix} \rightarrow \\ \rightarrow \\ \rightarrow \\ \rightarrow \\ \rightarrow \end{matrix} \begin{matrix} f(x^1) \\ f(x^2) \\ \vdots \\ f(x^{ps-1}) \\ f(x^{ps}) \end{matrix} \tag{1}$$

Each row in the matrix corresponds to a student and presents a design solution. ps denotes the population size, indicating the total count of students. ndv signifies the digit of design variables. The function $f(x^{1,2,\dots,ps})$ symbolizes the unconfined objective for every student in the group. The objective function identifies an optimal value from the available solutions. The student with a profound understanding will become the class instructor. The instructor aids in redrafting the optimal amount of knowledge for the students in the class in accordance with Eq. 2.

$$x^{new,i} = x^i + r(x_{instructor} - T_F x_{mean}) \tag{2}$$

In the provided equations, r stands a number chosen within the range of [0, 1], T_F (teaching factor) typically equals 1 or 2, the new student is denoted as $x^{new,i}$, while the current student is represented as x^i. Defined as $x_{mean} = (mean(x_1^1)\dots mean(x_1^{ps}))$, this represents the average of the class. If the new student possesses preferential information ($f(x^{new,i})$), they will replace the current student. Knowledge is exchanged during the second phase, known as the learning phase. This phase is analogous to the first one. A new student will take the place of an existing student if they provide superior information. The updating of student information within the class is carried out according to Eq. 3.

$$\begin{gathered} if\ f(x^i) < f(x^j) \Rightarrow x^{new,i} = x^i + r(x^i - x^j), \\ \text{Otherwise} \Rightarrow x^{new,i} = x^i + r(x^j - x^i). \end{gathered} \tag{3}$$

Comprehensive details regarding the TLBO algorithm can be found in the works of Togan (2012), Artar (2016), and Zou et al. (2019).

2.2. Particle Swarm Optimization (PSO)

The PSO algorithm was initially conceived by Kennedy and Eberhart in 1995. Subsequent advancements to this algorithm were introduced by Pedersen and Chipperfield in 2010. PSO represents a stochastic search methodology that employs a population-based strategy for effectively exploring intricate solution spaces. The active foraging behavior of animal species, as they seek out food sources, serves as a basic concept for understanding this technique. This food-seeking behavior encompasses the formation of groups shaped by social influences that rely on the collective memory of each member and the data collected by the swarm.

The approach begins with random solutions and then progressively modifies the velocity and location of particles through iteration. Every particle is characterized by its position x_i^m and velocity v_i^m. The initial position x_i^0 is randomly scattered and taken from the given solution. The initial velocity v_i^0 is presumed to be zero. The initial parameters can be obtained from Eqs. 4-5.

$$x_i^0 = x_{min} + r(x_{max} - x_{min}) \tag{4}$$

$$v_i^0 = 0 \tag{5}$$

In the provided equations, x_{min} and x_{max} signify the lower and top limit of the design parameters, respectively.

This particle velocity reflects the extent of change, while particle positions denote possible solutions for optimal design challenges. Each particle is updated based on two optimal values during every iteration of its movement. The first optimal value is called $p_{best,i}^m$, which signifies the best position attained by the i^{th} particle. The second optimal value, p_{gbest}^m, indicates the best position among all particles at time m. The position and velocity of the i^{th} particle for the m iteration are adjusted according to Eqs. 6-7.

$$v_i^{m+1} = w^m v_i^m + c_1 r_1 (p_{best,i}^m - x_i^m) + c_2 r_2 (p_{gbest}^m - x_i^m) \tag{6}$$

$$x_i^{m+1} = x_i^m + v_i^{m+1} \tag{7}$$

In the formulas mentioned above, r_1 and r_2 serve as arbitrary values ranging from 0 to 1. The particle's inertia, denoted as w^m,influences the algorithm's exploration characteristics. The trust parameters c_1 and c_2 represent the coefficients for individual and collective learning, respectively. For further information on the PSO algorithm, one can refer to various sources, including Kennedy and Eberhart (1995), Saka and Geem (2013), and Gad (2022).

3. Integration of semi-rigid connections within connection topology optimization

The behavior of connections in steel frames is vital for structural performance and cost-effectiveness. Steel frames are typically designed with either fully rigid or pinned connections. Fully rigid connections improve lateral stiffness and can lead to lighter designs, but they often incur higher costs in fabrication, welding, inspection, and erection (Carter, Murray, & Thornton, 2000; Evers & Maatje, 2000). Thus, rigid connections may yield a lighter structure, but they are not always the most economical option when considering all related expenses (Kripakaran, Hall, & Gupta, 2011). To address this issue, each beam is considered a design variable that introduces the connection topology approach. As a result, nine specific beam types will be defined, which is depicted in Fig. 1:

- Type-1 is completely rigid-connected.
- Type-2 is fully semirigid-connected.
- Type-3 is fully pinned-connected.
- Type-4 features a rigid left-end connection and a semirigid right-end connection.
- Type-5 features a rigid left-end connection and a pinned right-end connection.
- Type-6 features a semirigid left-end connection and a rigid right-end connection.
- Type-7 features a semirigid left-end connection and a pinned right-end connection.
- Type-8 features a pinned left-end connection and a rigid right-end connection.
- Type-9 features a pinned left-end connection and a semirigid right-end connection.

Semi-rigid connections emerge as a vital intermediate solution between rigid and pinned behaviors within this optimization process. Semi-rigid connections possess partial rotational stiffness, offering a practical compromise that enhances frame stability without incurring the complete cost associated with rigid connections (Chen & Kishi, 1989; Degertekin & Hayalioglu, 2010). In alignment with this objective, specific types of semi-rigid connections are incorporated into the optimization framework. Based on the classifications by Hayalioglu and Degertekin (2004), six types of semi-rigid connections have been identified, with their moment-rotation characteristics illustrated in Fig. 2. For this study, two semi-rigid connection types are selected: top and seat angles and end plates with column stiffeners to balance cost and stiffness effectively. As shown in Fig. 3, these connections exhibit rotational stiffness values of 8.47×10^7 kNmm/rad and 3.39×10^8 kNmm/rad, respectively.

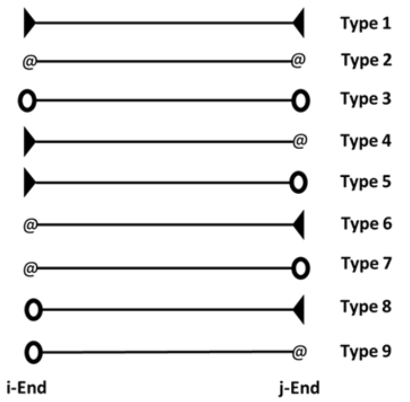

Fig. 1. Beam types incorporated in connection topology

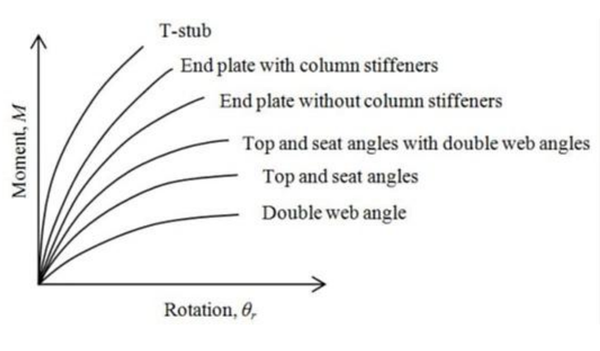

Fig. 2. The moment-rotation curves for semi-rigid connections (Hayalioglu & Degertekin, 2004)

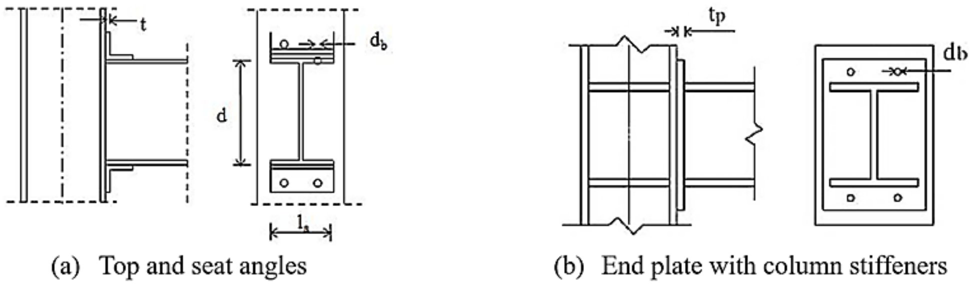

Fig. 3. Types of semi-rigid connections used in the connection topology optimization

4. Mathematical formulation of optimal structural design

In discrete optimization problems, the lowest weight of 3-dimensional steel frame is treated as the unconstrained objective function. The formulations for the objective and penalized functions are provided in Eqs. 8-11 (Daloglu, Artar, Özgan, & Karakas, 2016).

$$Min\ W_{sf} = \sum_{f=1}^{ng} A_f \sum_{i=1}^{nf} \rho_i L_i \tag{8}$$

$$\mathrm{g_i}(x) > 0 \rightarrow c_{vi} = \mathrm{g_i}(x) \tag{9}$$

$$\mathrm{g_i}(x) < 0 \rightarrow c_{vi} = 0 \tag{10}$$

$$\varphi_{sf}(x) = W_{sf}(x)\left(1 + P\sum_{i=1}^{m} c_{vi}\right) \tag{11}$$

In this context, the variable W_{sf} represents the total weight of the 3-dimensional steel frame, while A_f denotes the cross-sectional area of element group f. The symbols ρ_i and L_i refer to the density and length of the steel members. The variable ng indicates the total number of groups, and nf signifies the number of members within group f. The function $\varphi_{sf}(x)$ is called the penalized objective function, and P represents the penalty constant. The variable c_{vi} corresponds to constraint violations, and $\mathrm{g}_i(x)$ designates the constraints applicable to the design.

This study considers various limitations based on Prakash et al. (2024), which are expressed as follows:

The displacement constraints are delineated in Eq. 12.

$$\mathrm{g}_{jl}(x) = \frac{\delta_{jl}}{\delta_{ju}} - 1.0 \leq 0 \qquad \begin{matrix} j = 1, \ldots, cd \\ l = 1, \ldots, nl \end{matrix} \tag{12}$$

In this context, δ_{jl} represents the displacement associated with the j^{th} degree of freedom for the specified load case l. Additionally, δ_{ju} indicates the established upper limit, while cd signifies the total count of constrained displacements. Lastly, nl refers to the overall number of loading scenarios considered.

Inter-storey drift constraints are delineated in Eq. 13.

$$\mathrm{g}_{jil}(x) = \frac{\Delta_{jil}}{\Delta_{ju}} - 1.0 \leq 0, \qquad i = 1, \ldots, nsc, j = 1, \ldots, ns, l = 1, \ldots, nl \tag{13}$$

In this context, Δ_{jil} denotes the inter-storey drift of the i^{th} column in the j^{th} storey during load case l. The symbol Δ_{ju} indicates the permissible limit value, ns refers to the total number of stories, and nsc signifies the count of columns within a storey.

Column-to-column geometric constraints are delineated in Eq. 14.

$$\mathrm{g}_n(x) = \frac{D_{un}}{D_{ln}} - 1.0 \leq 0 \qquad n = 2, \ldots, ns. \tag{14}$$

In this context, D_{un} and D_{ln} signify the depths of the upper and lower floors, respectively.

Beam-to-column geometric constraints are delineated in Eq. 15.

$$\mathrm{g}_{bb,i}(x) = \frac{b_{fbk,i}}{b_{fck,i}} - 1.0 \leq 0 \qquad i = 1, \ldots, n_{bf}. \tag{15}$$

In this context, n_{bf} denotes the joint number where the beam is attached to the column's flange, while $b_{fbk,i}$ and $b_{fck,i}$ signify the flange widths of the beam and column elements, respectively.

According to AISC-LRFD (2010), the stress limits are presented in Eq. 16.

$$\mathrm{g}_{jl}(x) = \begin{cases} \left(\frac{P_u}{\phi P_n}\right)_{jl} + \frac{8}{9}\left(\frac{M_{ux}}{\phi_b M_{nx}} + \frac{M_{uy}}{\phi_b M_{ny}}\right)_{jl} - 1.0 \leq 0 & if\ \frac{P_u}{\phi P_n} \geq 0.2 \\ \left(\frac{P_u}{2\phi P_n}\right)_{jl} + \left(\frac{M_{ux}}{\phi_b M_{nx}} + \frac{M_{uy}}{\phi_b M_{ny}}\right)_{jl} - 1.0 \leq 0 & if\ \frac{P_u}{\phi P_n} < 0.2 \end{cases} \quad \begin{matrix} j=1,\ldots\ldots\ldots,nm \\ l=1,\ldots\ldots\ldots,nl \end{matrix} \tag{16}$$

In this context, the symbol ϕ signifies the resistance factor, which is defined as ϕ_c for compression (0.85), ϕ_t for tension (0.90), and ϕ_b for flexural (0.90). P_n and P_u denote the nominal strength and required axial strength, respectively. M_{nx} and M_{ny} indicate the nominal flexural strength of the major and minor axes, respectively. M_{ux} and M_{uy} represent the necessary flexural strength around the major and minor axes. The integers nm and nl denote the total number of members and the loading conditions, respectively.

5. Implementation and results

This research aims to identify the most effective configuration of pinned, semi-rigid, and rigid connections using a connection topology-based method. This study divides connection topology into two categories: Connection topology (1) and connection topology (2). In connection topology (1), rigid connections, top and seat angles used as semi-rigid connections, and pinned connections are included. On the other hand, in connection topology (2), rigid connections, end plates with column stiffeners as semi-rigid connections, and pinned connections are included. Two reference examples from the current literature illustrate the importance of comparison. The appropriate cross-sections for the frame components are chosen from 64 W-section profiles. The steel material is assumed to have an elastic modulus of $200\,\mathrm{GPa}$, a yield strength of $250\,\mathrm{MPa}$, and a density of $7.85\,\mathrm{t/m^3}$. Additionally, particular beam types for the connection topologies are chosen from a list of nine beam types, as shown in Fig. 1. For both benchmark examples, the population size is established at 20.

5.1. Case study-1: 2-storey, 21-member space frame design

The case study showcases an optimization of an asymmetrical steel space frame with two stories and 21 members, as reviewed by Artar and Daloğlu (2020). The current study emphasizes the use of a connection topology approach for the analysis of steel space frames. The components of the space frame have been systematically divided into five separate groups, consisting of two beams and three columns, to optimize their dimensions, as shown in Fig. 4 (a). The beams of the steel space frame are classified into eleven groups for the purpose of optimizing the connection topology, as illustrated in Fig. 4 (b). Fig 4 depicts the spatial arrangement of the major and minor axes of the columns and beams. In Fig. 4, vertical loads of $20\,\mathrm{kN/m}$ are applied to each beam, along with a wind load of $50\,\mathrm{kN}$. The maximum displacement and inter-storey drift limitations are established at 4.0 cm and 1.02 cm, respectively.

Table 1 presents the optimum results for rigid frames as reported by Artar and Daloğlu (2020). It also showcases the best outcomes for different connection topologies in steel space frames utilizing the TLBO and PSO algorithms. Figs. 5 and 6 illustrates the optimal arrangement of beam-to-column connections for connection topology (1) and (2) achieved by the TLBO and PSO algorithms, respectively. Fig. 7 display the design histories for each scenario, reflecting the optimal population design for every iteration. The example provided is implemented in five separate simulations.

Table 1 demonstrates that the optimal values for steel space frameworks identified in this study are in close agreement with the results published by Artar and Daloğlu (2020). It can also observed in Table 1 for TLBO solutions, the minimum weights of frames with connection topologies (1) and (2) are 9.90 and 1.05 percent greater than the lowest weight of 51.665 kN, respectively. The maximum displacement remains significantly lower than the established limit across all instances. However, the highest inter-storey drift approaches the maximum allowable threshold. Figs. 5 and 6 illustrate that each beam is assigned a connection type from a predetermined set comprising rigid, semi-rigid, and pinned connections. The connection layout demonstrates a strategic distribution of connection stiffness throughout the frame, aiming to minimize the overall structural cost while maintaining adequate stiffness and stability.

It can be observed from these configurations that rigid connections are primarily located at joints requiring higher moment resistance and stiffness; semi-rigid connections are effectively employed in locations where a balance between stiffness and cost-efficiency is desirable; and pinned connections are assigned to areas where moment resistance is less critical, thereby contributing to reductions in fabrication and welding costs. This arrangement highlights the metaheuristic algorithm's capability to intelligently assign varying connection types, optimizing both structural performance and economic efficiency. Furthermore, Fig. 7 indicates that the minimum structural weight increases slightly when connection topology is considered. The results obtained from the Particle Swarm Optimization (PSO) algorithm closely match those of the Teaching-Learning-Based Optimization (TLBO) method, demonstrating a strong consistency between the two approaches.

5.2. Case study-2: 4-storey, 84-member space frame design

The current case study discusses optimizing the symmetrical steel space frame consisting of four stories and 84 members, as depicted in Fig. 8, previously examined by Artar and Daloğlu (2020). This study implements a connection topology method for analyzing steel space frames. The 84 frame members are divided into ten categories. The first category includes the external beams found on the fourth floor. The second category consists of the external beams on the third, second, and first floors. The inner beams on the fourth floor make up the third category. The fourth category contains the inner horizontal beams located on the third, second, and first floors. The fifth category consists of the corner columns on the fourth floor. The sixth category includes corner columns on the third, second, and first floors. The seventh category is made up of external columns positioned on the fourth floor. The eighth category covers external columns on the third, second, and first floors. The ninth category comprises internal columns on the fourth floor. Finally, the tenth category includes internal columns on the third, second, and first floors.

The maximum permitted lateral movement and inter-storey drift are 3.50 cm and 1.17 cm, respectively. The steel space frame is subjected to several loads: wind pressure ($p_w = C_e C_q q_s I_w$), live load ($L_l = 2.40\ \mathrm{kN/m^2}$), dead load ($D_l = 3.84\ \mathrm{kN/m^2}$), and nominal roof live load ($L_r = 2.40\ \mathrm{kN/m^2}$). In this regard, p_w stands for the design wind pressure, C_e denotes the exposure and guest factor coefficient along with the combined height, C_q is the pressure coefficient, which equals 0.8 for windward faces and 0.5 for leeward faces, q_s represents the wind stagnation pressure, quantified at $0.785\ \mathrm{kN/m^2}$, and I_w signifies the wind importance factor. The structure experiences wind loads in the X-direction. For each scenario, the following load combination is applied: $1.2D_l + 1.3W_l + 0.5L_r + 0.5L_l$, where W_l refers to the wind load.

Table 2 showcases the optimal results for rigid frames, as reported by Artar and Daloğlu (2020). It also highlights the best outcomes for various connection topologies in steel space frames using the TLBO and PSO algorithms. Figs. 9 and 10 illustrate the ideal configurations of beam-to-column connections for connection topology (1) and (2), respectively, achieved through the TLBO and PSO algorithms. Fig. 11 presents the design histories for each scenario, reflecting the optimal population design for each iteration.

Similar independent trials are conducted, similar to the previous example. Table 2 illustrates that the optimal values for steel space frameworks found in this research closely align with the findings reported by Artar and Daloğlu (2020). It can also be seen in Table 2 regarding TLBO solutions that the minimum weights for frames with connection topologies (1) and (2) exceed the lowest weight of 177.20 kN by 7.62 and 2.87 percent, respectively. The lateral displacement remains significantly below the established limit in all instances. Conversely, the inter-storey drift approaches the upper limit.

Figs. 9 and 10 illustrate a strategic distribution of connection stiffness throughout the frame to minimize overall structural costs while ensuring adequate stiffness and stability. This arrangement underscores the capabilities of the metaheuristic algorithm in intelligently assigning various connection types, thereby optimizing structural performance and economic efficiency. Additionally, Fig. 11 indicates a slight increase in the minimum structural weight when connection topology is considered.

The results derived from the Particle Swarm Optimization (PSO) algorithm show a high degree of consistency with those obtained from the Teaching-Learning-Based Optimization (TLBO) method, further validating the reliability of both approaches.

6. Conclusion

The primary aim of this study is to evaluate how randomly positioned beam-to-column connections influence the optimal design of steel space frames. TLBO and PSO are utilized to accomplish this goal. The effects of randomly positioned beam-to-column connections on steel frames are analyzed through connection topology optimization. The steel space frames are subject to various constraints, including geometry (beam-to-column and column-to-column), top and inter-story drift, and the stress requirements of LRFD-AISC. The total weight of the steel frame serves as the objective function in the analyses. The types of beams for connection topology optimization and the structural members for size optimization are identified as design variables.

Below are the comprehensive conclusions regarding the optimal design achieved through the C#-SAP2000 OAPI:

- Incorporating the effects of connection topologies into the optimization process for steel space frames slightly extends the time required to identify the most effective solution.
- In the conclusion of the first example, when the TLBO algorithm is used, it shows that the minimum weights of frames with connection topologies (1) and (2) are 9.90 and 1.05 percent greater than the lowest weight of 51.665 kN, respectively. Moreover, in the second example's conclusion, when the TLBO algorithm is used, it shows that the minimum weights for frames with connection topologies (1) and (2) exceed the lowest weight of 177.20 kN by 7.62 and 2.87 percent, respectively. These results indicate a slight increase in the minimum structural weight when connection topology is considered.
- The research indicates that inter-story drift and maximum lateral displacement limits are essential in determining the best design for the space frame.
- The connection layout demonstrates a strategic distribution of connection stiffness throughout the frame, aiming to minimize the overall structural cost while maintaining adequate stiffness and stability.
- The results indicate that the TLBO algorithm produces lighter frames than the PSO algorithm.

Abstract. The objective of this study is to investigate the progressive collapse behavior of multi-storey buildings under fire conditions, considering the use of carbon steel and stainless steel materials. To achieve this, a series of nonlinear dynamic explicit analyses were carried out using Abaqus software. In the study, the validation procedure for the collapse simulation of a building under fire conditions was first carried out. The validated model was subsequently employed to simulate the progressive collapse behavior of carbon steel and stainless steel building under fire exposure. Finally, both cases were compared in terms of the results obtained under fire exposure, including progressive collapse cases, displacements, and stress outcomes.

Keywords: Elevated temperature; Nonlinear dynamic explicit analysis; Progressive collapse simulation

1. Introduction

The structural integrity of buildings under extreme conditions, such as fire, is a significant concern in modern civil engineering. Progressive collapse - defined as sequential failure in structural components as a result of localized damage - reflects a significant risk of life security and property. The outbreak of a fire in a particulary steel structure, if the structure is not at least partially protected from heat exposure, can result in a considerable decline in the material's strength and stiffness, potentially leading to significant loss of life and property. This is due to the fact that steel's physical properties are dependent on temperature.

Traditional carbon steel is widely used in modern structural engineering due to its exceptional strength, durability, and versatility. Today, it plays a vital role in the construction of skyscrapers, bridges, industrial buildings, and residential frameworks. Its high strength-to-weight ratio allows for taller and more open structures without compromising stability. Additionally, steel is recyclable, making it an environmentally responsible choice in sustainable building practices. With advancements in fabrication and design technologies, steel continues to be a cornerstone material in the development of safe, efficient, and innovative structures around the world. While steel is a strong and reliable material in construction, it is highly susceptible to damage at high temperatures. In the event of a fire, steel can lose up to 50% of its strength at around 550°C, which can compromise the structural integrity of a building. Therefore, it is essential to protect steel structures with fire-resistant materials. Common fire protection methods include applying fire-retardant coatings, such as intumescent paint that expands when exposed to heat, as well as encasing steel elements in fireproof boards or concrete. These protective systems help maintain the structural performance of steel during a fire, giving occupants more time to evacuate and emergency services more time to respond.

Stainless steel offers improved fire resistance compared to many other building materials due to its ability to retain strength at elevated temperatures. Unlike carbon steel, certain grades of stainless steel, such as austenitic types, maintain their structural integrity longer during a fire, making them a safer choice for critical components in buildings. Additionally, stainless steel does not burn, produce toxic fumes, or contribute to the spread of flames. These properties make it a preferred material in environments where fire safety is a high priority, such as in transportation hubs, high-rise buildings, and industrial facilities (Rossi, 2014; Karabulut et al., 2018; Molkens et al., 2021).

[1*]Corresponding author, E-mail: anuhair@uowasit.edu.iq

https://doi.org/10.31462/icearc2025_ce_sme_697

Stainless steel is widely recognized for its excellent corrosion resistance, structural flexibility, and ability to retain mechanical properties at elevated temperatures, making it a strong candidate for high-altitude and performance-critical structures. However, despite its increasing use in architectural and industrial applications, research on its behavior under fire-induced thermal loading remains limited (Gardner and Baddoo, 2006; Gardner, 2007; Wang et al., 2020; Segura et al., 2021). Most existing studies focus primarily on carbon steel frames (Jiang et al., 2014; Qin, 2016; Shan & Li, 2021; Shakeri et al., 2023), resulting in a significant knowledge gap regarding the response of stainless steel structures to localized fire exposure and their associated collapse mechanisms. This study aims to address this gap by investigating the collapse behavior of stainless steel frames subjected to realistic fire scenarios. The main objectives are twofold: (1) to monitor and analyze the structural performance of stainless steel during fire events, and (2) to explore the evolution of load-bearing capacity, progressive failure mechanisms, and structural hierarchy under fire conditions.

2. Case study

The case study presented in this research is based on the framework developed by Shan & Li (2021), with the bare frame configuration modeled and further analyzed in the current study. The study numerically investigates the impact of infill walls on the collapse performance of three-dimensional steel frames exposed to fire using nonlinear dynamic analysis. Two eight-story composite steel frames-one bare and one with infill walls—are analyzed under single-compartment and traveling fire scenarios, considering parameters such as load ratio, opening percentage, and number of infill walls. A preliminary analytical method is also proposed to predict collapse modes under traveling fire conditions.

In the present study, a multi-storey building without infill walls (Fig. 1a) subjected to single-compartment fire scenarios (Fig. 1b), as detailed by Shan & Li (2021), was modeled to simulate progressive collapse using carbon steel under fire conditions. Additionally, the same configuration was analyzed using stainless steel to enable a comparative assessment of the collapse behavior between the two materials. The fire analysis of the building using carbon and stainless steel was carried out against a corner compartment fire.

The modeled building, designed as a small shopping mall, is situated on Type II soil. The structural design accounts for a roof dead load of 3.5 kN/m² and 1.5 kN/m² for the typical floors, excluding the self-weight of slabs and framing members. Live loads are defined as 2.0 kN/m² on the roof and 3.5 kN/m² on all other floors. The structure consists of H-shaped steel members, composite concrete slabs, and reinforcing bars. Table 1 presents the cross-sections of frame members adopted in building. The first story of the building has a height of 4.2 m, while each of the remaining stories is 3.3 m tall. See the study by Shan & Li (2021) for detailed information on the building and its material characteristic.

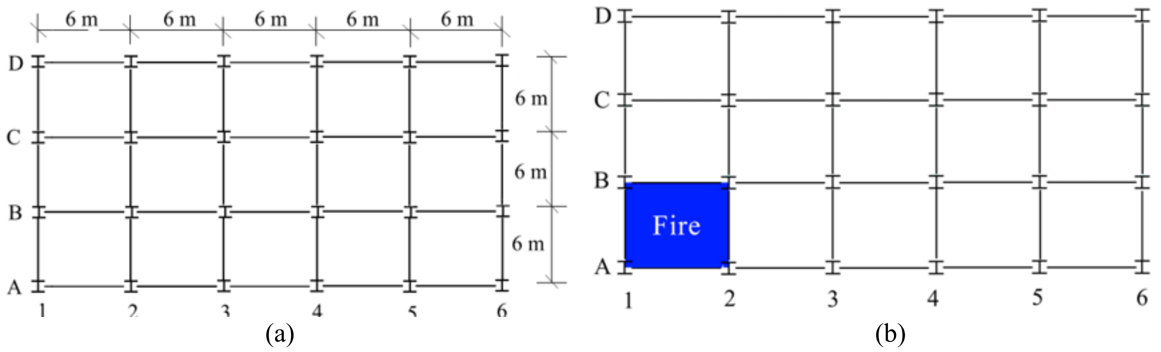

Fig. 1. View of the building (a) plan view, (b) single-compartment fire scenario

Table 1. Cross sections of the frame members used in the building

Structural member	Story		
	1	2-3	4-6
Corner column	HW250×250×9×14	HW250×250×9×14	HW250×250×9×14

Interior beam	HN399×199×7×11	HN399×199×7×11	HN350×175×7×11

Note: the first to the fourth number represent the section height, section width, thickness of web and flange, respectively

3. Validation study

Before conducting the main numerical study, several validation analyses were performed to ensure the accuracy and reliability of the simulation results. These validation studies involved comparing the numerical model against experimental or numerical data and established benchmarks to confirm that the structural behavior under fire conditions was realistically captured. In this step, the numerical models were developed for selected case studies from the literature, and the simulation results were compared with the published findings to further validate the accuracy and robustness of the modeling approach.

Two specific studies were used to validate a line-element modeling approach. The first involved frames tested by Rubert and Schaumann (1986), known as the EHR (span x height, 1.24 m x 1.17 m) and ZSR (span x height, 1.20 m x 1.18 m) frames, which are given in Fig.2. The frames (IPE80 I-section) were uniformly heated using ISO-834 standard fire curve (Fig. 3) under the applied loads. The numerical analysis was carried using Abaqus softwarte (Abaqus, 2022). The mid-span deflections of the columns and beams in the EHR frame, as well as the lateral displacements of the ZSR frame, were evaluated and compared with both the simulation results obtained in this study and the corresponding data previously reported in the literature (Fig. 4). As can be seen in Fig. 4, the displacement–temperature curves of the validation models (current study in graphic) showed good agreement with other studies reported in the literature.

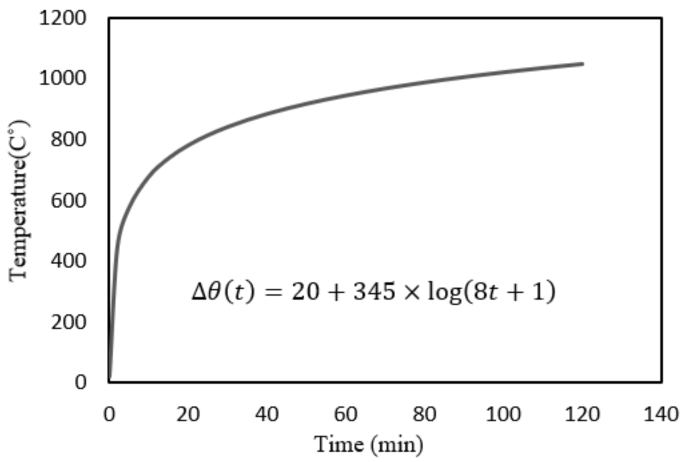

Fig.3. ISO-834 standard fire curve and relavant equation

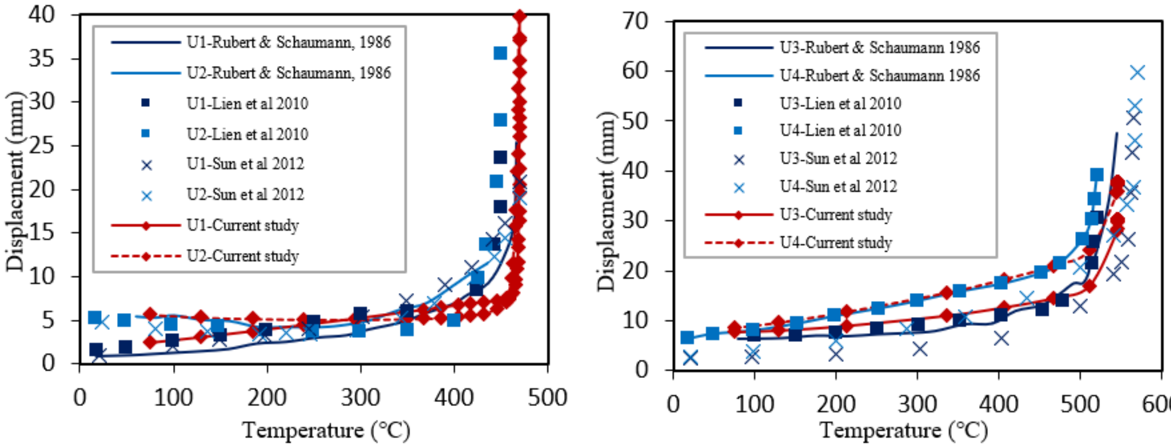

Fig.4. Displacement–temperature curves of the validation models and previously reported data

The second case study involved a five-by-three-bay, six-story steel frame tested by Shan & Li (2021). The same model was used to analyse further. The Finite Element (FE) model (Fig. 5) of the building was created using Abaqus softwarte (Abaqus, 2022). An explicit nonlinear analysis procedure was in place for the collapse simulation. In the numerical model, beams and columns were modeled using 2-node wire beam elements (B31), while floor slabs were represented with 4-node shell elements (S4R). Reinforcing bars within the slabs were included as embedded rebar layers within the shell elements. All beam-column connections were assumed to be rigid, which is a common simplification in the seismic analysis of steel frame structures. Secondary beams were excluded from the model. To represent the interaction between steel beams and concrete slabs, tie constraints were employed. A damping ratio of ξ = 0.05 was used for the steel frame.

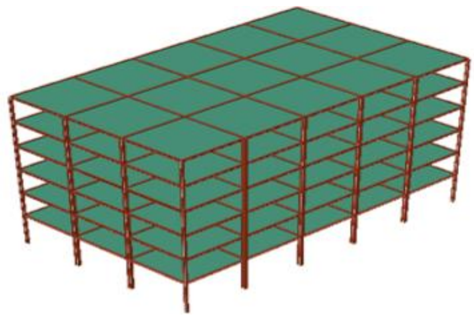

Fig. 5. FE model of the building

The building was exposed to corner compartment fire scenario, as illustrated in Fig. 1b. The simulation follows a two-phase loading protocol to realistically capture the structural response under fire conditions. In the first phase, gravity-induced loading is applied to the structure. This load is determined using the GSA-recommended combination of 1.2 times the dead load (DL) plus 0.5 times the live load (LL), as specified in GSA (2013). The gravitational load is gradually introduced over a period of 3 seconds to avoid sudden dynamic effects. Once the full load is applied, it is held constant for an additional 2 seconds to allow any transient structural responses to dissipate before the fire exposure begins. After the initial stabilization phase, thermal loading is introduced. The frame members exposed to fire, are heated in accordance with the parametric fire curve of Eurocode 1 (Fig. 6) (Eurocode 1- EN 1991-1-2), while the gravitational load applied earlier remains constant throughout this phase. To ensure the structural response remains quasi-static and is not influenced by excessive dynamic effects, the model's kinetic energy is continuously monitored. This monitoring helps verify that any failure of fire-exposed columns is captured accurately, ensuring that the simulation reflects realistic structural behavior under fire-induced material degradation. See the study by Shan & Li (2021) for detailed information on the paramaters of fire curve such as fire load density, an opening factor, thermal inertia value. Fig. 7 shows the variation of axial force and vertical displacement with increasing temperature for the columns located along the A1 and B1 axes. These relationships were systematically examined and compared with established results from the literature given by Shan & Li (2021). The close agreement between our findings and previously published data confirms the accuracy of the numerical model. This strong consistency validates the computational approach used in this study and demonstrates that the model is sufficiently robust to accurately capture the structural behavior under various conditions, including different fire scenarios considered in the collapse simulation.

4. Further analyses for staninless steel

In this section, the progressive collapse analysis and corresponding results of the multi-storey building-previously validated-are presented. The building, modeled with stainless steel (colums and beams), was subjected to the corner compartment fire scenario illustrated in Fig. 1b. The same scenario had been previously applied to a carbon steel building, allowing for a direct comparison of structural performance. The analysis focuses on the fire-induced behavior and progressive collapse mechanisms of the stainless steel structure, highlighting differences in thermal response and structural resilience between the two material types.

The elevated temperature material properties for both carbon steel and stainless steel were adopted from Eurocode 1 and Eurocode 3, respectively. For carbon steel, the yield strength and elastic modulus were taken as 235 MPa and 2.06×10^5 MPa. For stainless steel, specifically the austenitic grade 1.4301 as defined in Eurocode 3 (EN 1993-1-4), the yield strength was set to 230 MPa and the elastic modulus to 1.9798×10^5 MPa.

The reduction in strength and stiffness of structural materials at elevated temperatures is a critical consideration in fire-resistant design. Stainless steel, owing to its alloying elements, exhibits better high-temperature performance than carbon steel. As illustrated in Fig. 8a, grade 1.4301 (304) austenitic stainless steel exhibits significantly better strength retention than carbon steel at elevated temperatures, particularly beyond 500 °C-a critical range for fire-resistant design. While carbon steel retains nearly 100% of its strength up to approximately 450 °C, it experiences a rapid decline afterward, maintaining only about 10% of its strength at 800 °C. In contrast, stainless steel maintains around 90% of its strength at 200 °C and still retains approximately 75% at 500 °C. These values are represented by the strength reduction factor $k_{y,\Theta}$ which is defined as the ratio of the material's strength at elevated temperature (based on 2% total strain) to its 0.2% proof strength at room temperature. As shown in Fig. 8b, stainless steel exhibits superior stiffness retention at elevated temperatures compared to carbon steel. At

700 °C, stainless steel retains approximately 70% of its initial stiffness, while carbon steel drops sharply to about 13%. This indicates a more gradual degradation in stainless steel, which is beneficial for maintaining structural stability under fire conditions. Both materials, however, approach near-zero stiffness as the temperature nears 1200 °C. The stiffness reduction factor $k_{E,\Theta}$ represents the ratio of the tangent modulus at elevated temperature to that at room temperature.

These differences further highlight the advantages of stainless steel in fire-resistant design, particularly under severe conditions where temperatures exceed 700 °C-such as in standard 30-minute fire exposure scenarios. To support this analysis, the stress–strain relationships at various elevated temperatures were calculated for both materials and are illustrated in Fig. 9. These calculations are based on Eurocode 1 for carbon steel and Eurocode 3 for stainless steel of grade 1.4301.

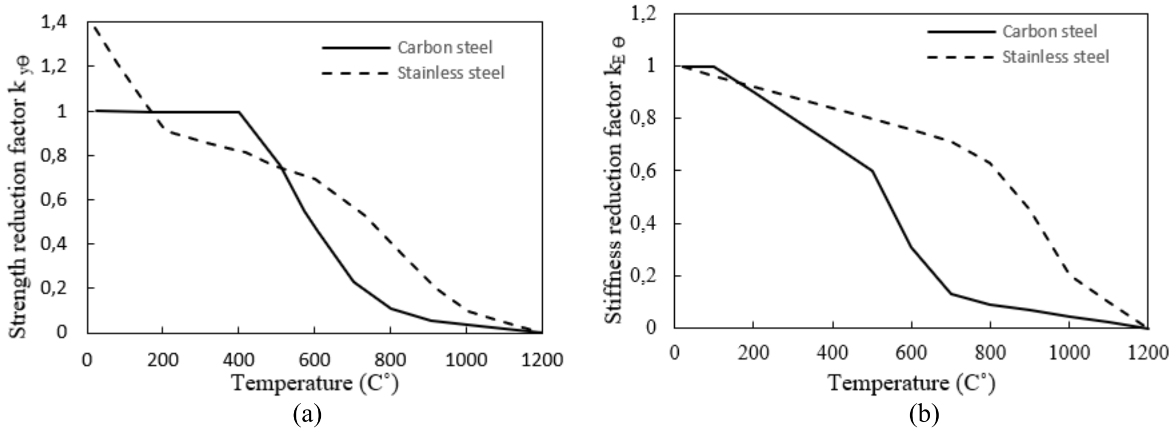

Fig. 8. Strength reduction (a) and stiffness reduction (b) of carbon steel and stainless steel at elevated temperatures

Figure 9 clearly illustrates the different thermal-mechanical behaviors of carbon steel and stainless steel (grade 1.4301) under elevated temperatures. According to Eurocode 1 for carbon steel and Eurocode 3 for stainless steel, the stress–strain relationships at elevated temperatures were derived and compared to assess their suitability for fire-exposed structures. Carbon steel (Fig. 9a) shows a sharp decline in mechanical strength beyond 500 °C, with a well-defined yield plateau at lower temperatures that disappears as the temperature rises. This degradation is particularly critical around 700 °C, where carbon steel loses most of its load-carrying capacity and becomes highly susceptible to sudden failure. Such behavior limits its effectiveness in maintaining structural integrity during prolonged fire exposure, even within standard fire durations (e.g., 30-60 minutes), where internal temperatures can exceed 700 °C. Conversely, stainless steel (Fig. 9b) demonstrates more gradual degradation. It exhibits no clear yield plateau but maintains ductile behavior with continuous strain hardening. Even at temperatures of 700 °C and beyond, the material retains significant stress capacity and deformation potential. This is consistent with previous findings that highlight the superior high-temperature stability of stainless steels due to their alloy composition, particularly the presence of nickel and chromium, which contribute to delayed strength and stiffness loss under thermal loading.

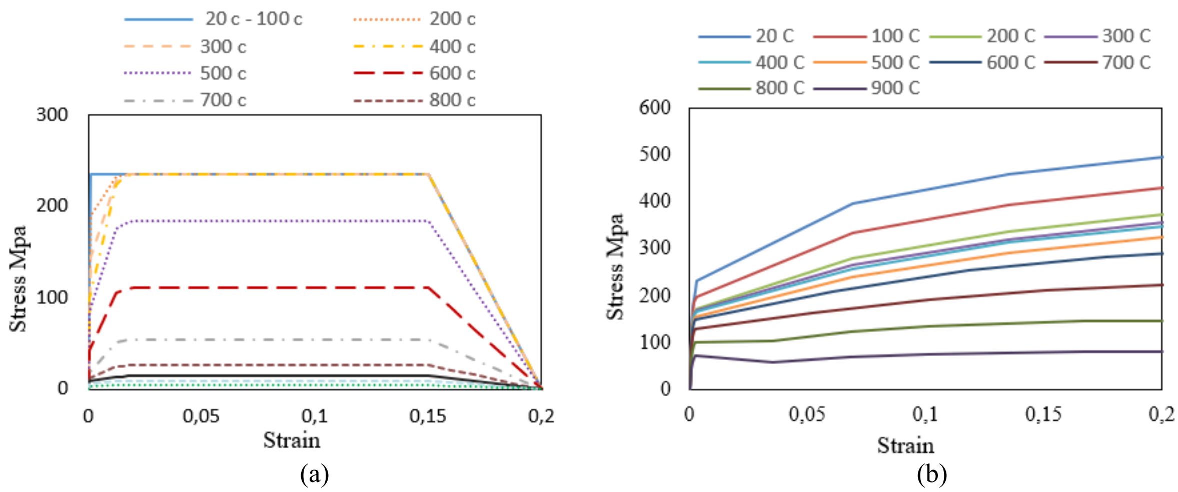

Fig. 9. Stress–strain curves of carbon steel (a) and stainless steel (b) at elevated temperatures

All metals expand when heated; however, in structural systems with continuity and localized fire exposure, this thermal expansion can be partially restrained, leading to additional internal forces and deformations. Fig. 10 illustrates the thermal elongation behavior of carbon steel and stainless steel used in this study. As can be seen, stainless steel undergoes greater thermal expansion-up to 50% more than carbon steel at high temperatures-highlighting the need to consider thermal strain effects carefully in fire-resistant design.

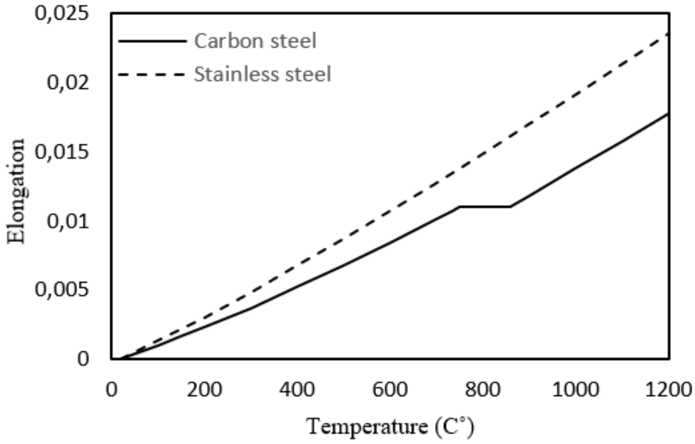

Fig. 10. Thermal elongation of carbon steel vs. stainless steel at elevated temperatures

Emissivity is defined as the ratio of a material's thermal radiation to that of a black body at the same temperature, ranging from 0 to 1 ($0 \leq \varepsilon \leq 1$) according to Eurocode 3. For carbon steel, emissivity increases with temperature due to the formation of an oxidized surface layer above 300 °C. This oxidation increases surface roughness and enhances heat absorption. In contrast, stainless steel forms a passive chromium-rich oxide layer even at room temperature. This layer remains stable at elevated temperatures and inhibits further oxidation, resulting in lower surface roughness and reduced emissivity. According to Eurocode 3, the recommended emissivity values are 0.7 for carbon steel and 0.4 for stainless steel.

The thermal conductivity of stainless steel and carbon steel exhibits distinct behavior as temperature increases, as illustrated in Fig.11a. Carbon steel begins with a relatively high conductivity of approximately 53 W/m·K at room temperature, which decreases steadily to around 27 W/m·K by 800 °C. This reduction stabilizes due to phase transformations occurring at elevated temperatures. In contrast, stainless steel does not undergo phase changes and shows an opposite trend: its thermal conductivity increases with temperature, rising from about 15 W/m·K at room temperature to nearly 30 W/m·K at 1200 °C. Below 1000 °C, stainless steel generally maintains lower conductivity than carbon steel, resulting in more localized heating. However, this difference in conductivity has a relatively limited impact on the overall fire performance of structural elements.

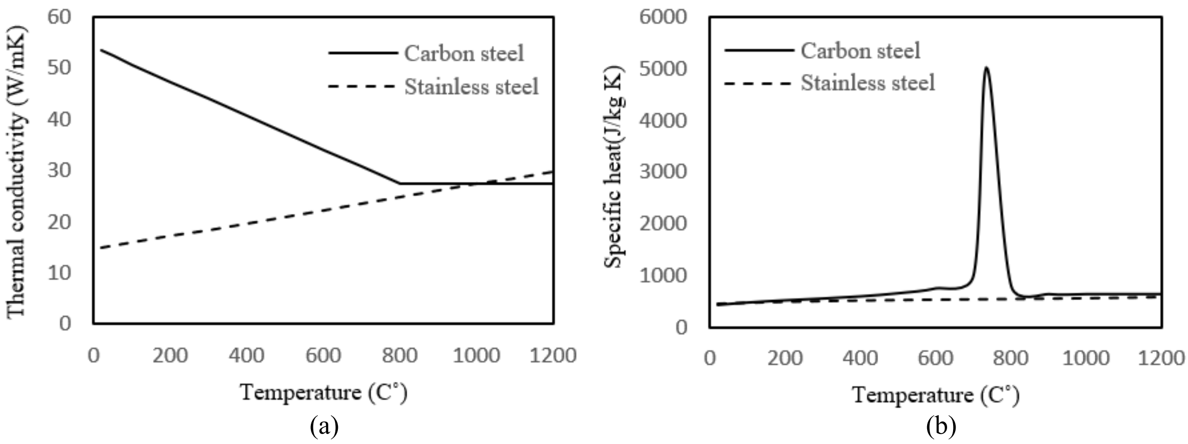

Fig. 11. Distribution of (a) thermal conductivity and (b) specific heat for carbon steel and stainless steel at elevated temperature

Specific heat is a key thermal property that affects how quickly a material heats up under thermal exposure. In this study, specific heat was incorporated into the simulation / numerical analyses for both carbon steel and stainless steel, as shown in Fig. 11b. Stainless steel exhibits a smooth and continuous increase in specific heat with rising temperature, due to the absence of phase transformations. In contrast, carbon steel shows a slightly higher average specific heat-approximately 600 J/kg·K compared to 550 J/kg·K for stainless steel-and features a pronounced peak near 735 °C, which corresponds to a phase transition. Materials with higher specific heat absorb more energy before experiencing a temperature rise, meaning they heat up more slowly when exposed to fire. This property plays an important role in determining the thermal response and fire resistance of structural components.

The numerical simulation assumed a compressive strength of 32.8 MPa for the concrete slab. The Concrete Damage Plasticity (CDP) parameters were estimated using the Kent and Park parabolic constitutive model (Kent & Park, 1971; Park & Paulay, 1991), as shown in Fig. 12. This model provided estimates for damage-related parameters in both compression and tension, as well as definitions for crack and inelastic strain behavior. The calculation of concrete compression damage parameters and inelastic strain values was based on the methodology proposed by Hafezolghorani et al. (2017). A summary of the adopted CDP parameters is presented in Table 2.

5. Results and discussion

For buildings constructed of carbon steel and stainless steel, an explicit non-linear analysis procedure was carried out at elevated temperatures. Fig. 13 presents the axial force and vertical displacement response of carbon steel and stainless steel components under elevated temperatures. The results reveal distinct differences in thermal-structural behavior between the two materials. The axial force–temperature curves indicate that stainless steel elements experience a more gradual reduction in axial force, maintaining load-carrying capacity up to approximately 600 °C. In contrast, carbon steel elements show a sharper and more sudden decline beyond this temperature, with some specimens (e.g., A2-Carbon, B2-Carbon) exhibiting abrupt force drops, likely due to local instability or phase transformation effects. This behavior aligns with the material's known loss of strength and stiffness at elevated temperatures (Fig. 13a). In addtion, the vertical displacement–temperature curves, as can be seen in Fig. 13b, further support these observations. Stainless steel components demonstrate controlled and stable displacement patterns, even at temperatures approaching 800 °C (approximately 55mm). Carbon steel elements, however, experience significant vertical displacement increases beyond 600 °C (approximately 300mm), including sudden drops indicative of structural collapse or progressive failure.

These findings confirm that stainless steel provides superior fire resistance by preserving both axial strength and deformation stability under elevated temperatures. This performance advantage is particularly relevant for critical load-bearing members in fire-exposed structures, where delayed collapse and maintained integrity are essential for occupant safety and structural performance.

Moreover, the deformation of the building for the carbon steel and stainless steel and the Mises stress contour with collapse sequence are given in Fig. 14. It is obvious that the building built stianless steel withstands the collapse during corner compartment fire. The stainless steel building displays much smaller displacements, with a peak value around 50 mm. The displacement is more evenly distributed, indicating higher stiffness retention and better structural integrity under thermal loading. However, fort he building built using carbon steel, the displacement field shows a significant concentration of deformation at the lower levels, especially around the fire-exposed region. The peak displacement reaches 300 mm, indicating severe vertical and lateral deformation and possible onset of progressive collapse (Fig. 14a). As can be seen in Fig. 14b, high stress concentrations are observed at the heated levels, exceeding 2.5×10^8 Pa, which likely exceed the yield strength of the material at elevated temperatures. This suggests a high potential for plastic deformation or local failure. Also, stress levels are more moderate and better distributed for the stainless steel. The highest stress values reach approximately 2.1×10^8 Pa, but do not localize as critically as in the carbon steel.

5. Conlusion

This study presented a comprehensive numerical investigation of multi-storey steel-building exposed to fire, focusing on the comparative performance of carbon steel and stainless steel. The evaluation was carried out through temperature-dependent material properties, structural response parameters, and damage accumulation under fire scenarios. The results consistently indicate that stainless steel outperforms carbon steel in fire-exposed conditions in terms of both strength retention and deformation control:

- Material properties such as strength, stiffness, and thermal conductivity showed that stainless steel retains its mechanical characteristics more effectively at elevated temperatures. Specifically, stainless steel preserved up to 75% of its strength at 500 °C, while carbon steel dropped sharply beyond 450 °C.
- In terms of thermal expansion and specific heat, stainless steel demonstrated smoother and more stable behavior due to the absence of phase transitions which contributes to greater predictability in structural fire response.
- The load–temperature and displacement–temperature relationships revealed that carbon steel members experienced earlier and more severe stiffness loss and vertical displacement, indicating a higher susceptibility to collapse.
- Carbon steel building exhibited large displacement concentrations and severe stress localization near the heated regions, whereas stainless steel building maintained more uniform stress distribution and reduced deformation.

These findings support the conclusion that stainless steel is a more robust and fire-resistant material for critical structural components in buildings exposed to elevated temperatures. Although its initial cost may be higher than that of carbon steel, its performance advantages under fire conditions are substantial. Stainless steel demonstrates a progressive and ductile failure behavior, retaining both strength and stiffness across a wider temperature range. This enhances overall structural resilience, delays collapse mechanisms, and provides a greater window for safe evacuation and emergency response. Its ability to maintain load-bearing capacity and reduce post-fire damage also contributes to lower repair demands, making stainless steel a technically and economically viable alternative for fire-prone or high-risk structures.

Effect of cracks on dynamic behavior of stepped beams with general boundary conditions

Ezgi Sevilmiş*[1], Volkan Kahya[1], Sebahat Şimşek[1]

[1] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. This study investigates the effects of cracks on the dynamic characteristics of structures, particularly in terms of natural frequencies and mode shapes. A stepped beam is considered as the primary structure, and cracks with varying depths are modeled at arbitrary locations on the beam. These cracks are represented as massless rotational springs to account for stiffness loss at the cross-sections. General boundary conditions are considered for the beams.The transfer matrix method is employed for the analytical solution of the problem. Using this method, analytical equations are developed to relate the beam segments separated by cracks. The resulting analytical model provides the capability to determine the mode shapes and natural frequencies of damaged beams. In the analyses, crack locations and depths, physical parameters of the beam and the effects of boundary conditions on vibration characteristics are examined.This study provides an analytical basis for artificial intelligence-based inverse analyses (damage detection) and enables the development of a training database that can be used for estimating parameters such as crack depth and location in beams with known frequencies.

Keywords: Stepped beam; Transfer matrix method; Crack; Vibration; Damage detection

1. Introduction

When mechanical structural members are subjected to static and dynamic loading, they undergo stress and deformation. These stresses and deformations can induce damage within the structure, thereby shortening its service life; as a result, both the safety margin against collapse and the overall reliability of the system decrease. Accordingly, evaluating the load-carrying capacity of damaged members is of critical importance. Structural vibrations arising from external loads generate cyclic stresses, which are regarded as primary precursors to crack initiation. Hence, damage detection can be carried out by analysing the vibration characteristics of the structure in both its intact and damaged states. Beams are among the elements most susceptible to cracking due to their dynamic behaviour; consequently, extensive research has been devoted to modelling and formulating cracks in beams and investigating their influence on structural performance.

Dimarogonas (Dimarogonas, 1996) proposed the local flexibility concept—derived from stress-intensity factors in fracture mechanics for modelling an open-edge crack. Under the most general loading, local flexibility can be represented by a 6×6 matrix (Papadopoulos,1987). The coefficients of this matrix depend on the crack size and the geometry of the crack plane. According to the theory, the local compliance introduced at the crack site is idealised as a massless rotational spring.

Research on the vibration behaviour of cracked beams that employs the local flexibility concept under general loading generally falls into two main categories:Direct problem – Investigation of how single or multiple cracks influence structural dynamic properties such as the natural frequencies and mode shapes of damaged beams.Inverse problem.- Estimation of crack location and size from measured dynamic data of the damaged beam system.

The Euler–Bernoulli beam theory has been extensively adopted in numerous investigations of cracked beams subjected to various boundary conditions. Narkis and Elmalah (Narkis,1996) analysed the vibration of a simply-supported cracked beam by modelling the crack as a massless rotational spring and partitioning the beam into two sub-beams. Zheng and Fan (Papadopoulos,1987) studied hollow beams with rectangular and circular cross-sections, while Lele and Maiti (Lele,2002) proposed a novel crack-identification method based on Timoshenko beam theory. Loya et al. (Loya et al., 2006) further examined the influence of cracks on the natural frequencies of a simply-supported Timoshenko beam.

Research carried out roughly two decades ago was largely confined to beams containing only one, or at most two, cracks. Chang and Bert (Jang et al, 1989) investigated the free vibration of stepped beams with various boundary conditions, and Naguleswaran (Naguleswaran, 2003) explored the vibrational behaviour of a stepped

*Corresponding author, E-mail: ezgisevilmiss@gmail.com

https://doi.org/10.31462/icearc2025_ce_sme_709

beam subjected to an axial load. Nandwana and Maiti introduced a crack-detection scheme for stepped cantilever beams, whereas Shifrin and Ruotolo (Shifrin et al., 1999) proposed a technique for analysing the dynamic characteristics of beams with multiple cracks; however, their approach was applicable only to beams with a limited number of cracks.

The present study aims, building upon previous research, to investigate the free-vibration behaviour of a stepped beam containing an arbitrary number of transverse open cracks under general boundary conditions; to quantify the influence of multiple cracks on the beam's dynamic characteristics; and to devise a methodology that will supply input data for future diagnostic systems by exploiting the differences between the intact and damaged states.

In the proposed model, the general boundary conditions are represented by concentrated masses attached to both beam ends, each supported by linear (K_1, K_2) and rotational (K_{R_1}, K_{R_2}) springs. The local flexibility introduced by each crack is idealised as a massless rotational spring. Differential-equation solutions obtained for every cracked sub-segment are assembled consecutively—linking the beam's tip to its root—to construct a transfer matrix. Coupling this transfer matrix with the boundary conditions yields the characteristic equation, which is solved analytically to determine the natural frequencies of the beam.

2. Theoretical background

Consider an intact steped beam with N cracks and a uniform area. The beam is assumed to be connected by massless rotational springs at cracked section as shown in Fig1 The differential equation that an elastic Euler–Bernoulli beam can be expressed as

$$EI\frac{d^4y(x,t)}{dx^4} + \rho A\frac{d^2y(x,t)}{dt^2} = 0 \tag{1}$$

where $Y_i(x,t)$ is the deflection function, EI is the flexural rigidity ρ is the mass density, A is the cross-sectional area of the beam

$$y(x,t) = Y(x)\,T(t) \tag{2}$$

$$\frac{d^4Y(x)}{dx^4} - \beta^4 Y(x) = 0 \tag{3}$$

$$\frac{d^2T(t)}{dt^2} - \omega^2 T(t) = 0 \tag{4}$$

where $\beta^4 = \omega^2(\rho A/EI)$ and ω is the natural frequency of the entire uniform beam. The solution of the Eq. 3 can be expressed ain Eq. 5

$$Y(x) = B_1\cos(\beta x) + B_2\sin(\beta x) + B_3\cosh(\beta x) + B_4\cos(\beta x) \tag{5}$$

in which $B_1 - B_4$are unkown constant.

As shown in Fig. 1 a section of uniform beam with an open edge crack is divided into two beam segments and the crack position is assumed as the separation point. If we write the sections in Eq. 5 obtaining a matrix form for each section as Eq. 6 – 7.

$$\begin{Bmatrix} Y_i(x) \\ \theta_i(x) \\ M_i(x) \\ V_i(x) \end{Bmatrix} = [T] * \begin{Bmatrix} Y_{1,i}(x) \\ \theta_{1,i}(x) \\ M_{1,i}(x) \\ V_{1,i}(x) \end{Bmatrix} \tag{6}$$

$$\begin{Bmatrix} Y_{i+1}(x) \\ \theta_{i+1}(x) \\ M_{i+1}(x) \\ V_{i+1}(x) \end{Bmatrix} = [T] * \begin{Bmatrix} Y_{1,i+1}(x) \\ \theta_{1,i+1}(x) \\ M_{1,i+1}(x) \\ V_{1,i+1}(x) \end{Bmatrix} \tag{7}$$

where;

$$[S(x)] = \begin{bmatrix} \cos(\beta x) & \sin(\beta x) & \cosh(\beta x) & \sinh(\beta x) \\ -\beta\sin(\beta x) & \beta\cos(\beta x) & \beta\sinh(\beta x) & \beta\cosh(\beta x) \\ -\mathrm{EI}\beta^2\cos(\beta x) & -\mathrm{EI}\beta^2\sin(\beta x) & \mathrm{EI}\beta^2\cosh(\beta x) & \mathrm{EI}\beta^2\sinh(\beta x) \\ \mathrm{EI}\beta^3\sin(\beta x) & -\mathrm{EI}\beta^3\cos(\beta x) & \mathrm{EI}\beta^3\sinh(\beta x) & \mathrm{EI}\beta^3\cosh(\beta x) \end{bmatrix} \tag{8}$$

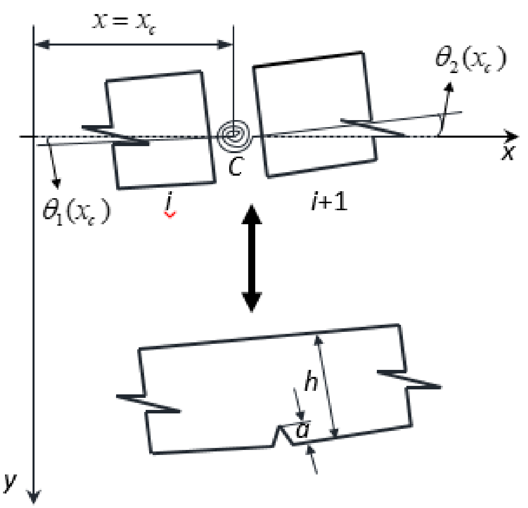

Fig. 1. Equivalent massless rotational spring and discontinuity of slope at crack position

Expressing the general equality more concisely given in Eq. 9.

$$Q_{i,j} = [S(x)_i] * \{B_{i,j}\} \tag{9}$$

There is continuity among the deflection, bending moment and shear force at the crack position for segments i and i+1. But there is a discontinuity between slopes which is revealed by the bending moment and rotation of the spring representing the crack. These boundary conditions at crack position given in the Eqn. 10-13.

$$Y_i(x_c) = Y_{i+1}(x_c) \tag{10}$$

$$M_i(x_c) = M_{i+1}(x_c) \tag{11}$$

$$V(x_c) = V_{i+1}(x_c) \tag{12}$$

$$\theta_{i+1}(x_c) - \theta_i(x_c) = C\, M_i(x_c) \tag{13}$$

Where C is obtained by Zheng(Zheng,2003). Written in matrix form in Eqn. 14

$$\begin{Bmatrix} Y_{i+1}(xc) \\ \theta_{i+1}(xc) \\ M_{i+1}(xc) \\ V_{i+1}(xc) \end{Bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & C & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} * \begin{Bmatrix} Y_{1,i+1}(xc) \\ \theta_{1,i+1}(xc) \\ M_{1,i+1}(xc) \\ V_{1,i+1}(xc) \end{Bmatrix} \tag{14}$$

Now consider a multi-stepped beam with an arbitrary cracks as shown in Fig.2. It consist of n uniform beam steps and the length of its step is L_i , the moment of inertia is I_i and the number of cracks in each step is N_i. These cracks located at points $x_{(i,j)}$ with size $a_{(i,j)}$. The model is created with general boundary conditions the both edge carry lumped masses (m is the mass , e is the eccentricity and J is the rotary inertia) and both side supported by linear springs (K) and the rotational springs (K_R) as shown in Fig 2 . For instance, springs stiffness coefficients for five common end conditions are listed in Table 1.

In the stepped-beam model, two types of continuity (connection) conditions are considered. The first concerns the internal connection within a segment; Eqn. 14 specifies how successive segments i and i+1 are linked. When segments i and i+1 are connected in accordance with the constraint this analytics process has been done in detail by Attar.2012.The Q matrix at the end of a segment can be related to the Q matrix at the beginning of the same segment give in the Eqn. 15-16. As a second concern, two steps should be connected to each other. Based on this principle, the formula for connecting the last point of the beam to the first point is given in Eqn. 17-18-19.

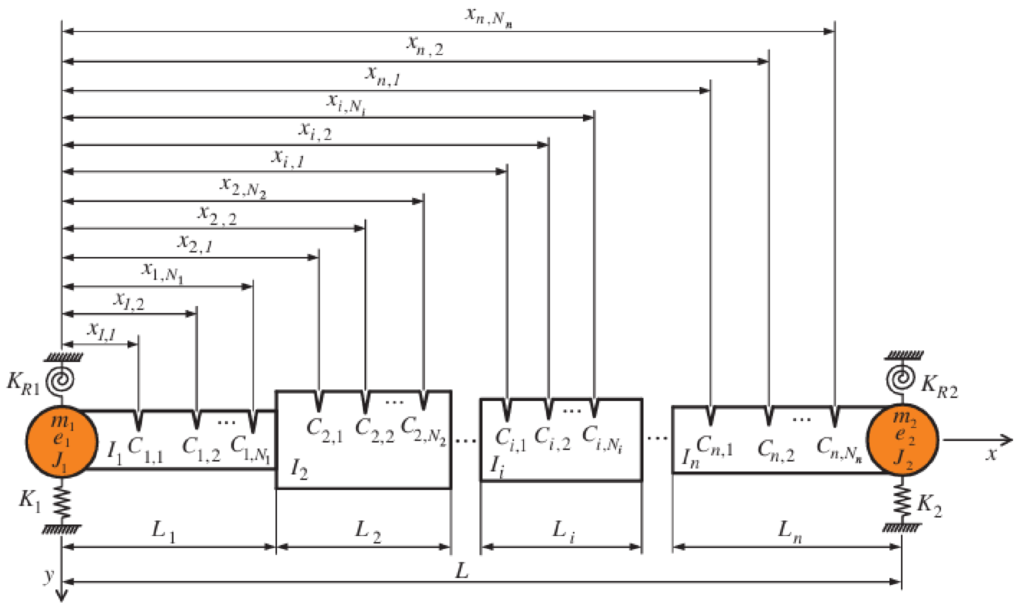

Fig. 2. A multi-stepped free-free beam with N edge open cracks composed of uniform beam segments and carrying lumped masses, linear and rotational springs at both ends

$$Q_{j,(N_n+1)}(x_{j,(N_n+1)}) = T_{i,j} * TC_{i,j-1} * TC_{i,j-2} * \dots\dots * TC_{i,1} * Q_{j,0}(x_{j,0}) \tag{15}$$

$$[T]_i = T_{i,j} * TC_{i,j-1} * TC_{i,j-2} * \dots\dots * TC_{i,1} \tag{16}$$

$$Q_{j,(N_n+1)}(x_{j,(N_n+1)}) = [T]_{N_n} * [T]_{N_{n-1}} * \dots\dots * [T]_i * \dots\dots * [T]_2 * [T]_1 * Q_{0,0}(x_{0,0}) \tag{17}$$

$$[T] = [T]_{N_n} * [T]_{N_{n-1}} * \dots\dots * [T]_i * \dots\dots * [T]_2 * [T]_1 \tag{18}$$

$$Q_{j,(N_n+1)}(x_{j,(N_n+1)}) = [T] * Q_{1,0}(x_{1,0}) \tag{19}$$

Matrix [T] has a general form given in Eqn. 20.

$$\begin{Bmatrix} Y_{n,N_{n+1}}(L) \\ \theta_{n,N_{n+1}}(L) \\ M_{n,N_{n+1}}(L) \\ V_{n,N_{n+1}}(L) \end{Bmatrix} = \begin{pmatrix} T_{11} & T_{12} & T_{13} & T_{14} \\ T_{21} & T_{22} & T_{23} & T_{24} \\ T_{31} & T_{32} & T_{33} & T_{34} \\ T_{41} & T_{42} & T_{43} & T_{44} \end{pmatrix} * \begin{Bmatrix} Y_{1,1}(0) \\ \theta_{1,1}(0 \\ M_{1,1}(0) \\ V_{1,1}(0 \end{Bmatrix} \tag{20}$$

The boundry conditions of general form given in Eqns 21-24

$$M(0) = -e_1 m_1 \omega^2 Y(0) + K_{R_1}\theta(0) - (J_1 + m_1 e_1^2)\omega^2\theta(0) \tag{21}$$

$$V(0) = -K_1 Y(0) + m_1\omega^2 Y(0) + e_1 m_1 \omega^2 \theta(0) \tag{22}$$

$$M(L) = e_2 m_2 \omega^2 Y(L) - K_{R_2}\theta(L) + (J_2 + m_2 e_2^2)\omega^2\theta(L) \tag{23}$$

$$V(L) = K_2 Y(L) - m_2\omega^2 Y(L) - e_2 m_2 \omega^2 \theta(L) \tag{24}$$

Substitutting Eqns . 21-24. into 20. From there Eqns 25 obtainin Eqns. 26-27.

$$\begin{Bmatrix} Y_{n,N_{n+1}}(L) \\ \theta_{n,N_{n+1}}(L) \\ e_2 m_2 \omega^2 Y(L) - K_{R_2}\theta(L) + (J_2 + m_2 e_2^2)\omega^2\theta(L) \\ K_2 Y(L) - m_2\omega^2 Y(L) - e_2 m_2 \omega^2 \theta(L) \end{Bmatrix} = [T]\begin{Bmatrix} Y_{1,1}(0) \\ \theta_{1,1}(0) \\ -e_1 m_1 \omega^2 Y(0) + K_{R_1}\theta(0) - (J_1 + m_1 e_1^2)\omega^2\theta(0) \\ -K_1 Y(0) + m_1\omega^2 Y(0) + e_1 m_1 \omega^2 \theta(0) \end{Bmatrix} \tag{25}$$

$$\begin{Bmatrix} Y_{n,N_{n+1}}(L) \\ \theta_{n,N_{n+1}}(L) \end{Bmatrix} = \begin{Bmatrix} T_{11} - e_1 m_1\omega^2 T_{13} + (m_1\omega^2 - K_1)T_{14} & T_{12} + \left(K_{R_1} - (J_1 + m_1 e_1^2)\omega^2\right)T_{13} + e_1 m_1 \omega^2 T_{14} \\ T_{21} - e_1 m_1\omega^2 T_{23} + (m_1\omega^2 - K_1)T_{24} & T_{22} + \left(K_{R_1} - (J_1 + m_1 e_1^2)\omega^2\right)T_{23} + e_1 m_1 \omega^2 T_{24} \end{Bmatrix}\begin{Bmatrix} Y_{1,1}(0) \\ \theta_{1,1}(0) \end{Bmatrix} \tag{26}$$

$$\begin{bmatrix} e_2 m_2 \omega^2 & -K_{R_2}(J_2 + m_2 e_2^2)\omega^2 \\ K_2 - m_2\omega^2 & -e_2 m_2 \omega^2 \end{bmatrix}\begin{Bmatrix} Y_{n,N_{n+1}}(L) \\ \theta_{n,N_{n+1}}(L) \end{Bmatrix} = \begin{Bmatrix} T_{31} - e_1 m_1\omega^2 T_{33} + (m_1\omega^2 - K_1)T_{34} & T_{32} + \left(K_{R_1} - (J_1 + m_1 e_1^2)\omega^2\right)T_{33} + e_1 m_1 \omega^2 T_{34} \\ T_{41} - e_1 m_1\omega^2 T_{43} + (m_1\omega^2 - K_1)T_{44} & T_{42} + \left(K_{R_1} - (J_1 + m_1 e_1^2)\omega^2\right)T_{43} + e_1 m_1 \omega^2 T_{44} \end{Bmatrix}\begin{Bmatrix} Y_{1,1}(0) \\ \theta_{1,1}(0) \end{Bmatrix} \tag{27}$$

Subtutiting Eqn. 26 into Eqn. 27 gives the general form of frequency equation for cracked beam in Eqn. 28.

$$F = f_1 f_4 - f_2 f_3 \tag{28}$$

As a result, the free vibration analysis of the cracked multi-stepped beam under general boundary conditions is found with $F = 0$.

3.Results

In this section, the developed solution methodology will be validated for accuracy by comparing it against various alternative approaches.Model 1. Free vibration of square-sectional cantilever beam having three cracks Fig 3. shows a square sectional cantilever beam with three open cracks. The material parameters for beam are, E=2,06×10^{11} N/m^2, ρ = 7800 kg/m^3 L = 900 mm and dimensions are 1cm x 3cm (h x b) . For this model, experimental (Karaca, 2016) and two-dimensional SEM analyses (Attar,2012) were compared with the results of the present study, and the corresponding values are provided in Table 2.

Model 2. Free Vibration of a stepped beam having three cracksFig 4. shows a square sectional cantilever beam with three open cracks. The material parameters for beam are . E= 210 Gps. ρ = 7860 kg/m^3 . L = 0.3 . $L_1 = L_2 = L_3$= 0.1 m dimensions are h_1 . h_3= 0.0075 m . h_2 =0.009375 m. For this model. Finite element model (ANSYS) analyses (Attar, 2012) were compared with the results of the present study. and the corresponding values are provided in Table 3.

Model 3. Free Vibration of a stepped beam having one cracks with the positional variationIn this example. the free-vibration response of a beam as a function of the positional variation of a single crack investigating using the configuration depicted in Fig. 3 of the preceding example. The material parameters for beam are . E=2.06×10^{11} N/m^2. ρ = 7800 kg/m^3 . L = 900 mm and dimensions are 1cm x 3cm (h x b). $x_{1.1}$=0.225. $x_{1.2}$=0.45. $x_{1.3}$= 0.675.values are provided in Table 4.

Abstract. The inter-story drift ratio is a critical parameter strongly associated with building damage, particularly under earthquake ground motions. Therefore, seismic codes in various countries impose limitations on this parameter to ensure safe design of earthquake resistant structures. This study introduces an innovative continuous model approach to approximate the inter-story drift ratio, its variation along building height, and the location of its maximum value. This model represents an equivalent continuous beam composed of a combination of a shear beam and a flexural beam. In solving the continuous model, the rotational boundary condition at the base is expressed in terms of the first-story inter story drift, and closed-form solutions for the equation of motion of the model are derived. Two dimensionless parameters are required for solving the continuous model: i) the lateral stiffness ratio (α), which controls the structural behavior, and ii) the location of the first-story (θ). Here, the parameter α is defined through a simplified mathematical expression as a function of the number of stories (N) and the stiffness ratio between the beams and columns (ρ). Dynamic analyses were conducted using the response spectrum for low-rise and high-rise building models with various structural characteristics. Structural responses, including lateral displacements and inter story drift ratios, were investigated. The finite element model results obtained from the SAP2000 program were compared with the analytical solution results, revealing good agreement between the two sets of results.

Keywords: Continuous model; Lateral stiffness ratio; First-story location; Blume coefficient (index); Interstory drift ratio

1. Introduction

In the field of structural engineering, the accurate estimation of structural responses under earthquake loads is an important issue, particularly given the direct correlation between seismic-induced deformations and building damage. Among the various response parameters, the inter-story drift ratio has been consistently recognized as a key indicator of structural and non-structural damage during earthquakes (Miranda & Akkar, 2006; Neam & Taghikhany, 2016; Eroğlu Azak, 2013; Qu & Pan, 2022; Morfidis et al., 2023). Consequently, a considerable number of seismic design codes worldwide impose limitations on drift ratios. These limitations are implemented to ensure the safety and serviceability of buildings (FEMA 356, 2000; TBEC-2018, 2018).

Given the significance of drift demands, a range of analytical and numerical methodologies have been developed to estimate lateral displacements and inter-story drift distributions in buildings subjected to seismic loading. Among these, continuous beam models have gained increasing attention for their efficiency and simplicity in approximating the dynamic behavior of multi-story buildings, particularly in preliminary design and seismic assessment studies (Heidebrecht & Stafford Smith, 1973; Iwan, 1997; Miranda, 1999; Miranda & Taghavi, 2005; Miranda & Akkar, 2006; Khaloo & Khosravi, 2008; Wiebe & Christopoulos, 2015; Alonso-Rodríguez & Miranda, 2016, 2018; Alonso-Rodríguez & Tsavdaridis, 2021; Veladi et al., 2020). These models provide a representation of structural systems by idealizing the building as a continuous shear, flexural, or shear–flexural beam, enabling closed-form or semi-analytical solutions under various boundary conditions.

The coupling beam concept was subsequently enhanced by Heidebrecht and Stafford Smith (1973) and by Miranda (1999). Miranda (1999) introduced the coupling beam concept as a basis framework for modeling the seismic behavior of buildings. Building upon this research, Miranda and Reyes (2002) analyzed the effects of such stiffness variations and concluded that they do not significantly alter structural response unless the changes are abrupt and considerable. Expanding on this, Taghavi and Miranda (2005), Miranda and Taghavi (2005) and

https://doi.org/10.31462/icearc2025_ce_sme_715

Reinoso and Miranda (2005) examined floor acceleration demands by using a continuous shear–flexural beam model, applying it to buildings of different heights and incorporating nonuniform stiffness distributions. In further elaboration on this subject, Miranda and Akkar (2006) developed a generalized spectrum for inter-story drifts in buildings subjected to earthquake-induced ground motions.

However, despite their widespread use, most existing continuous beam models adopt assumptions at the base, such as a zero-rotation boundary condition, which does not adequately reflect the inter-story drift at the first-story (Miranda & Akkar, 2006; Khaloo & Khosravi, 2008; Alonso-Rodríguez & Tsavdaridis, 2021). Given that maximum drift does not occur uniformly along the height, but is influenced by structural properties and boundary effects (Khaloo & Khosravi, 2008), accurate representation of boundary conditions becomes essential in determining both the magnitude and location of critical responses. Çolak et al. (2023) proposed a novel equivalent continuous beam model by improving the continuous shear-flexural beam model by including a rotation boundary condition at the base. Çolak (2024) investigated the higher mode effects using this novel equivalent continuous beam model and also pointed out that the solution of this model can be improved for buildings with different first-story heights.

In addressing these limitations, this study introduces a novel equivalent continuous beam model for the seismic performance evaluation of multistory buildings. This model incorporates a rotational boundary condition at the base, expressed in terms of the first-story drift. By considering a combination of shear and flexural deformation behavior, the model allows for a more realistic representation of structural dynamics and drift demand distribution. Closed-form solutions for lateral displacements and inter-story drift ratios are derived based on two key dimensionless parameters: the lateral stiffness ratio (α), and the first-story location (θ). The stiffness ratio α, which significantly influences the overall structural behavior, is defined as a function of the number of stories and the stiffness ratio between beams and columns.

The proposed model is distinct from previous studies (Heidebrecht & Stafford Smith, 1973; Iwan, 1997; Miranda, 1999; Miranda & Taghavi, 2005) in that it captures the influence of first-story drift on overall building response and enables more accurate estimation of maximum drift demands. Furthermore, a simplified mathematical expression for the lateral stiffness ratio is introduced, incorporating both geometric and material properties of the building through the beam-to-column stiffness ratio (ρ) and the number of stories (N). This formulation facilitates practical implementation while preserving analytical rigor. To evaluate the accuracy and robustness of the proposed method, dynamic analyses were conducted for a range of low-rise and high-rise structural configurations using response spectrum analysis. The analytical results derived from the continuous model were compared with detailed finite element simulations conducted in SAP2000. The comparisons demonstrated a high degree of agreement, thereby validating the proposed model's capability to effectively approximate structural responses under seismic loads.

2. A Novel equivalent continuous beam model

Continuous models are commonly employed in the literature as approximate methods for predicting structural responses, serving as alternatives to multi-degree-of-freedom systems. These models typically idealize the structure as a continuous cantilever beam with uniform mass and stiffness distributions and assume zero displacement and rotation at the base. However, this a simplification that overlooks the efficient of base rotation to drift. Addressing this limitation, the present study proposes a closed-form solution that incorporates a rotational boundary condition at the base, aiming to enhance the accuracy of structural response predictions. In this study, a novel equivalent continuous beam model for the seismic performance evaluation of multistory buildings is presented. The model was improved to continuous shear-flexural beam model proposed in Miranda and Taghavi (2005) by including a rotation boundary condition at the base.

Under the effect of a horizontal ground acceleration $\ddot{u}_g(t)$ applied at the base, the undamped dynamic behavior of the continuous beam model is governed by a partial differential equation, as presented in Eq. (1).

$$\frac{m}{EI}\frac{\partial^2 u(\zeta,t)}{\partial t^2}+\frac{1}{H^4}\frac{\partial^4 u(\zeta,t)}{\partial \zeta^4}-\frac{\alpha^2}{H^4}\frac{\partial^4 u(\zeta,t)}{\partial \zeta^4}=-\frac{m}{EI}\frac{\partial^2 u_g(t)}{\partial t^2} \tag{1}$$

In this context;
m ; the mass per unit length,
H ; the total height of the building,
$u(\zeta,t)$; the lateral displacement at a dimensionless height ζ at time t,
EI ; the flexural rigidity of the beam,
α ; the lateral stiffness ratio

Here, α is a dimensionless parameter that governs the relative contribution of flexural and shear deformations in the continuous model, thereby influencing the lateral displacement profile. The model reduces to an Euler–

Bernoulli beam when α = 0 and approaches a shear beam as α tends to infinity, with intermediate values capturing the combined behavior typical of multistory structures Miranda and Taghavi (2005).

$$\alpha = H\sqrt{\frac{GA}{EI}} \tag{2}$$

GA represents the shear rigidity of the continuous beam. According to Miranda and Reyes (2002), the stiffness ratio α varies with structural system type: it ranges from 0–2 for shear wall systems, 1.5–6 for dual systems, and 5–20 for moment-resisting frames, while values exceeding 30 indicate shear-dominated behavior. Taghavi and Miranda (2005) proposed representative α values of 3.125 for dual systems and 12.5 for moment-resisting frames.

The dynamic response of a linear elastic continuous system can be represented as a linear superposition of all modes, yielding the displacement u(ζ,t) as a function of dimensionless height (ζ) and time (t). With classical damping assumptions, modal expressions for lateral displacement ($u_i(\zeta,t)$) and inter-story drift ratio ($IDR_i(\zeta,t)$) can be derived to quantify each mode's contribution to the structural response.

$$u_i(\zeta,t) = \Gamma_i \phi_i(\zeta) D_i(t) \tag{3}$$

$$IDR_i(\zeta,t) = \frac{1}{H}\Gamma_i \phi_i'(\zeta) D_i(t) \tag{4}$$

The modal participation factor (Γ_i) corresponding to the continuous system with a uniform mass distribution, is expressed as follows:

$$\Gamma_i = \frac{\int_0^1 \phi_i(\zeta)d\zeta}{\int_0^1 \phi_i^2(\zeta)d\zeta} \tag{5}$$

Substituting Eq. (3) into Eq. (1) and applying the separation of variables technique for the free vibration case yields two decoupled equations: one spatially dependent ($\phi_i(\zeta)$) and the other time dependent($D_i(t)$). The mode shape function ($\phi_i(\zeta)$) is derived as the general solution to the differential equation governing the spatial behavior.

$$\phi_i(\zeta) = B_1 \sin(\gamma_i \zeta) + B_2 \cos(\gamma_i \zeta) + B_3 \sinh(\beta_i \zeta) + B_4 \cosh(\beta_i \zeta) \tag{6}$$

Here $\beta=\sqrt{\gamma_i^2+\alpha^2}$, where B_1 to B_4 denote the integration constants determined by the imposed boundary conditions.

The eigenvalue (γ_i) is determined by solving for the circular frequencies (ω_i) as described in Eq. (7).

$$\omega_i^2 = \frac{EI}{mH^4}\gamma_i^2(\gamma_i^2 + \alpha^2) \tag{7}$$

Accurate dynamic properties and predictions require selecting the correct α value Miranda (1999), because of the mode shape ($\phi(\zeta)$), drift mode shape ($\phi'(\zeta)$), modal participation factor (Γ_i), and circular frequencies (ω_i) depend on the lateral stiffness ratio α (Miranda & Taghavi, 2005; Miranda & Akkar, 2006).

2.1 Application of Boundary Conditions

In the continuous model with a fixed base, the boundary conditions enforce both zero displacement and rotation at the base. However, in the proposed model, while the displacement at the base remains zero (Eq. 8), the rotational boundary condition is defined in terms of the first-story inter-story drift, which is non-zero (Eq. 9). The following equations represent these conditions:

$$\phi_i(\zeta)_{\zeta=0} = 0 \tag{8}$$

$$\left.\frac{d\phi_i(\zeta)}{d\zeta}\right|_{\zeta=0} = \frac{\phi_i(h_1/H)}{h_1/H} \tag{9}$$

Here, h_1/H is the ratio of the first-story height (h_1) to the total building height (H). This ratio is defined as the '*first-story location*', hereafter referred to as θ, through the normalized building height (ζ) . In this case, θ is defined as follows:

$$\theta = \frac{h_1}{H} = \frac{h_1}{h_1 + (N-1)h_j} \tag{10}$$

In the case where all stories are assumed to have equal heights (i.e., $h_1=h_j$), the first-story location θ becomes equal to "*1/N*", where *N* is the total number of stories. In this study, equal story heights are considered for all stories unless stated otherwise. Notably, the special case of $\theta=0$, which corresponds to a zero rotational boundary condition at the base, yields results identical to those presented by Miranda and Taghavi (2005).

Correspondingly, in the continuous model, the boundary condition at the normalized height (ζ=1) (representing the free end) yields zero moment and shear force:

$$\left.\frac{d^2\phi_i(\zeta)}{d\zeta^2}\right|_{\zeta=1} = 0 \tag{11}$$

$$\left.\left(\frac{d^3\phi_i(\zeta)}{d\zeta^3} - \alpha^2 \frac{d\phi_i(\zeta)}{d\zeta}\right)\right|_{\zeta=1} = 0 \tag{12}$$

The following integration constants are obtained through the application of the boundary conditions:

$$\begin{gathered} B_2 = \left(-\frac{\beta_i \gamma_i^2 \theta \sin(\gamma_i) + \beta_i^2 \gamma_i \theta \sinh(\beta_i) - 2\beta_i^2 \sin(\gamma_i \theta)\sinh(\beta_i) - 2\gamma_i^2 \sin(\gamma_i)\sinh(\beta_i \theta)}{\left(\gamma_i^2 \cos(\gamma_i) + \beta_i^2 \cosh(\beta_i)\right)\left(\beta_i \theta - 2\sinh(\beta_i \theta)\right)} \right) B_1 \\ B_3 = \left(-\frac{\gamma_i \theta - 2\sin(\gamma_i \theta)}{\beta_i \theta - 2\sinh(\beta_i \theta)} \right) B_1 \\ B_4 = -B_2 \end{gathered} \tag{13}$$

The integration constants B_1 through B_4, defined in Equations (8)–(11), are employed to insert the mode shape function (Eq. 6) into the boundary condition (Eq. 12), leading to the formulation of the characteristic Eq. (14).

$$\left(\begin{gathered} -2\gamma_i \beta_i^3 \left(\gamma_i \theta - \sin(\gamma_i \theta)\right) + 2\gamma_i^2 \beta_i^2 \sinh(\beta_i \theta) - \sin(\gamma_i)\sinh(\beta_i)\left(\beta_i^2 \left(\alpha^2 \gamma i \theta - 2\beta_i^2 \sin(\gamma_i \theta)\right) + 2\gamma_i^3 \beta_i \sinh(\beta_i \theta)\right) + \\ \cos(\gamma_i)\cosh(\beta_i)\left(\beta_i \left(-\left(\left(\alpha^4 + 2\gamma_i^2 \beta_i^2\right)\theta\right) + 2\gamma_i^3 \sin(\gamma_i \theta)\right) + 2\beta_i^4 \sinh(\beta_i \theta)\right) \end{gathered} \right) = 0 \tag{14}$$

The eigenvalues (γi) are determined by solving the characteristic equation (Eq. (14)) as a function of α and θ. In the novel equivalent continuous beam model, presented in this study, with uniform mass and stiffness, mode shapes, period ratios, and participation factors are governed by the first-story location (θ) and lateral stiffness ratio (α). Base rotation is defined by the first-story drift. While the lateral stiffness ratio must be known, the literature offers only approximate values based on structural systems, without a definitive method. Although, this study proposes a simple empirical equation to improve response predictions, as well.

2.2 Formulation and identification of the lateral stiffness ratio

The lateral displacement of buildings under horizontal loads primarily results from column bending and the rotation of beams at column ends, both influenced by their relative stiffness. Blume (1968) showed that the structural and dynamic characteristics of frame systems depend on the stiffness ratio between beams and columns, defined as Blume coefficient (ρ), which reflects combined deformation behavior. ρ is a key structural parameter indicating relative joint rotations and is given by Eq. (15), assuming equal elastic modulus for beams and columns (Blume, 1968). It characterizes the contribution of flexural and shear deformations: ρ=0 represents a flexural system, ρ=∞ a shear system, and intermediate values indicate combined behavior (Miranda, 1999).

$$\rho = \frac{\sum_{beams} \left({I_b}/{l_b} \right)}{\sum_{columns} \left({I_c}/{h_c} \right)} \tag{15}$$

where I_b and I_c are the beam and column moments of inertia, and l_b and h_c are their respective lengths.

Additionally, ρ influences the natural period and mode shapes, providing insight into the dynamic response of moment-resisting frames (Chopra, 2012; Akkar et al., 2005). Unlike the dimensionless parameter α used in continuous models, ρ is independent of building height. In this study, the number of stories (N) is used instead of building height, relating the estimation of α to both ρ and N.

To determine this relationship, discrete frame models were used to estimate the lateral stiffness ratio (α) in the continuous beam model. Ten sets of moment-resisting frames with varying Blume coefficients (ρ), ranging from flexural to shear behavior values, were analyzed, each including buildings with low-rise to high-rise story buildings. The models were based on a six-span layout with 5 m beam lengths and 3 m story heights. The beam-to-column stiffness ratio (ρ) for building models, calculated via Eq. (15) . Dynamic analyses were performed by the response spectrum. Detailed information on the models can be found in Çolak et al. (2023) study.

To assess the efficacy of the proposed model in predicting structural responses, analyses were conducted on a range of sample building models that have been defined above. These structures, varying from 5 to 20 stories, were modeled and analyzed using SAP2000 software. The analysis results were then employed to generate predictions based on the proposed rotational base condition concept (θ=1/N) and the lateral stiffness ratio (α), as expressed by the relevant equations. An iterative trial-and-error procedure was employed to determine the optimal α value that provides the most accurate estimation of structural behavior. The main objective was to identify the α value that results in the best alignment between the predicted and actual structural responses. Specifically, this involved comparing the mode shape profiles obtained from the SAP2000 (FEM) analyses with those derived from the proposed model and iteratively adjusting α to achieve the closest match.

Closed-form analytical expressions of the continuous shear–flexural beam models' (lateral displacements, inter-story drift ratios, and mode shapes) were solved using MATHEMATICA in the calculations. Subsequently, these results were compared against dynamic responses from SAP2000, which was applied UBC97 response spectrum analysis by finite element model. This is treated here as the reference solution. Assuming a uniform mass distribution, the lateral displacement, as depicted in Eq. 3, is dictated by the parameters α and θ. The parameter θ, denoting the location of the first story, is delineated by Eq. 10. In the present study, θ was regarded as 1/N. Consequently, a comparison was conducted between the normalized displacement profile from SAP2000 and the mode shape (ϕ) and its derivative (ϕ′) from the continuous model. In this comparison, the parameter α was calibrated through iterative refinements to achieve maximum proximity to the target value. Furthermore, an evaluation of the SAP2000 models displacements was conducted in relation to the modal mode shape (Γϕ), while a comparison of the corresponding modal drift ratios with Γϕ′ was also undertaken.

However, in this section of the study compares the maximum inter-story drift ratios (IDR_{max}) of the proposed model (*θ=1/N*) and the fixed-base case (*θ=0*), as shown in Fig. 1. Lateral deformation profiles derived using Miranda's recommended average value (*α=12.5, θ=0*) were evaluated against those obtained using the estimated α values for the proposed condition (*θ=1/N*). These comparisons were carried out for sample building models in each group, and the results were benchmarked against FEM outputs. In Fig. 1, circular markers labeled A indicate results from Miranda's approach, while star-shaped markers labeled B represent outcomes from the proposed method. In all cases, the continuous model predictions slightly overestimated the FEM results.

The analytical results obtained with the proposed model demonstrated a marked enhancement in comparison to the fixed-base cases, particularly in the context of low-rise models. However, this improvement decreased with increasing story number, as first-story location value tends toward zero with higher N, approximating the fixed-end condition. Although continuous models are more suited to tall buildings, it was shown that incorporating base rotational condition extends to model their applicability to low-rise structures as well.

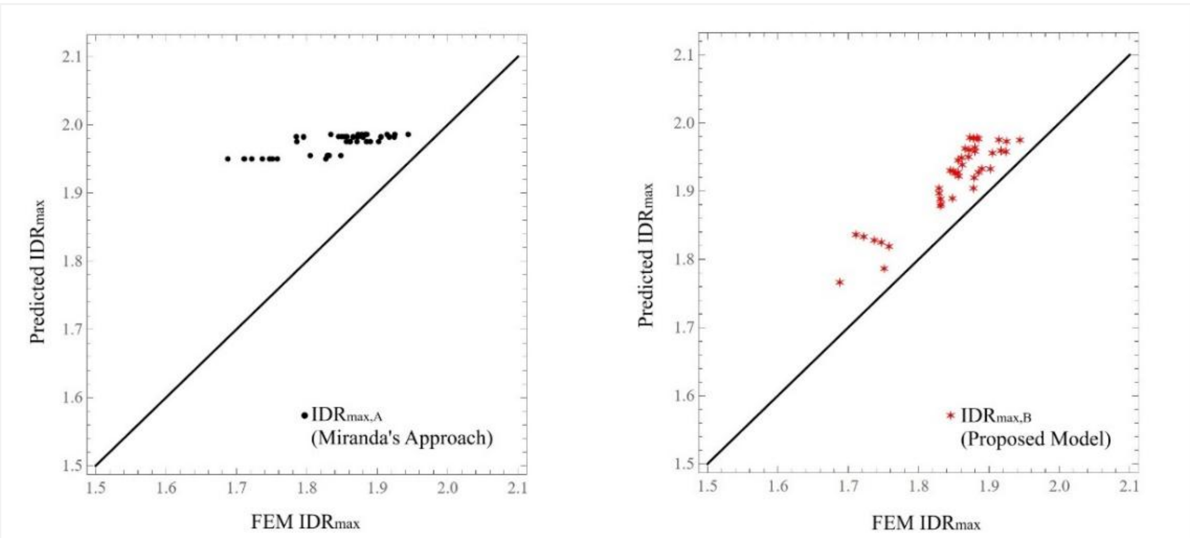

Fig. 1. Comparison of IDR_{max} for sample buildings

2.3. A New approach for lateral stiffness ratio (α)

In the previous section, the lateral stiffness ratios (α) were obtained through iterative procedures for structural models with varying numbers of stories and Blume coefficients (ρ). In light of these results, Çolak et al. (2023) showed how α evolves in conjunction with both the number of stories (N) and ρ, emphasizing their inherent interdependence.

The parameter ρ, defined for discrete systems, significantly affects structural displacements, as does α for continuous beams. As the parameter ρ increases, the lateral displacements show a significant increase, especially in the 0.0-0.125 range. At this point, the behavior of the system undergoes a transition from flexural to a combined flexural-shear mode. Beyond this threshold, the displacement variations become more gradual. A similar trend is observed in the inter-story drift patterns, with the maximum drift shifting to lower floors. Systems with ρ = 0.0

exhibit flexural-dominated behavior, while those with ρ = ∞ exhibit shear-dominated responses, with drift concentrated in the upper and lower floors (Akkar et al., 2005; Çolak et al., 2023).

To model the nonlinear relationship between α, ρ, and N, Çolak et al. (2023) proposed a piecewise regression approach. Assuming that ρ and N are independent variables, two equations were derived: one expressing the transition from flexural to mixed behavior (Eq. 16) and another expressing the transition to shear-dominated behavior (Eq. 17). These equations provide a more accurate and efficient means of estimating α, facilitating its application in structural analysis and design.

$$\alpha_{fc}(\rho, N) = a_1 N^{b_1} \rho^{c_1} \tag{16}$$

$$\alpha_e(\rho, N) = a_2 + b_2 N + c_2 \rho \tag{17}$$

The corresponding equation constants were; "$a_1 = 2.672$, $b_1 = 0.851$, $c_1 = 0.401$" for $0.0<\rho<0.125$ and "$a_2 = 0.0946$, $b_2 = 0.877$, $c_2 = 2.722$" for $\rho \geq 0.125$.

3. Accuracy and applicability of the proposed model

To verify the proposed model, one moment-resisting frame building model was consisted as detailed characteristics of this frame is provided below. The dynamic properties are obtained through eigenvalue analysis of comprehensive finite element model and compared with those derived from the simplified method developed in this study. In addition, response spectrum analysis is performed to evaluate the lateral deformation profiles and inter-story drift ratios, and results from the simplified model are compared. The model was constructed as two-dimensional linear elements using SAP2000, with the eigenvalue-based FEM results considered as the benchmark.

Example building model is consisted of five-story moment-resisting frame model. The beam–column rigidity ratio (ρ) was 0.53, the spans and story heights were equal, measuring 5 m and 3 m, respectively. The floor weights in the frame were uniformly distributed, with each floor weighing 907 kN. The first-mode period of vibration was 0.48 s. Dynamic analysis was performed using the response spectrum. The lateral deformation responses and the maximum inter-story drift ratio estimations along the building height for the fundamental mode were compared between the continuous beam model and FEM; the results are shown as graphically in Fig. 2 and Fig.3, respectively. The parameter α for this model was calculated via Eq. (17) for use in the proposed method.

Using the proposed method ($\phi_B(\alpha=5.93, \theta=1/5)$), the maximum inter-story drift ratio differed by only 3.4% from the finite element model results, with the peak value occurring at the same height level in the SAP2000 model. In contrast, applying Miranda's method ($\phi_A(\alpha_{ort}=12.5, \theta=0)$) resulted in a 10.0% difference. This indicates an improvement of about 6.5% in accuracy for the proposed model. The results confirm that a proper definition of α leads to more precise estimations of structural behavior along the height of the building.

4. Conclusions

This study presented a novel equivalent continuous beam model for evaluating the seismic performance of multi-story buildings, with a particular focus on estimating inter-story drift ratios—an essential parameter in earthquake-resistant design. The model combines shear and flexural behavior to represent the overall structural response and enables closed-form analytical solutions.

By introducing a rotational boundary condition at the base expressed in terms of the first-story drift, the model simplifies the equation of motion and requires only two dimensionless parameters: the lateral stiffness ratio (α) and the location of the first story (θ). It was also observed that the expression α developed as a function of the number of storeys (N) and the stiffness ratio between beams and columns (ρ) contributed to more accurate prediction of the results.

Comparative dynamic analyses using the SAP2000 software confirmed that the proposed model provides reliable predictions of displacement profiles and maximum inter-story drift ratios across various structural configurations. The proposed model has also demonstrated its effectiveness in approximating the inter-story drift ratio, its variation along the building height, and the location of its maximum value. The results demonstrate that the method is both accurate and computationally efficient.

In conclusion, the continuous beam model proposed in this research offers a valuable tool for preliminary seismic design and assessment, particularly in identifying critical drift demands along the building height. Its simplicity, generality, and compatibility with code-based design criteria make it a strong candidate for both academic and engineering applications.

Chaotic Rao (Ch-Rao) algorithm for optimization of RC symmetric spread footings

Hasan Tahsin Öztürk[*1]

[1] Karadeniz Technical University, Faculty of Technology, Department of Civil Engineering, 61830, Trabzon, Türkiye

Abstract. The main objective of this study is to assess the efficacy of the recently developed and proposed chaotic Rao (Ch-Rao) algorithm in the optimization of the design of a symmetric reinforced concrete spread footing with minimum cost. The Ch-Rao algorithm was formulated by interchanging the convergence equations of the Rao1, Rao2, and Rao3 algorithms with chaotic maps, with a view to enhancing the variable performance of these three algorithms. The effectiveness of the developed algorithm was tested on a spread reinforced concrete foundation problem suite. For this purpose, a problem suite was created consisting of six different problems with only axial loading and combined bending in one and two directions. The Turkish Reinforced Concrete Standard (TS500) was used in the designs. In the optimisation problems, the objective function consists of reinforcement and concrete costs. Design variables include the thickness of the foundation, the dimensions of the foundation in the plan, and the diameters and numbers of the main reinforcements to be placed in two directions. The problems with a total of seven design variables were designed as discrete optimization problems, and the optimum solutions obtained from independent simulations performed on this problem suite were statistically evaluated. The performance of the developed Ch-Rao algorithm was compared with the original Rao algorithms using statistical data, the Friedman test, and Wilcoxon paired comparison tests. By evaluating the optimum solutions obtained from the problems for different bending moment levels, it was revealed how the optimum designs and costs change at different levels. The results showed that the Ch-Rao algorithm performs better than the original Rao algorithms.

Keywords: Reinforced concrete; Spread footing; Minimum cost; Optimization; Ch-Rao algorithm

1. Introduction

Optimal design in engineering problems is known to be a powerful tool for ensuring sustainability in engineering designs. Due to the difficulties in applying classical optimization methods to real-world problems, metaheuristic search algorithms have been increasingly used in the optimization of engineering problems. In this context, optimization with metaheuristic search algorithms has become a frequently used optimization tool in the field of civil engineering.

The optimum design of reinforced concrete spread footings at minimum cost is of critical importance in the building design process in terms of both economic and building performance. This is because foundations with larger capacity than necessary will increase the cost of concrete and steel consumption in the production of the structure and unnecessarily increase the project cost. On the other hand, foundations designed with insufficient capacity may endanger the stability of the structure and cause high repair and strengthening costs in the long term. For this reason, optimum design of spread footings with minimum cost by taking into account the loads acting on them and the soil conditions will not only ensure economical foundation designs, but will also guarantee safe designs.

A review of the extant literature reveals a notable interest among researchers in the optimization of spread footing with metaheuristic algorithms, a subject that is the focus of this study. A review of recent studies reveals that optimization studies on spread footings are performed for footings subjected to axial load (Arabali et al., 2022; Camp & Assadollahi, 2013; Islam & Rokonuzzaman, 2018), one uniaxial combined bending (Chaudhuri & Maity, 2020; Kashani et al., 2020; Khajehzadeh et al., 2012, 2013; Khajehzadeh, Iraji, et al., 2022; Öztürk, 2018) and biaxial combined bending (Nigdeli et al., 2018). The predominant focus of these studies is on spread footings subjected to uniaxial combined bending. The majority of the studies aim to minimize the cost, and a few studies aim to minimize carbon dioxide emissions (Arabali et al., 2022; Camp & Assadollahi, 2013; Khajehzadeh et al., 2013). However, it is seen that almost all of the studies in the literature use American reinforced concrete standards,

[*] Corresponding author, E-mail: htozturk@ktu.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_716

one study uses the Indian standard (Chaudhuri & Maity, 2020) and one study uses the Turkish reinforced concrete standard (Öztürk, 2018). In the reviewed studies; Gravitational Search Algorithm (GSA) (Khajehzadeh et al., 2012), Genetic Algorithm (GA) (Chaudhuri & Maity, 2020; Islam & Rokonuzzaman, 2018; Kashani et al., 2020; Khajehzadeh et al., 2012), Sequential Quadratic Programming (FaSQP) hybridized with Firefly algorithm (Khajehzadeh et al., 2013), Big Bang-Big Crunch Algorithm (Camp & Assadollahi, 2013), Differential Evolution (DE) Algorithm (Kashani et al., 2020; Nigdeli et al., 2018), Particle Swarm Optimization (PSO), Harmony Search (HS) and Flower Pollination (FPA) Teaching-Learning Based Optimization (TLBO) algorithms (Nigdeli et al., 2018), Teaching-Learning Based Optimization (TLBO) algorithm (Nigdeli et al., 2018; Öztürk, 2018), Artificial Bee Colony (ABC) and Cuckoo Search (CS) algorithms (Öztürk, 2018), Unified Particle Swarm Optimization (UPSO) (Chaudhuri & Maity, 2020), Evolution Strategy (ES), Biogeography-Based Optimization (BBO), Improved Differential Evolution (IDE), Weighted Differential Evolution (WDE), Linear Population Size Reduction Adaptive Differential Evolution Based on Success History (LSHADE) and Covariance Matrix-Based Migration with Biogeography-Based optimization algorithms (CMM-BBO) (Kashani et al., 2020), Adaptive Tunicate Swarm Algorithm (ATSA) and Tunicate Swarm Algorithm (TSA) (Arabali et al., 2022), Modified Rat Swarm Optimization and Rat Swarm Optimization Algorithms (MRSO and RSO) (Khajehzadeh, Keawsawasvong, et al., 2022).

This study presents a new Caotic Rao (Ch-Rao) algorithm by combining the convergence equations of the RAO algorithm using chaotic mapping reference signals. Thus, it is thought that by selecting a problem-specific signal, it is possible to create an algorithm that shows higher performance in variants of Rao algorithms. For this purpose, performance tests were performed on single foundation problems subjected to axial load, combined bending in one direction and combined bending in two directions at different bending moment levels. The results obtained are compared with those obtained from the variants of Rao algorithms by various statistical tests.

The structure of this study is as follows: The first section discusses the motivation and goal of the present study. The second section describes the formulation of the optimization problem, constraints, algorithm settings, and propoesed Ch-Rao algorithm. Findings and investigations are presented in the third section. The conclusions of the study are presented in the last section.

2. Method

2.1. Problem definition

2.1.1. Objective function and design variables

The objective function to be used in the optimization of the spread footing is represented by a relation expressing the cost of the footing, taking into account the cost of concrete and reinforcement.

$$f(\mathrm{x}) = \mathrm{V_c C_c} + \mathrm{W_s C_s} \tag{1}$$

Where $\mathrm{V_c}$ is the volume of concrete, $\mathrm{W_s}$ is the weight of reinforcement, $\mathrm{C_c}$ and $\mathrm{C_s}$ are the unit costs of concrete and reinforcement respectively. Unit costs will be taken from the catalog of construction and installation unit prices for 2024 of the Ministry of Environment, Urbanization and Climate Change. In the optimization problem, constraints will be defined to achieve a design that meets the desired conditions in terms of strength, durability and geometry. If these constraints are violated, the violation value is added to the objective function using a fixed penalty coefficient, thus creating a penalized objective function. In this case, the penalized objective function is given in Eq. 2, where CK denotes the penalty coefficient and g(x) denotes the constraint violations.

$$\Phi(\mathrm{x}) = \mathrm{f(x)} + \mathrm{CK} \cdot \sum \mathrm{g(x)} \tag{2}$$

Here, the objective function and constraint functions can be expressed as functions depending on the design variables. The penalty coefficient is taken as 10^8 in this study. The design variables are denoted by x.

In this study, the designed foooting was planned to be symmetrical, but it was enabled to be designed as a rectangular foooting. The design variables for this case are given in Fig. 1. According to this figure, design variables x_1 indicates the foundation thickness, x_2 indicates the length of the foundation cantilever in x direction, x_3 indicates the length of the foundation cantilever in y direction, x_4 indicates the diameter of the reinforcement in x direction, x_5 indicates the diameter of the reinforcement in y direction, x_6 indicates the number of reinforcements in x direction, x_7 indicates the number of reinforcements in y direction. There are 7 design variables in total in this problem. The lower and upper limits of the design variables of the spread footing problem to be created are given in Table 1.

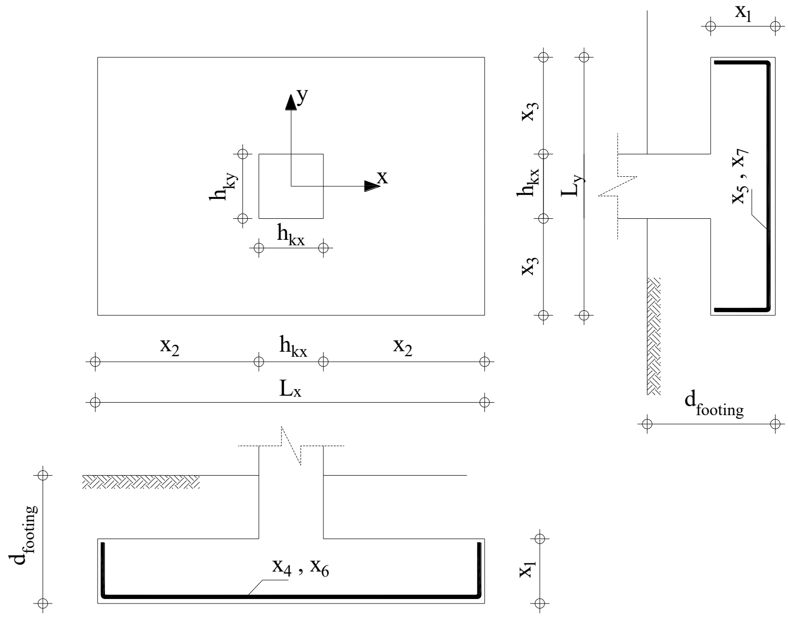

Fig. 1. Design variables for symmetric rectangular spread footing

Table 1. Lower and upper limits and increments of design variables for applications

Design Variables		Lower Bound	Upper Bound	Increment
x_1	Foundation thickness	250 mm	1000 mm	250 mm
x_2	Length of the foundation cantilever in x direction	300 mm	5000 mm	300 mm
x_3	Length of the foundation cantilever in y direction	300 mm	5000 mm	10 mm
x_4	Diameter of the reinforcement in x direction	{14 16 18 20 22 24 26 28} mm		
x_5	Diameter of the reinforcement in y direction	{14 16 18 20 22 24 26 28} mm		
x_6	Number of reinforcements in x direction	#1	#100	1
x_7	Number of reinforcements in y direction	#1	#100	1

2.1.2. Constraints

While searching for the minimum cost solution of the optimization problem, some constraints must be defined in order for the resulting design to meet the strength, durability and geometric conformity conditions. These constraints are listed below:

The maximum stress (q_{max}) under the foundation must be greater than the net strength of the soil ($q_{t,net}$). This condition is checked by Eq. 3 below.

$$g_1(x) = \frac{q_{max}}{q_{t,net}} - 1 \leq 0 \quad (3)$$

It is note that tensile stress should not occur under the foundation. Therefore, the minimum stress, (q_{min}), under the foundation must be greater than zero. The condition for this is specified in Eq.4.

$$g_2(x) = -\frac{q_{min}}{100} \leq 0 \quad (4)$$

The value 100 in this constraint is used to scale the constraint. The foundation thickness should be greater than 250 mm and one quarter of the cantilever overhangs. This condition will be checked for both directions.

$$g_{3-4}(x) = \frac{\text{Cantilever overhang (x or y dir.)}/4}{h_t} - 1 \leq 0 \quad (5)$$

Where h_t is the thickness of the footing. In this study, the condition that the footing thickness should be greater than 250 mm was achieved by taking the smallest value of 250 mm in the footing thickness data pool. On the other hand, according to TS500, the footing width should be at least 0.70 m. This condition was met with the upper and lower limits of the cantilever section selected in the data pool. Another condition, that the base area should be greater than 1 m^2 , is controlled by the constraint given in Eq.6.

$$g_5(x) = \frac{1}{L_x L_y} - 1 \leq 0 \quad (6)$$

The control of the punching strength of the footing is realized by the constraint given in Eq.7, where V_{pd} is the design punching force of the footing and V_{pr} is the punching strength of the footing.

$$g_6(x) = \frac{V_{pd}}{V_{pr}} - 1 \leq 0 \quad (7)$$

In shear control of the footing, the design shear force (V_d) acting on the cross section of the cantilever projections of the footing at the column face must be less than the shear crack strength (V_{cr}) of the footing. This condition is checked by Eq.8 in both directions.

$$g_{7-8}(x) = \frac{V_d}{V_{cr}} - 1 \leq 0 \quad (8)$$

In order to check the bending moment bearing capacity, the bending moment bearing capacity (M_{rx} or M_{ry}) at the critical sections in both directions, calculated according to the reinforcement placed in the section, should be greater than the design moment (M_d) at the column face of the footing.

$$g_{9-10}(x) = \frac{M_d}{M_{rx} \text{ or } M_{ry}} - 1 \leq 0 \quad (9)$$

In addition, the ratio of main reinforcement placed in both directions in the section must be greater than the minimum reinforcement ratio (ρ_{min}=0.002). This control is done with Eq.10 where ρx is the ratio of main reinforcement in x direction and ρy is the ratio of main reinforcement in y direction.

$$g_{11-12}(x) = \frac{\rho_{min}}{\rho_x \text{ or } \rho_y} - 1 \leq 0 \quad (10)$$

In addition, to guarantee adequate ductility, the reinforcement ratios in the x and y directions should be limited to a maximum reinforcement ratio no greater than 0.85 times the balanced reinforcement ratio.

$$g_{13-14}(x) = \frac{\rho_x \text{ or } \rho_y}{\rho_{max}} - 1 \leq 0 \quad (11)$$

The requirement that the distance between reinforcements is less than 250 mm is controlled by the following constraint in both directions, where s_x and s_y denote the spacing of the main reinforcements in the x and y directions respectively.

$$g_{15-16}(x) = \frac{s_x \text{ or } s_y}{250} - 1 \leq 0 \quad (12)$$

On the other hand, the net spacing between reinforcements should be at least 25 mm, less than the reinforcement diameter and 4/3 of the aggregate size. For this purpose, the constraint presented in Eq.13 is used, where s_{min} is the largest of these boundary conditions and s_{xnet} and s_{ynet} are the net spacing of the main reinforcements in the x and y directions, respectively.

$$g_{17-18}(x) = \frac{s_{min}}{s_{xnet} \text{ or } s_{ynet}} - 1 \leq 0 \quad (13)$$

2.1.3. Problems for parametric studies

In this study, the problem cases given in Table 2. below were created in order to examine the changes in minimum costs with the optimum designs of spreead footing under axial load, uniaxial and biaxial combined bending at different bending moment levels and to compare the minimum cost designs. In the table, Problem 1 corresponds to the axially loaded case, Problem 2 corresponds to the case subjected to uniaxial bending, Problem 3-6 corresponds to the case subjected to biaxial bending at various bending moment levels.

In all problems, concrete grade is C25/30 and reinforcement grade is B420C. Foundation depth is 1.50 m, foundation soil unit weight is 18 kN/m3, column size is 500 x 500 mm, net concrete cover is 50 mm, concrete unit weight is 25 kN/m3, reinforcement unit weight is 7850 kg/m3, maximum aggregate grain size is 16 mm, minimum reinforcement ratio is 0.002. Concrete and reinforcement unit costs are considered as 33511.95 ₺/kg and 2605.30 ₺/m3 respectively.

2.2. Proposed Ch-Rao algorithm

The difference of the proposed Chaotic Rao (Ch-Rao) algorithm from the Rao algorithms is presented in the green colored lines in Table 3. below. Rao 1, Rao 2 and Rao 3 algorithms each use different convergence equations in their update mechanisms. The proposed Ch-Rao algorithm switches between the convergence equations used by Rao 1, Rao 2 and Rao 3 algorithms according to a reference signal generated from chaotic maps according to the number of function evaluations. Therefore, the algorithm uses Rao 1, Rao 2 and Rao 3 convergence equations in a chaotic manner in its life cycle.

3. Results of simulation studies

3.1. Simulation environment and algorithm settings

The characteristics of the simulation environment are summarized in Table 4. The same equipment was used in all experiments to ensure a fair comparison.

In addition to the Ch-Rao algorithm proposed in this study, Rao1, Rao2, Rao3, were used in the study and statistical performance comparisons were made. For the tested algorithms, the settings recommended in the literature were used as a standard procedure. The algorithms tested on the symmetric spread footing problems investigated in this study, the reference works of the algorithms and the settings recommended in the reference works are presented in Table 5.

3.2. Optimum designs of problems

The details of the best solutions obtained from the optimum designs are presented in Table 6. With the help of the data in this table, the graph of the changes in the amount of main reinforcement in the problems is presented in Fig. 2, and the graph of the changes in concrete and reinforcement costs is presented in Fig. 3.

Table 4. The characteristics of the simulation environment

	Component	Description

An analysis of the design details presented in Table 6. reveals that the base dimensions of axially loaded foundations are nearly square. However, as the moment level increases, one side of the foundation becomes longer than the other. Similarly, foundation thickness increases in parallel with the moment level. In optimum designs, the maximum base pressure approaches the net bearing capacity of the foundation soil. As the moment level rises, the difference between the minimum and maximum base pressures also increases.

The graph showing the variation of steel weight in Fig. 2 indicates that the total amount of reinforcement increases with the moment level. The reinforcement weight in the X-direction increases with the rise in M_{yy} moment, whereas the reinforcement in the Y-direction remains nearly constant after the second case. This is due to the fact that the M_{xx} moment remains constant in these cases.

As shown in Fig. 3, the cost of concrete, reinforcement, and total construction increases with the moment level. A 40% increase in the M_{yy} moment leads to an approximate 54% increase in concrete cost and a 52% increase in steel cost.

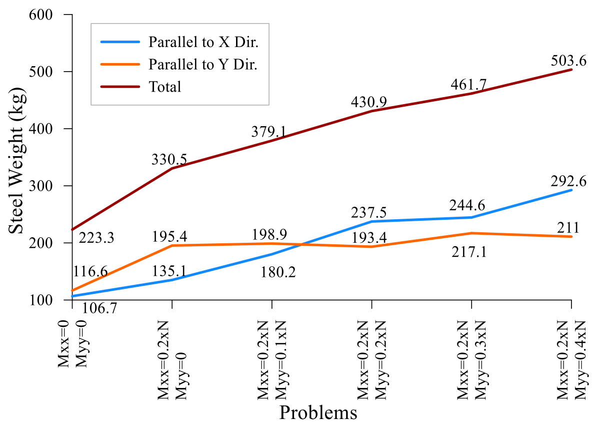

Fig. 2. Graph of the changes in the amount of main reinforcement in the problems

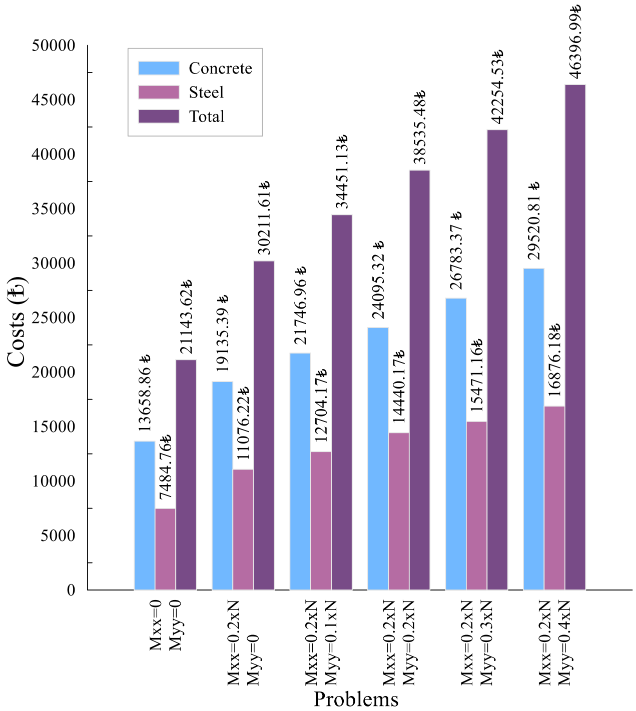

Fig. 3. Graph of the changes in concrete and reinforcement costs

3.3. Statistical performance tests

For the comparison of the proposed Ch-Rao algorithm with the Rao algorithms, two different statistical investigations were performed. The first performance evaluation is performed by comparing the mean solutions obtained from independent runs of the algorithms and their standard deviations. For this evaluation, Table 7. presents the mean costs and their standard deviations obtained from independent runs of the algorithms on six different problems. In order to better visually evaluate these statistical findings, box-plot plots have been prepared and are presented in Fig. 4.

When the mean costs and standard deviations of the costs obtained by the algorithms given in Table 7 are analyzed, it is seen that the Ch-Rao algorithm has the smallest mean cost value for all 6 different problems analyzed. However, the Ch-Rao algorithm achieved the lowest standard deviation in all problems except the fifth problem. This shows that Ch--Rao is statistically the most successful algorithm among the competing algorithms.

Similarly, examination of the box-plot graphs presented in Fig. 4 shows that the Ch-- Rao algorithm achieved the lowest means and the lowest standard deviation in all problems except the fifth problem. However, when an evaluation is made between the Rao algorithm variants, it is seen that Rao2 algorithm has lower mean and standard deviation in some problems and Rao3 algorithm in others. This proves that the Rao algorithm variants do not have a stable performance in these problems. When the performance of the proposed Ch-Rao algorithm is evaluated in this respect, it can be said that the Ch-Rao algorithm shows a much more stable performance than the Rao algorithm variants

Table 7. Mean and standard deviation of algorithms

Problem	Algorithms			
No #	Ch-Rao	Rao1	Rao2	Rao3
1	21152.24 (10.96)	21161.31 (10.52)	21160.71 (9.44)	21165.02 (13.14)
2	30211.61 ($3.73\ 10^{-12}$)	30244.48 (48.73)	30214.79 (14.58)	30212.35 (3.38)
3	34453.16 (9.27)	34510.47 (72.12)	34469.94 (35.25)	34463.45 (35.53)
4	38538.49 (8.99)	38582.85 (80.78)	38544.25 (32.50)	38574.90 (78.17)

6	46316.98 (14.18)	46355.06 (67.03)	46339.98 (53.94)	46321.09 (31.13)

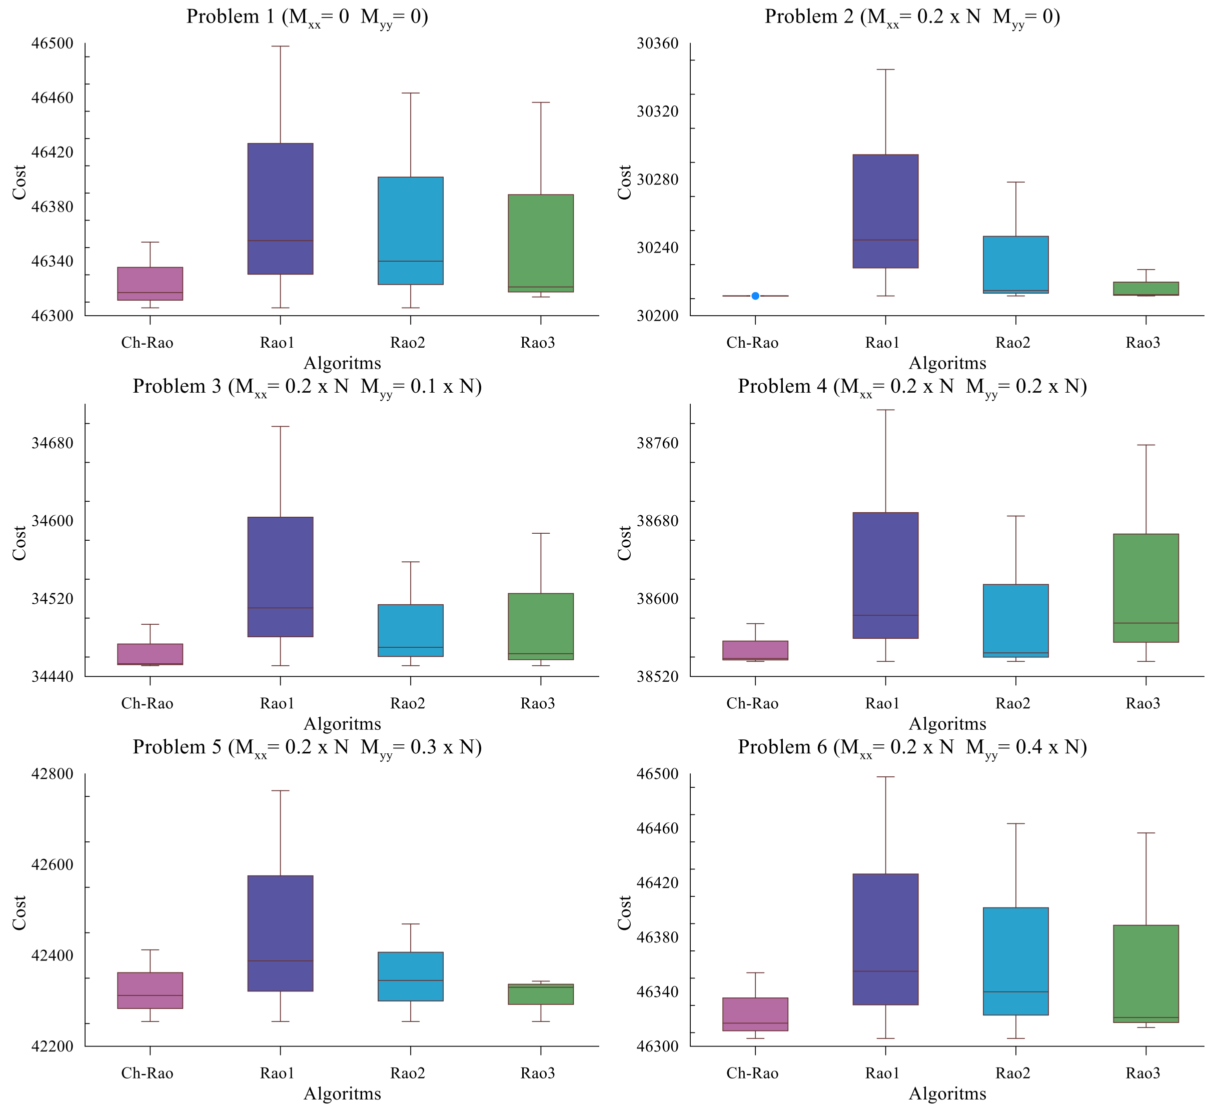

Fig. 4. Spread footing plans for the obtained best solutions

Table 8. Friedman scores of algorithms

	Friedman Scores						
Problem No #	1	2	3	4	5	6	
M_{xx} =	0	0.2xN	0.2xN	0.2xN	0.2xN	0.2xN	Mean
M_{yy} =	0	0	0.1xN	0.2xN	0.3xN	0.4xN	Score
Ch-Rao	1.79	2.26	1.98	2.07	2.24	2.12	2.08
Rao1	2.81	3.05	3.14	3.17	3.10	2.86	3.02
Rao2	2.60	2.33	2.50	2.24	2.24	2.60	2.42
Rao3	2.81	2.36	2.38	2.52	2.43	2.43	2.49

The second performance comparison was performed using the Friedman Test (Friedman, 1940). With this test, the scores of the algorithms on all problems are determined and presented in Table 8. Also, the mean score is calculated and given in the last column of Table 8.When Table 8. is analyzed, it is seen that the Ch-Rao algorithm ranked first in five problems. However, Ch-Rao algorithm and Rao2 algorithm share the first place in one problem. When the mean scores of all problems in the last column of Table 8. are analyzed, it is seen that Ch-Rao algorithm ranks first, Rao2 algorithm ranks second, followed by Rao3 and Rao1 algorithms respectively.

In summary, when all statistical investigations are evaluated together, it is understood that the proposed Ch-Rao algorithm is more successful than the Rao algorithms in this problem set where the optimum design of symmetric foundations subjected to axial load, one-axis combined bending and two-axis combined bending is performed.

4. Conclusions

In this study, a novel Chaotic Rao (Ch-Rao) algorithm was proposed to address the cost-optimal design of reinforced concrete spread footings subjected to axial load, uniaxial bending, and biaxial bending moments. The Ch-Rao algorithm enhances the original Rao family by incorporating chaotic reference signals to dynamically switch between different update equations, thereby improving exploration and exploitation capabilities during the optimization process.

The performance of the proposed algorithm was evaluated through a series of simulation studies on six parametric foundation design problems. These problems considered varying levels of moment and axial loading to reflect realistic structural demands. The optimization aimed to minimize total cost by balancing concrete volume and reinforcement quantity while satisfying structural, geometrical, and code-based constraints.

Results demonstrated that as the bending moment increased, the footing geometry and reinforcement demand changed accordingly, leading to increased foundation dimensions, thickness, and cost. The Ch-Rao algorithm consistently produced lower mean cost values than the original Rao algorithms (Rao1, Rao2, Rao3) in all problem cases, and achieved the lowest standard deviation in five out of six problems, indicating both accuracy and stability. Statistical analyses, including the Friedman test, further confirmed the superior performance of the Ch-Rao algorithm in terms of ranking and consistency.

Overall, the findings highlight that the Ch-Rao algorithm is an effective and robust optimization tool for the cost-efficient design of reinforced concrete spread footings under complex loading conditions. Its enhanced adaptability through chaotic switching mechanisms provides a promising direction for future research in structural optimization, particularly for real-world civil engineering applications where multiple objectives and constraints are involved.

Abstract. The increased use of functionally graded beams in many applications due to their attractive properties in strength, stiffness, and lightness has resulted in a growing demand for such mechanical, civil, mechatronics, and aerospace engineering in the design of structures (such as bridges, railways, and aircraft). The scope of this study is to investigate the static analysis behavior of axially functionally graded straight beams developed using different micromechanical models, utilizing the mixed finite element method. The two-noded mixed finite element formulation is based on the Timoshenko beam theory, and each node has twelve degrees of freedom, namely three translations, three rotations, two shear forces, one axial force, two bending moments, and one torque. The functionally graded material consists of metal-matrix and ceramic-particle materials. The volume fraction ratios of ceramic and metal materials vary along the beam axis. Effective material properties (modulus of elasticity and Poisson's ratio) have been described through three different micromechanical models (Voigt, Mori-Tanaka, and Reuss). Numerical solutions are performed to analyze the static behavior of axially functionally graded straight beams. The results obtained using the mixed finite element method are compared with those from the displacement-based finite element method (ANSYS BEAM188). In the benchmark example, the effect of different micromechanical models has been investigated through a parametric study on the static analysis behavior (displacements, forces, and moments) of axially functionally graded straight beams. In this parametric study, static analysis results for different material gradient parameters, ceramic material content, and boundary conditions have been discussed in detail.

Keywords: Axially functionally graded beam; Micromechanics model; Finite element method; Timoshenko beam theory; Static analysis

1. Introduction

The utilization of composite materials is prevalent in sectors such as the defense/space industry, mechanical and civil engineering (Saleh et al., 2020). Composite materials offer advantages over homogeneous isotropic materials in scenarios involving sudden temperature/load fluctuations or corrosion due to their inherent properties, such as high strength, light weight, and adaptability to environmental factors (Sofiyev, 2019). In traditional composite materials (e.g., laminated composites), sudden temperature changes and various loads can lead to delamination or cracks between layers. In recent years, advancements in material production technologies have facilitated the development of functionally graded (FG) materials, which possess excellent mechanical and chemical properties, such as low thermal conductivity, low friction coefficient, high hardness, and resistance to wear. FG materials are two-phase composite materials characterized by a continuously varying function in the desired directions. This continuous variation in material properties, or functional grading, enhances the durability of these materials under sudden temperature changes or impact loads (Kır et al., 2021).

The primary objective of material mechanics is to predict the behavior of materials. Known as homogenization, this method estimates the effective mechanical properties of a material composed of different components (Karami et al., 2019). In the absence of precise information regarding the size, shape, and distribution of the components of an FG material, the effective elasticity modulus of the graded microstructure should be determined based on the volume fractions of the relevant components and the approximate shape of the dispersed phase. Over the years, various micromechanical models have been developed to determine the effective mechanical properties of macroscopically homogeneous composites and graded composite materials like FG materials (Srividhya et al., 2018). Among these micromechanical models, the most widely recognized and utilized model is the rule of mix-

tures (Voigt, 1889). Other notable micromechanical models include the Hashin-Shtrikman bounds (Mishnaevsky, 2007), Mori-Tanaka homogenization scheme (Benveniste, 1987; Mori & Tanaka 1973), Reuss model (Reuss, 1929), Tamura model (Tamura, 1973; Zuicker, 1995), and the local cubic representative volume element (Gasik & Lilius 1994). Within this scope, numerous studies in the literature employ various micromechanical models to determine the effective material properties, such as elastic modulus and Poisson's ratio, of functionally graded (FG) materials. These studies examine the static, dynamic, and buckling behaviors of plates and beams (Akbarzadeh et al., 2015; Alshabatat et al., 2016; Ebrahimi & Barati, 2017; Fan et al., 2020; Gupta & Talha, 2017; Kiani & Eslami, 2015; Loja et al., 2012; Sahmani & Safaei, 2020; Shahsavari & Karami, 2022; Shen & Wang, 2012; Wang & Wu, 2016; Yadav et al., 2021; Yuan et al., 2020a and 2020b; Zhang & Wang, 2019).

Regarding studies investigating the structural behavior of axially FG beams; Aydogdu (2008) analyzes the free vibration and buckling behavior of axially FG simply supported beams using the Euler–Bernoulli beam theory and the semi-inverse method. Based on the Euler- Bernoulli beam theory, the linear dynamic behavior of axially FG simply supported beams under moving harmonic loads, has been investigated in (Şimşek et al., 2019). The elasticity modulus and density of the beam vary exponentially along its axis. The equations of motion are derived using Lagrange's equations. The unknown functions representing the transverse displacements of the axially FG beam are expressed in a modal framework, and the Newmark method is employed to determine its dynamic behavior. Babilio (2013) investigates the time-dependent dynamic behavior of axially FG simply supported beams under axial loading. In (Calim, 2016), the free and forced vibration behavior of axially FG Timoshenko beams resting on a two-parameter viscoelastic foundation is investigated. The complementary function method is applied in the Laplace domain for the forced vibration analysis, where differential equations are computed to obtain solutions. Subsequently, the solutions in the Laplace domain are transformed into the time domain using the Durbin method. Shafiei et al. (2016) investigate the size-dependent nonlinear vibration behavior of axially FG microbeams with variable cross-sections. The microbeam is modeled using the modified couple stress theory, incorporating the Euler–Bernoulli beam theory and von Kármán’s geometric nonlinearity. The study examines three distinct boundary conditions: clamped-clamped, simply supported, and clamped-fixed. The equations of motion and boundary conditions are derived using Hamilton’s principle. Subsequently, the constitutive relations are solved using the generalized differential quadrature method and the direct iterative approach. Wang and Wu 2016 investigate the dynamic behavior of axially FG beams subjected to temperature variations and moving harmonic loads, employing both the classical beam theory and the Timoshenko beam theory. The equations governing the thermal buckling of the functionally graded beam are derived using Lagrange's method. Subsequently, the critical buckling temperature is incorporated as a parameter in the Newmark method to characterize the dynamic response of the axially FG beam under thermal effects. Azimi et al. (2017) investigate the in-plane nonlinear free vibration behavior of rotating axially FG Timoshenko beams under thermal loading. The equation of motion for the nanobeam is derived using Hamilton’s principle, incorporating Eringen’s nonlocal elasticity theory to account for nanoscale effects in the axially FG beam. Subsequently, the constitutive relations are solved using the generalized differential quadrature method. Ghayesh (2018) examines the nonlinear free vibration behavior of axially FG beams with variable cross-sections under harmonic loading. The equations of motion for the axially FG beam are derived using Hamilton’s energy principle based on the third-order shear deformation theory. The forced vibration behavior of axially FG beams has been investigated in (Ermis et al., 2019) using the mixed finite element method. Aribas et al. (2019) analyze the damped forced vibration behavior of axially FG beams using the mixed finite element method. Sharma et al. (2020) investigate the modal analysis of axially FG beams under humidity and thermal effects using the finite element method. Wang et al. (2020) examine the structural behavior of axially FG microbeams subjected to moving mass effects under thermal and humidity influences. The microbeam model is developed based on the first-order shear deformation theory, incorporating the modified couple stress theory and a closed-form solution method that accounts for size effects. Ebrahimi-Mamaghani et al. (2022) investigate the thermo-mechanical behavior of axially FG fluid-conveying pipes under fluid interaction. The equations of motion are derived using Rayleigh beam theory, incorporating both linear and nonlinear temperature-stress relationships. To solve these equations, the stability region is determined using the Galerkin discretization method and eigenvalue analysis. Using the interpolation matrix method, Ge et al. (2022) determine the critical buckling load of axially FG Timoshenko beams with variable cross-sections. Wadi et al. (2022) present the static displacement solution of an axially FG cantilever beam, formulated based on Euler–Bernoulli beam theory, through the application of the Rayleigh method and the finite element method. Elyasi et al. (2023) determine the vibration behavior of axially FG beams with variable cross-sections and damping under axial loading using the Galerkin method and the state-space formulation. Yadeem et al. (2024) investigate the free vibration behavior of simply supported axially functionally graded beams using the Rayleigh method, incorporating a power-law material distribution model, and demonstrate its accuracy and effectiveness in capturing the influence of power-law index, modulus-ratio, and density-ratio on natural frequencies and mode shapes.

This study investigates the static behavior of axially FG straight beams using different micromechanical models within a mixed finite element framework. The formulation is based on Timoshenko beam theory. It employs a two-node element with twelve degrees of freedom per node, including displacements, sectional rotations, internal forces, bending moments, and a torsional moment. A parametric analysis is presented on the influence of micromechanical model selection, material gradation parameters, and boundary conditions on maximum displacements, shear forces, and bending moments by using the outcomes of Sayed (2023).

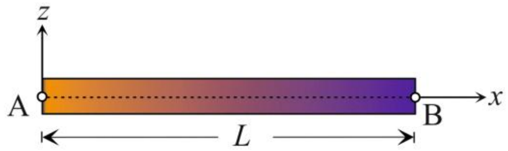

Fig.1 Axially functional graded (AFG) straight beam (Sayed, 2023)

2. Formulation for axially functionally graded straight beam

Functionally graded (FG) materials are derived by combining two different substances—one with a matrix and the other with particles or inclusions—in specified volume ratios. The volume fractions $(V_m$ and $V_i)$ of the matrix and particulate constituents within the functionally graded straight axis beams along the beam axis (x) direction can be defined through the following exponential function along the beam axis:

$$V_i\left(x\right)=V_{\mathrm{A}}+\left(V_B-V_{\mathrm{A}}\right)\left(\frac{x}{L}\right)^{n_h}, \quad 0\le x\le L \tag{1}$$

$$V_i\left(x\right)+V_m\left(x\right)=1 \tag{2}$$

The subscripts "i" and "m" represent the inclusions and the matrix, respectively. n_h is the non-homogeneity index $(n_h\ge 0)$. L is the total length of the beam. V_{A} and V_{B} are the volume fractions of the inclusions at the initial point A $(x=0)$ and the end point B ($x=L$) of the straight beam (Fig. 1). In this study, at the initial of the beam (point A, $V_{\mathrm{A}}=1$), the material is assumed to be composed of %100 ceramic, whereas at the end of the beam (point B, $V_{\mathrm{B}}=0$), it is assumed to be composed of %100 metal (Sayed, 2023).

2.1. Micromechanical material models

In this study, the micromechanical models used to determine the effective material properties (E_{eff}, υ_{eff}, ρ_{eff}) of functionally graded materials include the Voigt model, the lower bound of the Hashin-Shtrikman model (Mori-Tanaka), and the Reuss model (Benveniste, 1987; Mishnaevsky, 2007; Mori & Tanaka, 1973; Reuss, 1929; Voigt, 1889). The manner in which these micromechanical models (using the volume fractions V_m and V_i defined in Eqs. (1) and (2)) characterize the effective material constants is presented below, respectively.

Voigt model: The effective elasticity modulus, and Poisson's ratio can be obtained as follows:

$$P_{\mathrm{eff}}=P_iV_i+P_mV_m=\left(P_i-P_m\right)V_i+P_m \tag{3}$$

where P represents elasticity modulus and Poisson's ratio of the material.

Mori-Tanaka model: In this micromechanical model, also known as the lower bound of the Hashin-Shtrikman model, the effective bulk modulus and shear modulus can be given as follows:

$$K_{\mathrm{eff}}=K_m+\frac{V_i}{\dfrac{1}{K_i-K_m}+\dfrac{3\left(1-V_i\right)}{3K_m+4G_m}}, \quad G_{\mathrm{eff}}=G_m+\frac{V_i}{\dfrac{1}{G_i-G_m}+\dfrac{6\left(K_m+2G_m\right)\left(1-V_i\right)}{5G_m\left(3K_m+4G_m\right)}} \quad \left(i\ne m\right) \tag{4}$$

The effective elasticity modulus and Poisson's ratio are obtained using Eq. (4)

$$E_{\mathrm{eff}}=\frac{9K_{\mathrm{eff}}G_{\mathrm{eff}}}{\left(3K_{\mathrm{eff}}+G_{\mathrm{eff}}\right)}, \quad \upsilon_{\mathrm{eff}}=\frac{3K_{\mathrm{eff}}-2G_{\mathrm{eff}}}{2\left(3K_{\mathrm{eff}}+G_{\mathrm{eff}}\right)} \tag{5}$$

Reuss model: According to this model, the effective material properties are:

$$P_{\mathrm{eff}}=\frac{P_iP_m}{\left(P_m-P_i\right)V_i+P_i} \tag{6}$$

where P represents elasticity modulus and Poisson's ratio of the material. The effective density of material can be obtained by Voigt homogenization scheme for all considered micromechanical models.

$$\rho_{\mathrm{eff}}=\left(\rho_i-\rho_m\right)V_i+\rho_m \tag{7}$$

In this study, aluminum (Al) has been selected as the metal material, and zirconia (ZrO_2), silicon carbide (SiC), and alumina (Al_2O_3) as ceramic materials. The material constants are defined as follows: the modulus of elasticity is 70 GPa for aluminium (Al), 200 GPa for zirconia (ZrO_2), 302 GPa for silicon carbide (SiC), and 380 GPa for alumina (Al_2O_3). The corresponding Poisson's ratios are 0.30 for Al, 0.30 for ZrO_2, 0.17 for SiC, and 0.30 for Al_2O_3. The variation of the effective elastic modulus values obtained using the Voigt micromechanical model with respect to the normalized beam length (x/L) for the ceramic inclusions (Al_2O_3 , SiC , ZrO_2) and different material gradient parameter values $(n_h = 0.5, 1, 1.5, 2, 3 \text{ and } 5)$ is presented in Fig. 2. The variation of the effective elasticity modulus obtained using different micromechanical models (Voigt, Mori-Tanaka, Reuss) with respect to the normalized beam length (x/L) is also presented in Fig. 3 for the selected ceramic material (Al_2O_3) and the variation parameter $(n_h = 1)$.

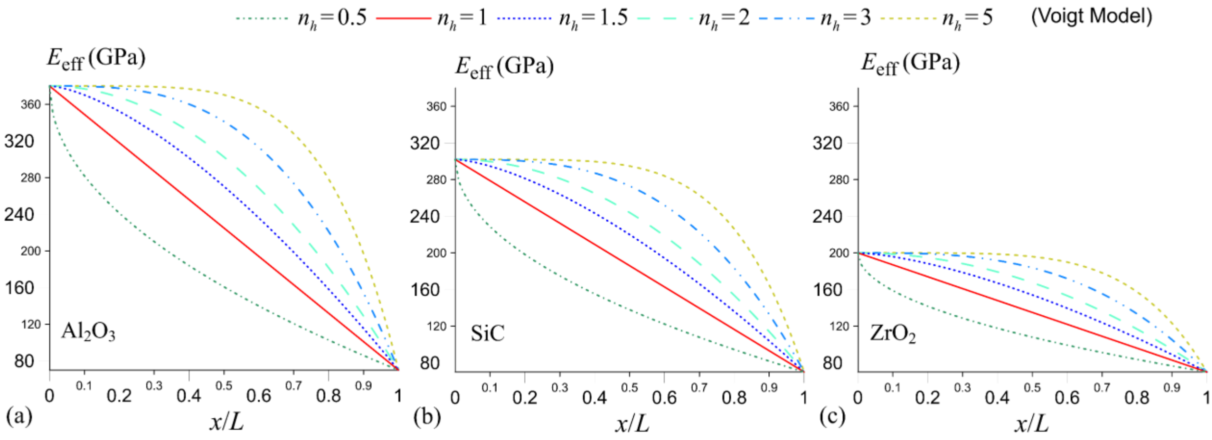

Fig. 2. Variation of the effective elastic modulus of the axially functionally graded straight beam with respect to the normalized AFG beam length (x / L) (Voigt model) (Sayed, 2023)

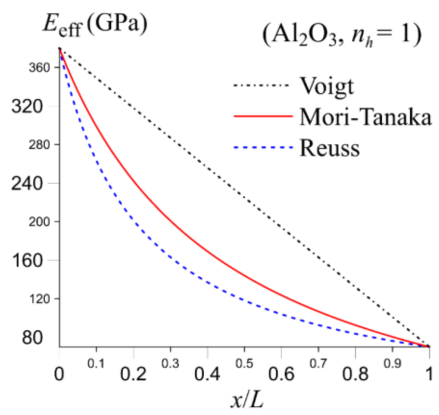

Fig. 3. Variation of the effective elastic modulus of the AFG straight beam with respect to the normalized beam length (x / L) for different micromechanical models (Al_2O_3 and $n_h = 1$) (Sayed, 2023)

2.2. Field equations

The field equations in Frenet coordinates (t, n, b) for isotropic spatial Timoshenko beams (Omurtag & Aköz, 1992) are extended to AFG straight beam in Fig. 1 and given as follows:

$$\left.\begin{aligned} -T_{x,x} + \rho_{\text{eff}} A\ddot{u}_x - q_x &= 0 \\ -T_{y,x} + \rho_{\text{eff}} A\ddot{u}_y - q_y &= 0 \\ -T_{z,x} + \rho_{\text{eff}} A\ddot{u}_z - q_z &= 0 \\ -M_{x,x} + \rho_{\text{eff}} I_x \ddot{\Omega}_x - m_x &= 0 \\ -M_{y,x} + T_z + \rho_{\text{eff}} I_y \ddot{\Omega}_y - m_y &= 0 \\ -M_{z,x} - T_y + \rho_{\text{eff}} I_z \ddot{\Omega}_z - m_z &= 0 \end{aligned}\right\} \quad \text{equations of motion} \qquad (8)$$

$$\left.\begin{aligned} u_{x,x}-T_x/E_{\text{eff}}A=0 \\ u_{y,x}-\varOmega_z-2\left(1+\upsilon_{\text{eff}}\right)k_y' T_y/E_{\text{eff}}A=0 \\ u_{z,x}+\varOmega_y-2\left(1+\upsilon_{\text{eff}}\right)k_z' T_z/E_{\text{eff}}A=0 \\ \varOmega_{x,x}-M_x/G(x)I_x=0 \\ \varOmega_{y,x}-M_y/E_{\text{eff}}I_y=0 \\ \varOmega_{z,x}-M_z/E_{\text{eff}}I_z=0 \end{aligned}\right\}\quad \text{constitutive equations} \tag{9}$$

where u, $\varOmega$, T and M are the displacement, the cross sections' rotation, the force and the moment, respectively. $\ddot{u}$ and $\ddot{\varOmega}$ are the acceleration of the displacement and rotation, respectively. A is the area of the cross section, I is the moment of inertia. ρ_{eff}, E_{eff} and υ_{eff} are the effective material density, elasticity modulus and Poisson's ratio, respectively. $G(x)I_x$ demonstrates the torsional rigidity by considering the warping effect in non-circular cross-sections (Ermis et al., 2022). Timoshenko beam theory is taken into consideration with the constant shear correction factor $k=5/6$, and $k'=k_y'=k_z'=1/k$. q and m are the distributed external force and moment, respectively.

2.3. Funtional

By employing the field equations expressed in Eqs. (8) and (9) the functional of an axially straight beam is derived using Gâteaux differential and the potential operator concept (Oden & Reddy 1976). The acceleration terms are $\ddot{u}$ and $\ddot{\varOmega}=0$ for static analysis.

$$\begin{aligned} I(y)=&-\left[T_{x,x},u_x\right]-\left[T_{y,x},u_y\right]-\left[T_{z,x},u_z\right]-\left[M_{x,x},\varOmega_x\right]-\left[M_{y,x},\varOmega_y\right]-\left[M_{z,x},\varOmega_z\right]-\left[\varOmega_z,T_y\right]+\left[\varOmega_y,T_z\right] \\ &-\tfrac{1}{2GI_x}\left[M_x,M_x\right]-\tfrac{1}{2E_{\text{eff}}I_y}\left[M_y,M_y\right]-\tfrac{1}{2E_{\text{eff}}I_b}\left[M_z,M_z\right]-\tfrac{1}{2E_{\text{eff}}A}\left[T_x,T_x\right]-\tfrac{(1+\upsilon_{\text{eff}})k_y'}{E_{\text{eff}}A}\left[T_y,T_y\right]-\tfrac{(1+\upsilon_{\text{eff}})k_z'}{E_{\text{eff}}A}\left[T_z,T_z\right] \\ &-\left[q_x,u_x\right]-\left[q_y,u_y\right]-\left[q_z,u_z\right]-\left[m_x,\varOmega_x\right]-\left[m_y,\varOmega_y\right]-\left[m_z,\varOmega_z\right]+\Big\langle\left(\left(T_x-\hat{T}_x\right),u_x\right)+\left(\left(T_y-\hat{T}_y\right),u_y\right) \\ &+\left(\left(T_z-\hat{T}_z\right),u_z\right)+\left(\left(M_x-\hat{M}_x\right),\varOmega_x\right)+\left(\left(M_y-\hat{M}_y\right),\varOmega_y\right)+\left(\left(M_z-\hat{M}_z\right),\varOmega_z\right)\Big\rangle_{\sigma} \\ &+\Big\langle\left(T_x,\hat{u}_x\right)+\left(T_y,\hat{u}_y\right)+\left(T_z,\hat{u}_z\right)+\left(M_x,\hat{\varOmega}_x\right)+\left(M_y,\hat{\varOmega}_y\right)+\left(M_z,\hat{\varOmega}_z\right)\Big\rangle_{\varepsilon} \end{aligned} \tag{10}$$

where the square brackets indicate the inner product, the terms with hats are known values on the boundary, and the subscripts ε and σ represent the geometric and dynamic boundary conditions, respectively (Eq. (10)).

2.4. Mixed finite element

A two-noded curved element based on Timoshenko beam theory is used in the construction of mixed finite element (MFE) matrices. Dimensionless coordinates (ξ) are used in the FE derivation and the linear shape functions are used as $\phi_i=1-\xi$ and $\phi_j=\xi$, where $\xi=(x-x_i)/\Delta L$, $0<\xi<1$ and $\Delta L=(x_j-x_i)$. The subscripts *i* and *j* is the local node number of start and end point for the element, respectively. The mixed type field variables at each node are

$$u_x,\ u_y,\ u_z,\ \varOmega_x,\ \varOmega_y,\ \varOmega_z,\ T_x,\ T_y,\ T_z,\ M_x,\ M_y,\ M_z \tag{11}$$

where u, $\varOmega$, T and M are the displacement, the cross sections' rotation, the force and the moment, respectively. Hence, the total DOF of the straight element are 24. The details of the mixed FE formulation and axially FG beam exist in (Omurtag & Aköz, 1992; Ermis et al., 2022; Oden & Reddy, 1976; Eratlı et al., 2016; Sayed, 2023).

3. Numerical examples

3.1. Convergence study – Mixed FEM and ANSYS analyses

A convergence test for mixed FEM and ANSYS-BEAM188 is carried out for the static analysis of axially FG straight beams subjected to uniformly distributed loaded, using Voigt micromechanics model. Parameters of the problem are: Ceramic material is Alumina (Al_2O_3), the non-homogeneity index is $n_h=1$, the length, width and height of the beam are $L=12\text{m}$, $w=0.5\text{m}$ and $h=0.4\text{m}$, respectively. The intensity of the uniform loading is taken $q_z=10$ N/m. The boundary condition is clamped-clamped. The convergence test for axially FG straight beams using Voigt micromechanics model is performed for the number of elements $n_e=10,20,30,40,60,80$ over mixed FEM and ANSYS-BEAM188. The results (the maximum displacement $u_z^{\max}$, the shear forces T_z^{A} and T_z^{B}, the moments M_y^{A} and M_y^{B} at the fix ends) are plotted in Fig. 4. Taking into account all micromechanical models

(Sayed, 2023), the maximum absolute percentage differences are 0.32% for the mixed finite element method and 0.04% for the displacement-type finite element method (BEAM188), respectively. In the following examples for axially FG straight beams, $n_e = 80$ is used.

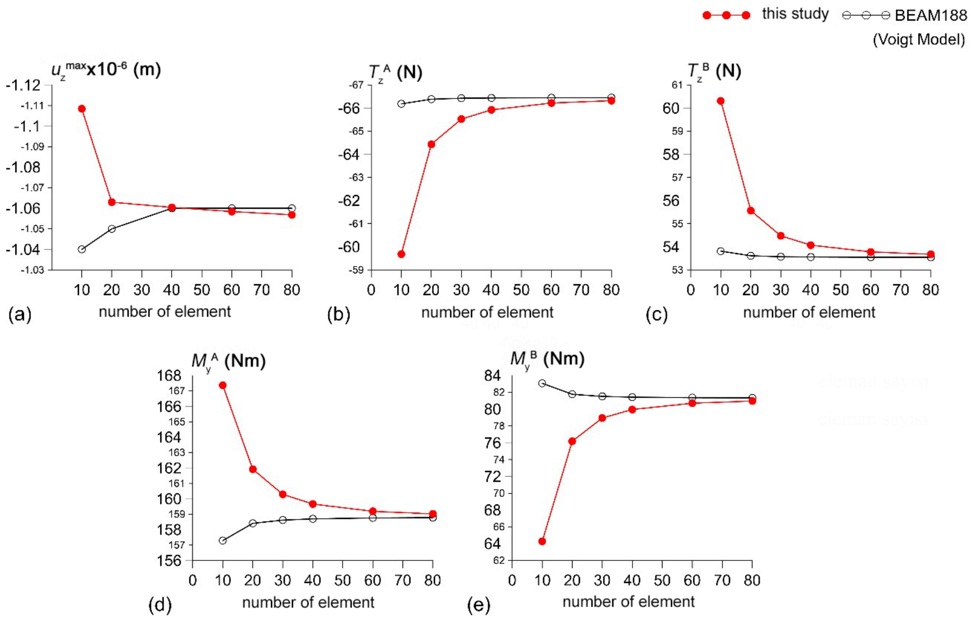

Fig. 4. Convergence analysis of the static analysis results (u_z^{max}, T_z^A, T_z^B, M_y^A, M_y^B) for the axially FG straight beam (Voigt model and clamped-clamped boundary condition)

3.2. Parametric analysis

This section examines the static behavior of axially FG straight beams developed through different micromechanical models under the effect of uniformly distributed loads. The investigation focuses on the maximum displacements, the shear forces, and bending moments through the beam domain. The effects of ceramic material, material variation parameter, and boundary conditions are analyzed comprehensively. The geometry and cross-sectional properties of the beam are the same as those presented in Section 3.1. The material and boundary condition information related to the problem under consideration is provided as follow: The ceramic inclusions are Al_2O_3, SiC and ZrO_2, respectively. Three different boundary conditions are considered: clamped-free, clamped-pinned, and clamped-clamped. The maximum displacements for all boundary conditions are plotted against the material gradient parameter in Fig. 5. The maximum shear forces and bending moments for the clamped-clamped and clamped-pinned boundary conditions are plotted against the material gradient parameter in Figs. 6 and 7, respectively.

3.2.1 The maximum vertical displacements

As the material gradient index increases from 0.5 to 5, the maximum vertical displacement decreases across all boundary conditions and micromechanical models. This reduction in displacement implies that a higher gradient index corresponds to a stiffer beam, as the increase in n_h makes the beam richer in ceramic material, thereby diminishing the displacement under the same load. The reduction in the vertical displacements is calculated by using the $\text{diff}^{n_h}.\% = \left|\Theta_{n_h=0.5} - \Theta_{n_h=5}\right| \times 100 \big/ \left|\Theta_{n_h=0.5}\right|$.

The maximum reduction of clamped-clamped boundary conditions are as follows:

- In case Al_2O_3, the percent differences are 54.4%, 52.0%, and 43.1% for the Reuss, Mori-Tanaka, and Voigt models, respectively.
- In case SiC, the percent differences are 49.0%, 46.5%, and 39.5% for the Reuss, Mori-Tanaka, and Voigt models, respectively.
- In case ZrO_2, the percent differences are 37.5%, 35.6%, and 31.6% for the Reuss, Mori-Tanaka, and Voigt models, respectively.

The maximum reduction of clamped-pinned boundary conditions are as follows:

- In case Al_2O_3, the percent differences are 59.5%, 58.1%, and 49.8% for the Reuss, Mori-Tanaka, and Voigt models, respectively.

- In case SiC , the percent differences are 54.4%, 52.8%, and 46.1% for the Reuss, Mori-Tanaka, and Voigt models, respectively.
- In case ZrO_2 , the percent differences are 43.1%, 41.6%, and 37.6% for the Reuss, Mori-Tanaka, and Voigt models, respectively.

The maximum reduction of clamped-free boundary conditions are as follows:

- In case Al_2O_3 , the percent differences are 63.0%, 56.2%, and 36.6% for the Reuss, Mori-Tanaka, and Voigt models, respectively.
- In case SiC , the percent differences are 56.2%, 49.5%, and 34.1% for the Reuss, Mori-Tanaka, and Voigt models, respectively.
- In case ZrO_2 , the percent differences are 42.1%, 37.1%, and 28.1% for the Reuss, Mori-Tanaka, and Voigt models, respectively.

Among the three ceramic inclusions, Al_2O_3 - based FG beams exhibit the lowest vertical displacement due to their higher stiffness, while ZrO_2 - based beams demonstrate the highest displacement owing to their relative flexibility. The increase in the vertical displacements is calculated by using the $\text{diff}^c.\% = \left|\Theta_{\mathrm{Al_2O_3}} - \Theta_{c=i}\right| \times 100 \big/ \left|\Theta_{\mathrm{Al_2O_3}}\right|$ where i=SiC and ZrO_2 .

The increase in vertical displacements of clamped-clamped boundary condition are as follows:

- In case SiC , the percent differences for n_h=0.5~5 vary between 3.6%~15.9%, 5.6%~17.7, and 14.1%~21.4% for the Reuss, Mori-Tanaka, and Voigt models, respectively.
- In case ZrO_2 , the percent differences for n_h=0.5~5 range between 12.3%~53.9%, 19.1%~59.8, and 42.5%~71.4% for the Reuss, Mori-Tanaka, and Voigt models, respectively.

The increase in vertical displacements of clamped-pinned boundary condition are as follows:

- In case SiC , the percent differences for n_h=0.5~5 lie within the range of 3.9%~17.0%, 6.1%~19.6, and 16.2%~24.8% for the Reuss, Mori-Tanaka, and Voigt models, respectively.
- In case ZrO_2 , the percent differences for n_h=0.5~5 vary between 13.4%~59.2%, 21.1%~68.9, and 49.0%~85.4% for the Reuss, Mori-Tanaka, and Voigt models, respectively.

The increase in vertical displacements of clamped-free boundary condition are as follows:

- In case SiC , the percent differences for n_h=0.5~5 range between 5.5%~24.7%, 8.6%~25.2, and 20.9%~25.8% for the Reuss, Mori-Tanaka, and Voigt models, respectively.
- In case ZrO_2 , the percent differences for n_h=0.5~5 change between 19.1%~86.2%, 30.7%~87.8, and 67.2%~89.7% for the Reuss, Mori-Tanaka, and Voigt models, respectively.

Also, the presented figures clearly demonstrate the effect of boundary conditions on the vertical displacement. The clamped-clamped configuration exhibits the lowest vertical displacement, indicating the highest stiffness among the three boundary conditions (see Figs.5 (a)-(c)). The clamped-pinned configuration shows a higher displacement compared to the clamped-clamped case (Figs. 5 (a)-(c)), indicating a reduction in stiffness due to the pinned end (Figs. 5 (d)-(f)). Furthermore, the influence of increasing material gradient index is more pronounced in this configuration, highlighting its more flexible response. Notably, the reduction in displacement with increasing material gradient index is more significant in the clamped-free configuration (Figs.5 (g)-(i)) compared to the other boundary conditions.

3.2.2 The maximum shear forces and bending moments

The Mori-Tanaka and Reuss models yield similar trends, both providing higher shear force and bending moment magnitudes compared to the Voigt model for higher values on the material gradient index for both boundary conditions (Figs, 6 and 7). In the clamped-clamped boundary condition (Figs.6 (a)-(c)), as the material gradient index (n_h) increases from 0.5 to approximately 1.5, the shear force values increase for both the Mori-Tanaka and Reuss models. However, when the gradient index continues to rise from 1.5 to 5, the shear forces decrease. In contrast, for the Voigt model, the shear force values increase up to $n_h = 1$, but then start to decrease as the gradient index increases beyond 1. For the Mori-Tanaka and Reuss models, the bending moment behavior (Figs. 6(d)-(f)) is similar to that of the shear force. As the material gradient index (n_h) increases from 0.5 to approximately 1.5, the bending moment values increase and then decrease as n_h continues to rise from 1.5 to 5. However, in the case of the Voigt model, the maximum bending moment value consistently decreases as n_h increases, indicating a distinct behavior compared to the other two models (Mori-Tanaka and Reuss). For both clamped-pinned (Fig.7) and clamped-clamped boundary conditions, the behavior of shear forces and bending moments exhibits a similar trend.

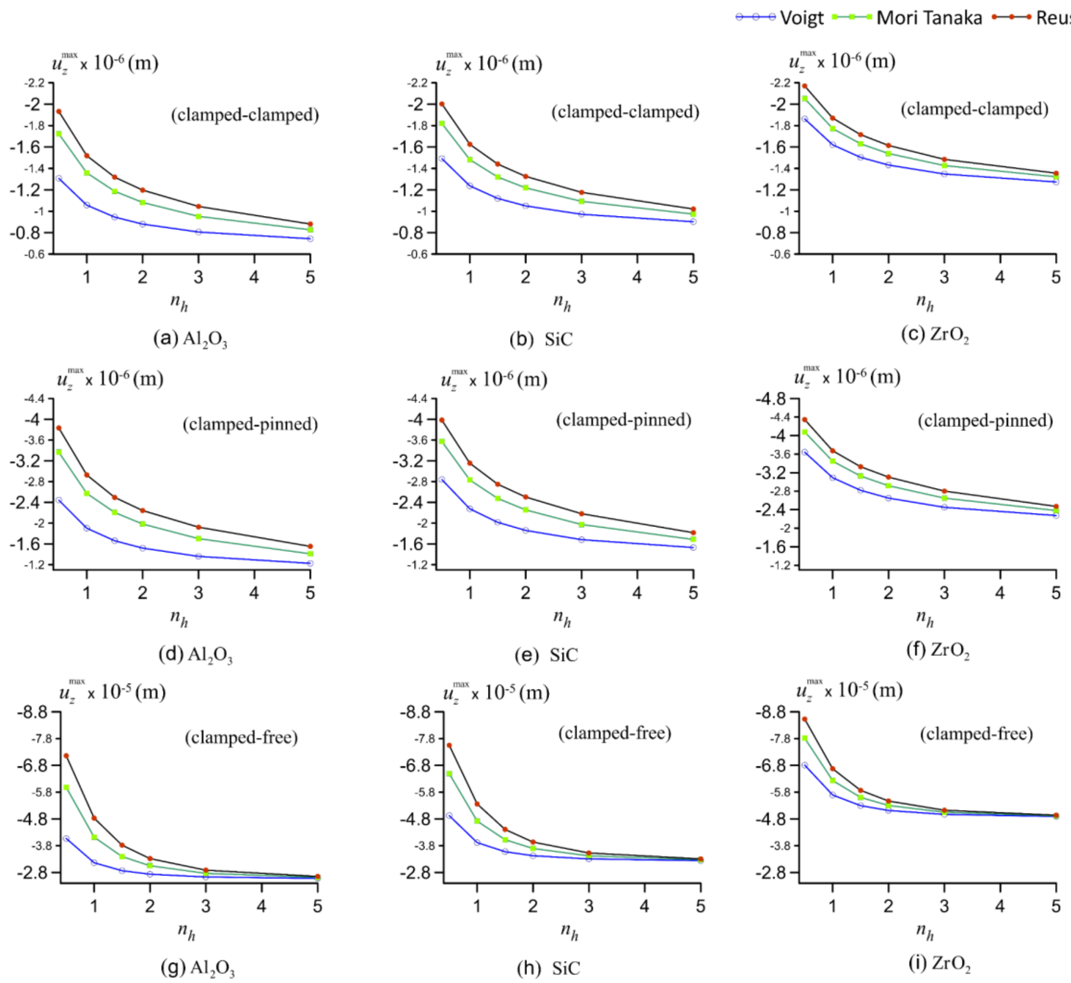

Fig.5 The maximum vertical displacements for different micromechanical models, ceramic constituents and boundary conditions.

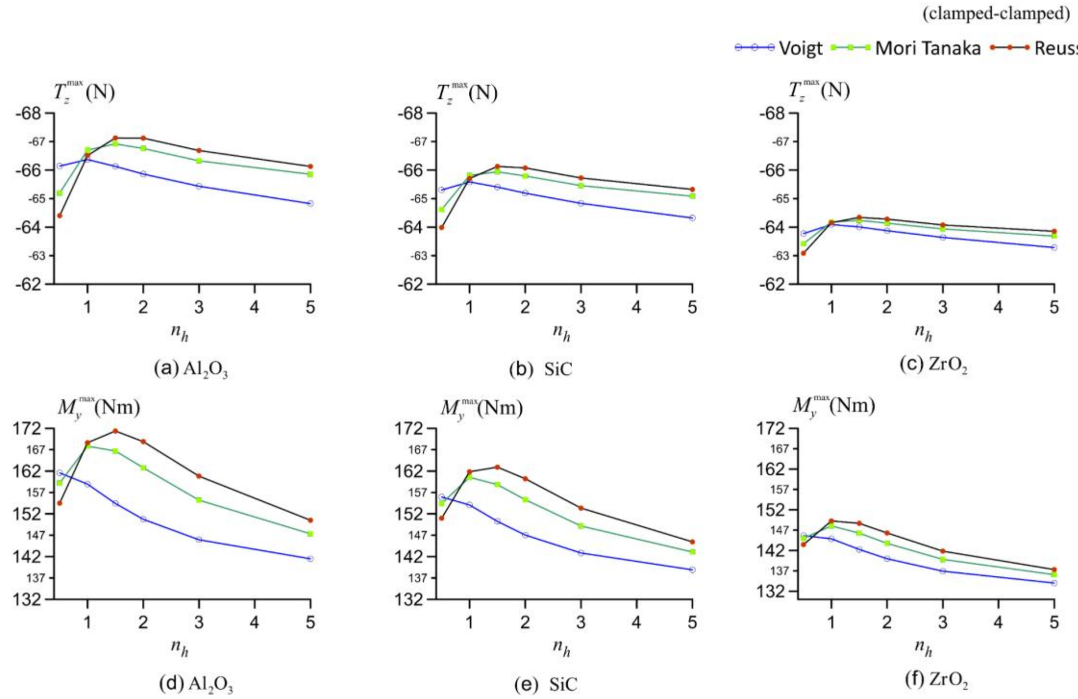

Fig.6 The maximum forces and moments of clamped-clamped boundary condition for different micromechanical models and ceramic constituents.

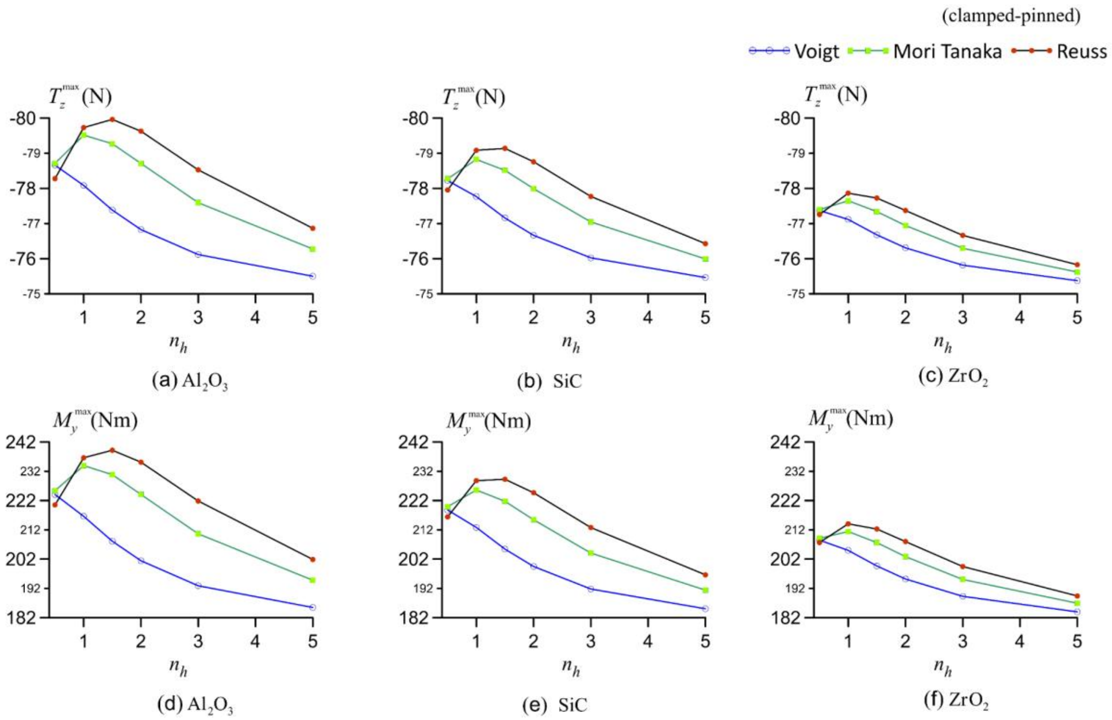

Fig.7 The maximum forces and moments of clamped-pinned boundary condition for different micromechanical models and ceramic constituents.

4. Conclusions

The static analysis behavior of axially FG straight beams under uniformly distributed loads has been investigated using the mixed finite element method with different micromechanical models. A mixed finite element formulation has been developed based on the Timoshenko beam theory, utilizing a two-node finite element. The results obtained from the mixed finite element method have been compared with those derived using the displacement-based finite element BEAM188 in ANSYS. It has been observed that the results from both methods are in good agreement (see Section 3.1). As part of the parametric analysis (Section 3.2), the influence of different micromechanical outcomes—such as displacements, shear forces and bending moments—has been examined in detail. The FG material consists of a metal matrix and ceramic models on the static analysis particle components, with the volume fractions of ceramic and metal materials varying along the beam axis. The effective material properties, including the elastisity modulus and Poisson's ratio, have been defined using three different micromechanical models: Voigt, Mori-Tanaka, and Reuss. The parametric analysis conducted within this study has thoroughly investigated the effects of varying ceramic content, material gradation parameters, and boundary conditions. The results of the parametric analysis are as follows:

- For each micromechanical model considered (Voigt, Mori-Tanaka, and Reuss), across different ceramic material (Al_2O_3 , SiC , ZrO_2) and boundary conditions (clamped-clamped, clamped-fixed, clamped-free), the maximum displacement u_z^{max} values reach their highest absolute magnitude at a material variation parameter of $(n_h = 0.5)$, while their lowest absolute magnitude is observed at $(n_h = 5)$.
- For each ceramic material, boundary condition, and material variation parameter considered $(n_h = 0.5, 1, 1.5, 2, 3 \text{ and } 5)$, the maximum displacement u_z^{max} values reach their highest absolute magnitude in the Reuss material model, while their lowest is observed in the Voigt material model.
- For an axially FG straight beam having clamped-clamped and clamped-pinned boundary conditions, the maximum shear force T_z^{max} and bending moments M_y^{max} initially increase as the material variation parameter rises, but then decrease. This behavior follows a continuous decreasing trend in the Voigt material model.

[1] Istanbul Arel University, Department of Civil Engineering, 34537 Istanbul, Türkiye

Abstract. In this study, a typical reinforced concrete building constructed according to the 1975 Turkish Earthquake Code (TEC) is analyzed in accordance with today's earthquake codes. For this purpose, the general building characteristics of the region were considered, and low- and mid-rise reinforced concrete buildings were considered. Buildings were first designed according to TEC-1975, and they were subject to static pushover analysis to determine the load and displacement capacity of the building by using the Turkish Building Earthquake (TBEC) 2018 code. Using this TBEC-2018, the performance levels of the buildings were also determined. Later, these buildings were strengthened with various strengthening methods such as Fiber Reinforced Polymer (FRP) and reinforced concrete (RC) jacketing methods separately. The behavior of strengthened buildings was also determined by static-pushover analysis. After determining the load and deformation capacity of the buildings, the effects of both methods on the structural behavior are investigated using the load-displacement behavior of existing and strengthened buildings. Displacement demands of both (as-built and strengthened) were determined by code-compatible elastic spectrum, and performance of the buildings were also obtained. Consequently, the behavior of strengthened and existing buildings was evaluated to determine the effectiveness of the methods for building frames considered.

Keywords: Reinforced concrete buildings; FRP; RC jacketing; Strengthening

1. Introduction

The severe earthquakes that occurred in recent years have caused loss of life and property. Especially, the Kahramanmaraş earthquakes affected a wide area, such as Kahramanmaraş, Hatay, Gaziantep, Adıyaman, Malatya, Kilis, Adana, Diyarbakır, Osmaniye, and Şanlıurfa. They caused many structures to be seriously damaged or collapsed (Kocakaplan Sezgin et al., 2024). These earthquakes showed the inadequacy of the building stock. Especially, RC columns with non-seismic detailing cannot provide principles and rules dictated by codes in terms of concrete quality, transverse and longitudinal reinforcement ratios (Orman Subaşi et al., 2024). Reconstruction of RC structures with such deficiencies is a process that requires time and cost. Another method for improving the performance of RC structures in terms of earthquake behavior is strengthening. In this way, time, cost, and material usage can be efficiently organized (Habib et al., 2020;Raza et al., 2019;Caglar et al., 2017).

RC jacketing, which has been used for many years in the reinforcement of RC structures, is widely used among the reinforcement methods (Aykaç & Can, 2008; Bousias et al., 2004). RC jacket is based on the casting of higher-strength concrete together with longitudinal and transverse reinforcement by expanding the cross-sectional area of the existing column on the RC structure (Minafò, 2015). The increase in the cross-sectional area increases the strength, stiffness, ductility, and earthquake performance of the RC columns, thus extending the service life of the structure. It is also a fact that this method may be a disadvantage from an architectural perspective. Another method widely used in the reinforcement of existing RC columns in recent years is the use of Fiber Reinforced Polymers (FRP). The main reasons for preferring the FRP jacketing technique are that it is easy to apply to the structural element, does not require special equipment, increases the axial load-carrying capacity and lateral displacement capacity of the columns, does not affect the architectural design, and can be applied to all types of building topologies (Pham & Hadi, 2014).

Goksu et al., (2006) investigated the changing seismic behavior of an RC building with inadequate seismic performance as a result of reinforcing RC jacketing and CFRP jacketing. The transfer of the reinforcing effect to the structure was done using finite element modeling. The ductility of the structure increased in both techniques. In addition, a slight increase in strength was observed in the case of CFRP jacketing. RC jacketing, the structure showed a much more significant increase in rigidity and strength. As a result, it was observed that the CFRP

* Corresponding author, E-mail: mehmetpalanci@arel.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_730

jacketing technique was preferable when it came to meeting the lateral displacement demand, but there was no increase in the seismic demand of the structure. Kalogeropoulos et al., (2019) compared the CFRP and RC jacketing methods with experimental studies on RC columns. The seismic performance of the RC column sample with low concrete compressive strength and plain reinforcement was improved by RC jacketing, especially in terms of rigidity and strength, while CFRP jacketing improved in terms of ductility. Latifi & Rouhi (2020) conducted a study in which they reinforced a two-story building with techniques such as FRP jacketing, RC jacketing, and the addition of shear walls to the structure, and they comparatively examined the results. It was shown that adding shear walls to the RC structure was the most effective way to reduce maximum roof displacements and the building foundation period. RC jacketing and adding shear walls to the structure caused a significant increase in the capacity curves. Although reinforcing with FRP caused an increase in ductility, it showed similar behavior to the existing structure. Mumtaz et al., (2021) studied the feasibility of using FRP in Afghanistan. While the RC jacketing method was found to be more efficient in terms of cost and strength, the FRP jacketing method was found to be more efficient in terms of time and lower CO_2 emissions.

In this study, two regular RC structures, a 5-story and a 7-story, were designed according to the 1975 earthquake regulations (TEC, 1975). Due to their regularity, buildings were modeled from the middle axes selected from the RC structures, and these frames were subjected to pushover analysis, and the building behavior of the buildings were determined. These buildings were then subjected to strengthening using RC and CFRP jacketing, considering only RC columns. During the strengthening of these buildings, special attention was paid to costs, and it was aimed at both methods being approximately equal. RC and CFRP jacketing were applied to all column sections, and moment-curvature analyses were obtained. As a result, the effects of different reinforcing techniques on RC structures with approximately equal costs were investigated.

2. Materials and methods

In this study, two reinforced concrete buildings that reflect existing building stock of Türkiye was considered. These models consist of five- and seven-story reinforced concrete residential structures, and they were designed according to TEC-1975. However, lateral confinement of columns was poorly considered to reflect existing building stock. In both structures, the floor height was determined to be 3 meters, and the horizontal and vertical axis distances were determined as 4.5 meters. Buildings were designed according to frame behavior consisting of column-beam connections. The 3D plot of the 5-story reinforced concrete residential structure is shown in Fig. 1.

In the five-story structure, the beam sections were 30×60cm, and the column sections were 40×40cm. In the seven-story structure, beam sections were considered as 30×70cm, and the column sections were generally determined as 45×45 cm, and the dimensions of the middle column was 50×50 cm.

The compressive strength of concrete was C16, and reinforcement steel was considered as S220. Since the buildings were planned regularly, the middle axis of both buildings was considered, and the necessary definitions (moment capacity, plastic rotations, etc.) for the analysis. In the final stage, static pushover analyses were performed for 5- and 7-story buildings in accordance with the first natural vibration mode, and the roof displacement of the structures were plotted against the base shear capacity of the buildings. In Fig. 2, the reinforcement details of the column and beam reinforcement details are given. Lateral spacing of confinement of all columns were taken as 200 mm for both buildings.

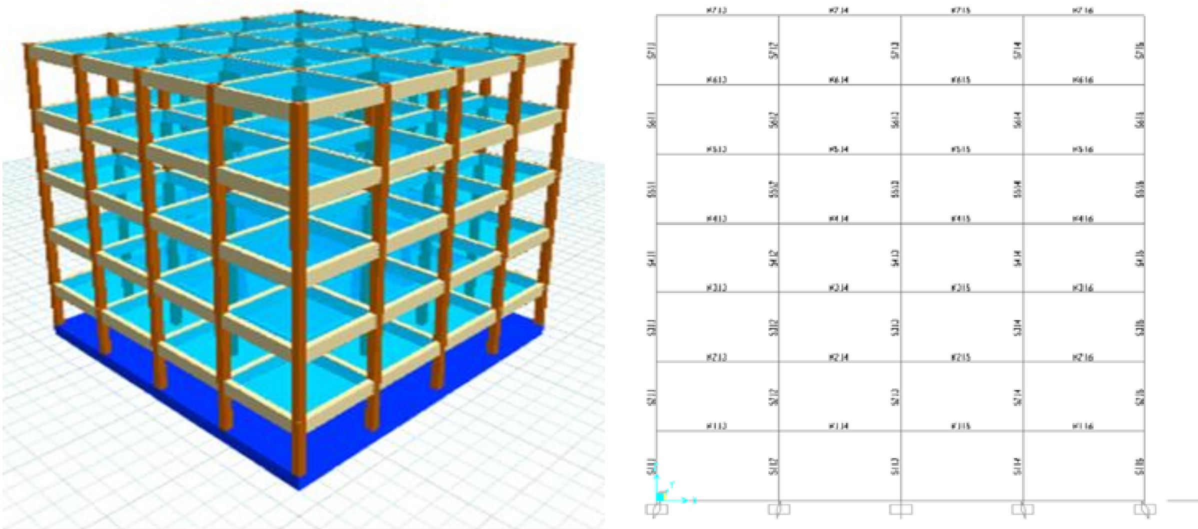

Fig. 1. 3D and 2D representation of typical RC building considered

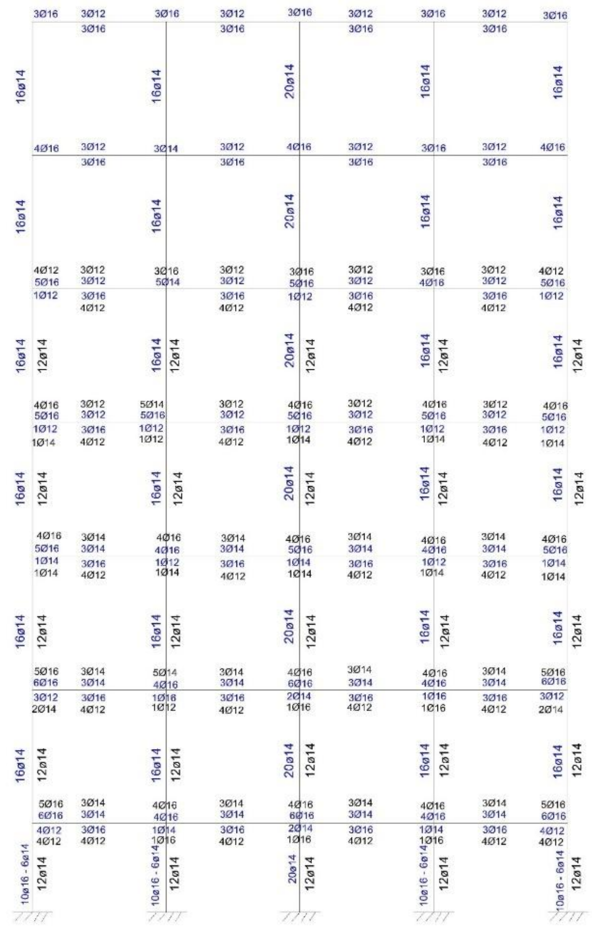

Fig. 2. Longitudinal reinforcement details of considered RC buildings (Blue color represents the 7-story building)

A large portion of the reinforced concrete building stock in Turkey built according to the 1975 Earthquake Code (TEC, 1975) does not meet the structural system and strength criteria of the earthquake codes in force today. Considering possible earthquakes, these building stocks pose a significant risk. For this reason, retrofitting applications to increase the strength of the existing building stock have become an important option to prepare buildings against earthquakes instead of demolishing and rebuilding buildings, considering the cost and time spent.

In this study, it is aimed to retrofit two different five- and seven-story reinforced concrete residential buildings designed according to the 1975 code. Accordingly, two different strengthening methods, FRP wrapping and the reinforced concrete jacketing method, were applied for both structures. In this way, the effects of both methods on both economic and structural performance were evaluated comparatively.

2.1. Damage limits for structural members

Damage limits of members are determined according to TBEC-2018. In the code, damage limits of members are determined in terms of concrete and steel strain limits, and moment-curvature analyses were performed, and limits are checked in each step. Later curvature responses are converted to rotation based on the TBEC equations. Damage limits and threshold values for these limits are shown in Fig. 3 for a typical RC member.

It can be seen from Fig. 3 that the unconfined concrete strain limit of MDL is constant at 0.0025 for concrete and 0.0075 for tensile reinforcement. Confined concrete strain limits of extensive damage limit (EDL) and collapse damage limit (CDL) are defined in terms of the ratio of mechanical transverse reinforcement ratio (w_{we}) and the MDL limit is calculated as 0.75 times the CDL. ε_{su} is the ultimate tensile strain, and it was taken as 0.08 for plain longitudinal bars as suggested in TBEC.

Material type	Damage limit	Strain values
Concrete strain limit	ε_{MDL}	0.0025
	ε_{EDL}	$0.75\varepsilon_{CDL}$
	ε_{CDL}	$0.0035 + 0.04\sqrt{w_{we}} \leq 0.0180$
Tensile reinforcement limit	ε_{MDL}	0.0075
	ε_{EDL}	$0.75\varepsilon_{CDL}$
	ε_{CDL}	$0.40\varepsilon_{su}$

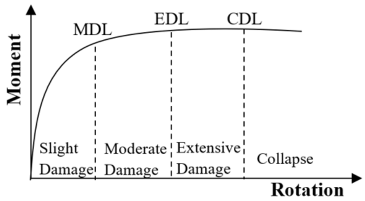

Fig. 3. Typical moment-rotation curve and damage limits definitions in TBEC-2018

2.2. Fiber reinforced polymer (FRP)

Fiber-reinforced polymer (FRP) composites are increasingly used in the reinforcement of reinforced concrete structures due to their high tensile strength, low specific gravity, corrosion resistance, and easy application (Hollaway & Leeming, 1999). These systems are applied to the surface of structural elements by means of epoxy-based adhesives. This application not only increases the axial and shear strengths of the element but also improves its ductility capacity and energy absorption ability (Seible et al., 1997; Teng et al., 2002).

All columns of the selected structures were wrapped with CFRP. The material behavior of CFRP developed by Palanci and Subasi (2024) based on Lam & Teng, 2003a and Lam & Teng, 2003b, was used to obtain the stress-strain relationship of concrete. The elastic stress at rupture was taken at 3530 MPa, and rupture strain was taken at 1.5%. It was assumed that the CFRP material is wrapped 0.5mm in two directions. Strain reduction factor (k_ε) was considered as 0.586 for carbon FRP material. Corner radius (r_c) was assumed 25 mm in all CFRP-wrapped RC sections.

In the model developed by Palanci and Subasi (2024), the compressive strength of FRP-wrapped concrete (f'_{cu}) is determined using Equation 1. ρ_j, E_j, f_{ju} and f'_c are volumetric ratio, tensile modulus, and strength of the FRP jacket and compressive strength of the unconfined concrete, ε_{co} is accepted as 0.002, b and h are the width and depth of the member section, respectively. Additionally, the ultimate unit strain (ε_{cu}) of FRP-confined concrete is determined by Equation 2. The coefficients a_2 and b_2 given in Equation 2 represent the coefficients that vary depending on the FRP volumetric ratio (ρ_j). The FRP volumetric ratio (ρ_j) is calculated by Equation 3. t_f is the thickness of CFRP.

$$\frac{f'_{cu}}{f'_c} = \left((48\left(\frac{k_\varepsilon}{0.4}\right)\left(\frac{f_{ju}}{700}\right)\left(\frac{1}{f'_c}\right)\left(\frac{h}{b}\right)^{-2.3}(r_c)^{0.37})\rho_j + 1\right) \tag{1}$$

$$\frac{\varepsilon_{cu}}{2\varepsilon_{co}} = \left(a_2 {\rho_j}^{b_2}\right) \tag{2}$$

$$\rho_j = \frac{2t_f(b+h)}{bh} \tag{3}$$

2.3. RC jacketing

Reinforced concrete (RC) jacketing is one of the common and effective retrofitting methods based on the principle of covering the existing structural system elements with a new layer of concrete by wrapping them with reinforcement. This method is frequently preferred to increase the performance of columns and beams with insufficient cross-sectional dimensions and low-strength materials against earthquake effects.

During the application, transverse and longitudinal reinforcement is placed around the existing element, then high-strength concrete is used to increase the strength capacity. As a result, the axial, flexural and shear strength of the element is significantly improved. According to TBEC (2018), RC jacketing thickness is recommended not to be less than 100 mm. Göksu (2004) emphasized that the thickness should not be less than 100 mm in case of single stirrups and 150 mm in case of double stirrups. In this study, the thickness was determined as 150 mm for easy settlement of reinforcement and concrete. Lateral and longitudinal reinforcement of jacket was considered as S420. The compressive quality of concrete was taken C40 and lateral spacing of jacketing was taken as 100 mm. In the 5-storey building, longitudinal reinforcement was used as 16ϕ20 in all columns. In the 7-storey building, longitudinal reinforcement was used as 18ϕ22 in the center column and 16ϕ22 in the other columns. The behavior of the RC jacketing model was reflected in the analysis with the concrete model developed by Campione et al., (2014). In the model, the concrete compressive strength of the concrete (f'_{cc}) is calculated via Equation 4. f_l is the effective confinement pressure and the ultimate unit strain (ε_{cu}) of reinforced concrete is calculated using Equation 5.

$$f'_{cc} = f'_c\left[2.254\sqrt{1+\frac{7.94f_l}{f'_c}}-2\frac{f_l}{f'_c}-1.254\right] \tag{4}$$

$$\varepsilon_{cu} = 0.004+\frac{1.4}{f'_{cc}}\left[\frac{f_{yc}\varepsilon_{suc}A_{sc}}{(b-c_c)s_c}+\frac{f_{yj}\varepsilon_{suj}A_{sj}}{(B-\delta)s_j}\right] \tag{5}$$

f_{yc}, A_{sc}, ε_{suc}, b, c_c, s_c are yield strength of longitudinal steel, area of longitudinal steel bars, ultimate strain of longitudinal steel, section width, cover, and pitch of stirrups in the core section, respectively. f_{yj}, A_{sj}, $\varepsilon_{suj}, B, \delta, s_j$ are yield strength of longitudinal steel, area of longitudinal steel bars, ultimate strain of longitudinal steel, section width, jacket thickness, and pitch of stirrups in the external jacket, respectively.

2.4. Cost analysis for retrofitting

In this study, two alternative strengthening methods were examined. As a result of the structural analysis, the elements where the damage was concentrated were identified, and retrofitting was applied for these elements. For this purpose, firstly, the reinforced concrete retrofitting cost was calculated by applying the RC jacketing method. Then, the FRP jacketing method was evaluated as an alternative solution. In the study, it was especially taken into consideration that the costs of both methods were approximately equal. Thus, the effect of retrofitting methods with similar costs on the behavior was examined. Cost calculations were based on the current unit price lists published by the Ministry of Culture and Tourism (2025) and the Ministry of Environment, Urbanization, and Climate Change (2025). Retrofitting operations were analyzed using both existing reinforced concrete buildings. During the calculation, both material and labor costs were considered.

Improving the performance of the existing building stock in areas with high earthquake risk is of great importance in terms of ensuring building safety. In this context, RC and FRP jacketing systems are prominent among the methods applied for retrofitting structures. However, it should be noted that structural conditions, damage distribution, architectural conditions, etc. are also important factors in the selection of retrofitting methods.

In Table 1 and Table 2, total costs of both methods are given in terms of Turkish Lira (TL). It can be seen from the tables that retrofitting costs of 5- story buildings are almost 1 million TL for 5-story buildings, while this cost is close to 2 million TL for 7-story buildings. The absolute difference between the costs is also given in the tables. It can be observed that the costs of both methods are very close in 5-story buildings, and the difference between the methods was calculated as 5%. This difference is observed as 7.5% in 7-story buildings. Although the percentage of difference seems higher, the difference in the costs between the methods is around 117 thousand TL, which can be considered minimal in terms of TL. Accordingly, it was assumed that the cost of both methods was approximately equal.

Table 1. Determination of RC and FRP jacketing costs for 5- story building

Method	Labor costs (TL)	Material costs (TL)	Total (TL)	Abs. difference (%)
RC jacketing	372326.78	575621.08	947947.86	5
FRP jacketing	765777.60	232830.72	998608.32	

Table 2. Determination of RC and FRP jacketing costs for 7- story building

Method	Labor costs (TL)	Material costs (TL)	Total (TL)	Abs. difference (%)
RC jacketing	565608.87	884935.39	1450544.26	7.5
FRP jacketing	1232901.94	334985.73	1567887.67	

3. Analysis results

Based on the material quality and quantities, moment-curvature, and hence the moment-rotation capacity of structural elements, were calculated using TBEC-2018. Later, buildings were applied lateral load according to their first mode shape. Finally, damage distribution of the building was determined according to target displacement determined according to the TBEC uniform hazard spectrum for DD-2. In the first case, as-built buildings are evaluated, and the damage distribution of the building at target displacements are shown in Fig. 4.

It can seen from the figure that due to lack of lateral confimement and strong column-weak beam behaviour both buildings were severely damaged at the base story. For both buildings, damages were most accumalated at the top and bottom of the columns due to lack of strength capacity. The lack of adequate confinement details also increased the damage distributions in both buildings. The damage at the beams are minimal and they were mostly around immediate occupancy (IO) or Life Safety (LS) damage levels. Pushover curve of existing buildings are also plotted in Fig. 5. It can be seen from the figure that displacement of both buildings is low and determined as around 6 cm and 8.2 cm at the roof story, for 5- and 7-story buildings, respectively. These values correspond to around 0.4% drift ratio (roof displacement/building height) for both buildings.

In the second case, the behaviour of buildings after retrofitting of CFRP is evaluated. Damage distribution of building at target displacement are plotted in Fig. 7. Target displacements for 5- and 7-story buildings were calculated as as 9.4 cm and 10.6 cm, respectvely.

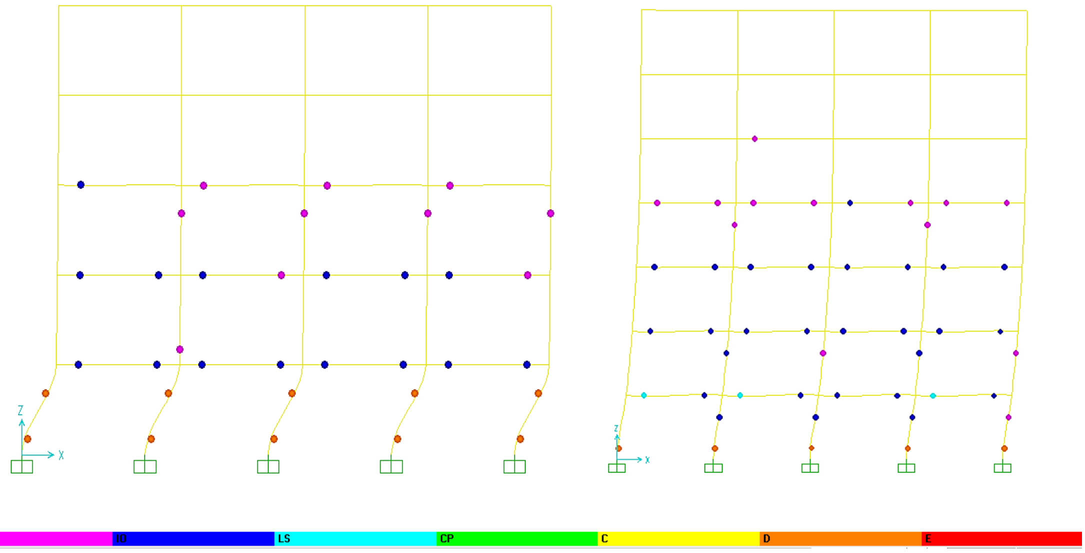

Fig. 4. Damage distribution of 5- and 7-story existing buildings at target displacement demand

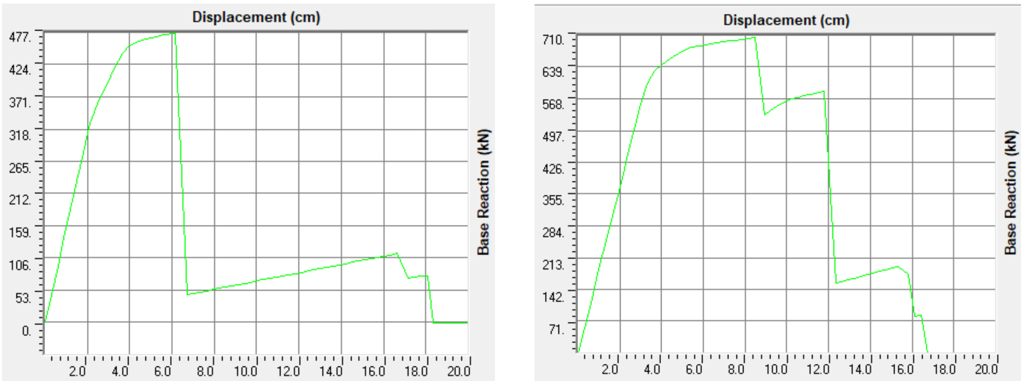

Fig. 5. Pushover curve of 5- and 7-story existing buildings

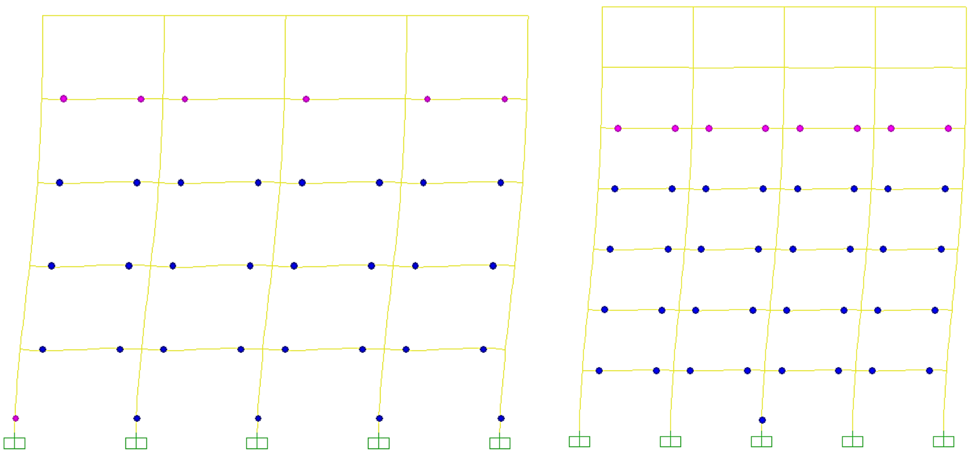

Fig. 6. Damage distribution of 5- and 7-story existing buildings at target displacement demand for CFRP retrofitting

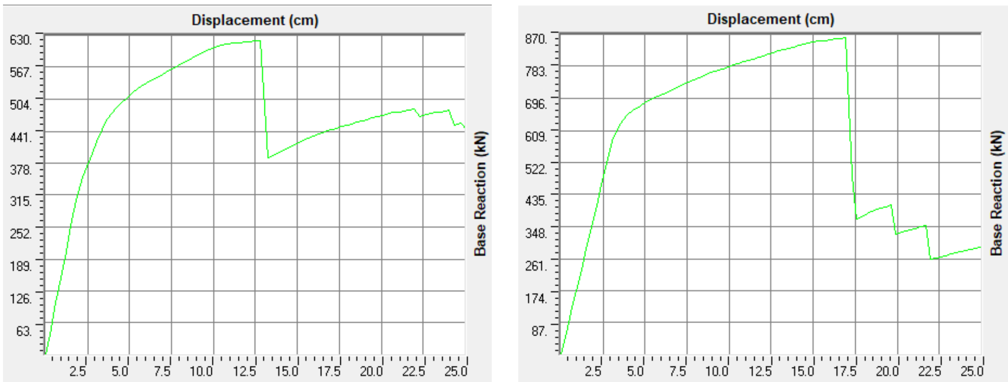

Fig. 7. Pushover curve of 5- and 7-story existing buildings for CFRP retrofitting

It can be seen from Fig. 6 that the damage distribution of buildings is dramatically changed when compared to the as-built case. In both buildings, both columns and beams were mostly in yield or IO level. In addition, the damage ratio of columns was dramatically reduced. For 5-story buildings, all columns were nearly yielding damage while columns at the middle of the frame were slightly damaged after the application of CFRP. When the pushover curve of buildings was observed (Fig. 7), it can be said that the lateral strength capacity of buildings was slightly increased. On the other hand, the displacement capacity of buildings was significantly increased. The application of two-directional FRP wrapping increased both capacities, but a more pronounced effect was observed for displacement capacity.

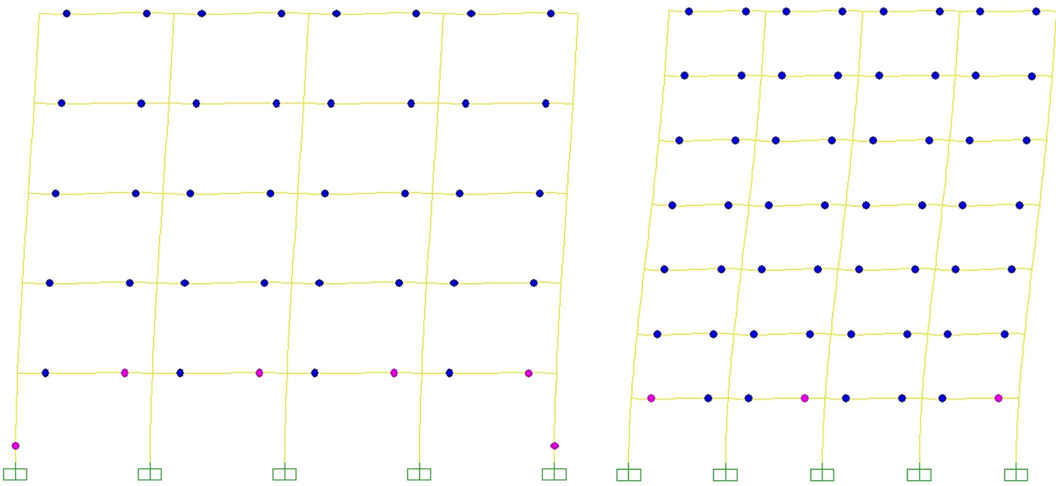

Fig. 8. Damage distribution of 5- and 7-story existing buildings at target displacement demand for RC jacketing retrofitting

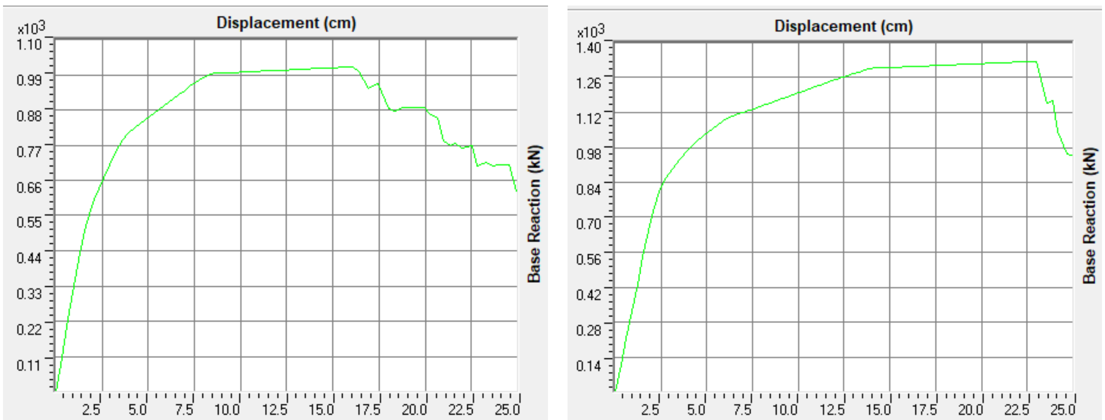

Fig. 9. Pushover curve of 5- and 7-story existing buildings for RC jacketing retrofitting

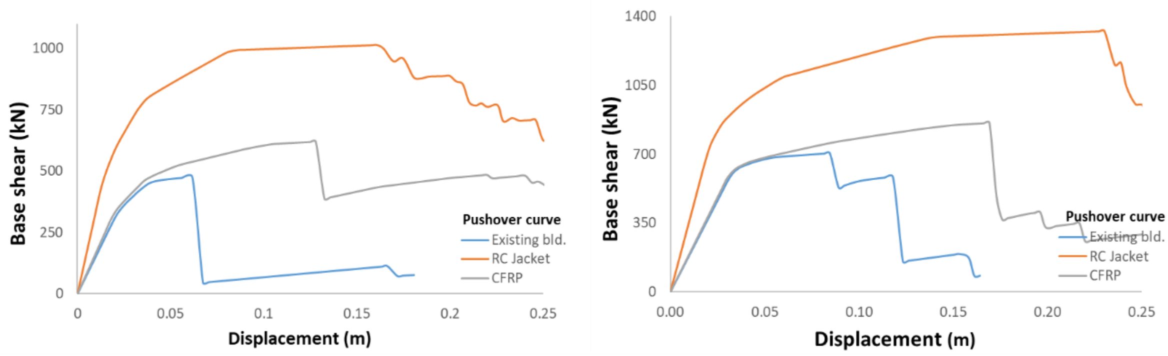

Fig. 10. Comparsion of Pushover curve of 5- and 7-story existing buildings for all three cases

In the third case, damage distributions at target displacement are plotted in Fig. 8 after retrofitting of RC jacketing. Target displacements for 5- and 7-story buildings were calculated as 7.73 cm and 9.24 cm, respectively.

It can be seen from Fig. 8 that the damage distribution of buildings are very close to the CFRP retrofitting case. In both buildings, all beams were mostly in yield or IO level. Furthermore, no column damage was observed. When the pushover curve of buildings was compared (Fig. 9), it can be said both the lateral strength and displacement capacity of buildings were dramatically increased compared to both the CFRP and as-built cases.

To make an overall comparison, pushover curves of all cases are plotted in a single figure to illustrate the change in building behavior and the results are plotted in Fig. 10. FRP was applied in both directions (transverse and longitudinal). FRP sheets in the longitudinal direction increased the moment capacity, while transverse sheets increased the shear strength and hence the ductility by enhancing the confinement effect. In the application, an equal amount of jacketing was applied in both directions. Thanks to this bidirectional application, both flexural and shear strengths of the structural elements were increased. It is worth mentioning that by changing the direction of the jacketing amount, the section behavior can be changed. However, this topic is not considered in this study.

As seen in Fig. 10, the FRP application showed a limited increase in initial stiffness in the 5-story building, while it seems not affected the 7-story building. Nevertheless, it provided a significant improvement in the strength and ductility for both structures. On the other hand, the capacity curve of both structures retrofitted by RC jacketing showed a significant increase in both initial stiffness and lateral strength capacity. The main reason for this increase can be attributed to the increase in the section dimensions because of RC jacketing. In addition, the ultimate displacement capacity has been postponed, and the ductile behavior of the system has become more pronounced. Considering the capacity curves of both reinforced concrete structures strengthened by taking into account the equivalent cost, it can be said that both methods increase the capacity and improve the performance significantly.

3. Conclusions

In this study, the structural behavior of the 5- and 7-story frame buildings designed according to TEC 1975 was investigated using RC and CFRP jacketing methods at approximately equal cost. The results can be listed as follows.

- In both structures, significant improvement in terms of strength, stiffness, and ductility was observed by RC jacketing.
- Although CFRP wrapping slightly increased stiffness in the 5-story structure, stiffness in the 7-story structure almost remained the same.
- CFRP wrapping increased the ultimate displacement value by about 2.1 for both structures.
- In both reinforcing methods, the strong column-weak beam mechanism is enhanced due to the strength in the structural member, and the damage mechanism was transferred to the beams.
- To increase the strength or ductility capacity of the member, the amounts of longitudinal and transverse FRP wrapping can be changed by assigning weighting ratios. In this study, equal (i.e., weights) amounts of transverse and longitudinal wrapping were applied, and the results were evaluated accordingly.

Abstract. During an earthquake, due to differences in the dynamic characteristics of adjacent buildings and insufficient separation distances, a phenomenon commonly referred to as "pounding" occurs as the buildings vibrate out of phase with one another. In this study, the seismic behavior and damage mechanisms of a RC building that sustained severe damage during the 2023 Kahramanmaraş earthquakes are investigated using nonlinear time-history analysis. During the earthquakes, pounding occurred between the selected building and its surrounding wall, resulting in significant damage to the impacted column. The finite element model of the building was developed using the SAP2000 software, and pounding effects were represented by a nonlinear elastic spring (Hertz model). In the analyses, real ground motion records obtained from a station located near the building during the 2023 Kahramanmaraş earthquakes were used. The analyses were carried out in two stages, with and without the pounding effect taken into account. Interstory displacements, floor accelerations, plastic hinge formations, and damage states were examined in detail. The results clearly demonstrate that the pounding effect significantly influences structural responses and should not be neglected in seismic design practices.

Keywords: RC building; Pounding; Nonlinear analysis; Kahramanmaraş earthquakes; FEM

1. Introduction

The rapid increase in housing demand driven by population growth has led to the widespread adoption of adjacent building construction, particularly in urban areas of major cities. This trend, combined with limited land availability, inadequate urban planning practices, and aesthetic-architectural considerations, has resulted in buildings being constructed in very close proximity to one another (Çetinkaya, 2011; Gökdemir, 2019; Sunca, 2023). However, one of the most critical damage mechanisms observed during the past earthquakes was the pounding effect between adjacent buildings.

In the literature, studies investigating the pounding effects between adjacent buildings have typically employed simplified and idealized building models. In the study conducted by Anagnostopoulos and Spiliopoulos (1992), the pounding effect between adjacent structures with different story heights, masses, and periods during earthquakes was investigated using multi-degree-of-freedom (MDOF) and nonlinear models. Rajaram and Ramancharla (2014) investigated the three-dimensional pounding effects between adjacent RC buildings with different story heights, mass distributions, and setback distances using nonlinear time-history analyses. Akköse and Sunca (2016) investigated the pounding effect between two adjacent RC buildings with different plan configurations using near-fault and far-fault ground motions. Tekin and Pala (2016) investigated the structural response of adjacent RC buildings with vertical discontinuity in load-bearing systems under seismic pounding. In the study conducted by Sak and Beyen (2017), the impact of seismic pounding on the structural performance of adjacent RC buildings with different story heights was investigated through nonlinear time-history analyses. They revealed that providing adequate seismic joints significantly improves structural performance, whereas insufficient separation distances prevent the structure from achieving the targeted performance levels. Miari and Jankowski (2022) investigated the pounding effect between two steel structure models with different dynamic characteristics placed on various soil types through shaking table experiments. Sunca et al. (2024) conducted shake table experiments on three half-scale, two-story RC building models to investigate the floor-to-floor pounding effect between adjacent buildings with different story heights.

The aim of this study is to investigate the seismic behavior of a RC building severely damaged by collision during the 2023 Kahramanmaraş earthquakes. During the earthquake, pounding occurred between the building and its surrounding wall, leading to severe damage, particularly in one column. In the first phase of the study, the seismic response of the structure was obtained without considering the pounding effect. Subsequently, nonlinear analyses were performed by accounting for the interaction between the building and the surrounding wall, and the results were compared accordingly.

2. Description of selected building

Within the scope of this study, a building that did not collapse but sustained severe damage during the February 6, 2023 Kahramanmaraş earthquakes was selected. Figure 1 shows the undamaged and damaged conditions of the selected building 2023 Kahramanmaraş earthquakes.

The building, constructed in 2014, was designed in accordance with Turkish Earthquake Code-2007 (TEC, 2007). The basement floor height is 3.0 meters, the ground floor height is 3.3 meters, and each of the remaining four normal floors has a height of 3.0 meters. The concrete used in the construction was classified as C25 (f_{ck} = 25 MPa), and the reinforcement bar was S420 (f_{yk} = 420 MPa). The general properties of the selected building are summarized in Table 1.

Fig 1. Undamaged and damaged conditions of the selected building

Table 1. General properties of selected building

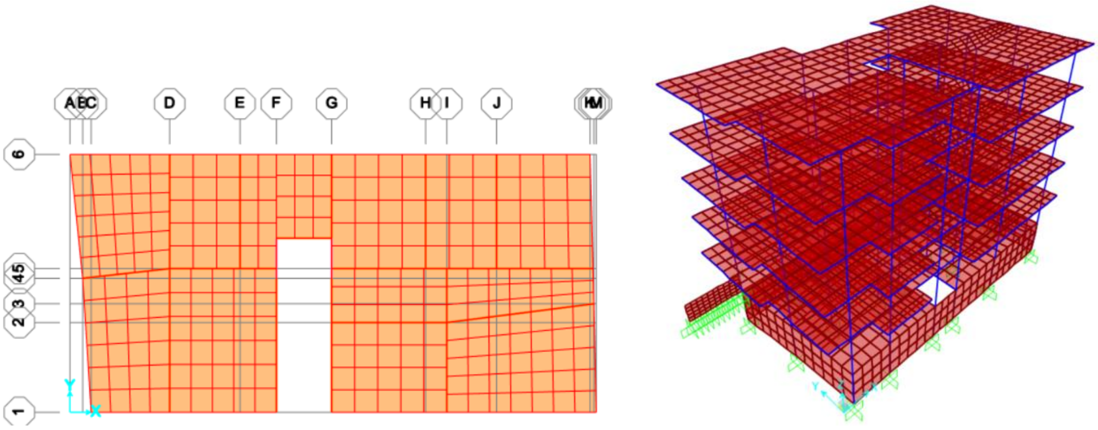
General information about selected building	
Purpose of usage	Commercial+Residental
Area of storey	Basement and ground floor: 242 m^2 Normal floor: 296 m^2
Building height	18.3m
Story heights	Basement and normal floor: 3.00m Ground floor: 3.30m
Slab System	Ribbed Slab System
Properties of structural elements	
Column section	30×70cm,35×70cm,30×50cm,45×35cm 40×70cm,70×30cm,70×35cm
Beam section	50×30 cm, 25×50cm,
Slab thickness	7cm
Material and soil properties	
Concrete	C25 (f_{ck} = 25MPa)
Reinforcement	S420 (f_{yk} = 420MPa)
Soil classification	Z2 (according to TEC-2007)
Considered loads	
Slab dead loads	3.0 kN/m^2
Slab live loads	Rooms: 2.0 kN/m^2 Stairs: 3.5 kN/m^2 Balconies: 5.0 kN/m^2
Infill wall	
Wall type	Brick wall

3.Finite element (FE) model of building

Within the scope of the study, two different FE models were developed using SAP2000 software in order to investigate the structural response under pounding effects. Collision effects were not taken into account in Model-1. In Model-2, the building and the surrounding wall were modeled and the collision effects between them were taken into account. The gap between the building and the wall was considered as 0.5 cm. Figure 2 presents both the three-dimensional and plan views of the FE model of the selected building. In the FE models, columns and beams were modeled as frame elements, shear walls and slabs were modeled using shell elements.

During the load assignment stage, the infill weight of the ribbed slab and the weight of the rib beams were calculated and applied as additional dead load (DL) on top of the self-weight of the slab. For live loads (LL), 2 kN/m² was applied to typical floor slabs and 5 kN/m² to balcony slabs based on architectural usage. Wall loads acting on beams were calculated as 6.75 kN/m for 10 cm thick walls and 8.64 kN/m for 20 cm thick walls. For the roof level, a live load of 1.5 kN/m² was considered, and wall loads on the beams were excluded.

To represent the nonlinear material behavior in the analyses, the concrete model developed by Mander et al. (1988) was adopted. According to the Turkish Building Earthquake Code (TBEC-2018), the nonlinear behavior of structural members can be idealized using either lumped plasticity or distributed plasticity models (Köse Sunca, 2019). In this study, the distributed plasticity model was used, which assumes plastic deformations occur continuously along the section. In this model, the cross-sections of structural elements are divided into fiber elements that allow independent tracking of the behavior of core concrete, cover concrete, and reinforcement. This modeling approach enables the consideration of nonlinear behavior both within the section and along the length of the element, allowing for a more detailed and accurate representation of the mechanical behavior of structural components (Yön and Calayır, 2013).



a) Plan view b) Three-dimensional

Fig 2. Plan and three-dimensional view of the building

In the FE model, various models are used to represent the impact behavior between adjacent structures. In this study, the nonlinear elastic spring model, known as the Hertz model, shown in Fig. 3, is employed to simulate the pounding effect.

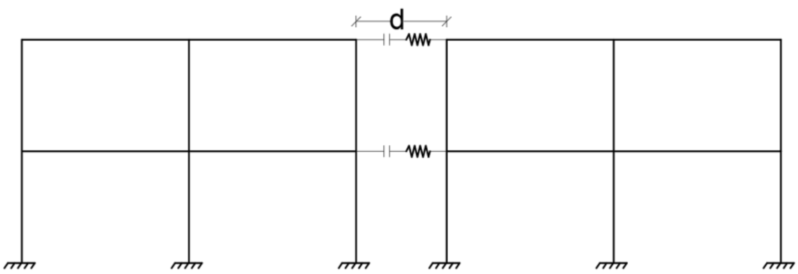


Fig. 3. Pounding model between buildings(Akköse et.al,2016)

This modeling approach simulates the dynamic interaction between structures through gap elements that are activated only at the contact. The force–deformation relationship of the gap element can be defined by the following equation:

$$f_G(t) = \begin{cases} k_g[u(t) - d]^{3/2}, & u(t) > d \\ 0, & u(t) \leq d \end{cases} \tag{1}$$

In the equation above k_g is the nonlinear spring stiffness of the gap element. $u(t)$ is defined as $u(t)_i - u(t)_j$, and d denotes the initial gap between the buildings at the beginning of the analysis. $u(t)_i$ and $u(t)_j$ represent the displacements of the adjacent structures in the same direction of the earthquake. The relationship between displacement and impact force in the Hertz model is illustrated in Figure 4.

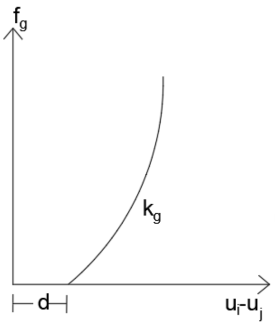

Fig 4. Pounding force-displacement relationship in the Hertz spring model (Muthukumar et al,2006)

4. Ground motion selection

The Turkish Strong Motion Database and Analysis System (AFAD-TADAS) of the Disaster and Emergency Management Authority (AFAD) was used to determine the ground motion to be applied to the structure. During the selection of earthquake records, data from the accelerograph stations closest to the location of the residential building were first examined. During the Kahramanmaraş-Pazarcık earthquake, five stations, ranging from 536 meters to 29 kilometers from the building, failed to record for the full duration of the earthquake. To evaluate the damage mechanism of the structure, it was necessary to select appropriate ground motion records. Therefore, the distances between the building and the epicenters of the earthquakes were calculated. The distance to the Pazarcık epicenter was approximately 120 km. To identify suitable ground motions, stations within a radius of 120 km were listed. Stations not representative of the local soil conditions of the building were eliminated. As a result, for the Pazarcık earthquake, the record from Station No. 6304, located 130.27 km from the epicenter, was selected. Figure 5 presents the acceleration records and the corresponding response spectra generated for a 5% damping ratio of the selected record.

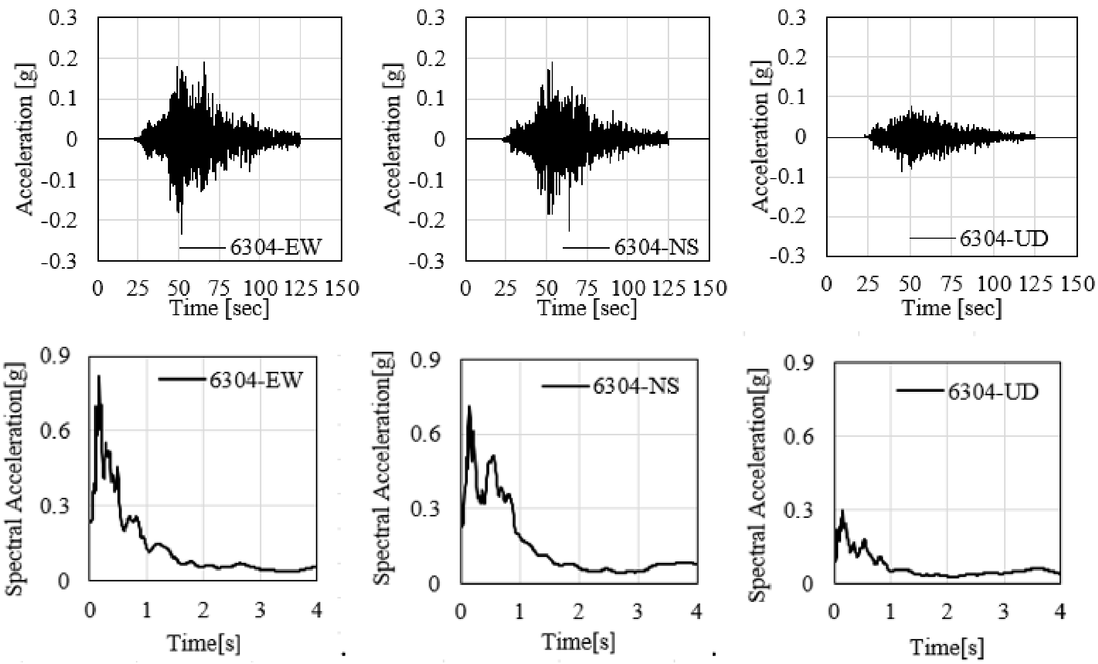

Fig 5. Acceleration-time and response spectrum graphs of the selected records

5.Result and discussion

In this section, the results obtained from the nonlinear time-history analyses of the selected building are presented. These results are comparatively evaluated for both pounding and non-pounding cases in terms of interstory displacements, acceleration, shear forces in the colliding column, pounding force, and the distribution of plastic hinges.

5.1. Accelerations and pounding forces

Collision effects between adjacent buildings cause sudden changes in velocity. This causes sudden spikes in acceleration responses. In the selected building, collisions occurred between the ground floor column and the surrounding wall during the 2023 Kahramanmaras earthquakes and significant damage occurred to the colliding column. The increases in acceleration due to the collision on the floor where the collision occurred are given in Figure 7. This twofold increase indicates that pounding significantly amplifies the seismic demands on the structure and raises the potential level of damage.

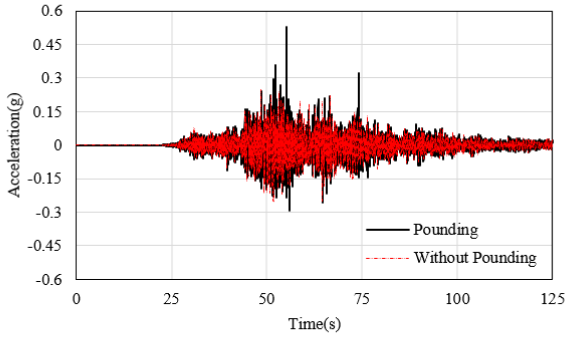

Fig 6. Increases in storey acceleration responses due to pounding

The maximum pounding force resulting from the pounding between the building and the surrounding wall was obtained as 420.9 kN. A comparative evaluation of Figures 6 and 7 shows that the time interval during which the pounding force reaches its peak coincides with the maximum acceleration. This indicates that the impact forces generated by pounding significantly increase the structural responses of the structure.

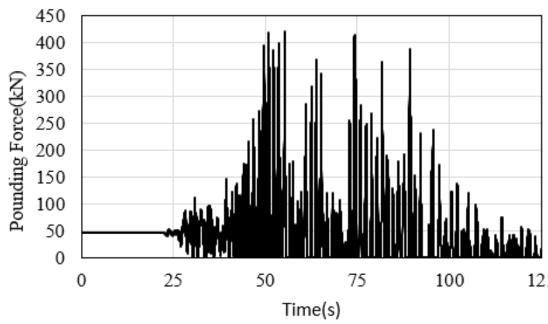

Fig 7. The time-histories of pounding forces at the ground floor

5.2.Storey displacements

When interaction occurs between two buildings due to insufficient gap, the displacement demands of the structures are affected in two different ways. In the direction where the collision occurs, a decrease in displacement responses is expected. However, due to the energy transferred in the free direction where there is no interaction, higher displacement demands can be observed, similar to accelerations. This is directly affected by the pounding forces and structural characteristics. The storey displacements obtained from the analysis with and without pounding cases are presented in Figure 8. It is observed that the displacements at each floor increase significantly in the impact case. As can be seen, displacement responses in the interaction direction decrease due to the collision, while displacements in the free direction increase.

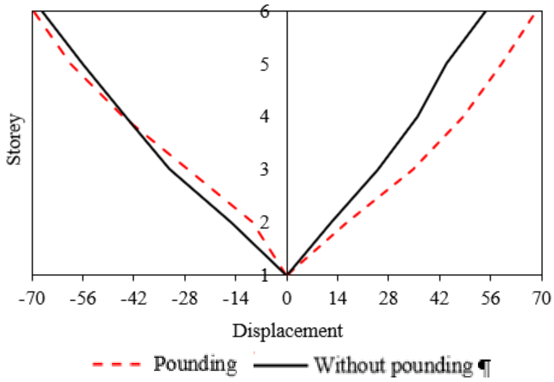

Fig 8. Changes in storey displacements responses due to pounding

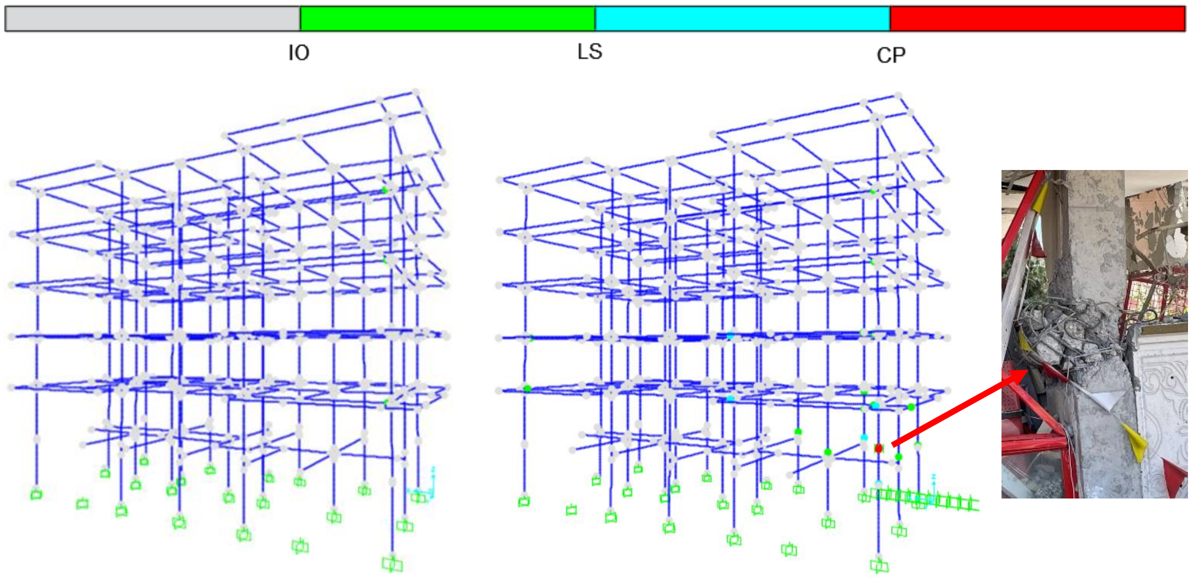
5.3. Performance level of load-bearing elements

As a result of the analyses, the plastic hinge formations in the structural elements are presented in Figure 9. According to this distribution, it is seen that almost all of the structural system elements are at Immediate Occupancy (IO) performance level in the analyses where collision effects are neglected. However, in the analyses where collision effects are taken into account, it is clearly seen that plastic deformations increase at the storey where the collision occurs. On the other hand, it was observed that the column where the pounding occurred collapsed as observed in the 2023 Kahramanmaraş earthquakes.



a. without pounding b. with pounding

Fig 9. Comparisons of performance level of load-bearing elements

5. Conclusion

In this study, the seismic behavior and damage mechanisms of a RC building that sustained severe damage during the 2023 Kahramanmaraş earthquakes are investigated using nonlinear time-history analysis. During the earthquakes, pounding occurred between the selected building and its surrounding wall, resulting in significant damage to the impacted column. The finite element model of the building was developed using the SAP2000 software, and pounding effects were represented by a nonlinear elastic spring (Hertz model). In the analyses, real ground motion records obtained from a station located near the building during the 2023 Kahramanmaraş earthquakes were used. The analyses were carried out in two stages, with and without the pounding effect taken into account. As a result of the analysis, it is seen that the structural responses are significantly affected by the pounding. It is also observed that the collisions cause significant damage to the structural elements where the interaction occurs. This situation clearly reveals that pounding effects neglected during design can have devastating effects.

Optimal design of steel frames with semi-rigid connections and column bases using particle swarm optimization

Jay Prakash*[1], Ayşe T. Daloğlu[1]

[1] *Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye*

Abstract. The particle swarm optimization (PSO) method is utilized for two-dimensional steel frames featuring semi-rigid connections between beams and columns, as well as between columns and bases. The metaheuristic algorithm generates optimized steel frames by selecting suitable sections from a predetermined collection of standard steel sections. The standard steel sections, which include wide-flange profiles (W), are supplied by the American Institute of Steel Construction (AISC). The initial example is subject to displacement, inter-storey drift, and stress constraints, as outlined by the AISC Load and Resistance Factor Design (LRFD) regulations. In the last examples, the displacement, geometric, and stress constraints of the AISC Allowable Stress Design (ASD) standard are implemented. In the course of the optimization process, three distinct steel frames are examined, including configurations both with and without semi-rigid connections between the beams and columns, as well as between the columns and bases. All optimization techniques are implemented using the high-level programming language C# version 17.10.5, which is designed to integrate with version 22 of SAP2000's Open Application Programming Interface (OAPI). The results of the analysis indicate that the rigidity of the connections serves as a critical parameter in the optimization of weight for steel frames.

Keywords: Particle swarm optimization (PSO); Semi-rigid connection; Optimization of steel frames; SAP2000-OAPI; Column bases

1. Introduction

The process of optimizing steel frames structures begin with choosing steel profiles for the structural elements from a specific collection of available steel profile tables. This method reduces the steel frame's weight by considering various constraints, such as material properties, displacement, deflection, and dimensions (Prakash & Daloglu, 2023). The field of computer-aided optimization advanced significantly in the 1970s (Pincus, 1970; Talbi, 2009; Rao, 2019). Then, in the early 1990s, heuristic search techniques developed as a response to engineers and designers' requirements for cost-effective designs and improved optimization strategies (Jenkins, 1991; Tang & Yao, 2008; Yang, 2010).

In recent years, significant progress has been made in the development of innovative stochastic search methods within the field of structural optimization. These techniques, which are inspired by natural processes, effectively address the inconsistencies commonly associated with traditional mathematical programming-based optimization approaches. Typically, meta-heuristic algorithms aim to identify feasible solutions to optimization problems through a systematic 'trial and error' process within a reasonable computational timeframe (Arafa, Khalifa, & Alqedra, 2015). Numerous researchers have recently formulated and implemented diverse meta-heuristic strategies specifically designed for steel structures, accommodating both fully rigid and semi-rigid connections (Kameshki & Saka, 2003; Hayalioglu & Degertekin, 2004; Hayalioglu & Degertekin, 2005; Degertekin, Hayalioglu, & Gorgun, 2009; Rafiee, Talatahari, & Hadidi, 2013; Hadidi & Rafiee, 2014; Artar & Daloglu, 2015).

A thorough examination of the existing literature reveals a significant deficiency in studies utilizing metaheuristic algorithms for the optimal design of steel frames, specifically those incorporating semi-rigid connections and column bases. Among metaheuristic algorithms, the Particle Swarm Optimization (PSO) algorithm is well-regarded for its simplicity, computational efficiency, and ease of implementation. Unlike other methods that rely heavily on user-defined parameters, the PSO algorithm features a straightforward numerical structure governed by only a few control parameters: inertia weight (w), cognitive acceleration coefficient (c_1), and social acceleration coefficient (c_2). These parameters define the exploration-exploitation behavior of the swarm and can often be standardized for structural optimization problems (Clerc, 2010; Sengupta, Basak, & Peters, 2018). Moreover, PSO leverages these general parameters and does not require algorithm-specific operations such

* Corresponding author, E-mail: jaypee@outlook.in

https://doi.org/10.31462/icearc2025_ce_sme_780

as crossover or pheromone update schemes, reducing implementation complexity (Papazoglou & Biskas, 2023; Adeyiga, Sotonwa, & Adenibuyan, 2022). In comparison, Genetic Algorithms (GA) require the specification of crossover probability, mutation rate, and selection method. Ant Colony Optimization (ACO) involves configuring four parameters and an extra parameter for search-space reduction in multiphase applications. Harmony Search (HS) necessitates the harmony memory consideration and pitch adjusting rate (Kennedy & Eberhart, 1995). The reduced parametric complexity of Particle Swarm Optimization (PSO) lessens its vulnerability to subjective tuning biases, enabling more robust convergence in complex design spaces (Clerc & Kennedy, 2002; Perez & Behdinan, 2007).

Consequently, the PSO technique can be utilized to enhance the design of steel frames featuring semi-rigid connections and column bases. By employing the PSO method, the optimal design for steel frames has been evaluated and compared to prior studies. Three particular case studies are examined for this analysis. The first case study originates from Değertekin (2008), while the other two are based on the work of Artar and Daloğlu (2015). The findings indicate that the PSO method performs effectively and is viable for addressing structural challenges.

2. Particle swarm optimization (PSO)

The PSO algorithm was initially conceived by Kennedy and Eberhart in 1995. Subsequent advancements to this algorithm were introduced by Pedersen and Chipperfield in 2010. PSO represents a stochastic search methodology that employs a population-based strategy for effectively exploring intricate solution spaces. The active foraging behavior of animal species, as they seek out food sources, serves as a basic concept for understanding this technique. This food-seeking behavior encompasses the formation of groups shaped by social influences that rely on the collective memory of each member and the data collected by the swarm.

The approach begins with random solutions and then progressively modifies the velocity and location of particles through iteration. Every particle is characterized by its position x_i^m and velocity v_i^m. The initial position x_i^0 is randomly scattered and taken from the given solution. The initial velocity v_i^0 is presumed to be zero. The initial parameters can be obtained from Eqs. 1-2.

$$x_i^0 = x_{min} + r(x_{max} - x_{min}) \tag{1}$$

$$v_i^0 = 0 \tag{2}$$

In the provided equations, r denotes a random integer that can take a value between 0 and 1. At the same time, x_{min} and x_{max} signify the lower and top limit of the design parameters, respectively.

This particle velocity reflects the extent of change, while particle positions denote possible solutions for optimal design challenges. Each particle is updated based on two optimal values during every iteration of its movement. The first optimal value is called $p_{best,i}^m$, which signifies the best position attained by the i^{th} particle. The second optimal value, p_{gbest}^m, indicates the best position among all particles at time m. The position and velocity of the i^{th} particle for the m iteration are adjusted according to Eqs. 3-4.

$$v_i^{m+1} = w^m v_i^m + c_1 r_1 \left(p_{best,i}^m - x_i^m\right) + c_2 r_2 (p_{gbest}^m - x_i^m) \tag{3}$$

$$x_i^{m+1} = x_i^m + v_i^{m+1} \tag{4}$$

In the formulas mentioned above, r_1 and r_2 serve as arbitrary values ranging from 0 to 1. The particle's inertia, denoted as w^m,influences the algorithm's exploration characteristics. The trust parameters c_1 and c_2 represent the coefficients for individual and collective learning, respectively. For further information on the PSO algorithm, one can refer to various sources, including Kennedy and Eberhart (1995), Saka and Geem (2013), and Gad (2022).

3. Two-dimensional steel frame modeling with semi-rigid connections

The analysis of the frame is based on the assumption that the connection between the column and beam is entirely rigid, facilitating straightforward calculations. However, experimental findings indicate that most connections exhibit moment-rotation behavior that lies between pinned and rigid connections. As a result, these connections can be classified as semi-rigid. In the context of simple models, Simoes (1996) presented a linear model for the analysis of semi-rigid frameworks. Furthermore, Soares Filho et al. (2004) employed a linear technique in examining a 20-storey steel frame employing linear static analysis. Nevertheless, it is important to note that the actual behavior of the connections across all moment-rotation curves is nonlinear (Artar & Daloglu, 2015). As a result, this paper acknowledges the moment-rotation relationship of the connection as being nonlinear.

In numerous published studies, it is often assumed that connections between beams and columns or between columns and their bases are entirely rigid (Toğan, 2012; Artar, 2016). Nonetheless, semi-rigid connections can range from being fully pinned to completely rigid, depending on their specific type. When analyzing the bending moment (M) at these connections, it is crucial to consider semi-rigid connections, as they can cause rotational movement (θ_r) (Artar & Daloglu, 2015). Figs. 1 and 2 depict moment-rotation curves and the types of connections, respectively (Hayalioglu & Degertekin, 2004).

In the present study, a polynomial model proposed by Frye and Morris (1975) is utilized. The subsequent equations, denoted as Eq. 5, pertaining to odd-power polynomials, elucidate this model:

$$\theta_r = C_1(\kappa M)^1 + C_2(\kappa M)^3 + C_3(\kappa M)^5 \tag{5}$$

In this context, κ is defined as the standardization constant, contingent upon the geometrical variables and the characteristics of the connections. The constants C_1, C_2, and C_3 serve as the coefficients employed for the purpose of curve fitting.

In the analysis of the steel frames, as mentioned in Fig. 2, two semi-rigid connections are applied in this study. Table 1 provides these two connections' curve fitting and standardization constants (Faella, Piluso, & Rizzano, 1999). The values for rotational stiffness are 2.26×10^8 kNmm/rad for end plates lacking column stiffeners and 3.39×10^8 kNmm\rad for end plates including column stiffeners (Hayalioglu & Degertekin, 2004). Additionally, the semi-rigid connection for the column base utilized by Hayaloglu and Degertekin (2004) is incorporated, as depicted in Fig. 3.

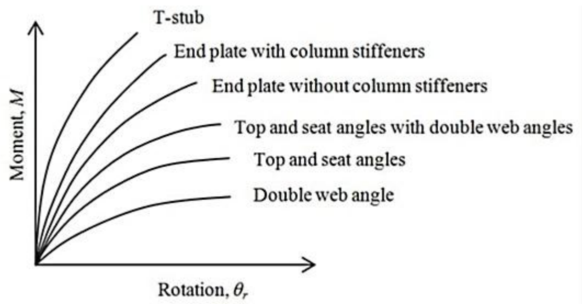

Fig. 1. The moment-rotation curves for semi-rigid connections (Hayalioglu & Degertekin, 2004)

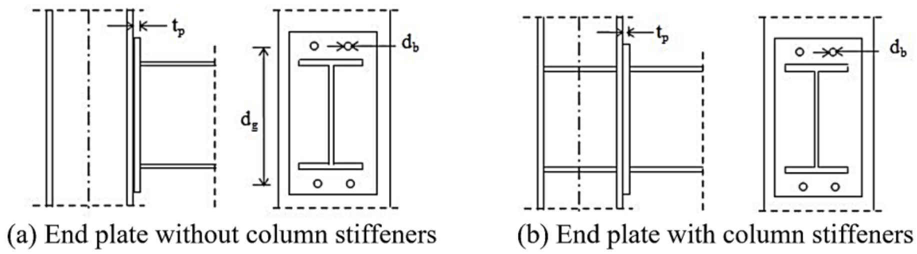

Fig. 2. Types of semi-rigid connections used in the study

Table 1. The details of semi-rigid connections used in the study

Connection Types	Curve fitting constants	Standardization constants
End plate without column stiffeners	$C_1 = 1.83 \times 10^{-3}$ $C_2 = 1.04 \times 10^{-4}$ $C_3 = 6.38 \times 10^{-6}$	$\kappa = d_g^{-2.4} t_p^{-0.4} d_b^{-1.5}$
End plate with column stiffeners	$C_1 = 1.79 \times 10^{-3}$ $C_2 = 1.76 \times 10^{-4}$ $C_3 = 2.04 \times 10^{-4}$	$\kappa = d_g^{-2.4} t_p^{-0.6}$

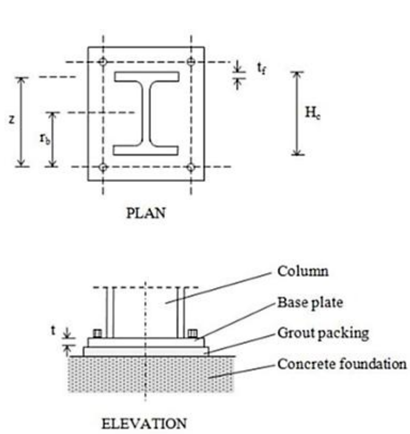

Fig. 3. Type of semi-rigid connection for column bases (Hayalioglu & Degertekin, 2004)

4. Mathematical formulation of optimal structural design

The lowest weight of unbraced steel structures is treated as the unconstrained objective function in discrete optimization problems. The formulations for the objective function and the penalized functions are provided in Eqs. 6-9 (Daloglu & Armutçu, 1998).

$$Min\ W_{sf} = \sum_{f=1}^{ng} A_f \sum_{i=1}^{nf} \rho_i L_i \tag{6}$$

$$\mathrm{g_i}(x) > 0 \rightarrow c_{vi} = \mathrm{g_i}(x) \tag{7}$$

$$\mathrm{g_i}(x) < 0 \rightarrow c_{vi} = 0 \tag{8}$$

$$\varphi_{sf}(x) = W_{sf}(x)\left(1 + P\sum_{i=1}^{m} c_{vi}\right) \tag{9}$$

In this context, the variable W_{sf} represents the total weight of the unbraced steel frame, while A_f denotes the cross-sectional area of element group f. The symbols ρ_i and L_i refer to the density and length of the steel members. The variable ng indicates the total number of groups, and nf signifies the total number of members within group f. The function $\varphi_{sf}(x)$ is referred to as the penalized objective function, and P representing the penalty constant. The variable c_{vi} corresponds to constraint violations, and $\mathrm{g_i}(x)$ designates the constraints applicable to the design.

This study considers various limitations based on Prakash and Daloglu (2023), which are expressed as follows:

The stress limits according to AISC-LRFD (2010) are presented in Eq. 10.

$$\mathrm{g_i}(x) = \begin{cases} \dfrac{P_u}{\phi P_n} + \dfrac{8}{9}\left(\dfrac{M_{ux}}{\phi_b M_{nx}} + \dfrac{M_{uy}}{\phi_b M_{ny}}\right) - 1.0 \le 0 & if\ \dfrac{P_u}{\phi P_n} \ge 0.2 \\ \dfrac{P_u}{2\phi P_n} + \left(\dfrac{M_{ux}}{\phi_b M_{nx}} + \dfrac{M_{uy}}{\phi_b M_{ny}}\right) - 1.0 \le 0 & if\ \dfrac{P_u}{\phi P_n} \le 0.2 \end{cases} \tag{10}$$

In this context, the symbol ϕ signifies the resistance factor, which is defined as ϕ_c for compression (0.85), ϕ_t for tension (0.90), and ϕ_b for flexural (0.90). P_n and P_u denote the nominal strength and required axial strength, respectively. M_{nx} and M_{ny} indicate the nominal flexural strength about the major and minor axes, respectively. M_{ux} and M_{uy} represent the necessary flexural strength around the major and minor axes, respectively, with the understanding that for a two-dimensional frame, M_{uy} is equal to zero.

The stress limits according to AISC-ASD (1989) are presented in Eqs. 11-12.

$$\mathrm{g_i}(x) = \left[\frac{f_a}{F_a} + \frac{C_{mx} f_{bx}}{\left(1 - \frac{f_a}{F'_{ex}} F_{bx}\right)}\right] - 1.0 \le 0 \qquad i = 1, 2, \dots, nc \tag{11}$$

$$\mathrm{g_i}(x) = \left[\frac{f_a}{0.60F_y} + \frac{f_{bx}}{F_{bx}}\right] - 1.0 \le 0 \qquad i = 1, 2, \dots, nc \tag{12}$$

If $\frac{f_a}{F_a}$ is less than or equal to 0.15, then Eq. 13 is used for calculations instead of Eqs. 11 and 12.

$$\mathrm{g_i}(x) = \left[\frac{f_a}{F_a} + \frac{f_{bx}}{F_{bx}}\right] - 1.0 \le 0 \qquad i = 1, 2, \dots, nc \tag{13}$$

In this context, The variable nc represents the total number of members, and C_{mx} is a factor typically assumed to be 0.85 for unbraced frame members. The terms F_{bx} and f_{bx} correspond to the allowable compressive bending stresses and the computed bending stresses about the major axis, respectively. Furthermore, F'_{ex} indicates the Euler stresses, and F_y refers to the yield stress of steel. f_a denotes the computed axial stress, while F_a signifies the allowable axial stress under axial compression, which is determined by the elastic or inelastic buckling characteristics of the member depending on its slenderness ratio, influenced by the effective length factor (K).

According to Dumonteil (1992), the effective length factor K is defined in Eq. 14.

$$K = \sqrt{\frac{1.6G_A G_B + 4.0(G_A + G_B) + 7.50}{G_A + G_B + 7.50}} \tag{14}$$

In this context, G_A and G_B denote the stiffness factors corresponding to the A^{th} and B^{th} ends of the columns, which can be determined using the equations provided in Eq. 15.

$$G = \left(\frac{\sum I_c/L_c}{\sum \alpha_{uf}(I_g/L_g)}\right) \tag{15}$$

In this context, I_c denotes the moment of inertia related to the column section that aligns with the buckling plane, while L_c signifies the column length. I_g refers to the moment of inertia associated with the beam section pertinent to the bending plane, and L_g represents the length of the beam. The coefficient α_{uf} reflects the connection state, equal to 1 for rigid connections. Semi-rigid connections are determined using Eq. 16 (Doğan, 2010).

$$\alpha_{uf} = \frac{1}{\left(1+\frac{6EI_g}{L_g K'}\right)} \tag{16}$$

Where, K' indicates the rotational spring stiffness at the member's end, expressed as M/θ_r.

The displacement constraints are delineated in Eq. 17.

$$g_{jl}(x) = \frac{\delta_{jl}}{\delta_{ju}} - 1.0 \leq 0 \qquad \begin{array}{l} j = 1, \dots, cd \\ l = 1, \dots, nl \end{array} \tag{17}$$

In this context, δ_{jl} represents the displacement associated with the j^{th} degree of freedom for the specified load case l. Additionally, δ_{ju} indicates the established upper limit, while cd signifies the total count of constrained displacements. Lastly, nl refers to the overall number of loading scenarios considered.

Inter-storey drift constraints are delineated in Eq. 18.

$$g_{jil}(x) = \frac{\Delta_{jil}}{\Delta_{ju}} - 1.0 \leq 0, \quad i = 1, \dots, nsc, j = 1, \dots, ns, l = 1, \dots, nl \tag{18}$$

In this context, Δ_{jil} denotes the inter-storey drift of the i^{th} column in the j^{th} storey during load case l. The symbol Δ_{ju} indicates the permissible limit value, ns refers to the total number of stories, and nsc signifies the count of columns within a storey.

Column-to-column geometric constraints are delineated in Eq. 19.

$$g_n(x) = \frac{D_{un}}{D_{ln}} - 1.0 \leq 0 \qquad n = 2, \dots, ns. \tag{19}$$

In this context, D_{un} and D_{ln} signify the depths of the upper and lower floors, respectively.

Beam-to-column geometric constraints are delineated in Eq. 20.

$$g_{bb,i}(x) = \frac{b_{fbk,i}}{b_{fck,i}} - 1.0 \leq 0 \qquad i = 1, \dots, n_{bf}. \tag{20}$$

In this context, $b_{fbk,i}$ and $b_{fck,i}$ signify the flange widths of the beam and column elements, respectively.

5. Implementation and results

Three particular unbraced steel frames are examined in this study to explore the impact of semi-rigid connections between beams and columns, as well as between columns and bases, utilizing the PSO optimization algorithm. The first example has been analyzed by several researchers (Pezeshk, Camp, & Chen, 2000; Camp, Bichon, & Stovall, 2005; Degertekin S. O., 2008), while the last two examples were investigated by Hayalioglu and Degertekin (2004) and Artar and Daloglu (2015). In this study, the permissible lateral displacement is limited to $H/250$, with H representing the overall height of the steel frame in centimeters, and the maximum inter-storey drift is constrained to $h_r/300$, where h_r denotes the height of the storey in centimeters. The rotational stiffness for the semi-rigid column-to-base connection in all frames is set at 1.13×10^8 kNmm/rad. The frame members are assumed to be made of steel with a Young's modulus of $E_s = 200$ GPa, a yield stress of $f_y = 248.2$ MPa, and a material density of $\rho_i = 7.85$ ton/m^3.

5.1. Case study-1: 2-bay, 3-storey frame design

A 2-bay, 3-story, 2-dimensional frame is depicted in Fig. 4, comprised of 15 members. Various researchers have assessed the steel frame, such as Pezeshk et al. (2000), Camp et al. (2005), Degertekin (2008). In this study, the steel frame is optimized with and without semi-rigid connections using particle swarm optimization in a hybrid SAP2000 and C# programming language approach. The stress limitations of AISC-LRFD, displacement limits, and inter-story constraints are applied to both the fully rigid and semi-rigid frames. The maximum lateral deflection and inter-story drift are constrained to 3.658 cm and 1.016 cm, respectively.

The frame components are categorized into two groups: the first group includes beam components, while the second group comprises column components. For the design, beam components are chosen from a selection of 276-W profiles, and column components are chosen from 38-W profiles. Dumonteil (1992) approximation equation is applied to determine the effective length factor regarding the major axis (K_x). The effective length factor concerning the minor axis K_y is assumed to be 1.0 for all column components and is considered to be 1/6th of the span length for each beam component.

The optimal outcomes for the rigid frame are presented in Table 2 for comparison with existing solutions in the literature. The ideal cross-sections for the semi-rigid structure, featuring both end plates without column stiffeners and those with stiffeners at the connections, are also shown in Table 2. Fig. 5 illustrates the design history of total steel weight through iterations for both the rigid and semi-rigid frames.

According to the PSO solution presented in Table 2, which pertains to the rigid frame, the weight of the 2-dimensional frame aligns with the minimum optimal design established in previous studies. The minimum weight of 8165 kg obtained in this study is roughly 4.4%, 4.4%, and 1.6% lighter than the lowest weights reported by Pezeshk et al. (2000), Camp et al. (2005), and Değertekin (2008), respectively.

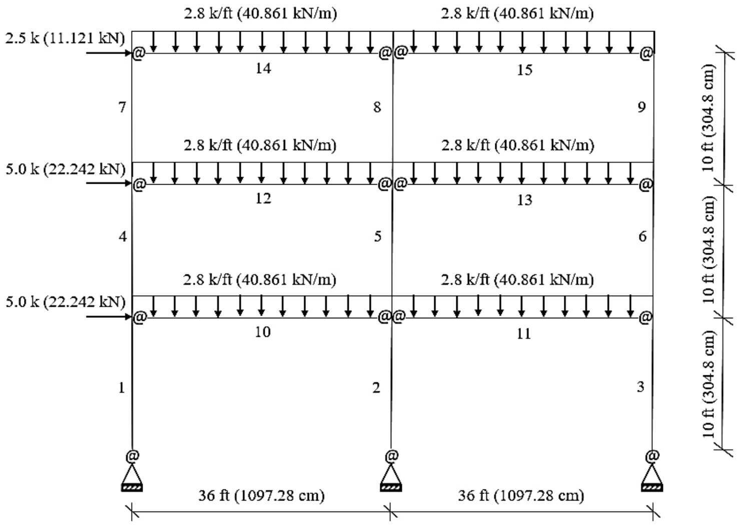

Fig. 4. A 2-bay, 3-storey steel frame

Table 2. Optimum design of 2-bay, 3-storey frame

Element Group	Member	Rigid frame				Semi-rigid frame	
						Present study	
		Pezeshk et al. (2000)	Camp et al. (2005)	Değertekin (2008)	Present study	End plate without column stiffeners	End plate with column stiffeners
		GA	ACO	HS	PSO	PSO	PSO
1 (Beam)	10-15	24 × 62	24 × 62	21 × 62	21 × 55	18 × 60	18 × 55
2 (Column)	1-9	10 × 60	10 × 60	10 × 54	10 × 68	10 × 68	10 × 77
Minimum weight (kg)		8524	8524	8297	8165	8655	8532
Maximum displacement (cm)		-	-	-	1.3947	1.6071	1.5433
Maximum inter-storey drift (cm)		-	-	-	0.8509	0.9571	0.8814

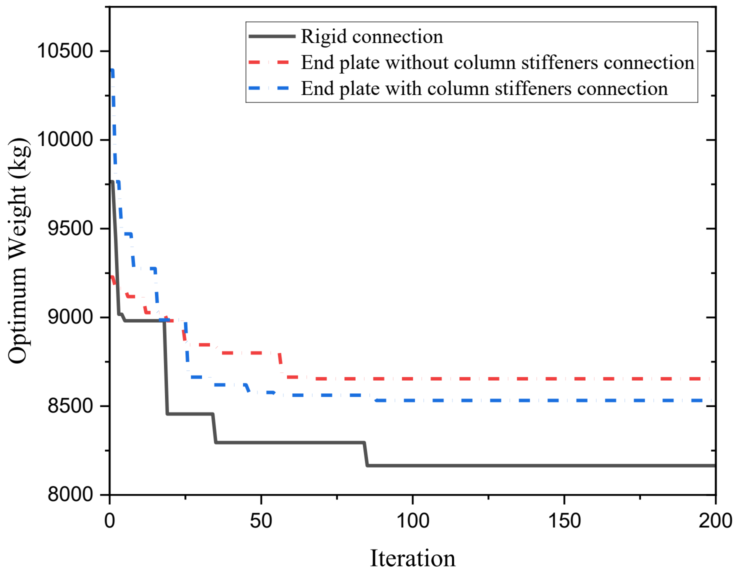

Fig. 5. Design histories of a 2-bay, 3-storey steel frame

Additionally, this research demonstrates a lower minimum weight than previous literature due to random initialization, stochastic search, and convergence criteria. The maximum top drift and inter-story drift are recorded at 1.3947 cm and 0.8509 cm, respectively. These values for top and inter-story drifts are significantly below the acceptable limits. Furthermore, as indicated in Table 2, the minimum weights for the semi-rigid frame with the end plate without column stiffeners and the end plate with column stiffeners are 6.0% and 4.5% heavier than the minimum weight of the rigid frame structure, respectively.

The optimal design of the steel frame is generated through the PSO algorithm after 200 iterations with a population of 20, resulting in an evaluation of 4000 frames. Additionally, a decrease in the rotational stiffness of the connection between the beam and the column leads to a considerable increase in the minimum weight. However, this research's findings are more cost-efficient than those of earlier studies.

5.2. Case study-2: 2-bay, 5-storey frame design

A 2-bay, 5-storey, 2-dimensional frame is depicted in Fig. 6, consisting of 25 elements. Hayaloglu and Degertekin (2004) and Artar and Daloglu (2015) employed a genetic algorithm to analyze the steel frame. This research optimizes the steel frame with and without semi-rigid connections using particle swarm optimization.

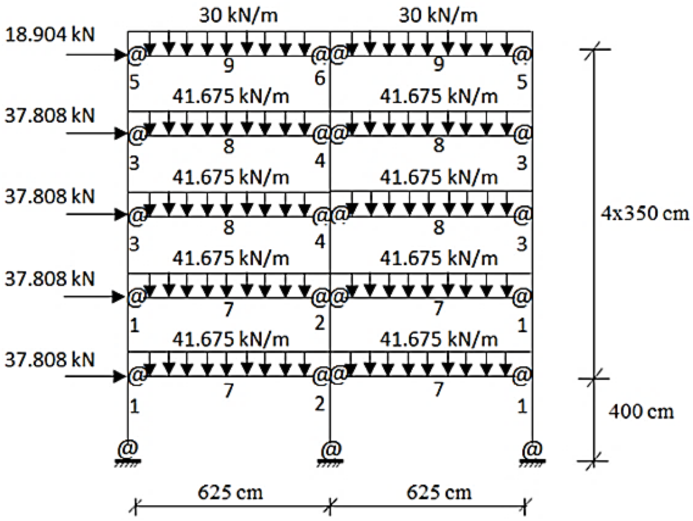

Fig. 6. A 2-bay, 5-storey steel frame

Table 3. Optimum design of 2-bay, 5-storey frame

Maximum displacement (cm)	3.68	2.17	5.10	6.74	4.97
Maximum inter-storey drift (cm)	-	-	1.254	1.822	1.395

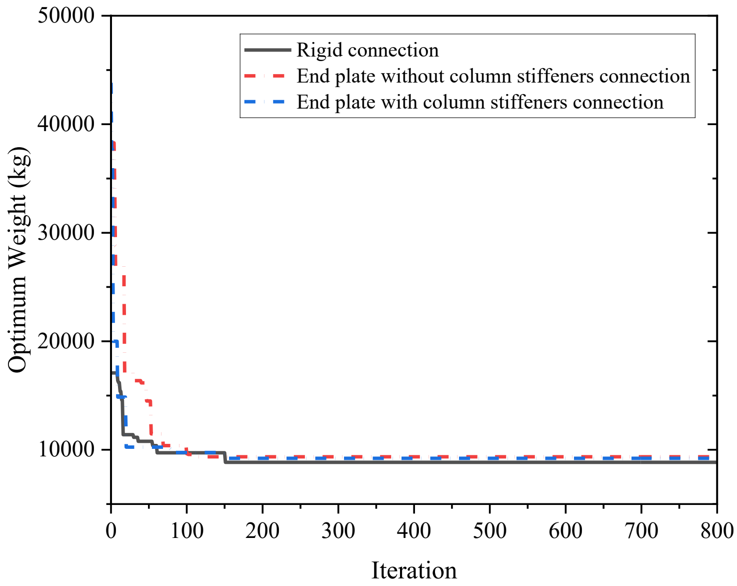

Fig. 7. Design histories of a 2-bay, 5-storey steel frame

The present study applies AISC-ASD stress limitations, restrictions on lateral displacement, and size constraints for column-to-column and beam-to-column connections to fully rigid and semi-rigid frames. The maximum allowable lateral displacement and inter-story drift are capped at 7.2 cm and 2.96 cm, respectively.

In the procedure, the cross-sections of the frame components are selected from a collection of 174-W sections provided by the American Institute of Steel Construction (AISC). Table 3 presents the optimal solutions identified for the completely rigid and semi-rigid frame based on solutions found in existing literature. Fig. 7 depicts the history of total steel weight design with iterations for both the rigid and semi-rigid frames.

Table 3 indicates that the optimal design outcomes from this research closely match the findings of earlier studies. According to the optimal design results for a fully rigid frame, the minimum weight achieved in this study is 8840 kg, which is about 0.5% and 4.5% lighter than the minimum weights reported by Hayaloglu and Degertekin (2004) and Artar and Daloglu (2015), respectively. This observation similarly applies to the optimal designs of semi-rigid frames (End Plate without Column Stiffeners and End Plate with Column Stiffeners connections, as detailed in Table 3). Furthermore, the weight of 8840 kg is roughly 5.5% and 4.0% below the minimum weights of 9355 kg and 9208 kg obtained from the optimal designs of the two semi-rigid frames, respectively. The maximum top and inter-story drifts are significantly below the allowable limits. As a result, stress and size constraints are crucial in achieving the best designs for fully and semi-rigid frames.

The PSO algorithm creates the optimal steel frame design after 800 iterations with a population of 20, resulting in the analysis of 16000 frames. Additionally, reducing the rotational stiffness value of the connection between the beam and column leads to a considerable increase in the minimum weight. Nonetheless, this study's findings are more cost-effective than earlier research's.

5.3. Case study-3: one-bay, 10-storey frame design

Fig. 8 depicts a one-bay, 10-storey 2-dimensional steel frame comprising 30 elements. Hayaloglu and Degertekin (2004) and Artar and Daloglu (2015) employed a genetic algorithm to examine the steel frame. The study optimizes the steel frame with and without semi-rigid connections using particle swarm optimization. This current study applies the same constraints as the earlier frame. The maximum lateral displacement and inter-story drift limits are set at 12 cm and 2.54 cm, respectively.

The cross-sectional dimensions of the frame components in the design are selected from 276-W sections as specified by the American Institute of Steel Construction (AISC). Table 4 summarizes the optimal solutions identified for the completely rigid and semi-rigid frames based on existing literature. Fig. 9 shows the total steel weight design histories with iterations for the rigid and semi-rigid frames.

Table 4 indicates that the optimal design results obtained from this study are very similar to the solutions found in existing literature. According to the optimal design for a fully rigid frame, the minimum weight of 12977 kg is approximately 7.3% heavier than the minimum weight reported by Hayaloglu and Degertekin (2004) and 7.0% lighter than the minimum weight noted by Artar and Daloglu (2015). This observation is also accurate for the optimal designs of semi-rigid frames (End Plate without Column Stiffeners and End Plate with Column Stiffeners connections, as shown in Table 4). Furthermore, the weight of 12977 kg is roughly 4.9% and 0.6% lighter than the minimum weights of 13646 kg and 13054 kg obtained from the optimal designs of the two semi-rigid frames, respectively. The top and inter-story drift measurements are significantly below the allowable limits.

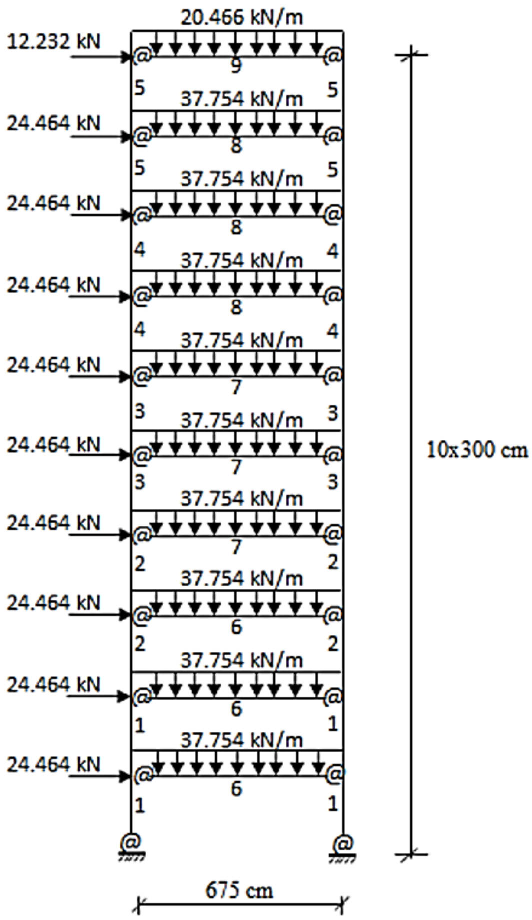

Fig. 8. A one-bay, 10-storey steel frame

Table 4. Optimum design of a one-bay, 10-storey frame

Element Group	Rigid frame			Semi-rigid frame	
				Present study	
	Hayalioglu and Degertekin (2004)	Artar and Daloğlu (2015)	Present study	End plate without column stiffeners	End plate with column stiffeners
	GA	GA	PSO	PSO	PSO
1	14 × 109	24 × 117	30 × 108	30 × 90	30 × 99
2	14 × 90	24 × 117	27 × 94	30 × 90	30 × 90
3	14 × 90	24 × 68	27 × 84	27 × 84	27 × 102

8	14 × 53	24 × 55	21 × 48	21 × 44	21 × 44
9	14 × 48	16 × 26	24 × 55	27 × 114	18 × 40
Minimum weight (kg)	12098	13951	12977	13646	13054
Maximum displacement (cm)	8.73	5.57	7.59	10.09	8.98
Maximum inter-storey drift (cm)	-	-	1.110	1.349	1.360

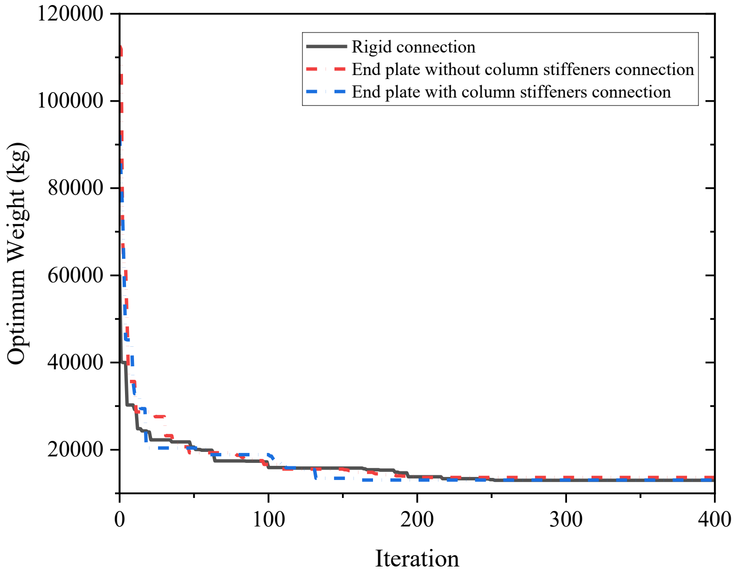

Fig. 9. Design histories of a one-bay, 10-storey steel frame

The PSO algorithm has yielded the most efficient steel frame design after conducting 400 iterations with a population of 40, resulting in an analysis of 16000 frames. In addition, reducing the rotational stiffness of the joint between the column and beam improves the minimum weight. Nevertheless, this research's findings are more economical than those from earlier studies.

6. Conclusion

The primary objective of this research is to utilize particle swarm optimization (PSO) for 2-dimensional frames featuring semi-rigid connections and column bases, aiming to determine the optimal weight of these steel frames. The high-level programming language C# implements the optimization technique to integrate with SAP2000 version 22 Open Application Programming Interface (OAPI). Stress constraints based on AISC-LRFD, along with displacement constraints and inter-story drift constraints, are applied in the first example. The subsequent two examples incorporate stress constraints based on AISC-ASD, displacement constraints, inter-story drift constraints, and geometric (dimension) constraints. The analysis results are presented in both tabular and graphical formats.

Key findings from the study are summarized below:

- The research outcomes across all three examples indicate that semi-rigid connections positively affect lateral displacements, leading to the selection of larger column profiles.
- Due to the influence of the rotational stiffness value, the minimum weight of the semi-rigid frames is greater than that of the fully rigidly connected frames.
- Analyzing the design histories of the 2-dimensional frames indicates that the third example was finalized after 400 iterations, whereas the first and second examples had 200 iterations and 800 iterations, respectively.
- Comparative analysis shows that the current study results are less weighted than previous works for the first two examples. However, for the third example, the current findings exhibit less weight than those of Artar and Daloglu (2015) yet greater weight than those of Hayalioglu and Degertekin (2004).

Abstract. According to national and international construction standards, concrete casting under cold weather conditions—typically defined as temperatures below 5°C—is permissible only if specific precautions are taken. Although these regulations mandate protective measures, they often lack detailed guidance, leaving implementation decisions to practitioners. In regions with a harsh continental climate, such as Erzurum, construction activities involving significant concrete work are largely suspended during the long, cold winters. This seasonal inactivity negatively impacts the local economy. Key reasons include uncertainty about appropriate precautions, concerns over costs, and skepticism regarding the reliability of cold-weather concreting. To address these issues, a research project supported by the Scientific and Technological Research Council of Türkiye (TÜBİTAK) under grant number 1001-219M403 was conducted. The project titled *"Experimental Investigation of the Flexural Behavior of Reinforced Concrete Beams Cast-in Cold Weather"* involved casting full-scale beams during both summer and winter seasons. Various protection strategies—such as greenhouse plastic insulation, use of set-accelerating admixtures, and external heating—were applied in different combinations. Temperature sensors placed within the most densely reinforced beam recorded internal concrete temperatures for 72 hours post-casting. These data were used to estimate the 3-day axial compressive strength. Temperature-time factor values were calculated with the internal concrete temperature data and an attempt was made to relate them to the 3-day axial compressive strength, but it was observed that there was a more powerful relationship between the internal concrete temperature measured at the end of 72 hours and the 3-day axial compressive strength.

Keywords: RC manufacturing in winter; Temperature monitoring, Thermocouple, Temperature-time factor; Compressive strength

1. Introduction

Modern concrete, which has completely transformed construction technique preferences worldwide since its discovery, has emerged as a building material that requires meticulous attention at every stage—from mix design to production, from formwork to curing—due to its sensitivity to the atmospheric conditions of the environment in which it is produced. During the production of a simple concrete flowerpot, the observed weakness of concrete under tensile stress led to the idea of reinforcing it with steel, which gave birth to the technique of reinforced concrete. Today, this method has become the most preferred construction technique in Türkiye. It can also be stated that the reinforced concrete construction method is favored due to its relatively economical solutions for the construction of large-scale and multi-story buildings.

Fresh concrete is sensitive to ambient temperature due to the water component it contains. Although this sensitivity is more evident during the first three phases of hydration—generally described in five stages—the volume of the concrete cast also significantly influences this effect. For instance, the extent to which concrete is affected by atmospheric temperatures differs between a mass concrete of a dam body and a beam in a residential project. Neville (1997) defines hydration as a series of irreversible chemical reactions between cement and water. The hydration process begins the moment cement comes into contact with water. During hydration, the cement-water paste sets and hardens. Cement particles gradually and partially dissolve, and the dissolved compounds react at different rates. These reactions release heat and produce new compounds known as hydration products. These products form a solid structure, allowing the plastic cement paste to harden, bond with aggregates in the concrete mixture, and create a strong, dense matrix. The measurable heat released during hydration does not drop to zero for several days, as the reactions slow down over time. Hydration can continue for years as long as water and

* Corresponding author, E-mail: burak.gedik@erzurum.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_783

unreacted cement remain in the concrete. This ongoing process contributes to continued strength gain and the development of desirable properties such as low permeability. A general understanding of hydration reactions helps prevent or resolve concrete-related issues and ensures that the mixture performs as designed. Hydration is commonly accepted to occur in five main stages: mixing, dormant (sleep), hardening, cooling, and densification. The mixing phase is when cement and water first come into contact; cement particles begin to dissolve, forming a thin layer of reaction product on their surface. Hydration reactions are initiated at this point. In the dormant phase, reactions slow down and the concrete remains workable. This stage allows time for placing and shaping the mixture in the formwork, with minimal heat release. At the end of this phase, the hardening stage begins; reaction rates increase, heat generation intensifies, new hydration products form, and concrete starts gaining strength rapidly. Setting and early strength development occur during this stage. In the subsequent cooling phase, chemical reactions become less active, though strength development continues. In the long-term densification stage, remaining cement and water continue to react slowly. Voids within the concrete microstructure reduce, making the material denser, stronger, and less permeable. This process can last for years.

The influence of environmental parameters—such as ambient temperature, humidity, and wind—on concrete development during the mixing, dormant, and hardening phases of the exothermic chemical process known as hydration has highlighted the necessity for standards regulating concrete casting parameters under varying atmospheric conditions. Moreover, concrete is not alone in reinforced concrete applications. Once placed into formwork, the temperature of the surrounding steel reinforcement cage and even the formwork itself becomes crucial for the performance of reinforced concrete, particularly in achieving full bond between steel and concrete. In Türkiye, two national standards are in effect that regulate concrete casting conditions according to atmospheric conditions. These standards assume that full bond between concrete and reinforcement is achieved when their guidelines are followed. The first of these is TS 1247 (2018), which governs concrete placement under normal weather conditions. According to this standard, normal weather conditions are defined as ambient temperatures not falling below +5 °C or exceeding +30 °C at any hour over three consecutive days after casting. In other words, ideal casting requires the ambient temperature to remain between +5 °C and +30 °C during placement and for at least the following 72 hours. This temperature range is critical for the healthy progression of the hydration process and for the development of mechanical strength. Atmospheric conditions outside of this specified range are considered abnormal, and concrete placement under such conditions is governed by a separate Turkish standard, TS 1248 (2017).

According to TS 1248 (2017), extreme cold weather is defined as conditions where the average air temperature remains below +5°C for three consecutive days following concrete placement, while extreme hot weather is defined as conditions where the average air temperature exceeds +30°C for three consecutive days after placement. The authors' interest in reinforced concrete production under cold weather conditions led them to focus on the section of the standard that addresses cold weather. Both the American ACI PRC-306 (2016) and the Canadian CSA A23.1/A23.2 (2019) codes define the same conditions for cold weather, while the Japanese JSCE (2007) standard adopts a lower temperature threshold of +4°C for cold weather. All of the mentioned regulations allow concrete casting-in cold weather with precautions, but they leave the decision on specific measures to practitioners, providing no clear guidance on the actions to be taken. The only explicit criterion emphasized is that the fresh concrete temperature during placement should not fall below 10°C, a condition specified in TS 1248 (2017).

The casting of concrete under extreme cold weather conditions, as defined in TS 1248 (2017)**,** remains a preferred option in Türkiye's regions exposed to continental climate. In contrast, countries with vast territories, such as Canada and the Russian Federation, which have regions affected by extreme cold weather for most of the year, must carry out concrete-related constructions as a necessity. An analysis of the climate map for the Russian Federation reveals that extreme cold weather conditions prevail across more than half of the country, regardless of the season, as shown in Fig. 1. This figure also provides a visual example of reinforced concrete construction under such conditions, where the use of nylon protection is clearly observed in practice.

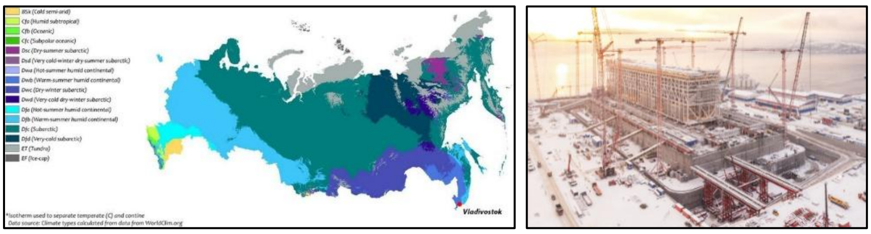

Fig. 1. Climate map of the Russian Federation, Khasikov (2020) and image of a reinforced concrete construction in the Murmansk Region, Novatek (2025)

More than half of Türkiye's land is dominated by a continental climate, with long and cold winters. As one moves eastward, the altitude from sea level increases, and the climatic conditions become more severe. According to data from the MGM (2019), the average monthly temperatures measured between 2012 and 2018 in Erzurum province were below +5°C in November, December, January, February, and March. The same source also indicates that the lowest temperatures, including those in May and June, fell below +5°C, while values as low as -30°C were measured during winter months such as January and February. Many settlements in regions with a continental climate, like Erzurum, experience similar harsh conditions, leading to a halt in the construction sector during the winter months. Studies by Koç et al. (2017) and KUDAKA (2014) emphasize that the suspension of the construction sector, which is the locomotive industry of the region, negatively impacts nearly 200 sub-sectors and causes significant economic and social problems. Although there is no legal barrier to concrete casting or reinforced concrete production during winter, the lack of clear data on the effectiveness and cost of the necessary precautions has prevented practitioners in the country from undertaking winter construction, even in cases of necessity. To address this issue and investigate the mechanical performance of reinforced concrete production in winter, the authors have conducted studies. The study by Gedik (2020) which examines the bond strength-shear behavior of reinforced concrete elements which were produced in winter, led to a comprehensive research project conducted by Okuyucu et al. (2023) and funded by he Scientific and Technological Research Council of Türkiye (TÜBİTAK), which investigates the mechanical behavior of full-scale reinforced concrete beams produced in winter.

Although there are studies in the accessible literature addressing concrete casting in winter, it has been observed that these studies are generally conducted on plain concretes without reinforcement, and the effects of various protective measures on the mechanical properties of concrete have not been sufficiently explored. It can also be stated that there is a greater focus on investigating the effects of chemical admixtures on the compressive strength and early-age behavior of concretes produced under cold weather conditions. Early works in this field, such as Karhonen (1990) and Karhonen (1992), conducted experimental research on the curing conditions, hydration process, and thermal behavior of concrete under cold weather. In Nmai (1998) study, the effects of chemical admixtures on the setting time and strength development of concrete at low temperatures were evaluated. In the works of Suk et al. (2012) and Nassif et al. (2013), the effects of antifreeze admixtures on fresh and hardened concrete properties were analyzed, and comparative results from field and laboratory environments were presented. The study conducted by Zhang et al. (2020) investigated the behavior of fresh concrete produced using the C-S-H (calcium silicate hydrate) seeding method under winter conditions and highlighted the significant potential of nanotechnological admixtures in enhancing early-age strength and optimizing the hardening process. As one of the recent studies, Pushpalal et al. (2022), conducted in Mongolia’s harsh winter conditions, evaluated the effects of various mineral admixtures on concrete performance, providing a comprehensive analysis of their impact on concrete durability and long-term performance.

This text presents information about the maturity index and internal temperature values calculated from the 3-day internal temperature tracking data taken from reinforced concrete beams cast under both summer (normal weather) and winter (abnormal weather) conditions, as part of the TÜBİTAK1001-219M403 project, which investigates the mechanical behavior of full-scale reinforced concrete beams produced in winter. In the winter production, set accelerator additive, greenhouse nylon protection and heating applications were applied in different configurations, and the mechanical test results carried out on concrete samples were examined and evaluations regarding the effectiveness of the protection measures were included. The study includes an investigation of axial compressive strength prediction using temperature-time factor, a type of maturity index, and concrete internal temperature values.

2. Materials and methods

The studies presented in this text, funded by the research grant from the TÜBİTAK1001-219M403 project, were conducted on the campus area of Erzurum Technical University. All sample productions carried out in summer and winter were made under real seasonal conditions. In practice, the mixture content was aimed at producing C30/37 class concrete based on the concrete recipe provided in Table 1.

Table 1. C30/37 class concrete mixture recipe, Okuyucu et al. (2023)

Material	Volume (dm^3)	Weight (kg)
Cement (CEMII - PC42.5-R)	133	400
Water	214	214

Concrete casting was carried out in three seasonal periods.These periods are referred to as Summer, Winter-1, and Winter-2, with explanatory information provided in Table 2.

In the Summer group, defined in Table 2, the concrete casting under normal weather conditions was performed in the open air, and the samples were kept moist by being watered at specific intervals for 72 hours. After 72 hours, the samples removed from the molds were wetted with water until the 7th day, depending on the air temperature. For the Winter group productions, wooden-frame, greenhouse plastic-covered maintenance tents with the smallest volume, capable of holding three full-scale reinforced concrete beams (0.3x0.5x4.5 m), were used. Since covering the casting area with plastic is a widely preferred method globally, it was chosen for this project as well; however, greenhouse plastic was used in practice. The reason for this choice is the relatively high number of sunny days in Erzurum during the winter. A total of two maintenance tents covered with greenhouse plastic were used, one of which was heated with a thermostat-controlled heater for 72 hours to ensure the temperature inside did not drop below +5°C. The section with heating was referred to as the heated tent, while the section without heating was called the unheated tent. A general view of the heated and unheated tents used in the winter concrete casting works is presented in Fig. 2.

In this study, the temperature measurements of the beam sample designed as a doubly reinforced section were taken from the center of the section using K-type thermocouple sensors. The volume of the steel reinforcement within the full-scale reinforced concrete beam measuring 0.3x0.5x4.5 m corresponds to 1.99% of the total beam volume. After the sensors were connected to the system, the data collection software was programmed to measure and record temperatures in °C at 10-minute intervals. To prevent power outages and data loss, the system was supported by an external power supply. A visual representation of the concrete internal temperature measurement setup is shown in Fig. 3.

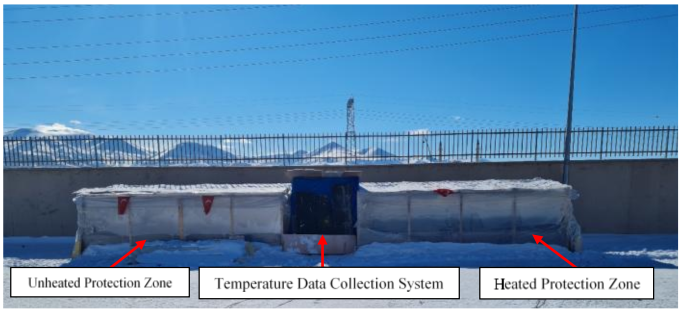

Fig. 2. Heated and unheated curing tents

Fig. 3. Thermocouple type sensor and data acquisition system used for reinforced concrete beam temperature monitoring

One of the objectives of measuring the internal temperature of concrete is to calculate a maturity index known as the temperature-time factor. TS13508 (2012) defines the maturity index as a value that indicates the maturity of a cement-based mixture, based on the temperature history of the material, using the maturity function. The calculated index is an indicator of maturity, assuming that sufficient water is provided for the pozzolanic reaction or hydration of cement-based materials during the calculation period. The two most commonly used maturity indices are the temperature-time factor and the equivalent age. In this study, the temperature-time factor is calculated as the maturity index. The formula presented in Equation 1 of TS13508 (2012) is used for the calculation of the temperature-time factor:

$$M(t) \; = \; \Sigma(T_a - T_o).\Delta t \tag{1}$$

In Equation 1:

M(t): temperature-time factor (degree-days or degree-hours) at age t,

Δt: Time interval (days or hours,

T_a: *Average temperature of concrete during Δt (ºC),*

T_o**:** Datum temperature (ºC).

The mathematical expression presented in Equation 1 essentially numerically calculates the area under the concrete’s internal temperature versus time graph, above the initial/datum temperature. The datum temperature used here is the lowest internal temperature at which the concrete can begin to gain strength or develop strength, and it will vary for each concrete mix. According to the ASTM C1074-19e1 (2019) standard, the datum temperature is a theoretical temperature value assumed to represent the point at which the hydration of concrete completely stops in the maturity method. In other words, this temperature is the threshold below which concrete gains no strength, and in the ASTM C1074-19e1 (2019) standard, it is generally accepted as -10°C. In the study by Elaty et al. (2017), experimental determination of the datum temperature was conducted for concretes made with different types and dosages of cement. In the examined study, for a mix close to the unmodified concrete used in this research, the datum temperature was determined to be -2.2°C, based on the type and dosage of cement. However, according to TS13508 (2012), the datum temperature is a parameter that needs to be determined experimentally. The datum temperature depends on the type of cement, the types and amounts of chemical or other admixtures that may affect the hydration rate, and the temperature range the concrete will be exposed to while hardening. In this study, an experimental procedure detailed in TS13508 (2012) for determining the datum temperature was not conducted. In cases where experimental studies cannot be carried out, TS13508 (2012) recommends using 0°C as the datum temperature value for concrete mixes made with unmodified CEM I cement and exposed to curing temperatures between 0°C and 40°C. For all the concrete mixtures produced in the project, CEM I type cement was used, and all the summer and winter samples were exposed to curing temperatures between 0°C and 40°C for the first 72 hours. Therefore, in this study, the datum temperature was taken as 0°C, and using the concrete internal temperature tracking data, the temperature-time factor values developed during the first 72 hours for all concrete groups were calculated.

As presented in Table 2, the use of setting accelerator additives is considered a parameter for winter group productions. In both the winter and summer concrete pours, concrete was supplied by Memişoğlu Erzurum Beton A.Ş., a company active in Erzurum. This company is the only facility in the region capable of producing concrete in winter due to its ability to adjust the temperature of mixing water, in addition to having a closed material loading area for its concrete mixer. In the application, the relationship between the freshly mixed concrete and the cold weather was interrupted by nylon protection, under which the concrete was placed in the mold. As experienced in Gedik (2020), where it was observed that fresh concrete can experience an abrupt temperature drop of 10-15°C when exposed to cold air in winter, this approach was adopted to prevent such drastic temperature reductions. The fresh concrete temperature under the nylon cover was kept above +10°C, in accordance with TS1248(2017). During the pouring, the fresh concrete temperatures were measured using probe thermometers and recorded. After 72 hours, the specimens were removed from the molds, the protection measures were terminated, and all samples were exposed to atmospheric conditions until the 28th day. Cube samples measuring 15x15x15 cm were taken for determining the axial compressive strength during both summer and winter concrete pours. General images related to the summer pour are shown in Fig. 4, and general images related to the winter pour are shown in Fig. 5.

Fig. 4. Images from the summer casting

Fig. 5. Images from the winter casting

Axial compressive strength tests were performed on the concrete samples in accordance with the TS EN 12390-3 (2019) Turkish standard. The experimental studies were conducted using a universal testing machine available at the Structural Materials and Structural Mechanics Laboratory, Department of Civil Engineering, Faculty of Engineering and Architecture, Erzurum Technical University.

3. Results and discussions

The results obtained from the experimental study are collectively presented in Table 3.

Upon examination of the data presented in Table 3, it is observed that the lowest fresh concrete temperature at the time of casting was measured as 10.4 °C for the Winter-1 group with admixture. Although the concrete was cast under greenhouse sheet protection, the ambient temperature of -19.0 °C at the start of casting is considered the primary reason for this low value.

Winter-1 Plain Concrete	*68*	*59*
Winter-1 Concrete with SAA	84	84

The fresh concrete temperature was measured as 12.2 °C for the Winter-1 group without admixture, 13.5 °C for the Winter-2 group with admixture, and 15.7 °C for the Winter-2 group without admixture. In all winter casting groups, the fresh concrete temperature exceeded the minimum threshold of 10 °C specified in the TS 1248 (2017) standard. For the summer group specimens, the fresh concrete temperature at the time of casting was recorded as 26.5 °C. According to TS EN 206+A2 (2021), the minimum fresh concrete temperature at the time of delivery should be +5 °C. However, it is not recommended for the temperature to fall below +10 °C, as it may prolong the setting time and negatively impact strength development. Therefore, it can be concluded that the fresh concrete temperatures measured during both summer and winter castings complied with the relevant standard requirements.

The fundamental mechanical property used for classifying concrete is the 28-day axial compressive strength. The aim of this study was to produce C30/37 grade concrete. Since 15x15x15 cm cube specimens were used for the axial compressive strength tests, it is essential to compare the 28-day axial compressive strengths with the target value of 37 MPa. According to Eurocode 2 (BS EN 1992-1-1:2004+A1:2014), with the use of Type R cement, the concrete is expected to reach approximately 76% of its 28-day axial compressive strength at the end of the 3rd day. Therefore, rather than evaluating the 3-day axial compressive strengths numerically, it is considered more beneficial to examine the percentage of strength gain relative to the 28-day strength. The ratios of the 3-day axial compressive strengths to the expected 28-day axial compressive strength of 37 MPa for all groups are presented in Table 4.

Upon examination of Table 4, it is observed that the summer group specimens reached only 51% of the target axial compressive strength by the 3rd day. This is significantly lower than the expected value of approximately 76% according to Eurocode 2 (BS EN 1992-1-1:2004+A1:2014). It is worth noting that water was added during the production of the summer group specimens in a way that disrupted the mix design, and this low strength gain percentage is believed to be a result of this modification. Similarly, for the Winter-1 group specimens without admixture, Table 4 shows that the 3-day strength development was below the expected 76% according to Eurocode 2 (BS EN 1992-1-1:2004+A1:2014). For the Winter-1 group specimens without admixture, when heating was applied, the strength gain percentage was 68%, whereas without heating, it was 59%. In all other groups, the expected strength gain percentages were achieved. This is a particularly striking result. For concrete cast at temperatures below -15°C, it is evident that heating, in addition to greenhouse sheeting protection, significantly impacts the 3-day strength gain. However, it is clear that in order to achieve the target strength gain percentage specified by Eurocode 2 (BS EN 1992-1-1:2004+A1:2014), the use of accelerating admixtures is necessary for concrete cast at temperatures below -15°C. Furthermore, it is concluded that the use of accelerating admixtures, along with greenhouse sheeting, is more effective than heating during concrete casting at these low temperatures. In cases where accelerating admixtures are used, heating is not necessary as a third protective measure. Under the Winter-1 conditions, with ambient temperatures between +5°C and -15°C, it is observed that by using only greenhouse sheeting concrete achieved 78% of the final strength by the 3rd day. The Winter-1 group specimens with admixture both reached 84% of the target strength, making them the highest strength gaining group. Notably, these specimens were exposed to sunlight for almost half of the 72-hour curing period in the protection tents after casting. The greenhouse effect of the sun/solar exposure is believed to have contributed to the rapid axial compressive strength gain of these specimens.

The primary aim of this study is to propose an approach for estimating early-age (3-day) concrete compressive strength using internal concrete temperature measurement data during winter concrete castings. Based on this proposed approach, the goal is to determine the optimal timing for terminating concrete protection measures and form removal during winter concrete production. Table 3 presents two parameters derived from the internal concrete temperature monitoring data. The first is the internal concrete temperature measured at the end of 72 hours, and the second is the calculated temperature-time factor at the end of 72 hours. The relationship between each of these parameters and the 3-day axial compressive strength was examined separately. The internal temperature of the concrete after 72 hours and the 3-day axial compressive strength were evaluated together, and a graph shown in Fig. 6 was prepared to illustrate this relationship.

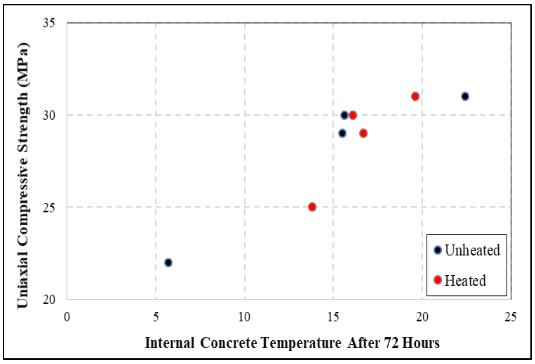

Fig. 6. Internal concrete temperatures and 28-day axial compressive strengths of winter poured concrete samples measured after 72 hours

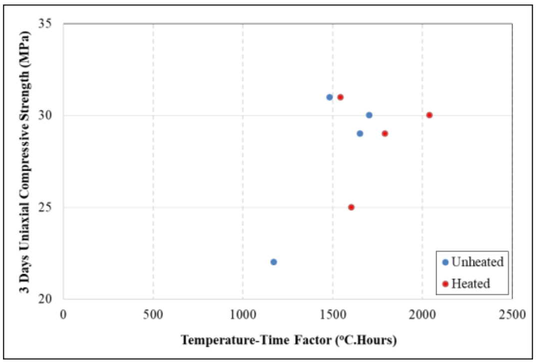

Fig. 7. Temperature-time factor and 3-day axial compressive strength of concrete produced in winter

Upon examining Fig. 6, it can be stated that the internal concrete temperatures at the 72-hour mark and the 3-day axial compressive strengths exhibit a nearly linear relationship, which can be represented by Equation 2 (R^2 = 0.83). In practice, CEMI-42.5R type rapid setting, high-strength cement was used. According to Eurocode 2 (BS EN 1992-1-1:2004+A1:2014), when R-type cement is used, it is expected that 76% of the target axial compressive strength will be achieved by the 72nd hour. This indicates that hydration occurs very intensely during the first 3 days, and the high internal temperatures at the 72-hour mark can be associated with high final strength. Based on this, it is suggested that by measuring the internal concrete temperature of concrete produced with CEMI-42.5R type cement under cold weather conditions as defined by TS1248 (2017), the 3-day axial compressive strength can be estimated using Equation 2.

$$f_{c3} = 0.6T + 19.0 \tag{2}$$

In Equation 2;

f_{c3}: 3-day axial compressive strength of the 15x15x15 cm cube sample, (MPa)

T: Internal concrete temperature measured at the 72-hour mark after casting, (°C)

Another parameter, the temperature-time factor, which was calculated using the temperature data, is presented in Table 3. A graph prepared to examine the relationship between the 3-day axial compressive strength of concrete produced in winter and the temperature-time factor, as a maturity index, is presented in Fig. 7.

Upon examining Fig. 7, it is clear that there is no significant relationship between the 3-day temperature-time factor values and axial compressive strengths of the concrete produced in winter with various protection measures. Since maturity-strength relationships in the relevant literature are generally presented as logarithmic functions, the equation presented in Equation 3 was derived from the data shown in Fig. 7.

$$f_{c3} = 12.6 \ln(M) - 54.5 \tag{3}$$

In Equation 3;

f_{c3}: 3-day axial compressive strength of the 15x15x15 cm cube sample, (MPa)

M: Temperature-time factor calculated at the 72-hour mark after casting, (°C.Hour)

The R^2 value of 0.40 was calculated in the derivation of the equation presented in Equation 3. This value indicates that the model has a relatively weak ability to represent the given data. Calculations were also made to introduce linear, exponential, and polynomial models, and it was observed that the obtained models had a determination coefficient smaller than 0.40. Therefore, it can be stated that a mathematical relationship capable of strongly representing the correlation between the temperature-time factor values and the 3-day axial compressive strength could not be established. It has been concluded that for concrete produced with CEMI-42.5R type cement, with the fresh concrete temperature at the time of casting not lower than +10°C and protected under greenhouse plastic sheeting, the linear expression presented in Equation 2 and the internal concrete temperature at 72 hours can be used to estimate the 3-day cube sample compressive strength.

4. Conclusions

Within the scope of the project titled *"Experimental Investigation of the Flexural Behavior of Reinforced Concrete Beams Cast in Cold Weather"* (TÜBİTAK 1001 – 219M403), full-scale reinforced concrete beams were cast both in summer and winter. Various combinations of protection measures such as greenhouse plastic sheeting cover, the use of setting accelerating admixtures, and external heating applications were implemented. Based on internal concrete temperature monitoring data, this study aimed to estimate the 3-day compressive strength of concrete. The main findings are summarized below:

- According to Eurocode 2 (BS EN 1992-1-1:2004+A1:2014), the target 3-day compressive strength was achieved for concretes cast at ambient temperatures between 5°C and -15°C, provided that the fresh concrete temperature was maintained above +10°C and CEM I 42.5R type cement was used. The only precaution was unheated greenhouse plastic covering.
- For concrete casting at temperatures below -15°C, in order to meet the 3-day compressive strength target set by Eurocode 2 (BS EN 1992-1-1:2004+A1:2014), in addition to maintaining the fresh concrete temperature above +10°C and using CEM I 42.5R type cement, the application of an accelerating admixture alongside greenhouse sheet protection was found to be necessary.
- It was determined that, for concrete cast-in winter conditions, evaluating the internal concrete temperature at the end of 72 hours yielded more meaningful results than using the traditional time-temperature factor in estimating 3-day axial compressive strength. A correlation equation was proposed for this purpose.
- Increasing the number of scientific studies on winter concreting will contribute to knowledge accumulation in this field and provide valuable guidance for practical applications. It is recommended that further studies be conducted under real winter conditions using concrete with diverse properties.

Acknowledgments

This study was supported by the Scientific and Technological Research Council of Türkiye (TÜBİTAK) under the project titled "Experimental Investigation of the Flexural Behavior of Reinforced Concrete Beams Cast in Cold Weather" (TÜBİTAK 1001 – 219M403). The authors would like to express their gratitude to TÜBİTAK for their support.

Effect of the connection shape of cables on behaviour of suspension bridges

Nefya Soysal*[1], Murat Muvafık[2]

[1] Yıldız Technical University, Graduate School of Science and Engineering, 34220 Istanbul, Türkiye
[2] Yüzüncü Yıl University, Department of Civil Engineering, Division of Structures, Van Turkey

Abstract. This paper aims to investigate the effects of suspension cables connected in different ways on the behavior of suspension bridges and to evaluate the results. In this study, 6 existing suspension bridges are modelled, and 10 additional suspension bridges were created by changing the number and diameter of the suspension cables. A total of 16 suspension bridges have been modeled and three-dimensional nonlinear analyses of these models have been performed.The results of Fatih Sultan Mehmet Bridge, 15 July Martyrs Bridge, Osmangazi Bridge, Humber Bridge, Tsing Ma Bridge and Yeoungjong bridges modeled in three dimensions were evaluated. Models FSM_40H, FSM_50H, FSM_60H, FSM_70H and FSM_80H were modeled in three dimensions by taking the Fatih Sultan Mehmet Bridge as an example and changing the number of suspensions in the middle span. Models FSM_50D, FSM_100D, FSM_150D, FSM_200D and FSM_250D were modeled in three dimensions by changing the diameters of the suspension cables in the mid-span.

Keywords: Suspension bridge; Hanger cable shape; Hanger cable number; Hanger cable diameter; Nonlinear static analysis

1. Introduction

Mubuli (2016), In this study, the structural behavior of Fatih Sultan Mehmet Bridge is investigated under self-weight, earthquake and vehicle loads. The cross-sectional effects and displacements of the bridge foundation elements under the effects of both earthquake and vehicle loads are presented in graphs and tables. They concluded that different earthquake acceleration records and different vehicle speeds significantly affect the dynamic behavior of the bridge.

Kartal (2012) modeled three different upper decks, namely rectangular hollow, trapezoidal hollow and circular hollow, using the Csi Bridge program. These models were analyzed under live load. As a result of this study, the stresses and strains in box girder upper decks increase with depth, but this increase is not proportional. It was found that these stresses and strains are at the lowest level in the rectangular section upper deck and the highest level in the circular section upper deck.

Rahwan (2019) carried out comparative two-dimensional and three-dimensional finite element analysis of the 15 July Martyrs Bridge Suspension Bridge with diagonal and vertical suspension systems using the Sap2000 program. First, he analyzed the 15 July Martyrs Bridge Bridge with diagonal suspension cables in two dimensions and three dimensions. Then, he modeled the suspension cables vertically and performed two and three-dimensional analyses. Static and dynamic analyses were performed on the models and all four models were compared. As a result, he stated that vertical cables have a better effect on the performance of suspension bridges.

2. Material and method

A total of 16 suspension bridge models have been created within the framework of this study, based on suspension bridges whose suspension cables are connected in different ways. The models created were analysed in the CsiBridge V.20 program. In all models; the deck width, tower heights, centre and side spans, fixed beams between the towers were kept constant and only the number and diameter of the suspension cables were changed according to the connection types of the suspension cables and the analysis results. The models whose elements' dimensions kept constant were analysed with the same dimensions of the Fatih Sultan Mehmet Bridge constructed in Istanbul in 1988.

As seen in Fig.1, the dimensions of the models used in the bridges the side spans of the bridges were modelled as 210 m, the centre spans as 1090 m, the deck width between the cables as 33.8 m, the deck height as 3 m and the

* Corresponding author, E-posta: nefyasoysal@gmail.com

https://doi.org/10.31462/icearc2025_ce_sme_805

tower heights from the deck level as 110 m. A total of 120 suspension cables of various lengths were used in the centre span. The suspension cables are connected to the deck by rigid links. The distance between the cables is 17.869 m along the x-axis and 33.8 m along the y-axis.

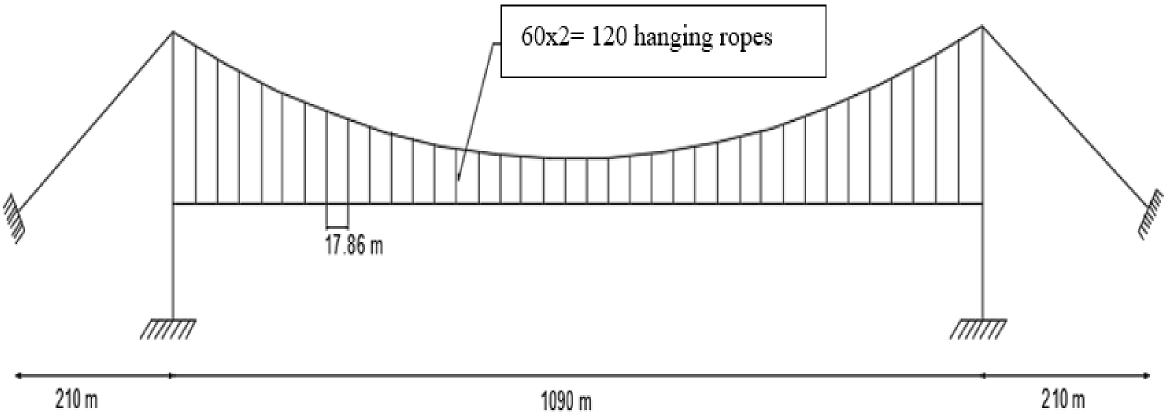

Fig. 1. General x-z view of the Fatih Sultan Mehmet suspension bridge

2.1. Suspension bridges in The World and in Türkiye

Bridges in the world and in our country with suspension ropes connected in different ways and their three-dimensional images are shown in Table 1. The Osmangazi Bridge has suspension cables in the centre span and both spans. Humber Bridge has diagonal cables in both the centre and side spans. Fatih Sultan Mehmet Bridge has vertical cables only in the centre span. 15 July Martyrs Bridge has diagonal cables only in the middle span. Tsing Ma Bridge has suspension ropes in both the centre span and a single side span. Yeoungjong Bridge has the side and centre span cables connected as 2 pairs of cables.

There are various bridges with suspension cables connected differently both in the world and in Turkey. Their three-dimensional images of some of them are shown in Fig. 2. There are suspension cables in the middle span and both side spans of the Osmangazi Bridge as well as of the Humber Bridge. Fatih Sultan Mehmet Bridge has vertical cables only in its central span. Between the mentianed bridges, The July 15 Martyrs Bridge is the only bridge that has diagonal cables only in the middle span. In the Tsing Ma Bridge, there exist suspension cables in the middle span and in only one side span. The side and middle span cables of the Yeoungjong Bridge are connected as 2 pairs of ropes.

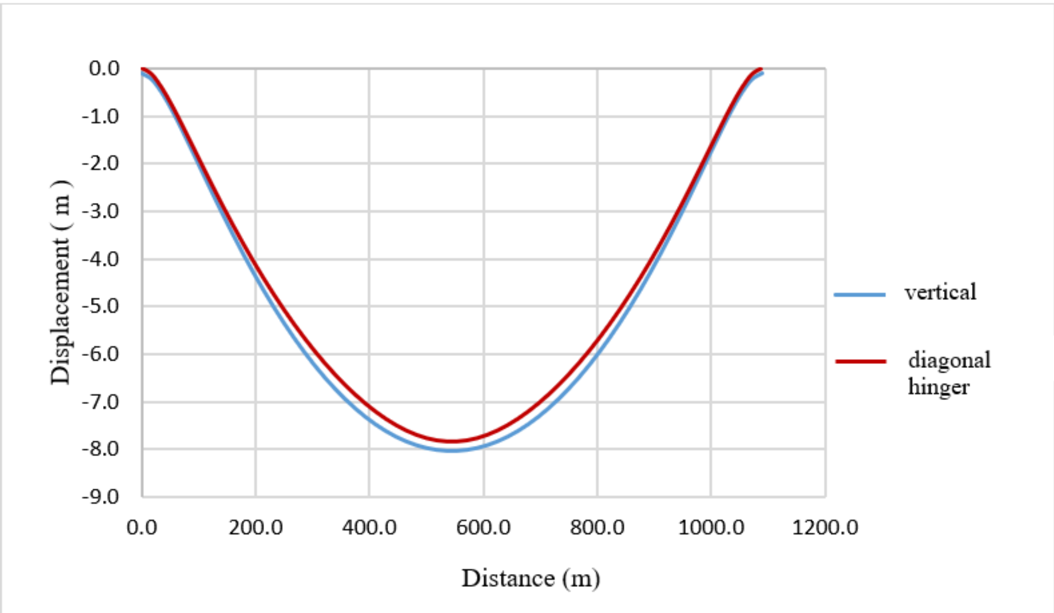

Fig. 2. Comparison of vertical displacements along the deck of the Fatih Sultan Mehmet Bridge and the 15 July Martyrs Bridge Bridge

Table 1. Suspension bridges with suspension cables connected in different shapes and positions

Osmangazi Suspension Bridge		Fatih Sultan Mehmet Suspension Bridge		15 July Martyrs Suspension		Tsing Ma Suspension Bridge		
Table 1. Continued

Humber Suspension Bridge		Yeoungjong Suspension Bridge		
2.2. The effect of the number of suspension cables

In this section, the number of suspension cables in the mid-span was changed and the effect on the main structural system has been investigated. The cross-sectional and dimensional characteristics of the bridge are the same as Fatih Sultan Mehmet Bridge, and the models were created by changing only the number of suspension ropes in the mid-span, and the models were named as FSM_40H, FSM_50H, FSM_60H, FSM_70H and FSM_80H respectively. In this section, 5 suspension bridges with different numbers of cables are modelled.

2.3. The effect of the diameter of suspension cables

In order to investigate the effect of the variation in diameter on the behavior of the structure, 5 different models with different diameters were created. The models have been chosen to have the same characteristics as the towers, decks, main cables and girders in the mid-span of the Fatih Sultan Mehmet Bridge and the only parameter that changes is the diameter of the suspension cables. Therefore, the models are named as given in Table 2 FSM_50D, FSM_100D, FSM_150D, FSM_200D and FSM_250D. Five models with different diameters were created in the CsiBridge V20 Program.

Table 2. Diameters of suspension cables used in suspension bridge

	Diameter(m)	Single hinger Area (m^2)	Double hanging Area (m^2)
FSM_50D	0.05	0.001963	0.003926
FSM_100D	0.1	0.00785	0.0157
FSM_150D	0.15	0.01767	0.03534
FSM_200D	0.2	0.0314	0.0628
FSM_250D	0.25	0.0491	0.0982

Moreover, for investigating whether the number of cables or their diameter is more important for the vertical displacement of suspension bridges. 6 existing suspension bridges were modelled and investigated. 10 additional bridge models were created as a result of the investigations.

3. Conclusion

3.1. Static analysis results

The Fatih Sultan Mehmet Bridge vs The 15 July Martyrs Bridge: The vertical displacement of the Fatih Sultan Mehmet Bridge is 7.88 m at the centre of the span and 67 cm at the apex of the tower. The centre span of the 15 July Martyrs Bridge has a vertical displacement of 7.835 m and a displacement of 69 cm at the top of the tower.

The The Osmangazi Bridge vs The Humber Bridge: It can be seen that the largest vertical displacement occurs in the centre span of Osmangazi Bridge and its value is 7.973 m. The same vertical displacement occurs in the decks in the side span and its value is found to be 1.594 m, 71 cm displacement is observed at the top of the tower. The maximum vertical displacement in the centre span of the Humber Bridge is 7.828 m. The maximum vertical displacement in the side spans is 1.668 m. The displacement at the top of the tower is 71.51 cm.

The The Osmangazi Bridge vs The Yeoungjong Bridge: The number of suspension cables connected to a single point in Yeoungjong Bridge is 4, while the number of suspension cables connected to a single point in Osmangazi Bridge is modelled as 2. As a result, the maximum vertical displacement at the centre span is 7.933 m and the displacement at the top of the tower is 71.59 cm. It can be seen that larger displacements occur in Osmangazi Bridge.

In the models created by increasing the number of suspension ropes, it is seen that the largest vertical displacement at the center span of the deck occurs in the FSM_40A bridge model and its value is 7.92 m. Increasing the number of suspension ropes increases the vertical displacement of the deck by 0.89%. The largest displacement at the top of the tower occurs in the FSM_80A bridge model and is 68.06 cm. The displacement at the top of the tower is 67.91 cm for the bridge model FSM_40A. By increasing the number of suspension cables, the axial force in the suspension cables decreased by 49%, the moments in the deck increased by 3.23% and the axial force in the main cable increased by 0.2%.

In the models created by increasing the suspension diameters, the largest vertical displacement at the centre of the deck occurs in the FSM_50D bridge model and its value is 7.94 m. Increasing the diameter of the suspension cables increases the vertical displacement of the deck by 3.5%. The vertical displacement at the top of the tower is 63 cm for the FSM_50Ç model and 68 cm for the FSM_250D model. Increasing the diameter couses the vertical displacement in the tower to increase by 7.93%. By increasing the diameter of the suspension cables, 13% amount of increments in axial forces in the suspension cables, 33% amount of increments in the moment in the deck and 7.4%. amount of increments in the axial forces in the main cable are observed.

The largest vertical displacement in the decks at the edge span occurs at the Tsing Ma Bridge. On the Tsing Ma Bridge, the vertical displacement is 3.35 m at the edge span without suspension cables.

The results obtained for The Humber Bridge with diagonal (inverted V) cables and those for The Osmangazi Bridge with vertical cables are compared in Fig. 3. It can be seen that there is more vertical displacement in The Osmangazi Bridge.

The vertical displacements of the deck of Osmangazi Bridge and the deck of Tsing Ma Bridge are compared in Fig. 4. It is seen that the vertical displacement of the deck with suspension cables is lower than the vertical displacement of the deck without suspension cables.

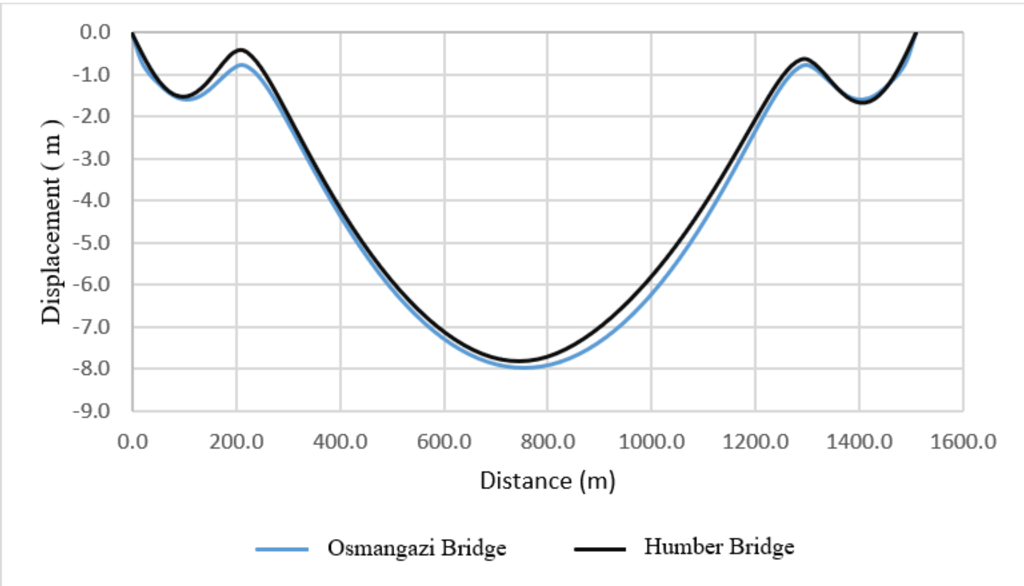

Fig. 3. Comparison of vertical displacements along the deck of The Osmangazi Bridge and The Humber Bridge

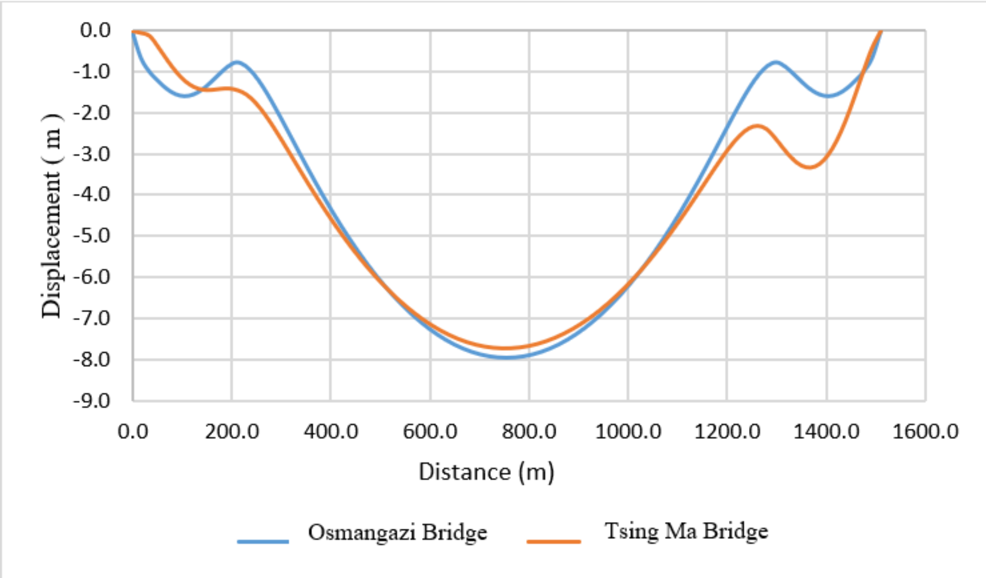

Fig. 4. Comparison of vertical displacements along the deck of Osmangazi Bridge and Tsing Ma Bridge

The versical dislacements obtained for the models FSM_50D, FSM_100D, FSM_150D, FSM_200D and FSM_250D are compared Fig. 5. The maximum vertical displacement of the deck is observed in FSM_50D. The lowest vertical displacement is observed with FSM_250D.

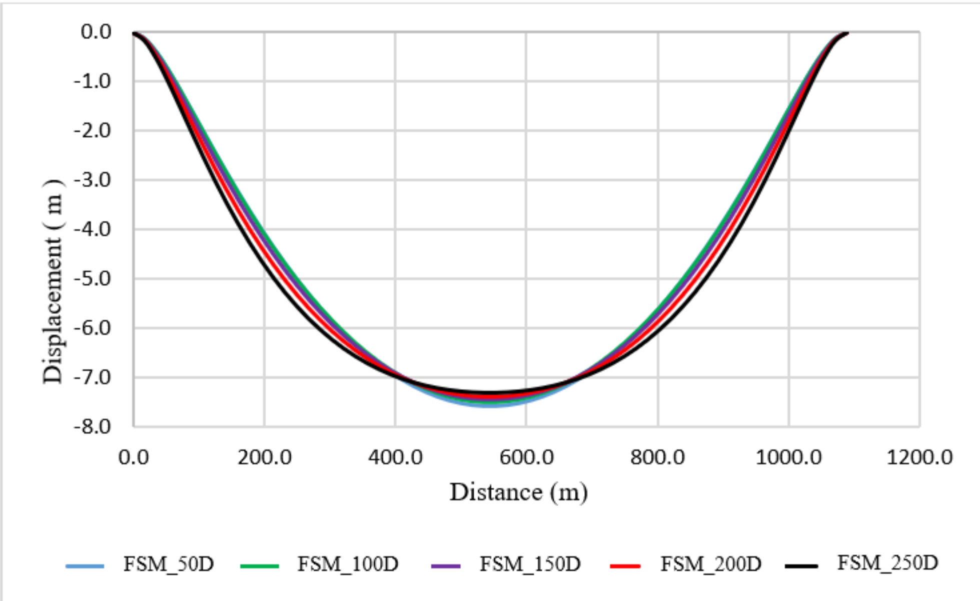

Fig. 5. Comparison of vertical displacements along the deck of FSM_50D, FSM_100D, FSM_150D, FSM_200D and FSM_250D bridges

3.2. Modal analysis results

By comparing the period values of Fatih Sultan Mehmet Bridge with 15 July Martyrs Bridge it can be seen that that the first one is between 11.37 seconds and 2.5 seconds. The period values of the 15 July Martyrs Bridge in the first 20 modes vary between 8.47 seconds and 2.54 seconds. In contrast, the period values of Fatih Sultan Mehmet Bridge are higher.

When comparing the Osmangazi Bridge and the Humber Bridge, it can be seen that the average period values in the first 20 modes of the former vary between 11.65 seconds and 3.08 seconds. The period values in the first 20 modes of the Humber Bridge vary between 8.67 seconds and 5.67 seconds.

It is clear that the largest period value is observed at Tsing Ma Bridge. In the first 20 modes, the period values vary between 12.17 seconds and 4.29 seconds.

It has been shown that the period values of bridges modeled with diagonal (inverted V) suspension cables are lower than the period values of bridges modeled with vertical suspension cables.

Comparison of the modal analysis results of the models created by increasing the number of suspension ropes reveals that there is no significant decrease between FSM_40H and FSM_80H.

Modal analysis of the bridge models created by increasing the suspension diameters reveals a decrease in the modal values. As shown in Fig. 1, the period in the first mode of the FSM_50D model is 11.16 seconds, while the period in the first mode of the FSM_250D model is 9.8 seconds.

4. Conclusions

When the results of the studies carried out in this thesis are analyzed, some suggestions are presented below. It is concluded that vertical suspension cables are more advantageous than diagonal (inverted V) cables, where the way the suspension cable is connected is important in the design phase of suspension bridge models. It is concluded that the effect of suspension cable diameter on the stiffness of the structure is more than the effect of the number of suspension cables. The reason why the moment value of the moment created in the deck due to the increase in mass with the change of suspension cable diameter is higher than the moment value created by the change of suspension cable is the increase in mass. For this reason, it should be more sensitive when deciding the suspension cable diameter. Based on the results of the Tsing Ma bridge, the vertical displacement of the deck with no suspension cable in the edge span is more than 2 times higher than the vertical displacement of the deck with a suspension cable in the edge span, which emphasizes the importance of suspension cables.

If the results obtained from this study are analyzed, some suggestions can be presented as follow:

It has been concluded that the connection type of the suspension cable is important in the design phase of suspension bridge models, and that vertical suspension cables are more advantageous than diagonal (inverted V) cables. It has also been concluded that the effect of the suspension cable diameter on the rigidity of the structure is greater than the effect of the number of suspension cables. The reason why the moment value formed on the deck due to the increase in mass with the change in the suspension cable diameter is higher than the moment value formed by the change in the number of suspension cables is the increase in mass. Therefore, there sould be more sensitive when determining the suspension cable diameter. According to the results of the Tsing Ma Bridge, the vertical displacement obtained in the deck for the bridge model without a suspension cable in the side span is more than 2 times of those obtained in the deck fro the bridge model with a suspension cable in the side span, which emphasizes the importance of suspension cables.

Free vibration analysis of FG-GPLRC straight beams via warping-included mixed FEM

Osman Guner[1], Merve Ermis[*1], Umit N. Aribas[2], Mehmet H. Omurtag[2]

[1] *Kırklareli University, Department of Civil Engineering, 39000 Kırklareli, Türkiye*
[2] *Istanbul Medipol University, Department of Civil Engineering, 34810, Istanbul, Türkiye*

Abstract. This study uses warping-included mixed finite element formulation to investigate the free vibration behavior of transversely functionally graded (FG) straight beams reinforced with graphene nanoplatelets (GPLs). The composite material consists of a polymer matrix reinforced with GPLs, where the volume fraction of the reinforcement varies through the thickness of the beam. The effective elastic modulus is derived using the Halpin-Tsai micromechanical model, which accounts for the geometry and distribution of GPLs within the matrix material. The warping-included mixed finite element formulation is developed based on the Timoshenko beam theory, employing a two-node element with twelve degrees of freedom per node. These degrees of freedom include three displacements, three section rotations, three forces, two bending moments, and one torsional moment, providing a robust framework for accurately modeling the dynamic behavior of the FG-GPL reinforced composite beam. A detailed parametric study examines the influence of GPL weight fraction, material distribution patterns, and boundary conditions on the vibration characteristics of the beam. The results highlight the significant influence of the GPL reinforcement and its distribution on the natural frequencies, providing valuable insights for optimizing the mechanical performance of composite beams in advanced engineering applications.

Keywords: Graphene nanoplatelets reinforced composites; Functionally graded material; Mixed finite element method; Free vibration analysis

1. Introduction

In recent years, composite laminated beams have attracted considerable attention in the fields of materials science and engineering, owing to their exceptional mechanical performance and versatility across various applications. The increasing demand for advanced materials with enhanced mechanical, thermal, and electrical properties has spurred the development of innovative composite structures. Among these, functionally graded materials (FGMs) have emerged as a promising category of composites, specifically designed to fulfill both structural and functional requirements through a gradual variation of material properties in a designated direction.

Functionally graded materials, originally developed in the mid-1980s by Japanese scientists, offer distinct advantages over traditional fiber-reinforced laminated composites, including improved stress distribution and enhanced performance under varying environmental conditions (Long et al. 2016; Ninh et al., 2020). These attributes have made FGMs particularly suitable for aerospace, marine, mechanical, and structural engineering applications. Functionally graded materials are advanced composites where the material properties vary continuously and smoothly with position, offering significant advantages in high-temperature applications and structural optimization (Cong and Duc, 2016). The concept of FGMs involves a gradual variation of material properties, often achieved by varying the volume fraction of the constituent materials (Chakraverty and Pradhan, 2016). This approach eliminates the abrupt interfaces found in traditional composites, reducing stress concentrations and improving the overall structural integrity.

Within the domain of FGMs, functionally graded graphene platelet-reinforced composite (FG-GPLRC) beams have emerged as a notable development. Graphene, known for its outstanding mechanical strength, high electrical conductivity, low density, and nanometric scale, serves as a highly effective reinforcement in composite materials (Ebrahimi et al., 2024; Priyadarshini, 2025; Rangappa et al., 2022). The integration of graphene platelets into FGMs significantly enhances their mechanical and physical properties, thereby improving the performance and durability of composite beams in various engineering applications. Some of the studies related to FG-GPLRC straight beams can be cited as follows: Wu et al. (2017) investigate the dynamic instability of functionally graded

multilayer graphene nanocomposite beams under thermal environments, employing the First-order Shear Deformation Theory. To determine the principal unstable region of FG multilayer GPLRC beams, the study utilizes the differential quadrature method in combination with Bolotin's method. The effective Young's modulus of the GPLRCs is estimated through the Halpin-Tsai micromechanics model. The effects of various parameters, including the distribution pattern, geometry, and dimensions of the GPL nanofillers, as well as the impact of initial static axial load and uniform temperature variation on the dynamic instability behavior, are thoroughly analyzed. The findings demonstrate that the GPL weight fraction and distribution pattern substantially impact the thermal buckling, free vibration, and dynamic instability of FG multilayer GPLRC beams.In contrast, the effects of GPL geometry and dimensions diminish when the width-to-thickness ratio of the GPL exceeds 10^3. Feng et al. (2017) comprehensively examine the linear and nonlinear free vibration behaviors of nanocomposite beams reinforced with non-uniformly distributed GPL reinforcements, employing the Timoshenko beam theory alongside the von Kármán nonlinear strain-displacement relationship. The study demonstrates that incorporating a small amount of GPL into the polymer matrix significantly enhances the natural frequency of the composite beam, highlighting its potential for innovative engineering applications. Furthermore, at the same weight fraction, GPLs characterized by a larger surface area and fewer graphene layers demonstrate superior reinforcement efficiency. Among the four examined GPL distribution patterns, the results indicate that positioning a higher concentration of GPLs near the top and bottom surfaces of the beam most effectively enhances beam stiffness, leading to increased natural frequencies. The study also verifies that a multilayer configuration with ten individual stacked layers adequately represents an ideal FG structure, ensuring a continuous and smooth variation in material properties. Song et al. (2020) investigate the nonlinear free vibration behavior of edge-cracked GPLRC laminated beams resting on a two-parameter elastic foundation under thermal conditions. The study assumes that the GPL nanofillers are randomly oriented and functionally graded in a layer-wise distribution along the beam thickness, with a uniform temperature distribution throughout the beam domain. To estimate the effective material properties of the GPL-reinforced nanocomposite, micromechanical models are utilized. Stress intensity factors are determined using finite element methods. The equations of motion for the cracked GPLRC beams are formulated within the framework of the first-order shear deformation beam theory, incorporating von Kármán-type geometric nonlinearity to account for large deformations. The bending stiffness at the cracked section is evaluated using a massless rotational spring model. To compute the linear and nonlinear natural frequencies, the differential quadrature method is applied. Karamanli and Vo (2021) conduct a comprehensive study on the bending, vibration, and buckling behavior of carbon nanotube-reinforced composite (CNTRC) and GPLRC beams. The governing equations of motion are derived by incorporating both normal and shear deformation effects. To evaluate the displacements, critical buckling loads, and natural frequencies of the beams under various boundary conditions, finite element analysis is utilized. Parametric analyses are performed to investigate the effects of crucial parameters, including the distribution pattern, volume fraction of CNTs, GPL weight fraction, slenderness ratio, and boundary conditions, on the structural performance. Vinh and Son (2022) propose a first-order mixed beam element formulation for analyzing the static bending behavior of functionally graded graphene oxide powder-reinforced composite (FG-GOPRC) beams. The formulation is based on a mixed finite element approach that utilizes the first-order shear deformation theory. The developed beam element consists of two nodes, each with three degrees of freedom, and employs linear shape functions, effectively eliminating shear locking without the need for selective or reduced integration. The study demonstrates that the proposed beam element can accurately predict static bending responses with a minimum number of elements, significantly reducing computational costs. To validate the efficiency and accuracy of the formulation, a comparative analysis is conducted, confirming the superior performance of the new element. Subsequently, the proposed beam element is applied to investigate the static bending behavior of FG-GOPRC beams. Fouaidi et al. (2023) propose a numerical approach that integrates the reproducing kernel particle collocation meshless method with the implicit Newmark time integration scheme to analyze the transient response of porous composite beams reinforced with FG-GOPs resting on elastic foundations. The study considers composite beams subjected to dynamic loads under various boundary conditions, with the elastic foundation modeled using the Winkler–Pasternak foundation model. To model the composite beams reinforced with FG-GOPs, the first-order shear deformation theory is employed. The effective material properties of the porous composite beams are estimated using the Halpin–Tsai homogenization technique and the rule of mixtures, taking into account the effects of porosity. The equations of motion are reformulated in a matrix–vector strong form and solved using the proposed numerical strategy. Aribas et al. (2021, 2022, 2023, 2024) developed a mixed finite element method based on the Timoshenko beam theory to analyze the structural behavior of laminated composite beams, considering the warping effect. This method provides results with engineering accuracy when compared to three-dimensional finite element methods. Furthermore, the mixed FEM, which incorporates the warping effect and is developed based on the Timoshenko beam theory, has been employed by Ermis 2024 to investigate the dynamic behavior of FG-GPLRC straight-axis and curved-axis beams. This study investigates the effect of GPL weight fractions and GPL distribution patterns on the natural frequencies of FG-GPLRC straight beams for different boundary conditions and slenderness ratios using the outcomes of Güner (2025).

2. Mathematcal formulation

2.1 Effective Material Properties of the FG-GPLRC Composite Beam

Nanocomposite materials reinforced with graphene nanoplatelets (GPLs) are obtained by combining polymer matrix material and graphene nanoplatelet material at specific volume fractions. The layered graphene nanoplatelet-reinforced composite beam with a rectangular cross-section, presented in Fig. 1, has a thickness of h and a width of w. This composite beam consists of N_L layers of equal thickness. The thickness of each layer is defined as $h_k=h/N_L$, arranged as k=1, h,…, N_L . In each layer, the GPLs are uniformly distributed within the matrix material. By varying the GPL ratios within the layers, functionally graded GPL-reinforced composite beams are formed.

In this study, the same amount of GPL material is considered with four different distribution types: UD, X, O, and A (Karamanlı and Vo 2021, Ermis 2024). In the uniform distribution (UD) type, the GPLs are homogeneously distributed within the cross-section, while the other distribution types vary along the thickness and exhibit a linear change. In the FG-X type, the upper and lower parts of the cross-section are rich in GPLs, while in the FG-O type, the opposite is true; in this model, the central part of the cross-section is GPL-rich. The FG-A type demonstrates a gradual increase in the GPL content from the top to the bottom of the cross-section.

For the GPL-reinforced nanocomposite beams, where GPLs are assumed to be randomly and homogeneously distributed within each layer, the volume fraction of GPLs in the kth layer for the aforementioned different distribution types can be expressed as follows.

$$
\begin{aligned}
&\text{UD} &&: V_{\mathrm{GPL}}^{(k)} = V_{\mathrm{GPL}},\\
&\text{FD-X} &&: V_{\mathrm{GPL}}^{(k)} = 2V_{\mathrm{GPL}}\left(\left|2k-N_L-1\right|/N_L\right),\\
&\text{FD-O} &&: V_{\mathrm{GPL}}^{(k)} = 2V_{\mathrm{GPL}}\left(1-\left|2k-N_L-1\right|/N_L\right),\\
&\text{FD-A} &&: V_{\mathrm{GPL}}^{(k)} = V_{\mathrm{GPL}}\left(\left(2k-1\right)/N_L\right),
\end{aligned}
\tag{1}
$$

Here, V_{GPL} represents the total volume fraction of GPLs and is calculated using the following formulation:

$$V_{\mathrm{GNL}} = \frac{W_{\mathrm{GNL}}}{W_{\mathrm{GNL}} + \left(\rho_{\mathrm{GNL}}/\rho_{\mathrm{M}}\right)\left(1-W_{\mathrm{GNL}}\right)} \tag{2}$$

ρ_{GPL} and ρ_{M} denote the densities of the GPL and the polymer matrix, respectively. W_{GPL} represents the total weight fraction of GPLs. The uniform and homogeneous dispersion of graphene/graphene derivative materials within the polymer matrix of the nanocomposite layer is valid only for low values of the weight fraction (W_{GPL}). According to Zhao et al. (2020), this value should be less than approximately 1% to 3%, as detailed in the referenced study. The Halpin-Tsai micromechanics model is used to estimate the effective material properties of two-phase nanocomposites (Rafiee et al., 2009). In this micromechanics model, the GPL reinforcement material in each layer is assumed to be randomly oriented and homogeneously distributed within the polymer matrix material. This multiscale material model for the two-phase nanocomposite approximately calculates the effective elastic modulus of the FG-GPL reinforced nanocomposites as follows (Yang et al., 2023)

$$
\begin{gathered}
E_{\mathrm{eff}}^{(k)} = \frac{3}{8}\frac{1+\xi_l\eta_l V_{\mathrm{GPL}}^{(k)}}{1-\eta_l V_{\mathrm{GPL}}^{(k)}}\times E_{\mathrm{M}} + \frac{5}{8}\frac{1+\xi_w\eta_w V_{\mathrm{GPL}}^{(k)}}{1-\eta_w V_{\mathrm{GPL}}^{(k)}}\times E_{\mathrm{M}}\\
\eta_l = \frac{\left(E_{\mathrm{GPL}}/E_{\mathrm{M}}\right)-1}{\left(E_{\mathrm{GPL}}/E_{\mathrm{M}}\right)+\xi_l},\ \eta_w = \frac{\left(E_{\mathrm{GPL}}/E_{\mathrm{M}}\right)-1}{\left(E_{\mathrm{GPL}}/E_{\mathrm{M}}\right)+\xi_w}
\end{gathered}
\tag{3}
$$

Here, E_{GPL} and E_{M} represent the elastic moduli of the GPL and polymer matrix, respectively. The scaled parameters ξ and η are dependent on the geometric characteristics of the GPL reinforcement material, as follows:

$$\xi_l = 2l_{\mathrm{GPL}}/h_{\mathrm{GPL}},\ \xi_w = 2w_{\mathrm{GPL}}/h_{\mathrm{GPL}} \tag{4}$$

Here, l_{GPL}, w_{GPL}, and h_{GPL} represent the length, width, and thickness of the GPLs, respectively. Additionally, the effective material density ρ_{eff} and Poisson's ratio υ_{eff} of the FG-GPL reinforced beam in the kth layer are calculated using the rule of mixtures as follows:

$$
\begin{aligned}
\rho_{\mathrm{eff}}^{(k)} &= \rho_{\mathrm{GPL}} V_{\mathrm{GPL}}^{(k)} + \rho_{\mathrm{M}} \left(1 - V_{\mathrm{GPL}}^{(k)}\right) \\
\upsilon_{\mathrm{eff}}^{(k)} &= \upsilon_{\mathrm{GPL}} V_{\mathrm{GPL}}^{(k)} + \upsilon_{\mathrm{M}} \left(1 - V_{\mathrm{GPL}}^{(k)}\right)
\end{aligned} \tag{5}
$$

Here, υ_{GPL} and υ_{M} denote the Poisson's ratios of the GPL and polymer matrix, respectively.

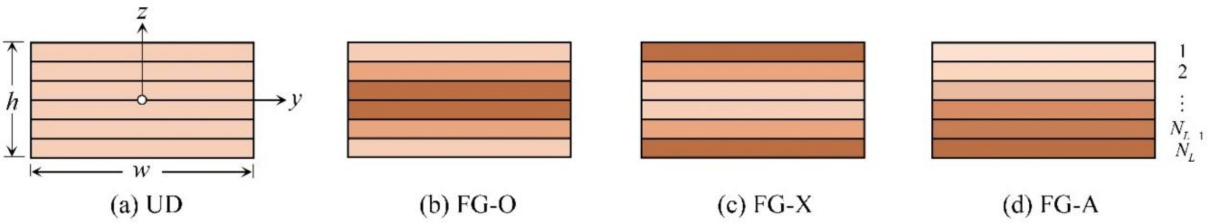

Fig. 1. Cross-sectional view of a functionally graded graphene nanoplatelet (FG-GPL) reinforced composite beam with different distribution models: (a)UD, (b) FG-O, (c) FG-X, (d) FG-A.

2.2. Field Equations

The field equations of spatial curved rods based on the Timoshenko beam theory (Omurtag and Aköz, 1992), and the field equations of FG composite beams through the cross-sectional height can be expressed as follows (Aribas et al. 2022, 2024):

$$
\left.
\begin{aligned}
-\mathbf{F}_{,x} - \mathbf{q} + \rho_{\mathrm{eff}} A \ddot{\mathbf{u}} &= \mathbf{0} \\
-\mathbf{M}_{,x} - \mathbf{i} \times \mathbf{F} - \mathbf{m} + \rho_{\mathrm{eff}} \mathbf{I} \ddot{\mathbf{\Omega}} &= \mathbf{0}
\end{aligned}
\right\} \quad \text{Equations of motion} \tag{6}
$$

$$
\left.
\begin{aligned}
\mathbf{u}_{,x} + \mathbf{i} \times \mathbf{\Omega} - \mathbf{C}_m \mathbf{F} - \mathbf{C}_{mf} \mathbf{M} &= \mathbf{0} \\
\mathbf{\Omega}_{,x} - \mathbf{C}_{fm} \mathbf{F} - \mathbf{C}_f \mathbf{M} &= \mathbf{0}
\end{aligned}
\right\} \quad \text{Constitutive equations} \tag{7}
$$

$$
\left.
\begin{aligned}
-\mathbf{u} + \hat{\mathbf{u}} = \mathbf{0}\,;\; -\mathbf{\Omega} + \hat{\mathbf{\Omega}} = \mathbf{0} \\
\mathbf{F} - \hat{\mathbf{F}} = \mathbf{0}\,;\; \mathbf{M} - \hat{\mathbf{M}} = \mathbf{0}
\end{aligned}
\right\} \quad \text{Boundary conditions} \tag{8}
$$

Here, $\mathbf{u}(u_x, u_y, u_z)$ represents the displacement vector, $\mathbf{\Omega}(\Omega_x, \Omega_y, \Omega_z)$ denotes the cross-sectional rotation vector, $\mathbf{F}(F_x, F_y, F_z)$ is the force vector, and $\mathbf{M}(M_x, M_y, M_z)$ is the moment vector. The parameter ρ_{eff} denotes the effective material density of the composite cross-section, A is the cross-sectional area, and $\mathbf{I}$ represents the moment of inertia vector. The vectors $\mathbf{q}$ and $\mathbf{m}$ represent the distributed force and moment vectors, respectively, while $\ddot{\mathbf{u}}$ and $\ddot{\mathbf{\Omega}}$ indicate the acceleration terms.The terms with a hat (e.g., $\hat{\mathbf{u}}$) denote the known boundary values.

2.3 Functional

Using the potential operator and Gâteaux derivative (Oden & Reddy, 2012; Omurtag & Aköz, 1992), the functional for the free vibration of composite straight beams is obtained in the following form by employing equations (6)-(8). In the free vibration analysis, when harmonic motion is considered, it is evident that the distributed force and moment vectors in equation (6) will be equal to zero, and the acceleration terms can be expressed in the form $\left[\ddot{\mathbf{u}}, \ddot{\mathbf{u}}\right] = -\omega^2 \left[\mathbf{u}, \mathbf{u}\right]$ and $\left[\ddot{\mathbf{\Omega}}, \ddot{\mathbf{\Omega}}\right] = -\omega^2 \left[\mathbf{\Omega}, \mathbf{\Omega}\right]$, where ω is the natural angular frequency as follows:

$$
\left.
\begin{aligned}
\mathbf{I}(\mathbf{y}) = & -\left[\mathbf{u}, \mathbf{F}_{,x}\right] + \left[\mathbf{i} \times \mathbf{\Omega}, \mathbf{F}\right] - \left[\mathbf{M}_{,x}, \mathbf{\Omega}\right] - \tfrac{1}{2}\left[\left(\mathbf{C}_m\right) \mathbf{F}, \mathbf{F}\right] - \tfrac{1}{2}\left[\left(\mathbf{C}_{mf}\right) \mathbf{M}, \mathbf{F}\right] - \tfrac{1}{2}\left[\left(\mathbf{C}_{fm}\right) \mathbf{M}, \mathbf{F}\right] \\
& - \tfrac{1}{2}\left[\left(\mathbf{C}_f\right) \mathbf{M}, \mathbf{M}\right] - \tfrac{1}{2} \rho_{\mathrm{eff}} A \omega^2 \left[\mathbf{u}, \mathbf{u}\right] - \tfrac{1}{2} \rho_{\mathrm{eff}} \omega^2 \left[\mathbf{I} \mathbf{\Omega}, \mathbf{\Omega}\right] + \left\langle \left(\mathbf{F} - \hat{\mathbf{F}}\right), \mathbf{u} \right\rangle_{\sigma} + \left\langle \left(\mathbf{M} - \hat{\mathbf{M}}\right), \mathbf{\Omega} \right\rangle_{\sigma} \\
& + \left\langle \mathbf{F}, \hat{\mathbf{u}} \right\rangle_{\varepsilon} + \left\langle \mathbf{M}, \hat{\mathbf{\Omega}} \right\rangle_{\varepsilon}
\end{aligned}
\right\} \tag{9}
$$

2.4 Mixed FEM

The mixed finite element formulation is developed based on a two-node finite element formulation derived from the Timoshenko beam theory. The finite element formulation is derived using the dimensionless coordinate ξ. The linear shape functions are denoted as $\phi_i = 1-\xi$ and $\phi_j = \xi$, where the nodal coordinates are defined as $\xi = 0$, and $\xi = 1$ respectively. The subscripts indicate the nodal points associated with the element. Each node of the linear element has a total of twelve unknowns. These unknowns include three displacements, three rotations, one axial force, two shear forces, one torsional moment, and two bending moments. The total number of degrees of freedom for the element is twenty-four. The natural frequencies of vibration in a structural system can be determined by formulating the problem as a standard eigenvalue problem. Detailed information on the mixed finite element formulation can be found in Omurtag and Aköz (1992) and Eratlı et al. (2016), while detailed information related to the FG beam can be found in Arıbas et al. (2024).

3. Numerical examples

In this study, the free vibration behavior of GPL-reinforced composite beams is investigated under various parameters. In Section 4.1, the effects of different boundary conditions, GPL distribution types, GPL weight ratios, and length-to-height ratios on natural frequency are evaluated. The accuracy of the presented mixed FEM is previously demonstrated in detail in Ermis (2024), hence the focus of this study is on parametric examples presented in Güner (2025). Four different configurations, namely UD, X, O, and A, are considered as GPL distribution types. The GPL weight ratios (W_{GPL}) are set as 0.1%, 0.3%, 0.5%, 1%, 2%, and 3%. According to the literature, to consider the GPL distribution as homogeneous, the GPL weight ratio should not exceed 3% (Zhao et al., 2020). Three different boundary conditions are evaluated: clamped-clamped, clamped-pinned, and clamped-free (see Fig. 2). The length-to-height ratios (L/h) are chosen as 10, 20, 30, and 40, respectively. The height and width of the cross-section are h = 0.4 *m and w* = 0.4 m, respectively. The out-of-plane first natural frequency values of the FG-GPLRC beam with clamped-free, clamped-pinned, and clamped-clamped boundary conditions are presented in Tables 1–3, respectively, for different length-to-height ratios, GPL distribution types, and GPL weight ratios. The material properties of the GPL are $E_{\text{GPL}} = 1.01\,\text{TPa}$, $\upsilon_{\text{GPL}} = 0.186$, $\rho_{\text{GPL}} = 1062.5\,\text{kg/m}^3$, $l_{\text{GPL}} = 2.5\,\mu\text{m}$, $w_{\text{GPL}} = 1.5\,\mu\text{m}$ and $h_{\text{GPL}} = 1.5\,\text{nm}$. The material properties of matrix material are $E_{\text{M}} = 3\,\text{GPa}$, $\upsilon_{\text{M}} = 0.34$, $\rho_{\text{M}} = 1200\,\text{kg/m}^3$. The effective material properties of each layer of the FG-GPLRC beam are obtained by using Eqs. (1)-(5).

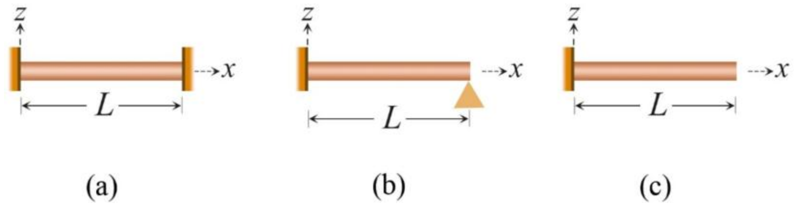

Fig. 2. Boundary conditions (a) clamped-clamped, (b) clamped-pinned, (c) clamped-free

When examining the fundamental natural frequency values (Tables 1–3) of FG-GPLRC beams with clamped-free, clamped-pinned, and clamped-clamped boundary conditions, it is observed that increasing the GPL weight ratio results in a significant increase in natural frequency values for each distribution type and *L*/*h* ratio. This increase shows noticeable differences depending on the material distribution types (UD, FG-X, FG-O, FG-A). In Tables 1–3, for each GPL weight ratio and *L*/*h* ratio, the highest natural frequency value is observed in the X-type distribution, while the lowest frequency value is found in the O-type distribution. This phenomenon can be attributed to the spatial distribution of GPL within the beam cross-section. In the X-type distribution, GPL concentration in the lower and upper regions significantly enhances bending rigidity, while in the O-type distribution, GPL concentration in the central regions is less effective in increasing rigidity. For example (Table 1), in the case of *L*/*h* = 10 with a clamped-free boundary condition, the first mode frequency values for the FG-X distribution are obtained as 7.73 Hz for a 0.1% GPL weight ratio and 25.14 Hz for a 3% GPL weight ratio. Under the same conditions, these values are calculated as 6.86 Hz and 15.81 Hz, respectively, for the FG-O distribution. Additionally, as the length-to-height ratio (*L*/*h*) increases, it is observed that the frequency values decrease for each distribution type and GPL weight ratio. For instance (Table 1), for the X-type distribution and 3% GPL content, the first mode natural frequency value is obtained as 25.14 Hz when *L*/*h* = 10, while it decreases to 1.58 Hz when *L*/*h* = 40. This indicates that the beam stiffness changes inversely with the *L*/*h* ratio.

	FG-A	2.88	3.42	3.85	4.72	6.08	7.17

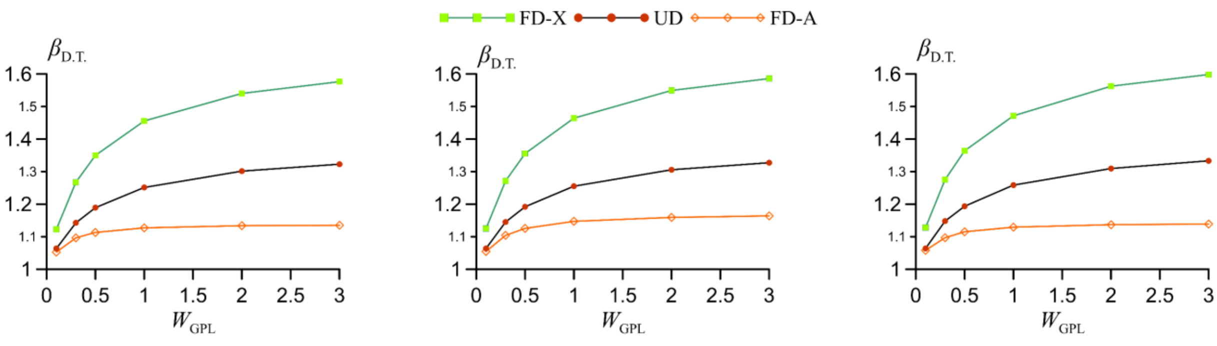

Fig. 4. The effect of GPL distribution type on the fundamental natural frequency in FG-GPL composite beams for different boundary conditions. (L/h=20, $\beta_{D.T.} = f_{D.T.=i} / f_{D.T.=O}$ where $i =$ UD, X, and A.)

3.1 The effect of GPL weight fraction

The effect of the GPL (W_{GPL}) weight fraction on the natural frequency values of the beam is examined through the ratio $\beta_{W_{GPL}}$, calculated using the formula $\beta_{W_{GPL}} = f_{W_{GPL=i}} / f_{W_{GPL}=0.1\%}$ where $i = 0.3\%, 0.5\%, 1\%, 2\%,$ and 3%. In this context, the variations of the $\beta_{W_{GPL}}$ ratio corresponding to the fundamental natural frequency for L/h=20 are presented in Figures 3(a), 3(b), and 3(c) for clamped-clamped, clamped-pinned, and clamped-free boundary conditions, respectively. Similar trends are observed for other L/h ratios (10, 30, and 40). As the GPL amount increases, a noticeable rise in natural frequency values is observed across all three boundary conditions and L/h ratios. This increase is clearly reflected in the rise of the $\beta_{W_{GPL}}$. The increase in the GPL weight ratio leads to a more pronounced enhancement in cross-sectional rigidity in the X distribution, where GPL is concentrated in the lower and upper regions, resulting in higher $\beta_{W_{GPL}}$ ratios for this distribution type. Consequently, in the graphs presented in Figures 3(a)-(c), the highest ratio is obtained for the X distribution, while the lowest values are observed for the O distribution. For example, for L/h = 10 with a 3% GPL ratio under clamped-free boundary conditions, the first natural frequency increases approximately 3.25 times for the X distribution, whereas this increase is only 2.30 times for the O distribution. Under the same conditions, for clamped-pinned boundary conditions, these values are 3.23 and 2.32, respectively, while for clamped-clamped boundary conditions, they are 3.20 and 2.34. Also, as the GPL weight fraction increases, the slope of the increase in $\beta_{W_{GPL}}$ ratios decreases, and this trend is consistent across all three boundary conditions. On the other hand, when the GPL weight ratio is at low levels (e.g., in the range of 0.1%~0.3%), it is noteworthy that the $\beta_{W_{GPL}}$ ratios corresponding to different distribution types are quite close to each other. This indicates that under conditions of low GPL content, the effect of the GPL distribution type on the free vibration frequency remains limited, and the differences between distribution types become less pronounced at these levels. However, as the GPL ratio increases (particularly at values of 1% and above), the differences between the $\beta_{W_{\text{GPL}}}$ ratios of the distribution types become more distinct.

3.2 The effect of GPL distribution type

The effect of the GPL distribution type on the natural frequency values of the beam is examined through the ratio $\beta_{\text{D.T.}}$, calculated using the formula $\beta_{\text{D.T.}} = f_{\text{D.T.}=i} / f_{\text{D.T.}=\text{O}}$ where $i =$ UD, X, and A. The natural frequencies (Tables 1-3) indicate that when the GPL reinforcement is predominantly concentrated in the central region of the beam cross-section (FG-O), the natural frequency values reach their minimum values. Conversely, when the GPL reinforcement is concentrated near the lower and upper surfaces of the cross-section (FG-X), the natural frequency values attain their maximum values. The frequency values corresponding to the UD distribution, representing a homogeneous distribution, and the FD-A distribution, where the GPL reinforcement material exhibits maximum concentration in the lower region and minimum concentration in the upper region, consistently lie between the natural frequencies observed for the FD-X and FD-O distributions across all L/h ratios and boundary conditions. In this context, the variations of the $\beta_{\text{D.T.}}$ ratio corresponding to the fundamental natural frequency for L/h=20 are presented in Figures 4(a), 4(b), and 4(c) for clamped-clamped, clamped-pinned, and clamped-free boundary conditions, respectively. Similar trends are observed for other L/h ratios (10, 30, and 40). At low GPL weight fractions, the effect of the distribution type is more pronounced, whereas this effect tends to diminish as the GPL weight ratio increases. Notably, when the GPL weight ratio exceeds 0.5%, the $\beta_{\text{D.T.}}$ ratio corresponding to the FD-A distribution remains approximately constant at around 1.1.

4. Conclusions

This study presents a comprehensive investigation into the free vibration behavior of transversely FG straight beams reinforced with GPLs using a warping-included mixed finite element formulation. The developed model, based on Timoshenko beam theory, effectively incorporates the warping effects through a two-node element with twelve degrees of freedom per node, providing an accurate representation of the dynamic response of FG-GPLRC beams. The findings can be summarized as follows:

- The results demonstrate that both the GPL weight fraction and the distribution type have a significant impact on the natural frequencies of the beams. Among the considered distribution types, the X-type distribution, where GPLs are concentrated near the top and bottom surfaces, consistently exhibits the highest natural frequency values, while the O-type distribution, with GPLs concentrated in the mid-region, shows the lowest.
- The natural frequencies increase with the GPL content, highlighting the reinforcement efficiency, particularly at higher weight ratios. Additionally, the influence of boundary conditions on the vibration characteristics is significant, indicating the necessity to consider both material distribution and support configurations during the design process.

Abstract. Cavity walls are made of an inner wall and an outer wall that could be of different materials separated by an air space and attached to each others using tie systems. In an attempt to reduce environmental impact of structures, cavity walls made of timber and clay bricks appear to be a good alternative to more traditional cavity walls made of concrete and masonry. In France, the design and implementation of such walls are not currently supported by specific standards or guidelines.While the NF DTU 31.2 and NF DTU 20.1 standards previously included provisions for these structures, they were removed in the last revisions due to insufficient experimental data.The Woodstone project funded by MECD aims to study the behavior of walls made of timber and clay bricks in details (stability of the structures under lateral and vertical loadings, waterproofing tests, mechanical behavior of the connections, etc.) in a way to provide more data regarding the behavior of this type of structures for the development of guidelines needed by practioners. As part of the project, several clay bricks walls were built with different ties and brick types. Then the walls were subjected to mechanical stress and their watertightness was assessed. More specifically, this article deals with the efficiency of one type of tie connections that could be used to attach cavity walls made of timber and fired clay bricks. First, the study focuses on the characterization of the considered flat tie type connection under traction (experimental and numerical confrontation). Then the interface between mortar and bricks is modeled to fit experimental shear tests. Finally, the mechanical behavior of connection blocks, comprising two bricks and a mortar layer with an embedded tie, is modeled and validated against experimental data.

1. Introduction:

The use of metal ties in brick masonry dates back to the load-bearing walls of the 19th century, when their design was based mainly on empirical approaches. Introduced in England in the mid-1800s with wrought-iron fasteners, their adoption spread to the USA, where tests revealed that walls bonded with metal ties were more resistant to water penetration than those simply made of masonry. Tie connections gained in popularity with the move away from solid walls to lighter systems, such as cavity walls and double-skin walls. Such evolution in construction practices came with several challenges that had yet to be faced, including frequent shear failures, inappropriate load transfer and a reliance on empirical choices for sizing and spacing of ties in some built cavity walls. While there are several types of existing tie connections in the practice (in terms of materials, size, layout), it is a necessaty to have clear rules and requirements regarding their design to avoid failure due to innaproriate design. In that regard, some building codes such as The Building Code for Masonry Structures (ACI 530 / ASCE 5 / TMS 402-02), also known as the MSJC (MSJC, 2008) provide clear guidelines for their use. Recent scientific articles also deal with the characterization of the behavior of such tie systems. Arslan et al. (2020/2021) for instance published studies regarding the behavior of tie metal connections in double skin walls made of an inner load-bearing brick masonry wall and an outer clay brick cladding, separated by an air gap.

The study by Aslan et al. (2021) is based on observations of damaged buildings, which revealed their vulnerability to out-of-plane failure when the connections between the two walls are insufficient. The study focuses on proposing analytical models for assessing the mechanical resistance associated with the different modes of failure observed in the practice. The study focuses exclusively on hook-zigzag type ties (or mortar ties) embedded

https://doi.org/10.31462/icearc2025_ce_sme_859

in a 10 mm thick mortar joint. Different mortar strengths, air gap lengths and anchor lengths were studied. This study compares analytical results with those obtained experimentally through elementary tests carried out on the ties. The study focuses only on axial loading (compression/tension). Failure modes that were observed are :- In tension : tensile failure of the tie; cone failure in mortar (failure associated with mortar/brick bond); tie/mortar sliding and tie/mortar bond failure - In compression: tie buckling; sliding of tie in the mortar expulsion of mortar cone.

The authors proposed various analytical models to evaluate the resistances associated with each of these failure modes. Following this, Javier Ortega et al. (2022) proposed a numerical model aimed at analyzing and understanding the mechanical behavior of metal ties connecting brick veneer walls to masonry infill walls, particularly under horizontal loads, such as those induced by earthquakes or wind. The work is based on experimental cyclic tension-compression tests carried out on brick-mortar-tie assemblies, during which various failure modes were observed: sliding of the tie, cracking of the mortar and buckling of the metal tie. In France, the design and implementation of double walls are not currently supported by specific standards or guidelines. While the (NF DTU 31.2,2019)and (NF DTU 20.1,2020) standards previously included provisions for these structures, they were removed in the last revisions due to insufficient experimental data. The Woodstone project funded by MECD aims to study the behavior of walls made of timber and clay bricks in details (stability of the structures under lateral and vertical loadings, waterproofing tests, mechanical behavior of the connections, etc.) in a way to provide more data regarding the behavior of this type of structures for the development of guidelines needed by practioners.

More specifically, this article deals with the efficiency of one type of tie connections that could be used to attach cavity walls made of timber and fired clay bricks. First, the study focuses on the characterization of the considered flat tie type under traction (experimental and numerical confrontation). Then the interface between mortar and bricks was modeled to fit experimental shear tests. Finally, the tensile behavior of connection blocks, made of two bricks and a mortar layer with an embedded tie, was modeled and validated against experimental data.

2. Traction of the flat tie system

2.1. Geometry

The studied tie is shown in Fig.1, (Leviat type). It is 19 mm wide and 2 mm thick. It has three round holes aligned horizontally: the first two have a diameter of 12 mm, while the third one has a diameter of 10 mm. These perforations reinforce its anchorage in the masonry. Between the holes and near the edges, 2.5 mm deep notches are symmetrically arranged, to insert the tie into the rail on the one hand, and to improve the positioning and adhesion of the tie in the mortar on the other. A special notch, known as a drop breaker, can be integrated into the flat part. The drop breaker was not present in the ties used for the elementary tests performed. However, its influence on the mechanical behavior of the connection should be accounted for in future parametric sudies since it was part of the ties used in the tested real size cavity walls.

The flat tie under consideration is embedded in mortar on the one hand, and fixed in a rail on the other hand.Fig. 2, shows the geometry of the rail. The rail is fixed to the timber frame using 6 mm diameter screws every 220 mm. The ties are simply inserted into the rail, allowing free movement of the tie along the length of the rail.

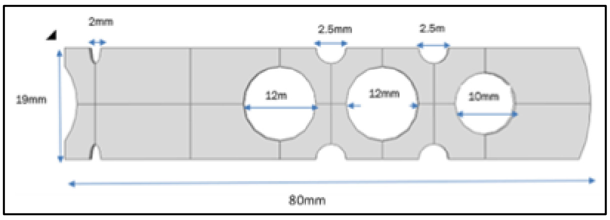

Fig. 1. Flat tie

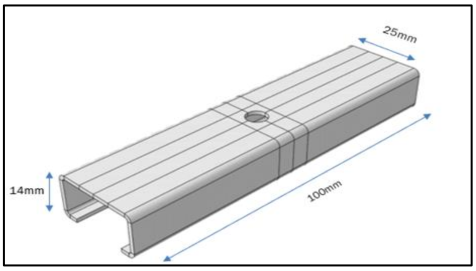

Fig. 2. Rail section

2.2. Material properties of the flat tie

A tensile test was performed on the flat tie. Thanks to a video extensometer, it was possible to track the relative displacement between 2 measuring points positioned around a hole in the tie (Fig.3). These points were then used as reference points to reproduce the test numerically and calibrate the material of the tie. The flat tie was modeled on Abaqus using quadratic volume elements.

A mesh sensivity analysis was carried out to determine the adequate mesh that should be used. Through such analysis, it appeared that a structural hexgonal mesh is appropriate. Two elements across the thickness of the flat tie were used in the numerical model (Fig. 4).

The material's behavior was modeled using an elastic-plastic law with strain-hardening, which accurately accounts for the progressive increase in stress after deformation observed experimentally. Fig. 5, shows the comparison between the numerical model and the experimental results. Table 1., shows the flat tie parameters determined though calibration and Table 2., shows the evolution of stresses with strains used in the numerical model.

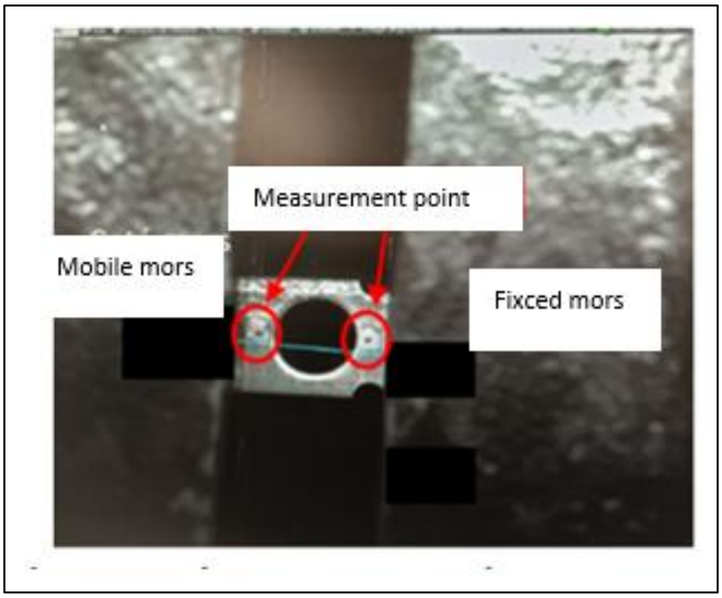

Fig. 3. Experimental set up used to perform the tensile characterization test on the flat tie

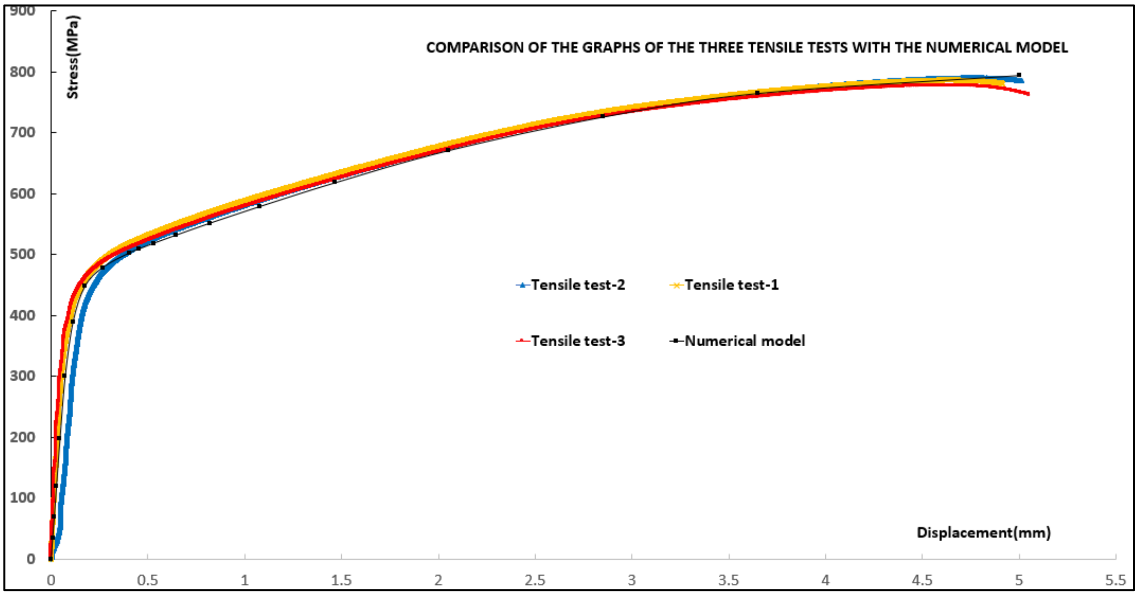

Fig. 5. Comparison of flat tie tensile test with numerical model

Table 1:Flat tie parameters

Young modulus (MPa)	Poisson modulus	Elastic stress (MPa)	Ultimate Stress (MPa)
200000	0.3	382	787

Table 2: Evolution of stresses with strain

Stress (MPa)	Strain (%)
368.43	0.02
516.96	0.023
650.83	1.10
744	0.18
786	0.3

2.3. Flat tie with rail

Another model was developed to study the tensile behavior of the flat tie associated with a metal rail. The objective of this study is to ensure that the model is representative of the specific mode of failure associated with the connection between the rail and the tie. The new model introduces a frictional contact law between the rail and tie, with a steel-to-steel friction coefficient of 0.3 (XP ENV1993-2).

To validate the Finite Element model, tensile tests were carried out on this assembly (Fig. 6,). The objective of the rail-tie tensile test was to determine the maximum force attainable before separation of the rail from the tie. It was observed that, during the tensile test, the tie tended to shift, coming out of the rail on one side and out of alignment on the other side. It was observed that the deformation of the rail largely predominated over the deformation of the tie.

Fig. 6, shows the model of the flat tie with rail. Fig. 7, compares the evolution of force versus displacement given by the finite element model and the 2 performed tests. For this purpose, the displacement used was that obtained between the 2 measurement points specified in Fig.6,. Good agreement can be observed between the model and the tests, with a maximum difference of 5.7%. The numerical model can then be used to study in detail the influence of the rail on the overall behavior of the ties, which appears to have a decisive influence on the system's stiffness and strength. The rail was not used in the tensile tests performed on the tie/brick/mortar complex.

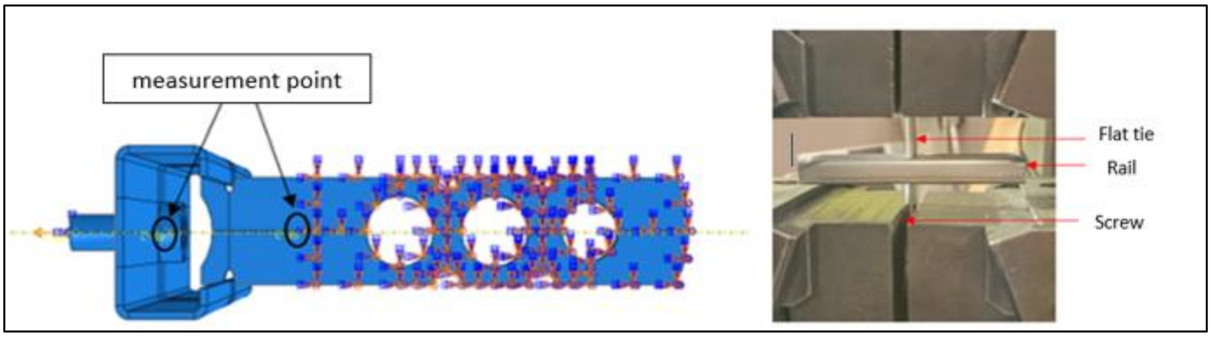

Fig. 6. Modeling the flat tie-rail tensile test ("embedded end versus free end-meshing1mm") and experimental test of the flat tie and rail connection system

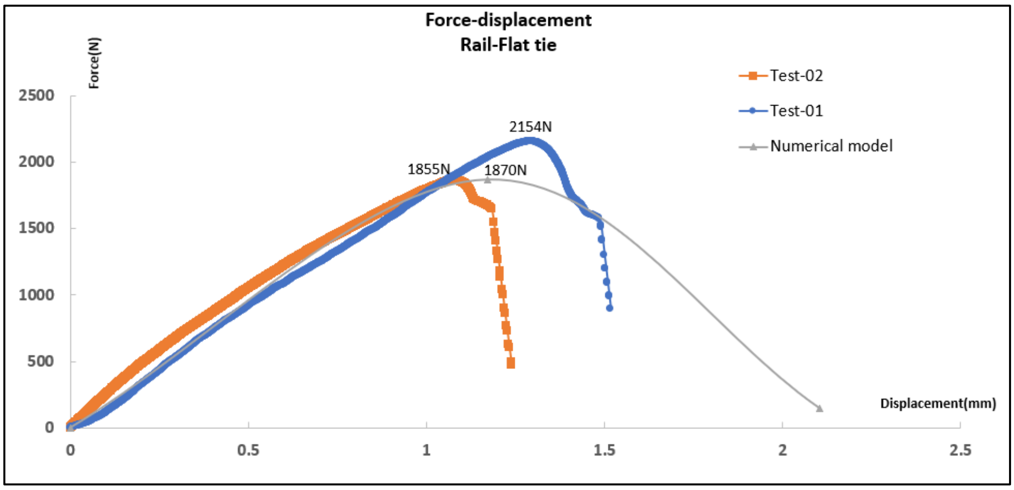

Fig. 7. Modeling the tie-rail tensile test (embedded end versus free end-meshing1mm)

3. Numerical simulation of the experimental Shear tests performed on the mortar/brick complex

3.1. Shear tests protocole

A series of shear tests were performed on mortar/brick complexes. Such tests were used to calibrate the brick to mortar cohesive interface model. Fig. 8, illustrates the experimental tests conducted and summarizes results obtained when testing 10 samples. An important variability was observed in the traction test results performed. It was chosen to model the test giving the minimum shear force (more conservative).

Sample	Failure Load (N)	Shear Strength (MPa)	Standard Error (MPa)	Variability (%)	Average Shear Strength (MPa)
1	27409	0.59			
2	11368	0.36			
3	27041	0.61			
4	13948	0.61			
5	18756	0.42	0.14	31	0.45

7	16636	0.29			
8	27624	0.62			
9	15952	0.58			
10	27628	0.61			

Fig. 8. Shear tests on bricks-mortar complexes

3.2. Material properties of the Mortar and the bricks

The value of the Young's modulus that was used to numerically simulate the behaviour of the mortar is equal to 3779 MPa. This value was taken from the literature based on the work published by M.A.Dalle (2025) on a similar mortar reference type as the one used in the project. A series of tests were conducted to evaluate both the tensile and compressive strength of the mortar.

For the numerical simulations, a compressive strength of 4.2 MPa and a tensile strength of 11.8 MPa were adopted. These values were obtained from the same literature source as the one used for Young's modulus..The stress versus strain curves for the mortar and its corresponding damage law were determined using a Mazars model, implemented on Matlab.

The curves giving the stress versus strain and damage law are shown in Fig. 9,Fig. 10,. For the plain bricks, the elastic properties were considered based on stress-strain curves provided in the CTTB report of 2006. From these curves, the Young's modulus of two tested bricks similar to those used in the WoodStone project was determined to be approximately equal to 5912 MPa.

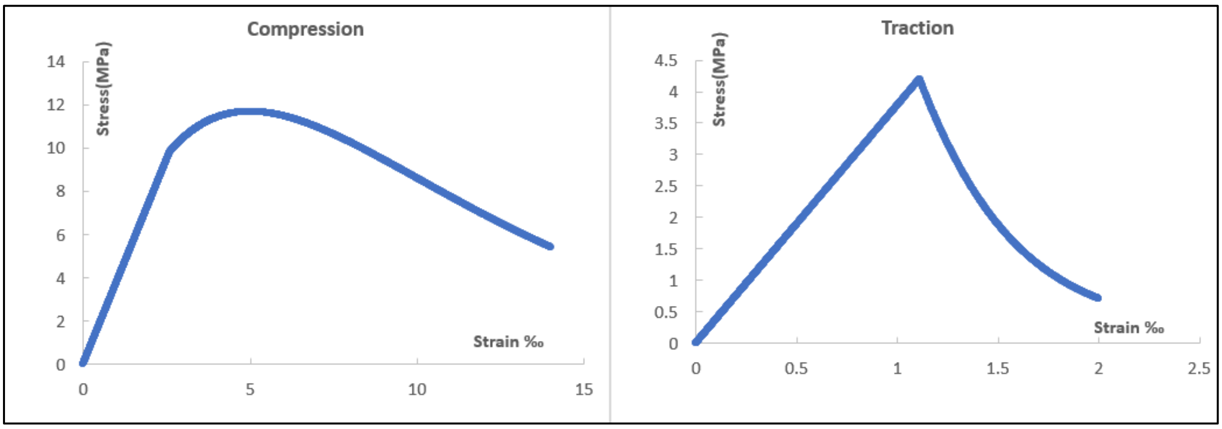

Fig. 9. Stress-strain curves for mortar : Compression and Traction

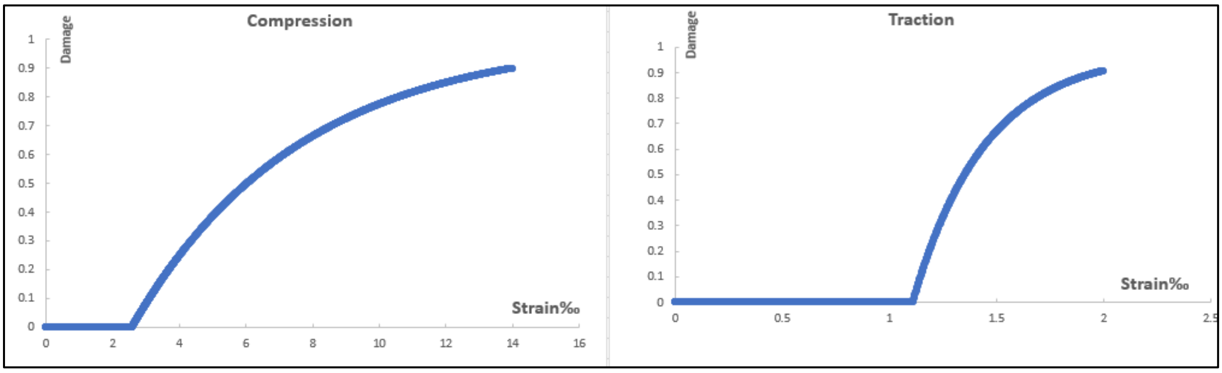

Fig. 10 . Damage of PRB MJ VIF mortar : Compression and Traction

3.3. Cohesive brick-mortar model

The connection between brick and mortar was modeled using a cohesive model at the interface of the two materials. This cohesive model was calibrated based on the shear tests. To account for this variability and assess its impact on the strength of the tie system, the cohesive model was calibrated on the 2 tests giving the maximum and minimum stiffnesses and strengths respectively, as shown in Table 3. To model the brick/mortar/tie complex in section 4, the minimum configuration was used.

This calibration determines 2 parameters of the cohesive model, one associated with tangential stiffness (Kt) and one associated with maximum shear strength (τ_t), corresponding to a limit stress beyond which the cohesive model is no longer active and allows sliding. Fig.11, shows the adequacy of the model for the minimum configuration corresponding to shear test n°2. This configuration is the one that was used later on to simulate the brick/mortar/tie traction test as it is the less conservative.

Table 3. Stiffnesses between brick and mortar

Configuration	Stiffness coefficient (MPa/mm)	Shear strength (MPa)
Minimum	1.1	0.6
Maximum	1.1	0.8

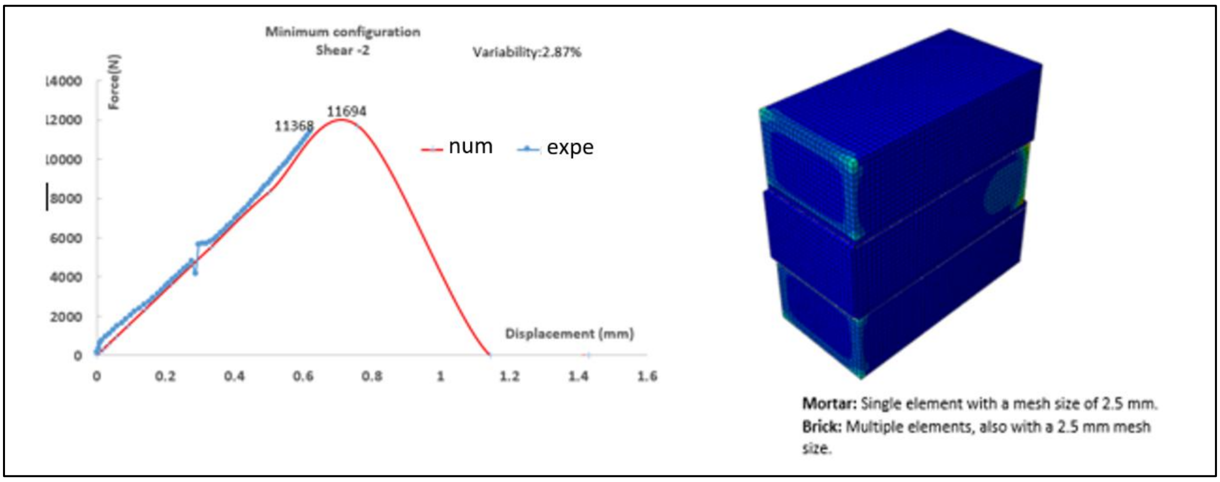

Fig. 11 . Superposition of numerical and experimental shear test

4. Numerical simulation of traction tests performed on Brick-mortar-tie connections:

4.1. Presentation of the model and results

Two solid bricks measuring 220mm × 105mm × 50mm, joined by 5mm-thick mortar were modeled. A flat tie without drain breaker was anchored in the center of the mortar to a depth of 50mm. The objective of this model was to calibrate the cohesive model between the mortar and tie on the basis of the performed tensile tests.

In total, 10 tensile tests with a certain variability were performed. Such variability was accounted for in the simulation by adjusting the properties of the cohesive model. Two experimental graphs were selected to calibrate the model: one corresponding to the configuration giving the weakest results (called minimum properties), corresponding to the tensile test no. 2, and the one giving the strongest results (called maximum properties), corresponding to the tensile test no. 4.

The parameters of the cohesive model for these 2 minimum and maximum configurations are presented in Table 4. The objective of this cohesive model is to take account of the failure between the mortar surrounding the tie and the mortar filling the holes in the tie (mortar balls). Experimentally, the cohesion between tie and mortar results mainly from the mortar passing through the tie. Fig. 12, illustrates the cross-section at tie level, with the mortar balls corresponding to the mortar in the holes.

A separation is observed between the mortar and the brick, as well as between the tie and the mortar. A separation of the mortar balls inside the tie is also visible, as shown in Fig. 12. This phenomenon is similar to that observed in the experimental tests, confirming a good agreement between the two approaches. Fig. 13 , compares the model with the tensile test, considering the 2 minimum and maximum configurations whereas Fig. 14, shows particularly the result obtained in the minimum force case scenario.

Table 4. Stifnesses between brick and mortar

Configuration	Stiffness coefficient (MPa/mm)	Shear strength (MPa)
Minimum	1.3	3.1
Maximum	2	7.5

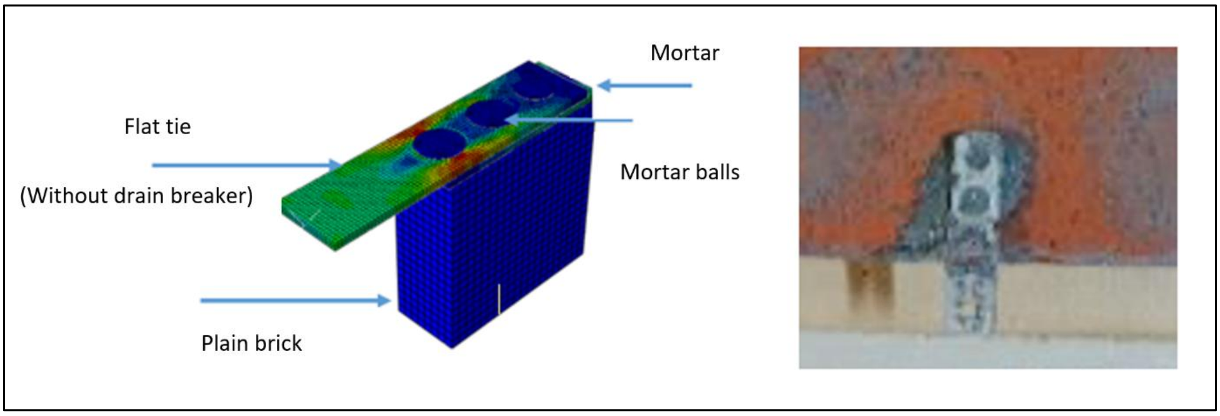

Fig. 12 . Traction test on the Brick-mortar-flat tie complex

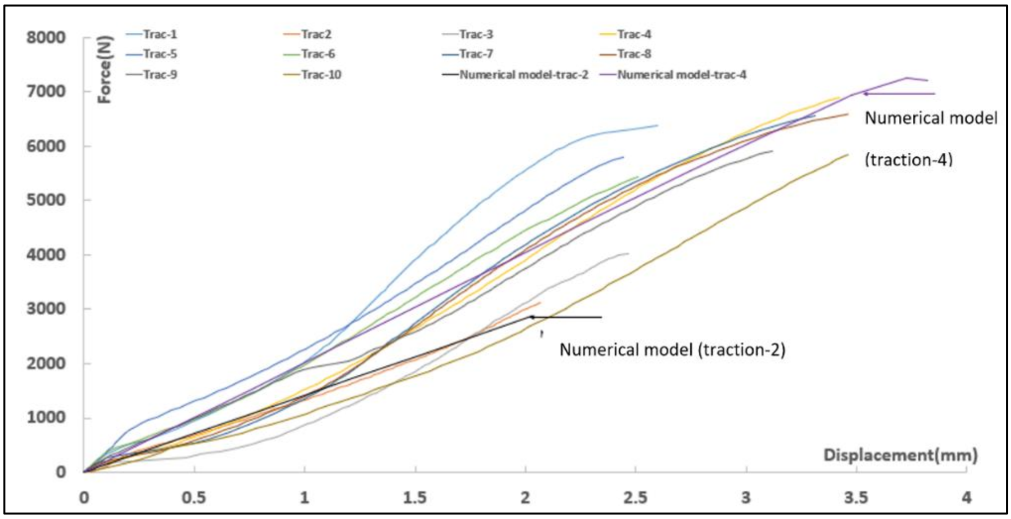

Fig. 13 . Superposition of numerical curves for tensile ytest of complete block(brick-mortar-flat

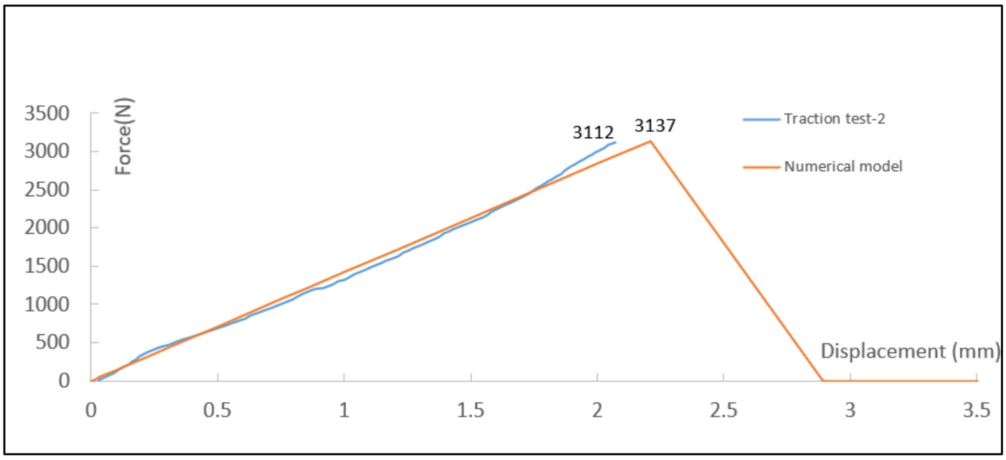

Fig. 14 . Comparison of the tensile test with the numerical model of the complete block(brick-mortar-flat tie) in the case of low forces.

4.2. Parametric analysis: Influence of the variability of the mortar Young modulus value

Additional 3-point bending tests were carried out at the Institut Pascal on mortar prismatic samples (40mm × 40mm × 160 mm) made from the same mix used to make the cavity walls and the small scale connections. The objective was to check the Young modulus value first used in the numerical model developed (based on the literature). It appeared that the mean value found for the Young's modulus is close to the one found in the literature reference : 3504 MPa versus 3779 MPa Table 5., However, an important variability was observed experimentally

Table 5., between testes samples. Therefore a parametric study was conducted to account for the impact of a variability of the mortar Young's modulus value on the behavior of the brick/mortar/tie complex.

Therefore, 3 additional traction tests on brick/mortar/tie connections were modeled by varying the Young modulus value of the mortar to account for its variability determined in experimental tests. The corresponding stress versus strain curves (true values) and damage evolution curves are given in Fig. 15., Fig. 16.

Results presented in the previous subsection were performed using a mortar Young modulus value derived from the literature. The objective of this subsection is to compare this case (referred to as the reference model) with simulated brick/mortar tie connections under traction with the three mortar laws presented in Fig. 16,. The purspose being to assess the sensitivity of the tensile behavior of the brick/mortar/tie connections for different mortar parameters.

Fig. 17, shows the force-elongation curve for the reference model (Young modulus value taken from the literature) and for 3 additional specimens whose mortar law has been modified based on experiments. Table 6, compares the results obtained with the overall calculations.

The mortar model derived from the literature is relatively close to the models derived from testing. Ultimately, the prediction error on maximum force and stiffness is less than 10%.

Table 5. Mortar Young Modulus variability

Function	Young modulus (MPa)	Variability %	Average (MPa)
Test specimen -1	2780	26.44	
Test specimen -2	4579	-21.17	3504
Test specimen -3	3154	15.54	
Reference model	3779

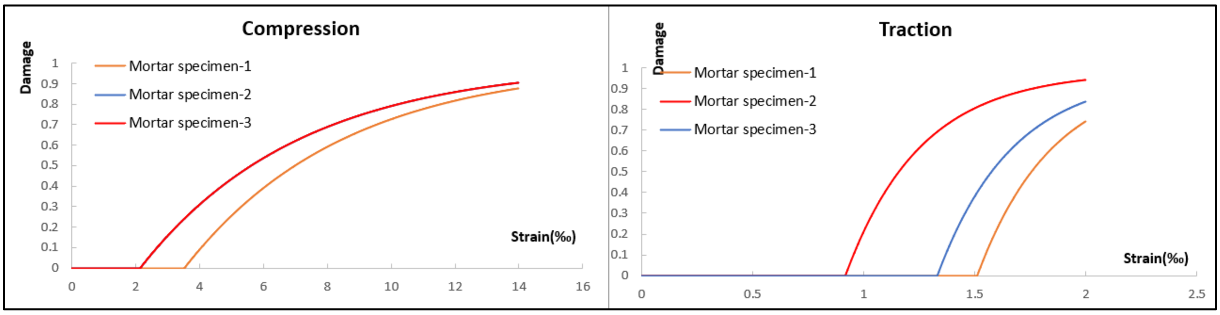

Fig. 16 . Damage evolutions used in the parametric study (to account for the variability of the mortar) : Both in compression and traction

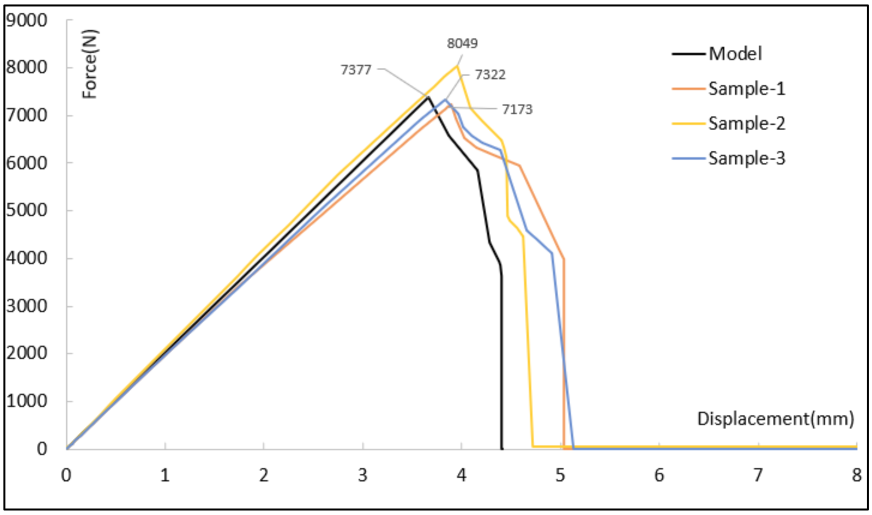

Fig. 17. Traction brick/mortar/tie model with variation of mortar parameters

Table 6. Comparison of the value of the maximum tensile forces and stiffnesses of the three specimens with the reference model

	Force Max(N)	Comparaison with reference model	Stiffnesse (N/mm)	Comparaison with reference model
Test piece-1	7131.94	-3,4%	1873.59	-2.96%
Test piece-2	8049	8,36%	2049.65	6.15%
Test piece-3	7322.45	-0.74%	1921.88	-0.46%
Reference model	7376.83		1930.81	

5. Conclusions

Finite element numerical modeling, developed on Abaqus, has enabled us to realistically represent the mechanical behavior of a flat tie connection system (for timber/brick cavity wall applications). The various components of the system - tie, mortar, brick - were modeled with behavior laws calibrated from experimental tests. Cohesive models were used to simulate the mortar/brick and mortar/tie bounds. Results show a good agreement between simulations and tests.

In particular, the use of cohesive models enabled us to account for failure mechanisms observed at mortar-tie and mortar-brick interfaces. This model has enabled parametric analyses to be carried out, objectifying the sensitivity of tie systems to various variable mortar characteristics. Such parametric study should be extended to account for other sources of variations, such as the presence of a drain breaker and the influence of the rail on the resistance of flat ties and their eccentricities. The developed model could also be used in order to simulate other load case scenarios that were experimentally tested (compression of the brick/mortar tie connection) to account for potential instability scenarios of the tie system (buckling, etc). Other tie types were experimentally tested as part of this project and their behaviour could also be modeled (flat tie with rail, zigzag tie) using the same approach. Models developed for the connection systems (made of brick/mortar and tie) can then be used in order to simulate the behavior of the complete cavity walls that were tested under different load scenarios.

Acknowledgement

Authors would like to thank MECD for the financial support. Many thanks for the Leviat company for providing the ties as well as Briqueterie du Nord and Wienerberger for providing bricks for the project.

Abstract. This study investigates the performance of a building model equipped with a tuned liquid damper through a series of shaking table tests under varying excitation directions. To assess directional effects, the model was rotated in 15-degree increments from 0° to 180°, while the excitation direction remained fixed. Acceleration and displacement time histories were recorded for each orientation to evaluate the damper's effectiveness. The results demonstrate that the TLD effectively reduced both accelerations and displacements of the structure. However, its efficiency declined progressively as the excitation angle increased from 0° to 90°.

Keywords: Different excitation direction; Shake table test; Tuned liquid damper; Vibration control

1. Introduction

Masonry structures are structures that constitute a significant portion of the building stock in our country. Although their construction has decreased in developed cities, their construction continues in rural areas and underdeveloped cities. Masonry structures are damaged due to poor ground conditions, construction activities that are not earthquake resistant, and similar reasons. These types of structures that do not have earthquake safety cause loss of life and property. Masonry structures are generally built by economically weak people in rural areas. The fact that masonry structures are seen as structures that do not require engineering services also has a great effect on the formation of earthquake-resistant building stock in our country. Therefore, earthquake-resistant masonry structure design and construction is of vital importance.

The walls of masonry structures are important structures used both as load-bearing and partition walls. Engineered and manufactured walls contribute to the behavior of the masonry building against earthquake forces. The material properties of the masonry units used contribute to the behavior of the structure. Modeling the structure under various loads and monitoring the behavior of the structure with engineering service are of vital importance.

1.1. Masonry building systems

1.1.1. Unreinforced masonry buildings

These are systems where the carrier systems are formed only with masonry units. Carrier walls are formed using masonry units and binding mortar. In the carrier systems of these systems, reinforcement or materials with high ductility are not used. Since the carrier systems exhibit brittle behavior rather than ductile behavior, they have less earthquake safety or resistance to earthquake effects compared to other systems. They can be made of natural stone, adobe, factory brick and concrete briquettes. It is the most common type of masonry structure in our country.

1.1.2. Reinforced masonry buildings

They are obtained by forming masonry walls with reinforcement. They are formed by knitting vertical and horizontal perforated or grooved brick or briquettes with reinforcement and binding mortar. Unreinforced masonry structures formed only from masonry units exhibit more brittle behavior compared to other systems. Supporting these types of structures with reinforcement allows the structures to exhibit more ductile behavior. Placing reinforcements both in the direction and horizontally provides earthquake resistance to the structure in both directions. These types of structures are not very common in our country.

golden light publishing

2. Code and standards

The first building earthquake regulation was published in Turkey in 1940 after the 1939 Erzincan earthquake. Later, in 1975, the Regulation on Buildings to be Constructed in Disaster Zones was published and entered into force. Since Turkey is an earthquake country and the regulations and standards were insufficient, an earthquake regulation was published again in 1998. In the light of scientific developments, these regulations have been updated and adapted to new techniques. They have been made compatible with international standards and regulations. Before TBEC-2018, many regulations and standards were used for the design of masonry structures in our country. Regulations such as the calculation and construction rules of masonry structures in TS 2510, the 1975 Regulation on Buildings to be Constructed in Disaster Zones, Eurocode-6 and later the 2007 Regulation on Buildings to be Constructed in Earthquake Zones (DBYBHY-2007) were used (Aldemir,2010).

2.1. Masonry building design principles according to TBEC-2018

2.1.1 Number of floors allowed

The number of floors allowed in masonry buildings in the Turkish Building Earthquake Code varies according to the load-bearing systems and earthquake design classes of the buildings (Fig. 1 and 2).

Masonry Building Systems			
Systems with High Ductility Level			
Reinforced Masonry Building	4	2	BYS ≥ 7
Reinforced Concrete Panel Buildings	4	2	BYS ≥ 7
Systems with Limited Ductility Level			
Confined Masonry Building	3	2	BYS = 8
Uneinforced Masonry Building	2.5	1.5	BYS = 8

Fig. 1. Structural System Behavior Coefficient for Building Structural Systems, Excess Strength Coefficient (TBEC,2018)

Building Height Class	Building Height Range Defined According to Building Height Classes and Earthquake Design Classes (m)		
	DTS = 1, 1a, 2, 2a	DTS = 3, 3a	DTS = 4, 4a
BYS = 1	$H_N > 70$	$H_N > 91$	$H_N > 105$
BYS = 2	$56 < H_N \leq 70$	$70 < H_N \leq 91$	$91 < H_N \leq 105$
BYS = 3	$42 < H_N \leq 56$	$56 < H_N \leq 70$	$56 < H_N \leq 91$
BYS = 4	$28 < H_N \leq 42$	$42 < H_N \leq 56$	
BYS = 5	$17.5 < H_N \leq 28$	$28 < H_N \leq 42$

BYS = 7	$7 < H_N \leq 10.5$	$10.5 < H_N \leq 17.5$	
BYS = 8	$H_N \leq 7$	$H_N \leq 10.5$	

Fig. 2. Building Height Classes and Building Height Ranges Defined According to Earthquake Design Classes (TBEC,2018)

2.1.2. Wall height and thickness

Our regulation states that the effective wall thickness and effective height should be determined according to TS EN 1996-1-1 (Eurocode-6) standards. These standards specify the effective thickness to be taken according to whether the wall is single-layered or double-layered; supported or unsupported.

It is desired that the additional height of the wall be determined according to the same standard. It is desired that these walls be formed with elements that increase the rigidity of the wall, such as floors and horizontal joists, and their rigidity be increased. It is mentioned that the door and window openings and support walls in the wall affect the effective heights of the masonry walls.

2.1.3. Materials

According to the regulation, the void ratios of the masonry units are divided into two. Fig. 3 shows the grouping of the masonry units according to their hole ratios. In these voids, the places where the reinforcement will come and the areas to be filled with mortar will be excluded from the brick void ratio, provided that it does not exceed 15% (TBEC,2018).

Masonry unit type	Grup I	Grup II
Brick	$\alpha \leq \%35$	$\%35 < \alpha \leq \%50$
Concrete	$\alpha \leq \%35$	$\%35 < \alpha \leq \%50$

Fig. 2. Grouping of Masonry Units According to Hole Ratios (TBEC,2018)

The characteristic compressive strengths of masonry load-bearing walls, fk, can be learned from the tests to be carried out as well as from the tests to be carried out on the masonry units. The strengths obtained with the two different methods are shown in Fig. 4 of the code.

Unit	Mortar	Mortar Compressive Strength	Masonry Unit Compressive Strength					
			5	10	15	20	25	30
Grup I	General Purpose Mortar	M10-M20	3.4-4.2	5.5-6.8	7.3-9.0	8.9-11.0	10.4-12.9	11.9-14.6
		M2.5-M9	2.2-3.3	3.6-5.3	4.8-7.1	5.9-8.7	6.9-10.1	7.8-11.5
		M1-M2	1.7-2.1	2.8-3.4	3.7-4.5	4.5-5.5	5.2-6.4	5.9-7.3
Grup II ve Cut Stone		M10-M20	2.8-3.4	4.5-5.5	6.0-7.4	7.3-9.0	8.5-10.5	9.7-12.0
		M2.5-M9	1.8-2.7	3.0-4.4	3.9-5.8	4.8-7.1	5.6-8.3	6.4-9.4
		M1-M2	1.4-1.7	2.3-2.8	3.0-3.7	3.7-4.5	4.3-5.3	4.9-6.0
Brick (Grup I)	Thin Layer Mortar		2.9	5.3	7.5	9.6	11.6	13.5
Brick (Grup II)			2.2	3.5	4.7	5.7	6.7	7.6
Concrete (Grup I),			3.1	5.7	8.0	10.2	12.3	14.4
Concrete (Grup II)			2.6	4.6	6.5	8.3	10.0	11.7

Fig. 3. Characteristic Compressive Strength of Masonry Bearing Walls, fk (MPa) (TBEC,2018)

Characteristic shear strength of walls in masonry structures;

$$f_{vk} = f_{vk0} + 0.4\sigma_d \leq 0.10 f_b \tag{1}$$

It is desired to be calculated as follows. The characteristic compressive strength is desired to be selected as the smaller of the total of 40% of the vertical compressive stress calculated under the joint effect of the characteristic shear strength in the absence of axial stress and the vertical loads multiplied by the load coefficients and earthquake loads, or 10% of the standardized average compressive strength of the masonry unit.

In all masonry building systems given in the regulation, the concrete quality in reinforced concrete components is required to be at least C25. In the calculation of material properties of load-bearing walls, if possible, it is required to obtain it by performing experiments, if it is not possible to perform experiments, the elasticity modulus Eduv is requested to be taken empirically as 750fk and in walls made of reinforced panels as 450fk. Wall shear modulus, Gduv, is calculated by taking 40% of the elasticity modulus.

2.1.4. Design of structures for earthquake

Permitted building heights and building height classes in masonry buildings vary according to earthquake design classes. Permitted building heights, load-bearing system behavior coefficient and strength excess coefficient depending on the building load-bearing systems in the regulation are given in Table 3.3 and Table 4.1 in TBEC-2018.

2.1.5. Modeling techniques of masonry wall elements

According to the regulation, it is stated that the structure should be made according to the principles of Section 4 of the earthquake calculation. After the structure is modeled, the analysis of the structure is required to be made under the effects of vertical and horizontal loads. This analysis should be done using the finite element method or the equivalent bar method.

In the finite element method, the structure can be modeled with 3 different methods. These models are detailed micro modeling, simplified micro modeling or macro modeling (Fig. 5). Detailed micro modeling is used as the closest model to reality. In this method, all units that make up the element are modeled in detail. In simplified micro modeling, the model is made by considering the units that make up the element together. In macro modeling, calculations are made by considering the wall as a whole element.

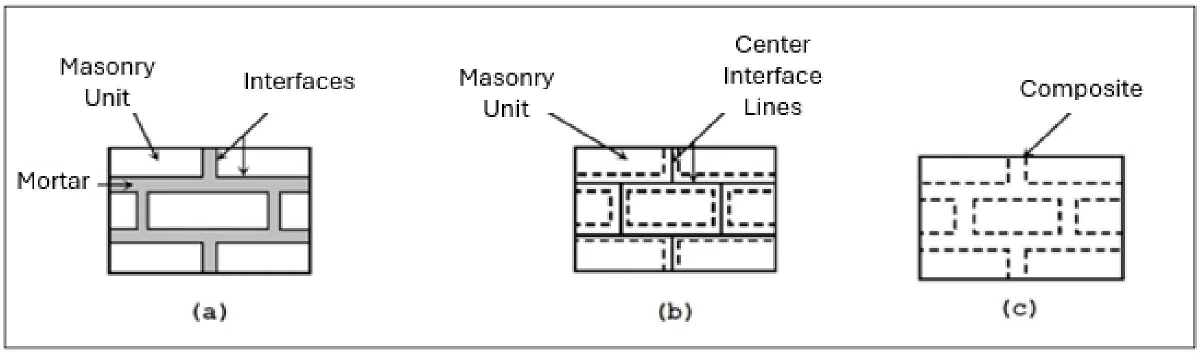

Fig. 5. (a) Detailed micro, (b) Simplified micro, (c) Macro modeling

In the equivalent bar method, the stiffness and elastic properties are applied using the wall's own material properties. The free height of the wall, H, is taken as the distance from the upper floor level to the lower floor level. If there is a joist, the joist lower level is used. Its length is used as the distance between the gaps. The stiffness is calculated with equation (2) assuming that both ends are fixed.

$$k_{duv} = \frac{1}{\left(\frac{H^3}{12E_{duv}I} + \frac{H}{1.2G_{duv}A}\right)} \tag{2}$$

2.1.6. Calculation according to bearing capacity method

According to TBDY-2018, the design force acting on masonry walls under axial load, Ned, is required not to be greater than the vertical load design strength, NRd. Here NRd;

$$N_{Rd} = \lambda A f_d \tag{3}$$

It is calculated by . Here fd is the masonry wall design strength. It is found by dividing the wall characteristic compressive strength by the material strength reduction capacity. The capacity reduction capacity, λ, varies according to the slenderness to slenderness ratio.

Design shear strength for unreinforced masonry walls, VRd;

$$V_{Rd} = f_{vd} t l_e \tag{4}$$

$$V_{Rd} = lt\frac{1.5f_{vd0}}{b}\sqrt{1 + \frac{N_{ed}}{1.5ltf_{vd0}}} \tag{5}$$

It is accepted as the smaller of the two equations calculated with. Here, in the calculation of shear strength, the part of the wall that works under pressure under the effect of bending, lc, is used. There is no calculation related to this length in TBDY-2018.

$$lc = 3\left(\frac{l}{2} - e\right) = 3\left(\frac{l}{2} - \frac{M_{ed}}{N_{ed}}\right) \tag{6}$$

It is calculated with . If the eccentricity is less than l/6, it is taken as l=lc, if it exceeds l/2, it is taken as lc=0. In this case, in-plane overturning occurs.

In order to take the shear reinforcement into account, the horizontal reinforcement must be continuous along the wall. The contribution of the shear reinforcement is VRd2;

$$V_{Rd2} = 0.9A_{sw}f_{yd} \tag{7}$$

$$V_{Rd1+}V_{Rd2} \geq V_{Ed} \tag{8}$$

$$(V_{Ed})/(tl) \leq 2.0MPa \tag{9}$$

Should be. VRd1 is the unreinforced wall design shear strength.

2.1.7. Geometric conditions

The architectural forms of masonry structures must be simple and planned. In masonry buildings consisting of complex wall arrangements, torsional effects are likely to occur under earthquake effects. Therefore, creating T, L, H shaped plans rather than complex plans increases the safety of the structure. In addition, the wall thicknesses and slenderness ratios limited in masonry structures are given in Fig. 6.

Masonry Type	$(t_{ef})_{min}$ *(mm)*	$(h_{ef}/t_{ef})_{max}$
Unreinforced masonry with natural or artifical cut stone	350	9
Unreinforced masonry with other masonry units	240	12
Confined masonry	240	15
Reinforced systems	240	15
Reinforced panel systems	200	15

Fig. 6. Geometric Conditions to be Applied to Masonry Walls Under Shear Force (TBEC,2018)

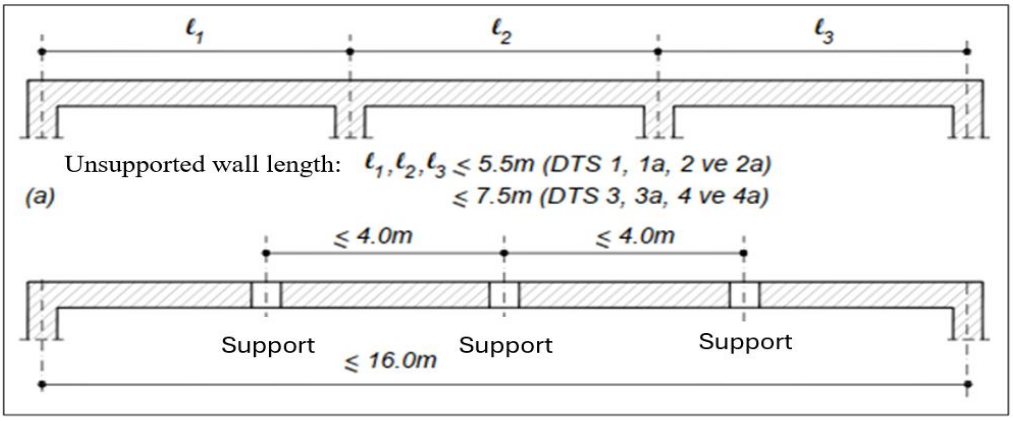

Fig. 7. Maximum Unsupported Length of Walls and Distance Between Vertical Beam (TBEC,2018)

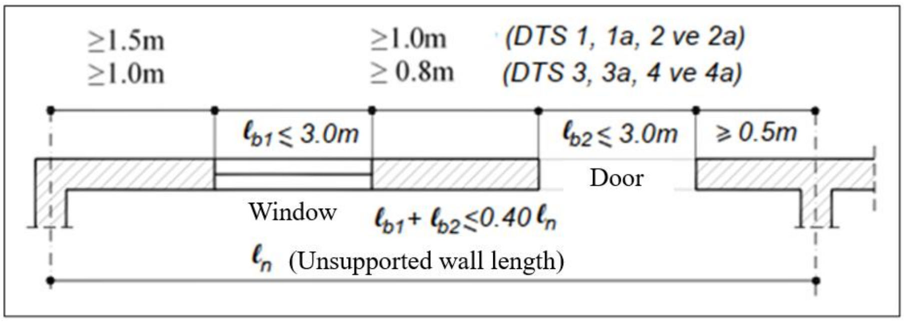

Fig. 8. Permitted Door and Window Openings (TBEC,2018)

3. Studies performed

The floor plan of the masonry building to be used in this study was created as in Fig. 9. These buildings to be used were designed as a lodging structure in Trabzon and Istanbul. These buildings are 2-storey and consist of 2 flats on each floor.

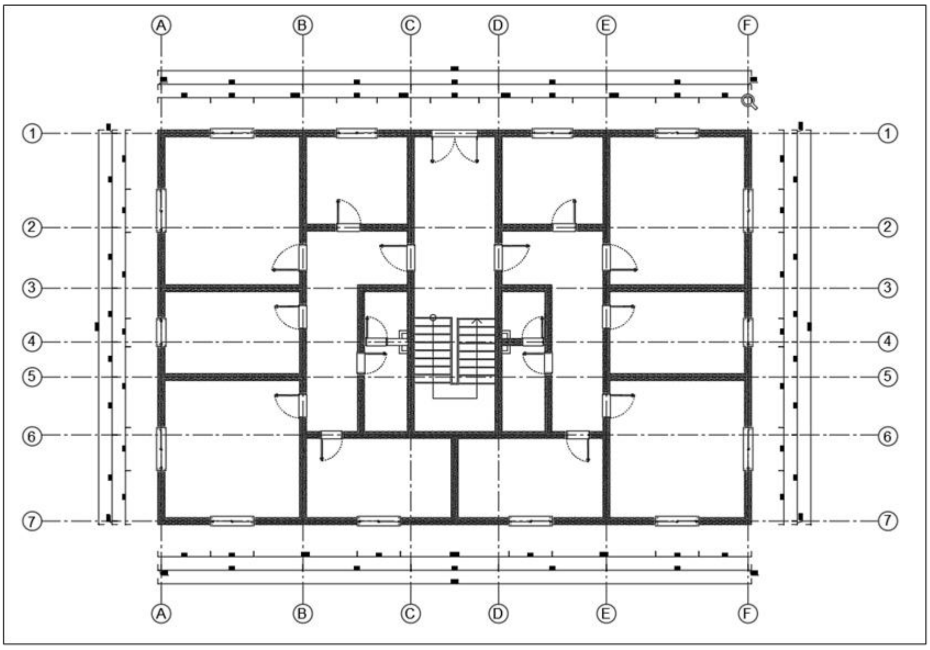

Fig. 9. Masonry Building Floor Plan

The materials to be used in masonry buildings were selected in accordance with the standards and the unit mechanical properties are given in Table 1.

Table 1. Mechanical Properties Of Masonry Building Unit

Definitions	Brick	Concrete
Brick space ratio	<%35	<%35
Group by vacation rate	Grup-1	Grup-1
Brick unit compressive strength (fb)	9 MPa	11 MPa
Mortar compressive strength (fm)	10 MPa	10 MPa
Masonry wall characteristic compressive strength (fk)	5.08 MPa	5.86 MPa
Wall initial shear strength (fvko)	0.3 MPa	0.2 MPa
Modulus of elasticity of walls (E=750*fk)	3810 MPa	4395 MPa
Shear modulus of walls (G=0.40*E)	1524 MPa	1758 MPa
Wall unit specific gravity (γ)	15 kN/m3	18 kN/m3
Masonry wall material coefficient (γ)	2.00	2.00

3.1. Earthquake parameters

In the first calculation, the location of the KTU Civil Engineering Department building in Trabzon was taken into account, and in the second calculation, the location of the YTU Civil Engineering Department building in Istanbul was taken into account. The necessary parameters for the earthquake load calculation taken from the Türkiye Earthquake Hazard Maps Interactive Web Application in these locations are given below (Fig.s 10-12).

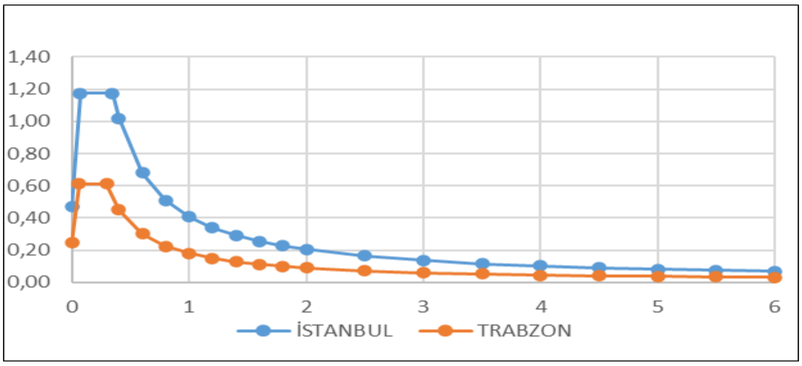

Fig. 10. Horizontal Elastic Design Spectra at Istanbul and Trabzon Locations

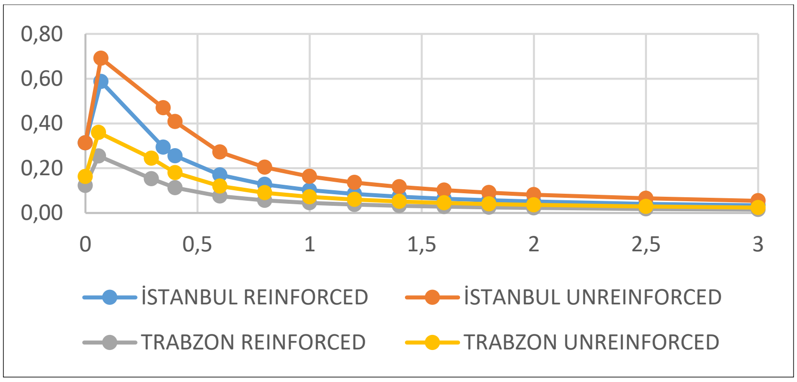

Fig. 11. Reduced Design Acceleration Spectra Used in Calculations

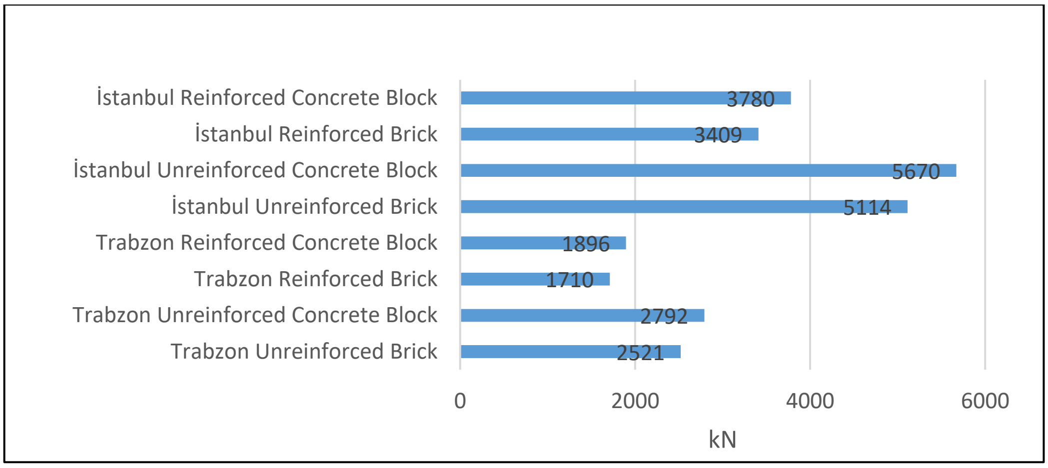

Fig. 12. Earthquake Loads on Buildings Based on Calculations

3.2. Axial capacity control

The axial capacity control of the walls was made according to the envelope function that gives the most unfavorable result of the 1.4G+1.6Q combination and the G+Q+0.2S+Ed(H)+0.3Ed(Z) combination given in the earthquake code. As a result of the calculations, it was determined that the axial capacity of the walls was sufficient (Tables 2 and 3).

DX5	2117.45	255.02	295.07	295.07	OK

3.3. Shear capacity control

The shear capacity control of the walls was calculated by considering the shear force obtained from each of the combinations G+Q+0.2S+Ed(H)+0.3Ed(Z) and the excess strength coefficient D=1.5. In the calculations, lc, specified in TBEC-2018 article 11.4.3, was calculated depending on the ratio (eccentricity) between the length of the wall working under pressure, the in-plane bending moment (M3) acting on the walls and the axial force (P) (Tables 4 and 5). As a result of the calculations, it was determined that the shear capacities of the 1st and 2nd floor walls were sufficient for a thickness of 29 cm.

3.4. Reinforced masonry building reinforcement calculation

In reinforced masonry building design, in accordance with TBEC-2018 article 11.5.7, excessive reinforcements should be formed in masonry walls in a way that they are not less than 0.05% of the gross wall section and not exceed 60 cm intervals. These Extreme reinforcements to be placed should be made inside the Extreme joints or in suitable notches (Tables 6 and 7).

3.5. Bending capacity control

In accordance with TBEC-2018 article 11.5.8, minimum vertical reinforcement was placed on the masonry walls, not less than 0.08% of the wall gross cross-sectional area. While placing the reinforcement, the vertical holes of the masonry wall unit were taken into consideration.

The bending calculations of reinforced masonry walls were made in the CSI Col v10.1 program using material models and vertical reinforcement placed in the sections. As a result of the calculations, it was determined that the bending capacities of all walls with the placed reinforcement were sufficient and that there were no pressure failures in the walls before the reinforcement yielded (Fig. 13).

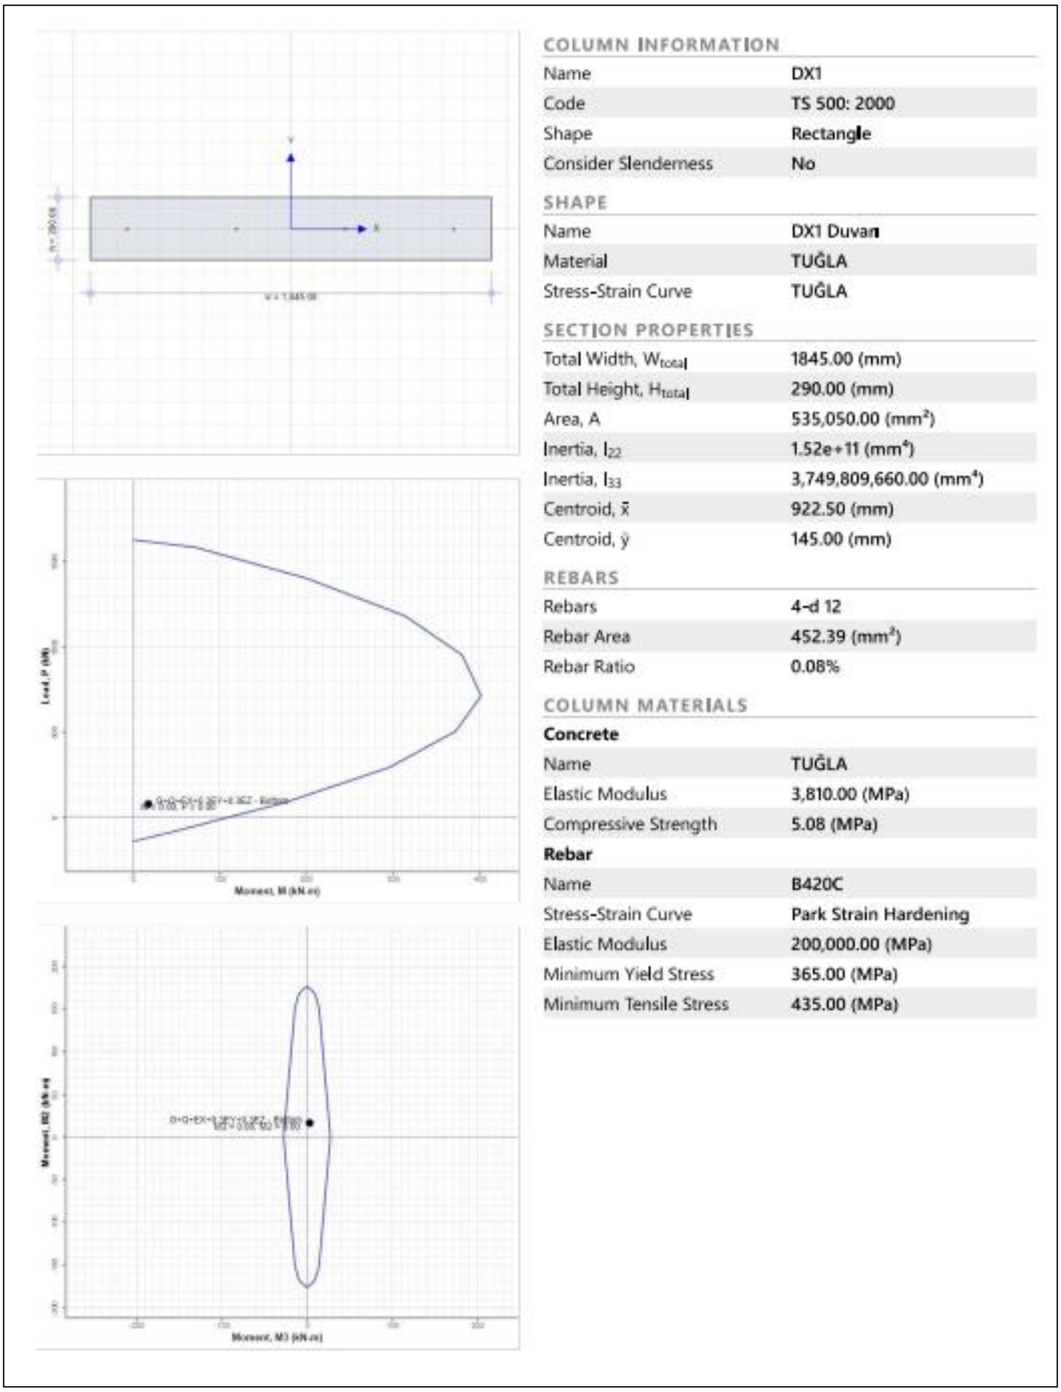

Fig. 13. Bending Capacity Control

4. Conclusions

In the continuation of the study, the Turkish Building Earthquake Code (TBEC-2018) and the codes used before this current code were examined. In addition to the Turkish codes and standards, the Eurocode-6 standard used in the design of masonry structures was also examined. The different types of buildings used in the study were created with the restrictions and standards in the light of these codes. Their designs and controls were made according to the Turkish Building Earthquake Code. These designs and controls were made with the help of various computer programs. ETABS and CSICol applications, which are widely used in building and section analyses, were used in the study.

In the study, buildings with the same architecture but different materials, locations and load-bearing systems were examined and the similarities and differences between them were revealed.

- Firstly, the earthquake parameters and dynamic properties to be used in calculations and designs were examined since they have different locations. In the light of these examinations, the reduced design spectrum acceleration graph obtained from the selected spectra is shown in Fig. 6. Here, it was observed that the acceleration spectra of the Istanbul location data were approximately twice as large as those of the Trabzon location data.

- The effects of the load-bearing system features, i.e. whether the building is unreinforced or reinforced, on the calculation and design of the structure have been examined. The design calculations of masonry buildings with different load-bearing systems in the regulation have been examined and the effects of these differences on the calculation and analysis of the buildings have been examined.
- Of the 8 buildings examined, 4 are made of factory bricks and the other 4 are made of concrete blocks. Material differences make the properties of the buildings different. It was observed that the concrete block building was a heavier building than the factory brick building and this weight was reflected in the base shear forces. The dynamic properties resulting from these material differences were also examined.
- The behavior of the walls under the effect of bending was investigated. Bending controls were performed with the help of auxiliary programs. In accordance with the regulation, it was shown that the reinforcement yielded before the compression failure in the sections. Mutual effect diagrams were created. The capacity ratios of the sections were given.

Abstract. The behavior of progressive collapse in precast post-tensioned concrete frames was investigated through Finite Element Analysis (FEA) using ABAQUS software. The study assessed concrete damage behavior by employing the Concrete Damaged Plasticity (CDP) model available in ABAQUS. This study addressed the finite element analysis of precast concrete frames by making certain assumptions, such as a perfect bond between steel and concrete, and applying the CDP model to define concrete properties. Additionally, for modeling the infill wall, a simplified micro-modeling approach was used. A simplified numerical model was developed, showing strong consistency with both experimental results and detailed simulations. This approach offers a significant reduction in computational time while maintaining an acceptable level of accuracy.

Keywords: Self-centering precast concrete frames; Progressive collapse; Concrete damaged plasticity; Numerical simulation; Micro-modeling

1. Introduction

Public and private buildings of all types are vulnerable to extreme events such as hurricanes, tsunamis, earthquakes, explosions, vehicle impacts, fires, human errors, or even terrorist attacks. These events often result in localized structural damage, which can trigger a full collapse. This phenomenon is known as progressive collapse, a process where localized damage initiates a chain reaction of failures, ultimately leading to the collapse of the entire building or a significant portion of it. Progressive collapses are invariably associated with severe personal and material losses (Ellingwood 2006). The progressive collapse is defined in ASCE (2017) as the spread of an initial local failure from element to element, eventually resulting in the collapse of an entire structure or disproportionately large part of it. The key characteristic here is that the total damage at the end is not proportional to the original cause (Engineers 2017). It was coined following the collapse of Ronan Point tower in 1968 (Pearson and Delatte 2005). The catastrophe was sparked by a gas explosion on the 18th floor of a corner unit, which resulted in the rapid collapse of an external bearing wall that served as the primary structural component for the above flat. Research effort further intensified following the collapse of Alfred P. Murrah building in Oklahoma (1995) (Corley, Sr et al. 1998) due to explosion by a terrorist attack, and the collapse of the World Trade Center Towers (Bažant and Zhou, 2001). Shan and Li (2022) study uses finite element analysis to examine how infill walls affect the progressive collapse resistance of post-tensioned (PT) RC frames under column removal. Results show that while infill walls improve strength, they reduce re-centering capacity and alter failure modes. Factors like tendon arrangement, PT force, and masonry properties significantly influence performance. A design method is proposed for predicting collapse resistance. Meng et. al (2021) analyzes six SF-SPSW substructures under different column failure scenarios to assess progressive collapse resistance. Using a simplified method with Cartesian connectors, it identifies key resistance mechanisms and shows that collapse can be prevented post-failure. Stiffened triangular steel plates enhance capacity, with their design parameters examined. Sasani (2008) evaluates the Hotel San Diego's response to the removal of two exterior columns. Using Finite and Applied Element Methods, it finds the structure resisted collapse with minimal displacement (6.4 mm). Load redistribution occurred mainly through 3D Vierendeel action aided by infill walls. Brittle failure modes and the impact of added loads and wall absence are also analyzed. Li et. al (2016) examines how infill walls affect the progressive collapse of RC frames. Tests on a scaled frame show that infill walls act as compressive struts, increasing strength and stiffness but reducing beam ductility and altering failure modes. Finite element analysis confirms key influencing factors. Brodsky and Yankelevsky (2017) investigates how masonry infill walls help prevent progressive collapse

[*] Corresponding author, E-mail: samkh5537@gmail.com

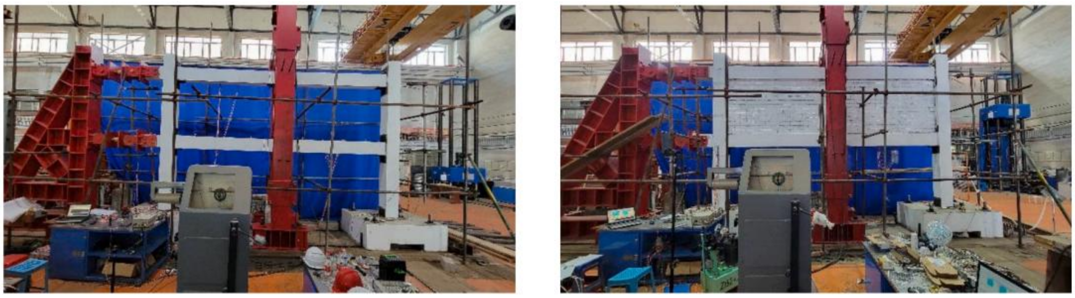
https://doi.org/10.31462/icearc2025_ce_sme_912

in RC frames during extreme events. Lab tests on half-scale infilled frames without a column show that infill walls significantly boost vertical load resistance—by 280% on average. Masonry type, shear connectors, and improved reinforcement details strongly influence performance and failure modes. Tsai and Huangstudy (2009) investigate models brick-infill panels as compression struts to assess their impact on progressive collapse in an earthquake-resistant RC building. Finite element analysis shows that infill location affects performance—panels near shorter spans reduce beam-end DCR, but may increase axial tension in beams spanning the removed column.

This study aims to contribute a modeling framework for re-centering precast frames, both with and without connections, by introducing several simplifying assumptions to reduce computational demands. The proposed approach is intended to save time and cost when analyzing such systems under column removal scenarios.

2. Proposed numerical model

The modeled frame is based on the experiment conducted by Li et al. (2023). A six-story self-centering precast concrete (PC) frame building was designed based on Chinese codes to study its resistance to progressive collapse. A scaled-down two-story model was tested with three frame types (SCBF, SCIF, SCIF-A), differing mainly in beam span. PC components were preassembled with unbonded prestressed strands and protected by steel jackets and plates. Infill walls used AAC blocks, adjusted to fit around steel joints and bonded with mortar. Two specimens were modeled Specimen SCBF and Specimen SCIF were the two specimens have the same dimensions but Specimen SCBF has no infill wall, while Specimen SCIF consider the effect of infill wall see Fig. 1.



(a) (b)

Fig. 1. Specimens adopted in this study (a) SCBF (b) SCIF (Li, Wang et al. 2023)

The system consists of five main components: precast concrete, reinforcing steel, prestressing strands, steel angles, and bolts.

Fig. 2 show the detailed model of spaciement SCBF. The dimensions of the steel angles are shown in Fig. 4. Two types of steel angles were used: one for connecting the beam to the column, and another for connecting the column to the foundation. The clear concrete cover of all PC members was 20 mm. The infill walls were composed of autoclaved aerated concrete (AAC) blocks with dimension of 285 mm × 90 mm × 90 mm. Table 1 summarize the Properties of modeled specimens. Fig. 6. show dimensions and reinforcement details of specimen SCIF.

Table 1. Properties of test specimens

Test ID	Beam			Column			Infill wall
	Section size (mm)	Net span (mm)	Diameter of strands (mm)	Section size (mm)	Net span (mm)	Diameter of strands (mm)	
SCBF	300×200	2400	2×15.2	300×200	3750	2×15.2	None
SCIF	300×200	2400	2×15.2	300×200	3750	2×15.2	Infilled

All the materials were clearly specified in the experiment) Li et al. (2023). As indicated in the test, the effective prestress of the steel strands used to connect beams to columns, as well as columns to foundations, was $0.65f_{ptk}$ and $0.7f_{ptk}$, respectively. Here, f_{ptk} represents the ultimate strength of the steel strands.

For modeling a detailed configuration (Fig. 3), it is important to account for the interaction among various elements. This can only be achieved by using 3D solid parts and introducing holes in the column and beam elements, as shown in (a) (b)

Fig. 6(a). A frictionless interaction was assumed between the concrete elements (beams and columns) and the strands, as illustrated in (a) (b)

Fig. 6(b). Regarding friction coefficients, a complete tie was used to represent the interaction between bolts and concrete, and a coefficient of 0.75 was adopted for the friction between concrete elements, determined through a sensitivity test.

However, creating a detailed model with numerous small holes requires a finer mesh, which significantly increases computational time. Since accurate analysis depends on mesh refinement, mesh size becomes a critical factor. To address this, simplifications were introduced to reduce computational time. Two models were proposed to streamline the analysis:

The first model included the fixation of the footing without modeling its detailed geometry. Since the experiment did not indicate any separation between the steel components and the bolts, the bolts were omitted for simplification.

The second, more simplified model represented the strand as a wire, with the assumption that the interaction between the strand and concrete was fully embedded. While prestress was included in this model, it assumes the strand is bonded to the concrete, thereby eliminating the re-centering effect. However, this system has proven sufficiently accurate due to the symmetry in the frame's loads and dimensions.

This aforementioned modification had a significant impact on mesh sizing (see Fig. 7). Larger mesh sizes contribute to improved time step stability, thereby reducing computational time. Table 2 presents the computational parameters for the different modeling techniques. For additional simplification, a complete tie between the concrete elements was adopted, as no splitting between them was observed. Because of the geometry complexity of the detailed model an optimazied tetrahedral mesh was employed resulting in a 5mm mesh, in contrast to the other two models where a hexahedral mesh utilized.

3. Concrete constitutive model

Based on the experimental data, the compressive strength of the precast concrete was reported as 32.8 MPa. However, the test did not provide the necessary Concrete Damage Plasticity (CDP) parameters. Therefore, the Kent and Park parabolic constitutive model (see Fig. 5) was adopted to estimate the damage parameters under both compression and tension, including crack and inelastic strain values (Hafezolghorani, Hejazi et al. 2017). All the derived parameters are summarized in Table 3. Typically, the uniaxial compressive behavior of concrete can be characterized through experimental testing or by employing well-established constitutive models, such as those proposed by Kent and Park (1971). This model assumes a simplified parabolic curve and sets the ultimate strain consistently at 0.002 for ease of calculations Park and Paulay (1991).

Table 2. Computational parameters for the different modeling techniques

Model technic	Minimum mesh size	Stable Time (s)	Approximate Computational Time by 12 cores for 40s analysis
Detailed Model	5 mm	1.24 e-8	750 hours
Simplified unbonded Model	10 mm	9.99 e-7	120 hours
Simplified bonded Model	50 mm	1.4 e-4	40 hours

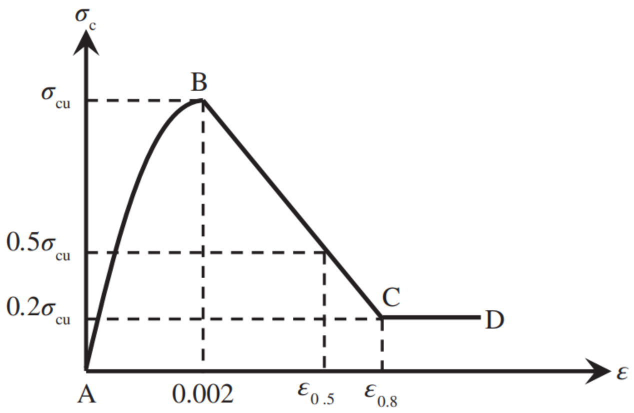

Fig. 8. Kent and Park parabolic constitutive model (Kent and Park 1971)

CDP parameters were adopted according to Mahdi (2023)'s study uses Abaqus to analyze how five CDP parameters affect UHPC beam behavior. The parameters used in the analysis are presented in Table 3.

4. Infill wall material modeling

In the SCIF specimen experiment, autoclaved aerated concrete (AAC) blocks and mortar with relatively low strength were used. A simplified micro-modeling approach (see Fig. 9) was employed to represent the material behavior at the microstructural level (Abdulla, Cunningham et al. 2017). This technique captures the essential mechanical characteristics of the materials without the computational cost of modeling each individual component in high detail. To accurately simulate the behavior of the infill wall under compression, it is necessary to determine specific mechanical properties. Given that the blocks are composed of AAC, they are well-suited for simulation using the Concrete Damage Plasticity (CDP) model.

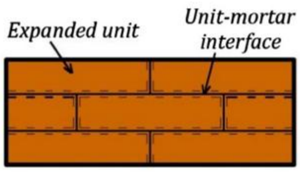

Fig. 9. Simplified micro-model (Lourenço 1997)

4.1. Estimation of interface cohesive parameters

Assuming that the contact stress is distributed uniformly on both the (AAC) blocks and mortar, the equivalent stiffness constants KN and KS are expressed as a function of the elastic and shear moduli of mortar and (AAC) blocks as shown in Eq. (1), and (2) respectively (Lourenço 1997).

$$K_N = \frac{E_b\, E_m}{h_m(E_b - E_m)} \tag{1}$$

$$K_S = \frac{G_b\, G_m}{h_m(G_b - G_m)} \tag{2}$$

Here, h_m represents the mortar thickness, while E_b, G_b, E_m, and G_m denote the elastic and shear moduli of (AAC) blocks and mortar, respectively. The shear stiffness, K_S, is approximately 0.43 times the normal stiffness, K_N, specified as $K_S = 0.43K_N$. This relationship is established through $G_{b,m} = E_{b,m}/2(1 + \nu)$, where ν represents the Poisson's ratios of both (AAC) blocks and mortar, typically assumed to be 0.16. The suggested relationship between the elastic moduli of (AAC) blocks and mortar and their corresponding strength is shown in Eq. (3).

$$E_b = 4467 f_1^{0.22}; \quad E_m = 1057 \tag{3}$$

Where f_1 and f_2 represent the average compressive strengths of the brick and mortar, respectively. According to the experimental results, the average compressive strength of the AAC block and mortar was measured to be 3.96 MPa and 3.44 MPa, respectively. When the compressive strengths of the brick and mortar are nearly equal or very close in value, it may lead to unrealistic estimations of the contact stiffness K_N. To address this issue, the value of the interface stiffness is adjusted as described in Eq. (4).

$$K_N = min\left(\frac{E_b\, E_m}{h_m|E_b - E_m|}, \frac{E_m}{0.5 \times h_m}\right); \qquad K_S = 0.43K_N \tag{4}$$

It indicates that the tensile and shear strength are only related to the strength of mortar, and the shear strength is slightly smaller than the tensile strength. Previous research (Karimi Ghaleh Jough and Golhashem 2020) recommended defining the mean shear strength in finite element (FE) analysis as 1.6 or 1.4 times the mean axial tensile strength i.e., $f_{v,m} = 1.6(\text{or}1.4) \times f_{t,m}$. At present, Eq. (5) is used to determine the peak tensile and shear stresses (Zhou, 2019).

$$T = 0.141\sqrt{f_2}; \qquad S = 2 \times 0.125\sqrt{f_2} \tag{5}$$

All parameters were calculated and summarized in Table 4.

Table 4. Parameters of cohesive contact

Eb (MPa)	Em (MPa)	KS (MPa/ mm)	KN (MPa/ mm)	T (MPa)	S (MPa)

4.2. Calibration of Mode I and Mode II ultimate fracture energy release rates of the interface
Determining Mode I and Mode II ultimate fracture energy release rates at an interface, i.e., G_{IC} and G_{IIC} typically involves a combination of experimental testing and numerical analysis. It is important to highlight that a definitive and standardized approach for determining fracture energy has yet to be established. Nonetheless, experimental findings consistently demonstrate that the ultimate fracture energy release rate tends to increase with the enhancement of mortar strength (Van der Pluijm 1999).

Determination methods are calibrated and validated using tension and compression-shear tests on brick-mortar-brick assemblies by (Van der Pluijm 1992), Van der Pluijm (1999). A finite element (FE) model with a 5 mm mesh size was developed. Interface stiffness (K_N and K_S) were computed from existing equations, while peak tensile and shear stresses were derived from test data (Van der Pluijm 1992, Van der Pluijm 1999). G_{IC} and G_{IIC} were then estimated by trial and error. The static and dynamic friction coefficients were taken as 0.7 and 0.6, respectively, following Chinese Code for Design of Masonry Structures (GB 50003- 2011). These parameters are essential for characterizing the fracture behavior of materials and interfaces.

5. Results and comparison

The simplified unbonded model was implemented, and its results showed strong agreement with both the experimental data and the detailed numerical simulations reported by Wang, Li et al. (2023). This was evident in the comparison of the vertical displacement-vertical force diagram for the SCBF and SCIF specimens (Fig. 11). It observed that the initial stiffness predicted by the FE models was slightly higher in some parts and lower in other parts than that obtained from the experimental results. In the case of specimen SCIF, a sudden reduction in load-bearing capacity was previously noted, primarily due to a transverse crack that developed in the left infill wall. This behavior is likely attributed to a minor installation imperfection, which may have caused slight out-of-plane movement of the central column during testing. Such physical irregularities, however, are not represented in the finite element (FE) model which also agreed with Wang, Li et al. (2023)'s simulation. As a result, the FE simulation of specimen SCIF did not exhibit any notable drop in structural resistance. The inclusion of the infill wall significantly enhanced the structural strength of the SCIF specimen, increasing its load-bearing capacity by approximately 90 kN. Additionally, the presence of the wall effectively prevented excessive vertical displacement, contributing to the overall stability of the structure. Moreover, the wall played a crucial role in extending the capacity of the compression arch action. This is evidenced by the sustained vertical force throughout the loading process, in contrast to the SCIF specimen without the wall, which exhibited a drop in vertical force around a displacement of 100 cm, which is an indicator of concrete cracking.

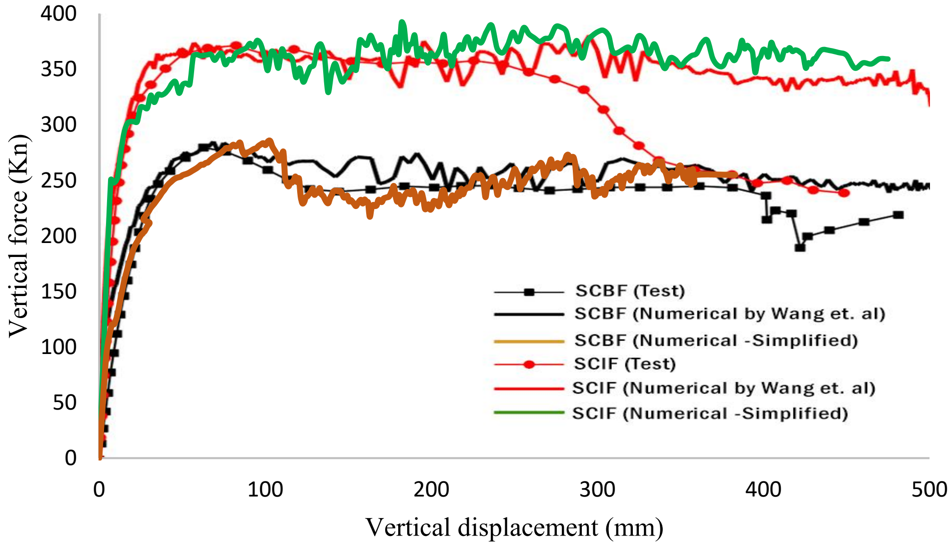

Fig. 11. Vertical applied force versus vertical displacement curves

Also compression damage in concrete compared with that in the experiment for SCBF Specimen Fig. 12 as well as for SCIF Specimen Fig. 13. which shows the final failure mode of the system.

Comparison of horizontal displacements at the exterior join of the right-hand column as illustrated in Fig. 14. As shown in

Fig. 14 the finite element (FE) simulations captured the overall deformation trends observed in both the experimental measurements and the detailed analysis by previous studies. Nonetheless, during the advanced deformation stage, the FE models predicted more pronounced inward movement than the physical tests. This discrepancy is likely due to the omission of strand re-centering effects in the simplified simulation framework.

6. Conclusions

This study explores a simplified unbonded finite element (FE) modeling approach for simulating the behavior of re-centering precast concrete frames. Aimed at balancing computational efficiency with modeling accuracy, the approach demonstrates strong agreement with both experimental data and detailed numerical analyses. Such simplified models show promise for early-stage structural design and assessment, particularly where computational resources are limited. However, its applicability to non-symmetric geometries and dynamic conditions requires further refinement. The study emphasizes the importance of cohesive interface modeling and realistic damage representation in enhancing the reliability of simplified structural simulations. This study conclude that:

- The inclusion of a structural wall significantly enhances the overall stiffness and load-bearing strength of the frame when compared to a bare frame configuration. This improvement is particularly noticeable under vertical loading conditions, where the wall provides additional resistance to deformation, thereby increasing the structural integrity and stability of the entire system. The wall acts as a crucial component that not only distributes the applied loads more efficiently but also restrains excessive displacements, contributing to better performance under column removal scenario.
- In the case of a symmetric structural system, the observed performance results demonstrate that there is little to no significant difference between the behavior of vertically bonded strands and unbonded strands. This suggests that the inherent symmetry of the structure leads to a uniform distribution of stresses and strains, which in turn mitigates any potential disparities in load transfer mechanisms between different types of vertical strand connections. As a result, both bonded and unbonded vertical strands perform comparably in terms of contributing to the overall structural capacity and deformation characteristics of the system.
- When comparing the structural behavior of a bare frame to that of a frame integrated with a wall element, it becomes evident that the latter configuration possesses a substantially higher capacity to form and sustain compression arches. This increased compression arch capacity is largely attributed to the added confinement and load path continuity provided by the wall, which facilitates more effective development of arching action within the frame. Consequently, the frame with the wall can resist higher compressive forces, reduce shear demand on beam-column joints, and improve the energy dissipation capabilities of the system under extreme loading events.

Comparative analysis of optimization algorithms for vibration-based damage detection in laminated composite beams

Sebahat Şimşek*[1], Volkan Kahya[1]

[1] Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye

Abstract. The increasing application of laminated composite beams as structural load-bearing elements necessitates the understanding of the complex damage mechanisms of such materials and the development of reliable and easy-to-apply methods for timely damage detection. The use of damage detection methods based on vibration data together with robust computational algorithms in such materials appears to be a very good option due to its ease of application. Recent research in this field has accelerated and garnered significant industrial and scientific interest worldwide. However, the practical application of optimization methods in vibration-based damage detection for composites remains limited.In this study, the damage detection problem is solved by optimization based finite element model updating. A general anisotropic composite beam under various damage scenarios is considered. A new objective function based on vibration characteristics is used in the solution. The damage detection results using four different optimization algorithms (HSA, GA, TLBO, PSO) are presented comparatively.

Keywords: Laminated composite beam, Finite element method, Free vibration, Damage detection, Optimization

1. Introduction

Composite materials have been attractive in industrial and engineering applications due to their superior characteristics such as high strength-to-weight ratio, better thermal properties, corrosion resistance, etc. However, they may possess damages either in production or during their service lives. The damages may be in the form of matrix cracking or delamination, which are not generally visible, and may cause failure (Ghobadi, 2017). The visual inspection method or experimental non-destructive methods such as acoustic or ultrasonic methods, magnetic field methods, radiographs, Eddy-current methods, or thermal field methods require the damage is on or near the surface of the structure. They cannot detect internal or hidden damages like matrix cracking and delamination, which are commonly encountered damage types in composite materials (Rao et al., 2015).

Health monitoring and damage detection in engineering structures are currently one of the most interesting research topics and there has been a lot of research in which new methodologies have been developed. Among them, vibration-based damage detection methods are of interest because they are efficient, easy to implement, and cost-effective. Natural frequencies, mode shapes, modal curvature, modal flexibility, frequency response function, and modal strain energy are commonly used damage identification indicators since they will drastically change due to the presence of damage (Avci et al., 2021; Chang et al., 2003; Das et al., 2016; Doebling et al., 1996, 1998; Sinou, 2009).

Finite element (FE) model updating is one of the commonly used approaches in structural damage detection based on vibration data. One way to solve the damage detection problem is to assume it as an unconstraint optimization problem in which an objective function based on vibration characteristics from the actual structure and FE model must be minimized or maximized. Metaheuristic-based algorithms are powerful tools to solve such types of optimization problems. Since they are population-based optimization methods, they can solve the problems by avoiding the local minima trap (Gomes et al., 2018). Regarding the issue of damage detection in laminated composites, there are different kinds of metaheuristic-based optimization algorithms available in the literature. Examples are Genetic Algorithm (GA) (Gomes et al., 2018; He & Hwang, 2007; Pan et al., 2019) and its hybrids with other metaheuristics (Gomes et al., 2019; Tran-Ngoc et al., 2021; Vosoughi & Gerist, 2014), Particle Swarm Optimization (PSO) and its improved variants (Hadi, 2016; Jebieshia et al., 2020; Masoumi et al., 2018; Rao et al., 2015), Differential Evolution Algorithm (DE) (Dinh-Cong et al., 2017; Dinh-Cong et al., 2017; Vo-Duy et al., 2016; Vo-Duy et al., 2016), Cuckoo Search Algorithm (CS) (Khatir et al., 2018), Sunflower Optimization (SFO) (Gomes et al., 2019; Gomes & Giovani, 2020), Jaya Algorithm (Dinh-Cong et al., 2018),

Lichtenberg Optimization (Pereira et al., 2021), Experience-Based Learning Algorithm (EBL) (Zheng et al., 2020), Lightning Attachment Procedure Optimization (LAPO) (Dinh-Cong et al., 2021) and so on. In these research works, a single- or multi-objective optimization process was used with single-, two- or multi-stage-based damage detection. The use of computational and intelligent techniques for structural health monitoring (SHM) and damage detection with an emphasis on composite materials was discussed in detail by (Gomes et al., 2018).

This study proposes a robust methodology for damage detection in generally laminated composite beams by utilizing optimization-based finite element model updating. The beam is modeled with a thirteen-degrees-of-freedom finite element formulation that can account for extension-bending, bending-torsion, and extension-torsion couplings, as well as Poisson's effect. To address the practical limitation of incomplete modal data, the Guyan reduction technique is applied. The damage detection problem is formulated as an unconstrained optimization task, and the performance of four different optimization algorithms—Harmony Search Algorithm (HSA), Genetic Algorithm (GA), Teaching–Learning-Based Optimization (TLBO), and Particle Swarm Optimization (PSO)—is evaluated comparatively. A parametric study is conducted on anisotropic laminated composite beams with cantilever and clamped boundary conditions under three predefined damage scenarios. The investigation is carried out with and without the inclusion of measurement noise to assess the accuracy and robustness of each method.

2. Theoretical background

2.1. Finite element model

For finite element simulations of the laminated composite beams with general lay-ups, the thirteen-DOFs beam element shown in Fig. 1 is used. This element was derived by the authors previously and applied to various problems of anisotropic composite beams (Kahya et al., 2021, 2022, 2019a, b). The main advantage of the element is being able to capture the bending-extension, bending-torsion, and extension-torsion couplings arising from material anisotropy. Here, a brief formulation of the model is given for the sake of completeness. The detailed formulation can be found in (Kahya et al., 2019a, b).

According to the first-order shear deformation theory (FSDT), the displacement field for an orthotropic lamina is expressed by

$$\begin{aligned} u(x,z,t) &= u_0(x,t) + z\theta(x,t), \\ v(x,z,t) &= z\psi(x,t), \\ w(x,z,t) &= w_0(x,t) \end{aligned} \tag{1}$$

where u, v, and w denote the displacement components in x-, y-, and z- directions, respectively. u_0 and w_0 are the extension and deflection at $z = 0$, θ and ψ are the rotations of the normal to the midplane about the y- and x-axis, respectively. t denotes time.

Assuming the followings for the unknown field variables

$$\begin{aligned} u_0 &= \sum_{i=1}^{3} \Omega_i(x)\, u_i(t), \quad w_0 = \sum_{i=1}^{4} \Psi_i(x)\, w_i(t), \\ \theta &= \sum_{i=1}^{3} \Omega_i(x)\, \theta_i(t), \quad \psi = \sum_{i=1}^{3} \Omega_i(x)\, \psi_i(t) \end{aligned} \tag{2}$$

where $\Omega(x)$ and $\Psi(x)$ are the second and third-order Lagrange polynomials, respectively, and using Lagrange's principle, the equation of motion can be obtained as

$$\mathbf{M}_e \ddot{\mathbf{u}}_e + \mathbf{K}_e \mathbf{u}_e = \mathbf{0} \tag{3}$$

where $\mathbf{M}_e$ and $\mathbf{K}_e$ are, respectively, the elemental mass and stiffness matrices, $\mathbf{u}_e$ and $\ddot{\mathbf{u}}_e$ are the nodal displacement and acceleration vectors, respectively.

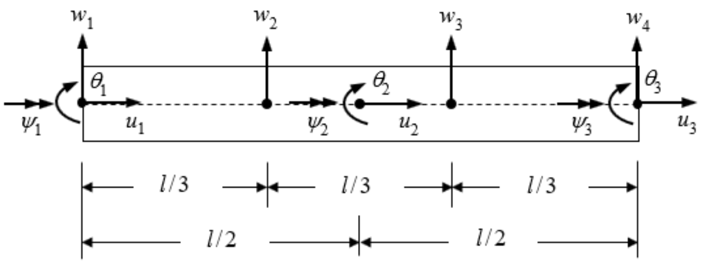

Fig. 1 Thirteen-DOF beam element

A stiffness loss parameter (or damage index) α_e ranging from zero to one is employed to simply assign damage to any element of the structure. This is a frequently preferred way by many researchers in problems related to damage detection, e.g., (Casciati, 2008; Das & Dhang, 2022; Dinh-Cong et al., 2018; Pereira et al., 2021; Ručevskis et al., 2009; Vo-Duy et al., 2016). Note that the elemental mass matrix is assumed to be unchanged due to damage. Thus, for the *e*th damaged element, the elemental stiffness matrix become

$$\mathbf{K}_e^D = (1-\alpha_e)\mathbf{K}_e^U \quad (0 \le \alpha_e \le 1) \tag{4}$$

where the superscripts D and U denote damaged and undamaged states, respectively. The value of stiffness loss parameter one represents full damage, and zero value indicates no damage to the corresponding member.

Based on the above-given assumption for the damage modelling, the global mass and stiffness matrices of the structure can be formed in $\mathbf{M} = \Sigma \mathbf{M}_e^U$ and $\mathbf{K} = \Sigma(1-\alpha_e)\mathbf{K}_e^U$, respectively, by the usual way of FE methodology to constitute the following:

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{K}\mathbf{U} = \mathbf{0} \tag{5}$$

where **M** and **K** denote the global mass and stiffness matrices, respectively, and the vector **U** includes the global unknowns. Assuming the solution of Eq. (5) as in the form $\mathbf{U} = \mathbf{\Phi} e^{i\omega t}$ where $i = \sqrt{-1}$ and using it into Eq. (5), the following standard eigenvalue problem is obtained:

$$(\mathbf{K} - \omega^2 \mathbf{M})\mathbf{\Phi} = \mathbf{0} \tag{6}$$

where ω denotes the natural frequency, $\mathbf{\Phi}$ is the corresponding mode shape vector. The non-trivial solution of Eq. (6) will result in the natural frequencies (eigenvalues). Then, the corresponding eigenvectors (mode shapes) can be obtained by the back-substitution.

2.2. Guyan condensation

FE modeling of a structure produces many DOFs that result in the system matrices being comparatively large. However, in an experimental measurement, the vibration data can be extracted by considering only a limited number of DOFs. To compare the vibration data of a large-scale model with that of the measurement for damage detection and structural health monitoring, the full system FE matrices can be reduced by a model-order reduction method. Here, the Guyan method (Guyan, 1965) is preferred because it is the traditional model reduction technique implemented in most commercial finite element analysis software.

Guyan or static condensation uses the stiffness equation (Marinone et al., 2018) as

$$\mathbf{K}_n \mathbf{X}_n = \mathbf{F}_n \tag{7}$$

where $\mathbf{K}_n$ is the stiffness matrix, $\mathbf{X}_n$ is the displacement response vector, and $\mathbf{F}_n$ is the force vector. Eq. (7) can be partitioned into

$$\begin{bmatrix} \mathbf{K}_{aa} & \mathbf{K}_{ad} \\ \mathbf{K}_{da} & \mathbf{K}_{dd} \end{bmatrix} \begin{Bmatrix} \mathbf{X}_a \\ \mathbf{X}_d \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_a \\ \mathbf{F}_d \end{Bmatrix} \tag{8}$$

where the subscripts a and d denote the active and deleted DOFs, respectively. Assuming the slave force vector $\mathbf{F}_d$ is zero, the second equation of Eq. (8) will result

$$\mathbf{X}_d = -\mathbf{K}_{dd}^{-1}\mathbf{K}_{da}\mathbf{X}_a \tag{9}$$

which gives the following coordinate transformation relation:

$$\mathbf{X}_n = \begin{Bmatrix} \mathbf{X}_a \\ \mathbf{X}_d \end{Bmatrix} = \begin{Bmatrix} \mathbf{I} \\ -\mathbf{K}_{dd}^{-1}\mathbf{K}_{da} \end{Bmatrix} \mathbf{X}_a = \mathbf{T}_G \mathbf{X}_a \tag{10}$$

where **I** is the identity matrix. Using the transformation matrix into the general energy balance formula yields the reduced stiffness and mass matrices as follows (Guyan, 1965; Marinone et al., 2018):

$$\mathbf{K}_a = \mathbf{T}_G^T \mathbf{K}_n \mathbf{T}_G, \quad \mathbf{M}_a = \mathbf{T}_G^T \mathbf{M}_n \mathbf{T}_G \tag{11}$$

where

$$\mathbf{K}_a = \mathbf{K}_{aa} - \mathbf{K}_{ad}\mathbf{K}_{dd}^{-1}\mathbf{K}_{da} \tag{12}$$

$$\mathbf{M}_a = \mathbf{M}_{aa} - \mathbf{K}_{ad}\mathbf{K}_{dd}^{-1}\mathbf{M}_{da} - \mathbf{M}_{ad}\mathbf{K}_{dd}^{-1}\mathbf{K}_{da} + \mathbf{K}_{ad}\mathbf{K}_{dd}^{-1}\mathbf{M}_{dd}\mathbf{K}_{dd}^{-1}\mathbf{K}_{da} \tag{13}$$

Since Guyan reduction is based on the static equilibrium, stiffness is preserved while neglecting the inertia forces. The eigenvalues of the reduced model are always higher than those of the full FE model, and the quality of their approximation depends on the location of preserved DOFs and the mode shape of interest. However, the first few lowest modes include less error and yield relatively accurate results.

3. Damage detection methodology

Vibration-based damage detection methods use the modal parameters as damage diagnostic parameters. An error function called objective function can be defined in terms of the modal parameters from the actual and numerical models. This objective function is minimized or maximized to localize and quantify damages in the structure.

Among modal parameters, natural frequencies are preferred due to their relative insensitivity to ambient noise and ease of measurement. However, using only frequency data often fails to provide sufficient accuracy in damage identification. Therefore, researchers have proposed incorporating mode shapes or mode shape-derived parameters in combination with frequency data. In this study, a new objective function is used and mathematically defined as follows:

$$f(\mathbf{x}) = \sqrt{\frac{1}{nm}\sum_{i=1}^{nm} W_{1i}\left(\frac{\omega_i^{\text{Target}} - \omega_i^{\text{Predicted}}}{\omega_i^{\text{Target}}}\right)^2} \\ + \sum_{i=1}^{nm} W_{2i}\left[1-\text{COMAC}(i)\right]^2 + W_{3i}\frac{\left\|\mathbf{F}^{\text{Target}} - \mathbf{F}^{\text{Predicted}}(x)\right\|_{Fro}}{\left\|\mathbf{F}^{\text{Target}}\right\|_{Fro}} \tag{13}$$

where ω_i^{Target} and $\omega_i^{\text{Predicted}}$ are the ith target and predicted frequencies, respectively nm is the number of modes considered. W_{1i}, W_{2i} and W_{3i} are weighting coefficients. In Eq. (13), COMAC(i) represents the Coordinate Modal Assurance Criterion, and **F** denotes the flexibility matrix. The symbol $\|\cdot\|_F$ indicates the Frobenius norm of a matrix. COMAC is a modified version of the traditional Modal Assurance Criterion, and it quantifies the correlation between two data sets at the coordinate level (Allemang, 2003). This allows for the identification of specific coordinates that disrupt the overall agreement providing a significant advantage in localizing damage. The COMAC is defined as follows:

$$\text{COMAC}(i) = \frac{\sum_{j=1}^{np}\left|(\phi_{ij}^{\text{Target}})^T \phi_{ij}^{\text{Predicted}}\right|^2}{\sum_{j=1}^{np}(\phi_{ij}^{\text{Target}})^2 \sum_{j=1}^{np}(\phi_{ij}^{\text{Predicted}})^2} \quad (i = 1, 2, \ldots, nm) \tag{14}$$

where np denotes the number of measurement coordinates. The elements of the COMAC vector range between 0 and 1, where 0 indicates no correlation and 1 denotes perfect agreement.

The flexibility matrix, which is the inverse of the stiffness matrix, is preferred due to its high sensitivity to damage. It is mathematically expressed as (Pandey & Biswas, 1994):

$$\mathbf{F} = \sum_{i=1}^{nm}\frac{1}{\omega_i^2}\mathbf{\Phi}_i\mathbf{\Phi}_i^T \tag{15}$$

where, ω_i represents the natural frequencies and Φ_i he corresponding mode shapes. The main advantage of the flexibility matrix is that it can be accurately approximated using only a few lower modes.

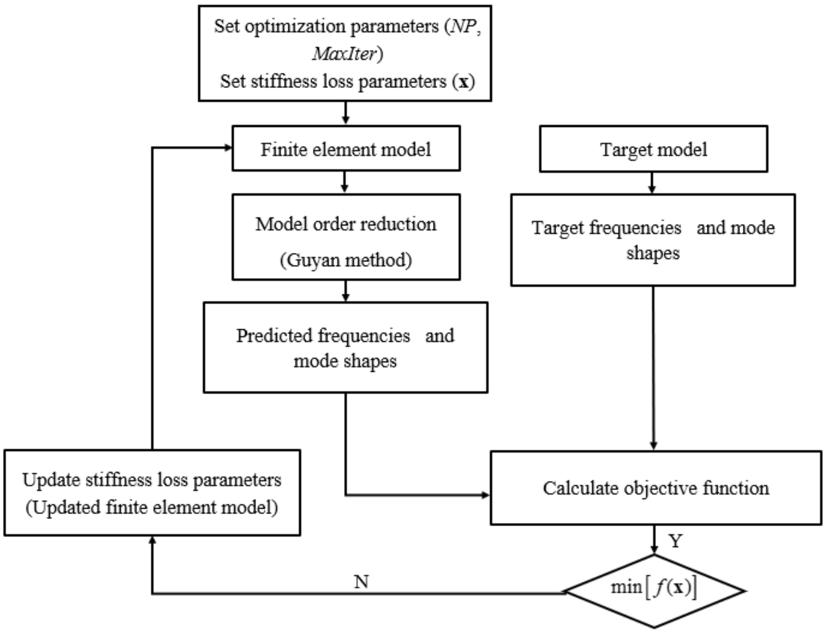

Fig. 2 Flowchart of the proposed damage detection methodology

The damage detection results were obtained using Harmony Search Algorithm (HSA), Genetic Algorithm (GA), Teaching–Learning-Based Optimization (TLBO), and Particle Swarm Optimization (PSO). The theoretical background and implementation details of these algorithms can be found in (Şimşek, 2024). The flowchart illustrating the proposed damage detection methodology is presented in the Fig. 2.

4. Results and discussion

Damage detection results using four different optimization algorithms (HSA, GA, TLBO, PSO) are presented comparatively in this section. The properties of the beam used in the numerical simulations for damage detection are presented in Fig. 3. and Table 1. The beam has a square cross-section with dimensions b = h= 24.5mm and a length of L = 381 mm. The laminated composite beam has a $[30/50]_2$ ply stacking sequence and all layers have equal thickness.

The beam was analyzed under three different damage scenarios, as listed in Table 2. The initial parameters selected for the four optimization algorithms are provided in Table 3. Each scenario was independently executed five times, and the average of the obtained results is presented through tables and figures.

Fig. 4 – Fig. 6 present the damage detection results obtained using four different algorithms for a clamped–clamped laminated composite beam. As can be seen from the figures, in all considered scenarios, the damaged elements were identified with high accuracy under both noise-free and noisy conditions by all four algorithms. Additionally, the influence of noise on the results was observed to be more significant in the Damage-3.

(b)

Fig. 7 Convergence of the objective function in damage detection using four different algorithms for a clamped–clamped $[30/50]_2$ laminated beam (Damage-3)

Fig. 7 illustrates the convergence curves of the objective function for the four algorithms used in Damage-3 of the clamped–clamped laminated composite beam. Since the maximum number of iterations varies among the algorithms, the first 100 iterations were considered to provide a common basis for comparison. As observed in the graphs, under both noise-free and noisy conditions, the convergence curves are ordered from top to bottom as HSA, PSO, GA, and TLBO. TLBO is the fastest converging algorithm, followed by PSO, GA, and HSA, respectively. Although HSA appears to converge much more slowly than the others, all algorithms completed the process in approximately the same computational time. In the noise-free case, the best convergence value (on the order of 10^{-5}) was achieved by TLBO, while under noisy conditions, all algorithms converged to nearly the same value.

Table 4 presents a comparative summary of the damage detection results obtained from five independent runs of four algorithms for Damage Scenario 3 in a clamped–clamped laminated composite beam. According to the table, under noise-free conditions, the TLBO algorithm provides the best convergence to the actual results compared to the other algorithms, with a standard deviation close to zero. When the effect of noise is considered, it can be stated that all four algorithms yield similar results.

Performance evaluations were carried out using the following error indices:

$$I_1 = \sum_{i=1}^{nd} \left| \frac{\alpha_i^{\text{actual}} - \alpha_i^{\text{predicted}}}{\alpha_i^{\text{actual}}} \right| \times 100 \tag{16}$$

$$I_2 = \sum_{i=1}^{nel-nd} \alpha_i^{\text{incorrect prediction}} \tag{17}$$

Table 5 shows that the I_2 index values obtained by the TLBO algorithm are closer to zero compared to the other algorithms. As previously mentioned, this indicates that the TLBO algorithm is capable of identifying the damaged elements with high accuracy. When evaluating the I_1 index values, it is observed that under noise-free conditions, TLBO provides the best results for all damage scenarios in the clamped–clamped beam. Under noisy conditions, however, the performance of all four algorithms decreases, and significant error rates occur, particularly in the detection of shallow damages.

4. Conclusions

This study presented a comparative investigation of four different optimization algorithms—HSA, GA, TLBO, and PSO—for vibration-based damage detection in clamped–clamped laminated composite beams. The performance of the algorithms was evaluated under both noise-free and noise-polluted conditions using convergence characteristics, damage localization accuracy, and error indices.

The key conclusions drawn from the results are as follows:

- TLBO algorithm consistently demonstrated the highest accuracy in identifying damaged elements, especially under noise-free conditions, with nearly zero standard deviation in results.
- In all three damage scenarios, TLBO achieved the best convergence of the objective function compared to other algorithms, particularly reaching values on the order of 10^{-5} in the absence of noise.
- Under noisy conditions, although the accuracy of all algorithms decreased, TLBO maintained a relatively better performance than the others.
- The convergence analysis revealed that TLBO was the fastest converging algorithm, followed by PSO, GA, and HSA, respectively.
- The HSA algorithm showed significantly slower convergence but had comparable computational time to the other methods due to fewer internal operations.
- The I_2 error index values for TLBO were the closest to zero in all scenarios, confirming its robustness in both noise-free and noisy environments.
- In shallow damage cases, especially under noise-polluted conditions, all algorithms showed decreased accuracy, with higher error rates observed.

Abstract. The need for high-rise structures with wide spans is increasing over time and steel construction technology is becoming importance day by day. Steel construction technologies are used in large structural systems, also referred to as mega structures. Therefore, every detail in the design phase is very important and it is necessary to investigate in detail which parameters are affected. In this study, welded connections in knife plate connections, which are frequently used in important projects such as bridges, high-rise structures and airports and can be damaged by repeated fatigue loads, were examined. Analyses were performed using the data of 7 specimens, the experimental studies of which were previously completed and the effect of the variability of the slot gap length between the welded plate and the slot opened in the HSS profile representing the connections under the effect of tensile forces on the fatigue performance was investigated. Tensile capacities were determined and a relationship was tried to be established between the fatigue performance. The results obtained from the experimental study were compared with the ABAQUS finite element analysis results. In addition, the stress range and cycle number were calculated by analytical method and the S-N diagram was determined and compared with the experimental results. It was observed that the experimental results and the finite element and analytical solution results converged.

Keywords: Fatigue; Steel structure; Knife plate connection; S-N diagram; Tensile capacity

1. Introduction

Steel bridges are among the most common civil engineering structures that must be designed for fatigue due to dynamic loads caused by repetitive traffic movements (EN, 1993). The increasing vehicle loads have raised concerns that fatigue-induced damage will become even more critical, highlighting the necessity for a more thorough investigation of connection details in steel bridges. Fatigue, which refers to the process of crack initiation and propagation due to irregular stress effects in steel structural connections can result in unforeseen and sudden failures, potentially leading to progressive collapse over time (Fisher et al., 1998). These fatigue cracks are caused by the repeated application of loads that are individually too small to cause immediate damage (Simulia, 2019).

The focus of this study, knife plate connections, are a commonly used type of connection in steel frame systems to enable joint configurations in structural steel design (Ebrahimi et al., 2019). Due to the repetitive loads occurring in these connections, exposure to fatigue loading is inevitable. Each parameter constituting knife plate connections, which are frequently used in steel structure design, must be investigated in detail. It is particularly important to identify the fundamental causes of fatigue-related problems frequently observed in connection elements in order to provide effective solutions. In this study, finite element analysis (FEA) was employed to develop fast and cost-effective solutions.

Due to the threat fatigue damage poses to structural safety, this process must be thoroughly investigated. The methods used in the fabrication of structural components should be evaluated from multiple perspectives. In this study, the aim is to investigate the effect of slot length on the tensile capacity of welded knife plate connections composed of box profiles, and to examine the relationship between tensile strength and fatigue performance.

In their study, Batistini et al. conducted experiments on knife plate connections of diagonal members fabricated from box sections with uniform slot lengths. Three of the specimens incorporated stress relief holes to reduce stress concentration, while the other three had slits directly welded using the plasma torch method without any drilled holes. The specimens with stress relief holes were classified as AASHTO Category E, with one specimen categorized as D. The remaining specimens without holes were classified under AASHTO Category E'. It was observed that the presence of stress relief holes led to a slight improvement in fatigue life. However, it was also

*Corresponding author, E-mail: elif.aydin@iku.edu.tr

https://doi.org/10.31462/icearc2025_ce_sme_935

found that the connection configuration of the specimens without holes, fabricated using conventional methods, did not significantly affect fatigue life (Battistini et al., 2013).

Willibald et al. aimed to evaluate the tensile issues caused by shear lag in knife plate connections of elliptical and circular profiles according to existing design standards. To this end, they conducted tension and compression tests on 13 slot-type connections, incorporating various parameters such as weld thickness, weld length, and geometric properties of the profiles. Their findings indicated that the shear lag effect plays a critical role in gusset plate connections, and that in the compression-tested specimens, local buckling at the profile ends hindered adequate connection performance. Based on these observations, they proposed recommendations for improvements to current design provisions (Willibald et al., 2006).

Zhao et al. conducted experimental studies to investigate the influence of various parameters on shear lag and the effective utilization of net cross-section in HSS (Hollow Structural Section) members. A total of 30 specimens with different geometries were tested, examining three variables each for knife plate thickness, the L/w ratio, and the slot length between the knife plate and the HSS member. Slot lengths of 5 mm, 25 mm, and 50 mm were used in the experiments. The results indicated that the variation in slot length did not significantly impact shear lag to the extent of producing substantial differences in performance based on plate thickness. Moreover, comparisons of specimens with L/w ratios less than and greater than 1 revealed similar efficiency in the use of the cross-section. The study also demonstrated higher capacity values than those specified in Canadian and American codes, allowing for comparative evaluation (Zhao et al., 2008). However, the effects of fatigue were not considered in this study.

McDonald and Frank conducted experimental studies on welded connections composed of single and double L-shaped profiles in X-type bracing frame systems with varying cross-sectional properties. Their aim was to investigate the effects of gusset plate thickness and weld length on fatigue performance and stress concentration. The test results indicated that specimens with single L profiles and shorter weld lengths exhibited lower fatigue performance. However, weld length and plate thickness were found to have minimal influence on stress concentration (Mc Donald & Frank, 2009).

Liu et al. experimentally examined the effect of the gap left between the slot made in HSS members and the knife plate on the fatigue performance of cross-bracing frame systems. They concluded that the gap between the edge of the slot and the knife plate had negligible influence on fatigue behavior (Liu et al., 2006).

2. Materials and methods

In this study, finite element analyses were conducted using the ABAQUS software for 7 specimens (Liu et al., 2006), for which experimental tests had already been completed, in order to evaluate their tensile and fatigue performance. The results of the analyses were compared with the corresponding experimental data.

A total of 7 test specimens were prepared as shown in Fig. 1, by welding knife plates made of ASTM A36 steel to both ends of 1700 mm-long HSS profiles. The cross-sectional and connection detail information of the 7 specimens is presented in Table 1. In this study, the influence of different gap lengths between the slot and the knife plate on the connection strength and fatigue performance is investigated. As shown in Table 1, this gap length was set to 50 mm, 5 mm, and 0 mm for specimens KPC05, KPC06, and KPC07, respectively. For the remaining specimens (KPC01, KPC02, KPC03, KPC04), the gap length was fixed at 25 mm.

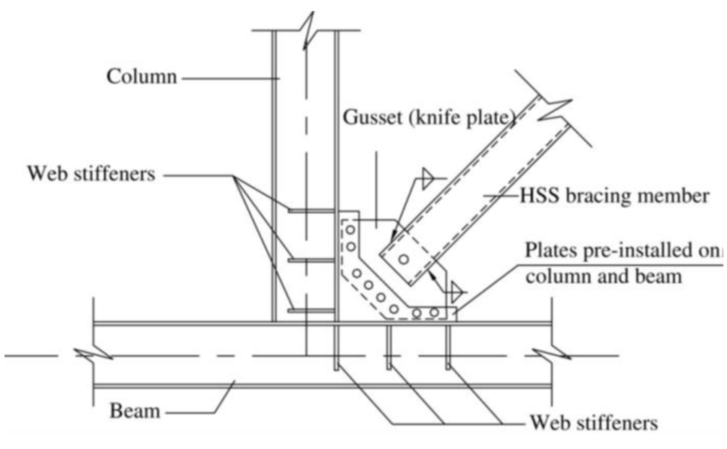

Fig. 1. Knife plate connection detail

Table 1. Test specimens

Specimen no	HSS length	HSS width	HSS thickness	Bolt hole diameter	Knife Plate width	Knife plate length	Knife plate thickness	Weld thickness	Weld length	Slot length

*All dimensions in mm.

3. Finite element analysis study

Finite element analysis for the 7 experimentally tested specimens was performed using the ABAQUS/Standard software (Simulia, 2018). In the modeling, the specimen length of 1700 mm was reduced to 450 mm, as shown in Fig. 2, to ensure a constant stress distribution along the length. This approach helped avoid excessive data and unnecessary computational time during the analysis.

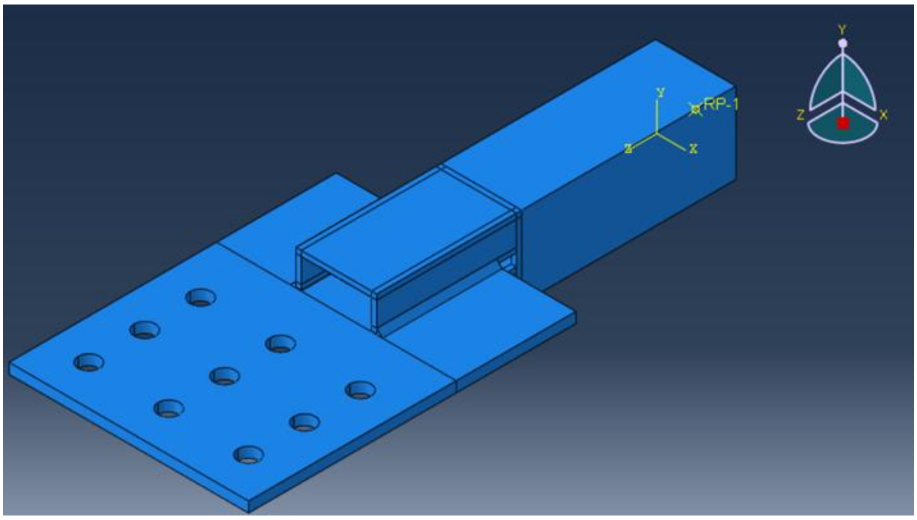

Fig. 2. Finite element model

In the finite element model, the gap lengths between the slit and the knife plate for specimens KPC05, KPC06, and KPC07 are shown in Fig. 3.

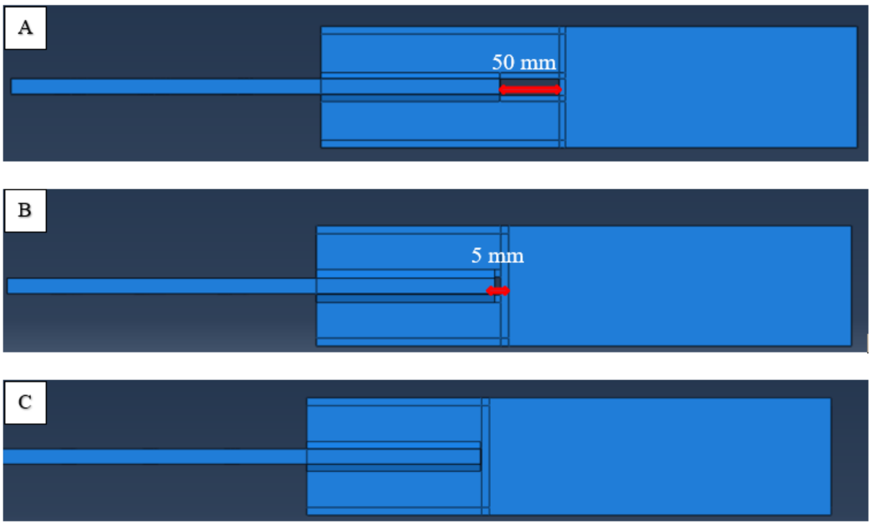

Fig. 3. KPC05 (A), KPC06 (B) ve KPC07 (C) FEM model

The material used is ASTM A36 steel. In ABAQUS, the material definition was provided in both elastic and plastic forms to represent the material's true behavior curve. The material properties are presented in Table 2.

Table 2. Material properties

Properties	Value
Steel	ASTM36
Modulus of Elasticity,E (MPa)	200000
Poisson ratio, ν	0.3

Considering the stress on the bolts, which are the main connection points of the Knife-plate, the bolt holes were divided into two and a pinned boundary condition was defined here. The boundary condition is shown in Fig. 4.

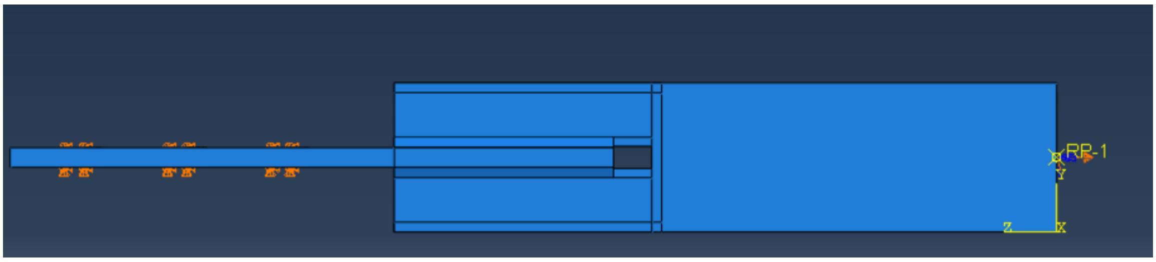

Fig. 4. Loading condition

The yield limit state of the connection was found to be critical and the displacement load corresponding to this condition was determined and 7 mm was given by defining the HSS surface to a reference point as shown in Fig. 5.

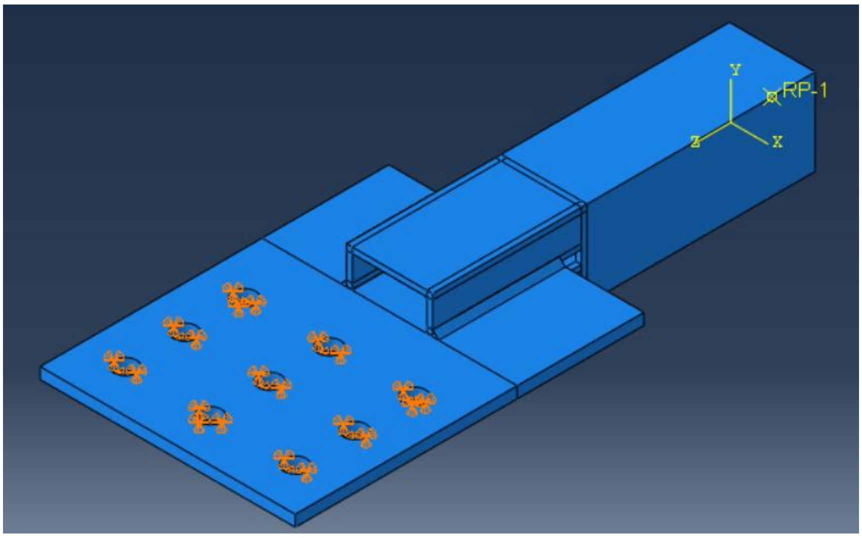

Fig. 5. Boundary condition

The regions where stresses are considered to be critical, including the weld and plate connection area as well as the regions near the weld in the HSS, were divided into smaller elements. As shown in Fig. 6, two types of mesh sizes were used.

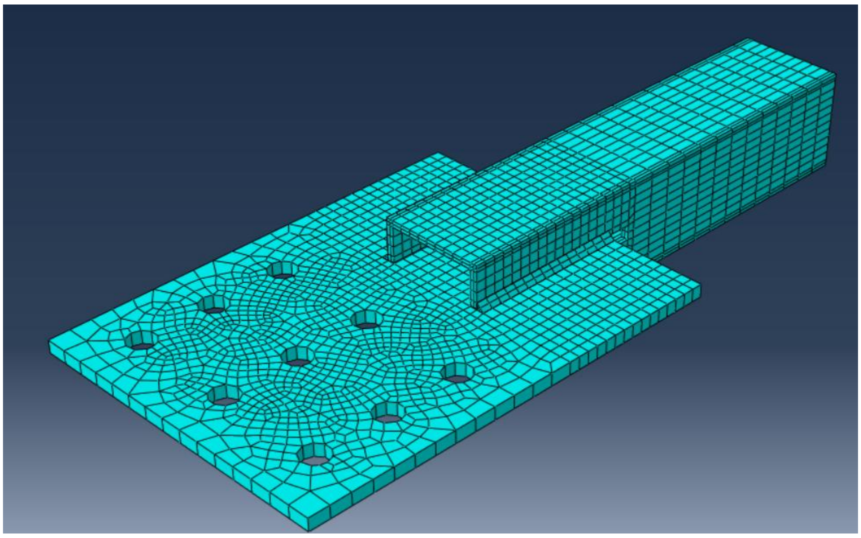

Fig. 6. Mesh configuration

4. Results and discussion

4.1. Finite element analysis results
In this study, the effect of the gap length between the initiation point of the slot in the HSS and the knife plate on both fatigue performance and tensile strength was investigated using 7 specimens subjected to experimental testing.

Table 3. Experimental and FEM comparisons

Specimen	Experimental strength (kN)	FEM strength (kN)	Displacement load for strength in FEM (mm)	Comparison (Experimental /FEM) (%)
KPC01	621	669	6.10	93
KPC02	625	669	6.21	93
KPC03	633	663	4.30	95
KPC04	645	689	6.73	94
KPC05	668	658	7.00	102
KPC06	668	684	4.00	98
KPC07	662	689	5.00	96

Based on the finite element analysis (FEA) results in Table 3, the distance between the slot and the knife plate was found to have no significant impact on the tensile capacity. The numerical results closely matched the experimental data. As confirmed by the experimental study, variations in this distance (50 mm, 5 mm, 0 mm) had minimal effect on fatigue performance. It was concluded that tensile strength and fatigue behavior follow similar patterns, suggesting that fatigue performance can generally be assessed based on this connection detail. The stress distribution from the FEA is shown in Fig. 7.

The strong correlation between experimental and numerical results suggests that parametric studies can be performed quickly and cost-effectively using FEA, eliminating the need for extensive physical testing for every variable. The load–displacemenet responses for specimens KPC05, KPC06, and KPC07 are illustrated in Fig. 8.

Comparisons with the standard specimen KPC01 are provided in the graphs in Fig. 9. The slot length used for KPC01 was 25 mm.

4.2. Analytical solution results

Fatigue time calculations according to Paris rule are presented in Table 4. Considering the fact that the results of the experimental study contain many uncertainties, the pattern of change in the number of cycles in the results obtained from finite element analysis and the pattern of change (increase-decrease) in the experimental study are compatible. Fig. 10 shows the cycle number-stress range results obtained from finite element analysis. In addition, for similar stress range values, close fatigue performance was obtained in KPC05-KPC06-KPC07 specimens. According to the analytical calculations, it is seen that the change in slot gap length (0, 5 mm, 25 mm, 50 mm) does not affect the fatigue performance much.

Table 4. FEM results for failure

Specimen	Load range (kN)	Stress range (MPa)	Load/tensile design strength of HSS (%)	Number of cycles to failure (Experimental results)	Number of cycles to failure (FEM results)
KPC01	0-669	0-95	32	104 475	1400209
KPC02	0-669	0-189	64	37 283	177528
KPC03	0-663	0-273	95	8 457	58872

5. Conclusions

In this study, the effect of slot gap length on the tensile capacity of knife plate connections—a commonly preferred detail in high-rise buildings and bridge structures—was investigated. Finite element analyses were carried out based on a previously conducted experimental study, with the aim of establishing a relationship between tensile capacity and fatigue performance. According to the results obtained:

- It was observed that different slot gap lengths did not significantly affect the tensile capacity.
- A strong correlation of over 90% was observed between the numerical and experimental findings, demonstrating the reliability of the finite element model.
- Although similar tensile capacities were observed across different slot gap lengths, the presence and size of the slot gap play a critical role in achieving a more uniform stress distribution. Properly adjusting this detail may contribute to forming a connection configuration that more accurately represents the behavior of the joint under applied loads.
- Consequently, it can be concluded that while slot gap length has limited influence on ultimate tensile strength, it remains a key parameter in optimizing the structural performance and durability of knife plate connections.
- As a result of the analytical results according to the Paris rule, it was observed that there was no significant difference in fatigue performance between the standard specimens KPC01-KPC02-KPC03-KPC04 and

KPC05 (0), KPC06 (5 mm) and KPC07 (50 mm), where the effect of slot gap length on fatigue performance was investigated.

Abstract. In this study, the development of hybrid (Fly Ash (FA)-Ground Granulated Blast Furnace Slag (GBSFS)-Marble powder (MP)) geopolymer mortars/composites was discussed with the aim of providing sustainable alternatives to traditional concrete by using different curing methods. Equal proportions of fly ash and ground granulated blast furnace slag were used as binder materials in geopolymer production. Equal proportions of marble powder and river sand were used as aggregates. In the activation process, it was aimed to improve the mechanical properties by using chemical activators at Na_2SiO_3 + NaOH ratios of 2:1 and 6, 8 and 10M. For this purpose, the effects of different curing processes on the mortars were investigated by applying electrical curing (30V), thermal curing (80°C, 24 hours) and ambient curing (23±2°C, 95% humidity) methods among the curing methods. In this context, physical properties such as unit volume weight, water absorption, void ratio and capillarity and mechanical properties such as pressure and bending strength tests were carried out on the 7th and 28th days. For the series (10M) with the highest average strength, the same tests were repeated by adding 0.5% carbon FIBER by volume. In the results, the compressive strength of the 10M-FIBER-ELECTRIC sample was found to be 30.13 MPa and the bending strength was found to be 7.22 MPa.

1. Introduction

Concrete, a pillar of contemporary construction and architecture, remains the most prevalent material in global construction activity. The annual use of concrete is currently estimated to exceed ten billion tons and is second only to water in the volume used by humans. This unrivaled dominance is largely a consequence of its beneficial engineering properties such as high compressive strength, ease of mold shape retention, ready availability of raw materials in most geographical locations, low cost of production, and flexibility in tolerating diverse environments and structure conditions. However, the very ubiquity of concrete and especially concrete produced with ordinary Portland cement (OPC) used as the main binding material has generated serious ecological and financial worries. Processing OPC is energy-intensive and depends almost singly upon calcination of raw materials and limestone at temperatures of about 1450°C. This releases enormous amounts of carbon dioxide (CO_2) and contributes almost 7% to the CO_2 emissions of the planet. Further, the energy needed to power these high-temperature processes contributes about 15% to the resultant industrial energy demand of the planet. These statistics of concern have triggered exhaustless research activity aimed at seeking alternative binders that can rival and even surpass traditional cement performance with lessening the ecological impact of traditional cement fabrication. One of the most promising alternatives in this endeavor is geopolymer technology (Malhotra, 2002; Meyer, 2009; Madlool et al., 2011)

Geopolymers constitute a group of amorphous aluminosilicate-based inorganic polymers that set at room temperature or mildly elevated temperatures by the alkali activation of precursors such as metakaolin, zeolite, industrial by-products, and fly ash and ground granulated blast furnace slag (GBFS). geopolymerization process is a sequence of sequential and related steps involving the dissolution of the source of aluminsilicate in a medium of alkaline nature, rearrangement and polycondensation of reactive monomers to oligomers, and resulting in the formation of a set of rigid, polymeric networks based predominantly of Si-O-Al bonds with properties being largely

golden light publishing

dependent on the Si/Al molar ratio, the type and concentration of the activator of the alkali, the curing regime, and the ratio of water to solid matter. Geopolymer has significant benefits from a sustainability standpoint. Besides having a production carbon footprint up to 80% lower than that of OPC in terms of CO_2 release, geopolymers also use industrial by-flow streams as major feedstocks, hence encouraging material flow recycling and valorization of wastes. Moreover, geopolymers have good chemical resistance, good thermal stability, low shrinkage, and great mechanical properties and hence can be used in various applications such as in construction concrete, refractory fire panels, hazardous waste immobilization, and advanced composites (Luga, 2015; Boyaci, 2018; Sahin et al., 2020; Singh & Middendorf, 2020).

Current research is conducted in this context and aims to develop and examine a high-performance geopolymer mortar that is a promising substitute to conventional cement-based composites. In the current investigation, Class F type fly ash (FA) and GBFS were mixed in similar weight proportions to act as the reactive binding phase. For activating the system, a binary alkaline solution of sodium hydroxide (NaOH) and sodium silicate (Na_2SiO_3) was used. Three different concentrations of NaOH of 6M, 8M, and 10M were used to examine the role of alkalinity in reaction kinetics and material properties. NaOH to Na_2SiO_3 ratio was kept constant at 1:2 by weight in all of the blends to be uniform and comparable in nature. For the filler materials, a 1:1 mixture of marble powder (MP) and river sand was added to take advantage of the fine particle size and chemical inertness of the MP to improve packing density and minimize permeability. Carbon fibers (CFs) were also added to some of the mixes to determine the influence of micro-reinforcement on strength properties. CFs ossess high tensile strength, low density, and chemical stability and can be capable of spanning microcracks and countering brittle modes of failure typically seen in geopolymer matrices. The primary aim of this research is to examine the synergistic impact of molarity change and carbon fiber reinforcement on fresh and hardened properties of geopolymer mortars. An extensive set of tests was employed to assess compressive strength, flexural strength, ultrasonic pulse velocity, water absorption, void percentage, unit weight, and capillarity properties. These tests give not just information about the mechanical strength, but also the durability and long-term performance of the resultant geopolymer mortar. Finally, the results look to add to the literature supporting sustainable construction methods and to pinpoint available routes to de-carbonize the built environment.

2. Materials and methods

2.1. Materials

GBFS was used in the composition of the geopolymer mortar system used in the current experimental study as the main binding component. GBFS with a specific gravity of 2.91 g/cm³ was used in the study and is in correspondence with the general density range of high-calcium slag products. Because of its glassy and amorphous nature and also high reactivity in the presence of alkaline environments, GBFS is most favorable to be used in geopolymerization reaction and in contributing to the development of a resistant aluminosilicate network structure.

Class F was the type of FA used and is a low-calcium type typically recovered from coal combustion operations. It had a relatively low specific gravity of 1.96 g/cm³ because of its relatively low particle size and porosity. GBFS-fly ash synergistic reaction under alkaline activator conditions leads to the formation of a denser microstructure and increased setting times and appreciable thermal stability.

Supplementary filler was also provided in the form of MP to be used in conjunction with the binders. This had a specific gravity of 2.70 g/cm³ and was largely made up of calcium carbonate material. MP was added to the mixture to enhance packing density and lower permeability and also to enhance the surface finish of the set mortar. Its chemical inertness prevents it from disrupting the geopolymerization reaction whilst providing additional physical contributions to the system.

Fine aggregate used was natural river sand with particle size distribution from 0 to 5 mm. Specific gravity of the natural river sand was 2.65 g/cm³ and absorbed water at a rate of 1.2%. These figures reflect a high-quality aggregate to be used in mortar purposes. Pre-washing and drying of sand was performed to eliminate impurities and achieve uniformity. Its gradation curve in Figure 2.1 shows accordance with ASTM C33 standards of fine aggregate in use in structural concrete to assure a good balance of workability and mechanical interlocks in the matrix.

CFs were added as a micro-reinforcement material to enhance the tensile and flexural properties of the mortar. These fibers were of 7 mm length with a density of 1.80 g/cm³ and a specific volume weight of 390 g/l and were added at a dosage of 0.5% by volume to achieve optimal fiber dispersion and bonding without influencing the workability. CFs with high tensile strength, chemical inertness, and good crack-bridging capacity are recognized to enhance the ductility and sustainability of cementitious and geopolymer composites. In the current research, the fibers were evenly distributed into the matrix during the mixing to achieve uniform reinforcement and avoid fiber clustering and segregation problems.

Chemical composition of the main materials—GBFS, FA, and MP—involved in the current research is shown in Table 1 and gives information on the elemental constituents that affect the geopolymerization reaction and the physical-mechanical properties of the resulting geopolymer mortars.

Table 1. Chemical properties of materials

Oxide/Component	GBFS (%)	FA (%)	MP (%)
SiO_2	40.5	57.72	1.12

In this study, NaOH was used as the primary alkaline activator and was prepared at molar concentrations of 6 M, 8 M and 10 M. The solutions were dissolved in deionized water for at least 24 h before sample casting to ensure complete dissolution and thermal stabilization. Na_2SiO_3 was used as a secondary activator to increase silicate availability during the geopolymerization process. Synergistic interaction between NaOH and sodium silicate plays an important role in regulating the dissolution kinetics of aluminosilicate precursors and promoting the formation of geopolymeric networks.

Detailed physical and chemical properties of sodium silicate are presented in Table 2, while the compositional properties of sodium hydroxide are given in Table 3.

3. Results and discussion

3.1. Physical properties

Unit volume weight in the 19 tested samples ranged from a low of 2.33 g/cm³ for Sample 19 (10M-Fiber-Electric) to a high of 2.46 g/cm³ in Sample 2 (6M-Thermal). Average unit weight was determined to be 2.393 g/cm³ with a standard deviation of around 0.045 g/cm³. In comparison with the average, Sample 2 registered a positive deviation of +2.8%, and Sample 19 registered a negative deviation of -2.6%. Coefficient of variation (CV) of all the samples was 1.88%, which shows that relatively uniform density levels were observed with small fluctuations depending upon molarity and fiber quantity. Observably, carbon fiber mixes registered an average weight loss of 0.06 g/cm³ compared to fiberless mixes. Weight difference between electric-cured and thermally cured samples at 6M molarity was 0.02–0.04 g/cm³ showing the densifying action of heat treatment (Table 4).

Void ratio values were between 15.91% (Sample 8, 10M-Ambient) and 24.83% (Sample 12, 6M-Electric) with a total range of 8.92%. The mean of all samples was 19.71% with a deviation of 2.76%. Sample 12 was the most porous in deviation from the mean at +25.9%, and Sample 8 at -19.3%. Regression of molarity against the void ratio was linear and negative with $R^2 \approx 0.78$ and demonstrates that higher alkaline concentration leads to a more closely packed matrix. In the comparison of curing methods, electric curing had a mean void ratio of 21.94%, thermal curing 18.38%, and ambient curing 17.69%. This indicates that ambient and thermal curing methods are more effective in reducing the formation of voids at similar molarities. Void ratio was negatively proportional to unit weight ($r = -0.68$) and therefore supported to be inextricably linked with them (Table 5).

19	23.78

Water absorption ranged from 8.00% to 13.46%, having a mean of 10.29% and the standard deviation of 1.61%. Sample 12 (6M-Electric) with the highest absorption was +30.8% above the mean and the lowest absorptive Sample 8 (10M-Ambient) was -22.3% below it. Comparison indicated that water absorption was positively correlated with the void ratio (r = +0.82) and negatively correlated with molarity (r = -0.74). This is in accordance with the fact that higher alkaline activation reduces accessible pores and hence water absorption. Electric curing at lower molarity produced the maximum absorption with unformed areas of gels and trapped microvoids. Addition of carbon fiber additives caused hardly any change in water absorption in a direct way, yet it indirectly affected outcomes by changing internal connectivity of the matrix (Table 6).

Table 6. Water absorption rate of geopolymer mortars

Sample No.	Water Absorption (%)
1	9.94
2	10.05

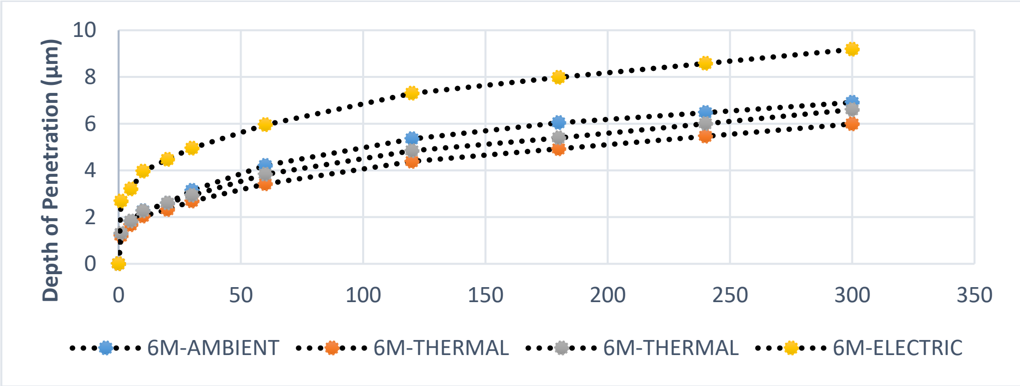
15	11.65
16	11.32
17	11.25
18	9.31
19	13.41

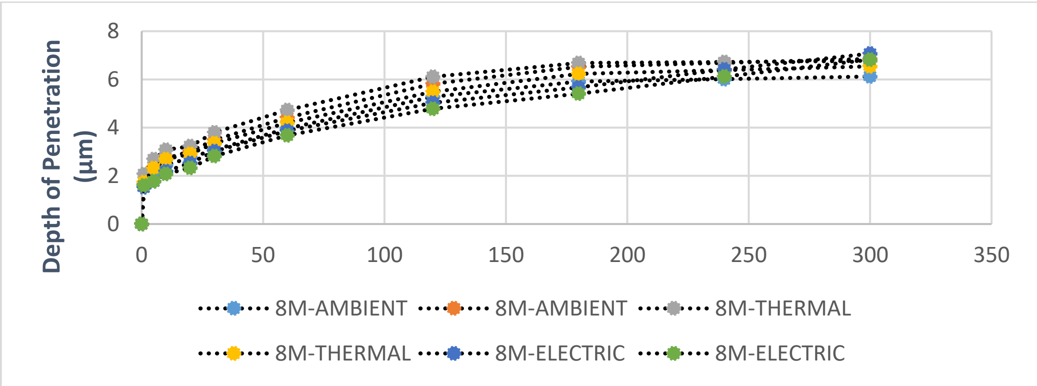
Range in capillary rise was from 5.29 µm (Sample 16, 10M-Electric) to 9.18 µm (Sample 12, 6M-Electric) with an average of 7.14 µm. Standard deviation was 1.15 µm and coefficient of variation was 16.1%. Similar to other properties, with increasing molarity, capillarity decreased. 6M samples had a mean of 8.72 µm and 10M samples had a mean of 6.11 µm—reduced by 29.9%. In comparison of electric-cured samples only, from 9.18 µm at 6M to 5.29 µm at 10M gave evidence of a 42.3% improvement in capillarity. $R^2 = 0.81$ was what regression gave from molarity vs. capillarity that confirmed that concentration of the activator plays a dominant role in controlling water transport routes. Reduced capillarity is translated to increased durability and resistance to water in actual applications, especially in freeze-thaw or coastal conditions (Fig. 1.).

3.2 Mechanical properties

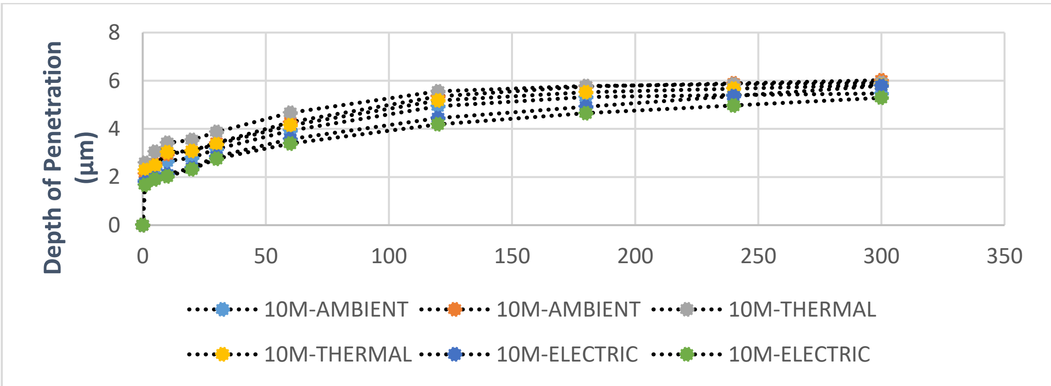
When the compressive strengths of geopolymer mortars were examined, it varied between 9.25 MPa and 22.83 MPa for the 7th day. Maximum compressive strength was observed in sample number 11 (10M-FIBER-THERMAL) and the minimum compressive strength was observed in sample number 7 (10M-AMBIENT). In AMBIENT and THERMAL curings, the compressive strength decreased with increasing molarity. In ELECTRIC curing, the compressive strength increased with increasing molarity and THERMAL curing method showed better performance than other curing methods at all molarities. Carbon fiber showed positive performance for compressive strength in all curing methods. Compressive strength of geopolymer mortars varied between 14.1 MPa and 30.13 MPa for the 28th day. Maximum compressive strength was observed in sample number 12 (10M-FIBER-ELECTRIC) and minimum compressive strength was observed in sample number 3 (6M-FIBER-ELECTRIC). While compressive strength was maximum at 8 M in AMBIENT curing, compressive strength decreased with increasing molarity in THERMAL curing and compressive strength increased with increasing molarity in ELECTRIC curing. In 10M-FIBER, ELECTRIC curing showed better performance than THERMAL and AMBIENT curings. Carbon fiber showed positive performance for compressive strength in all curing methods (Fig. 2.).



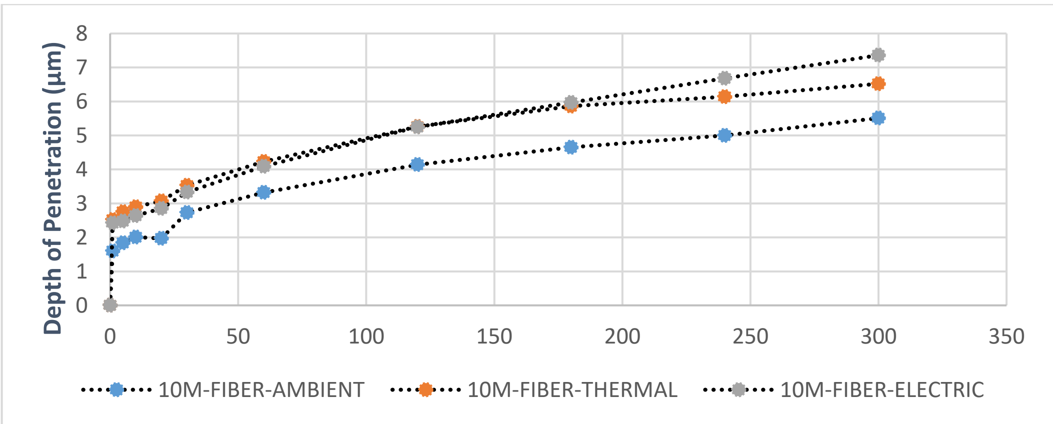
a) (6M)



b) (8M)



c) (10M)



d) (10M FIBER)

Fig. 1. Capillarity test results (6M, 8M, 10 M and 10M-FIBER series).

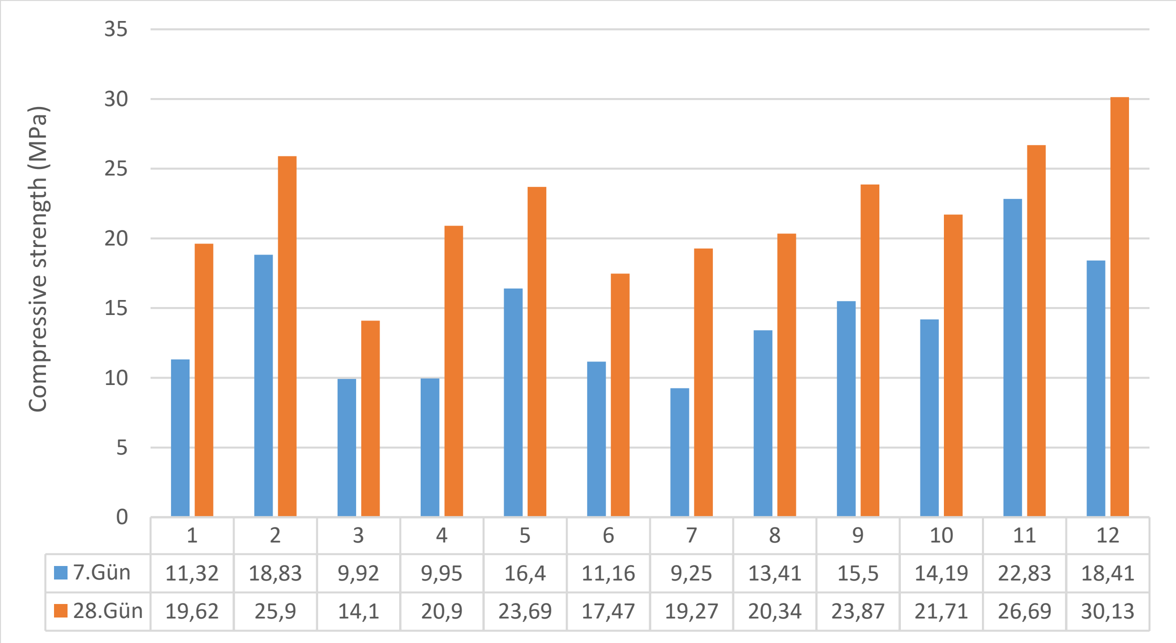


Fig. 2. Compressive strength results (7 and 28d).

Flexural strength of geopolymer mortars varied between 3.19 MPa and 7.08 MPa for day 7. The maximum flexural strength was observed in sample number 12 (10M-FIBER-ELECTRIC) and the minimum flexural strength was observed in sample number 7 (10M-AMBIENT). In AMBIENT and THERMAL curings, flexural strength decreased with increasing molarity, but in ELECTRIC curing, flexural strength increased with increasing molarity and carbon fiber exhibited positive performance for flexural strength in all curing methods. On day 28, flexural strengths were obtained between 3.68 MPa and 7.22 MPa, while the maximum flexural strength was determined in sample number 12 (10M-FIBER-ELECTRIC) and the minimum flexural strength was determined in sample number 3 (6M-FIBER-ELECTRIC). While carbon fiber provided an increase in bending strength similar to compressive strength in all curing methods, almost all of its strength was gained on the 7th day in all curing methods (Fig. 3.).

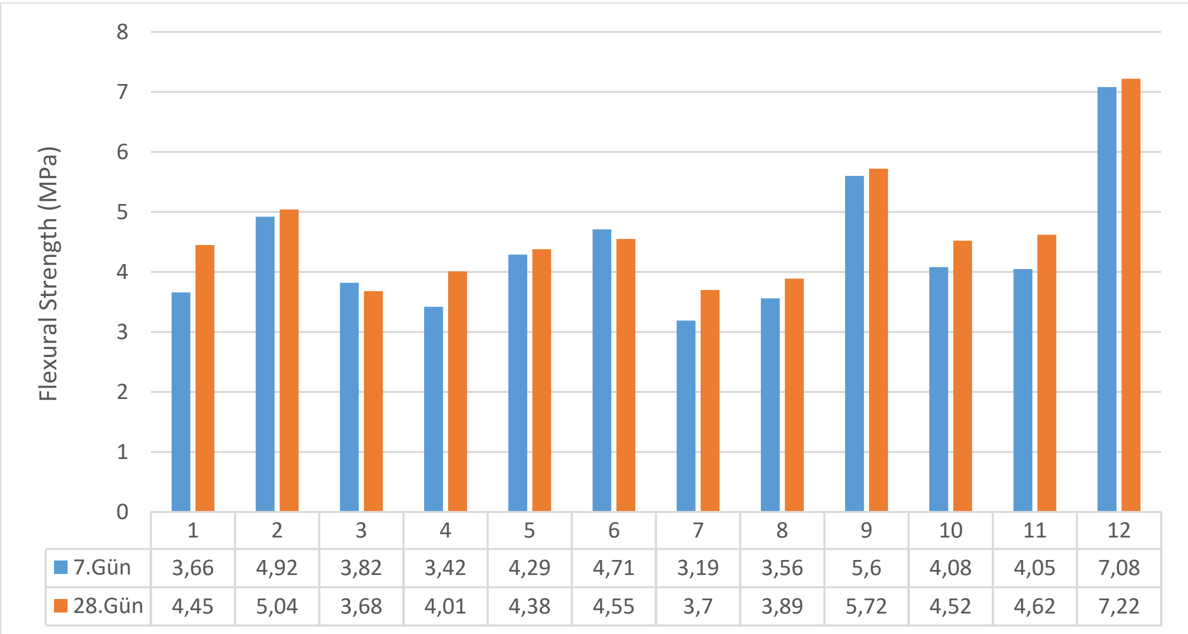

Fig. 3. Flexural strength results (7 and 28d).

4. Conclusions

- 10M-FIBER-ELECTRIC, which reached 7.08 MPa in flexural strength, is the sample that gave the best performance in 7 days.
- 10M-AMBIENT, which reached 3.19 MPa in flexural strength, is the sample that gave the worst performance in 7 days.
- 10M-FIBER-THERMAL, which reached 22.83 MPa in compressive strength, is the sample that gave the best performance in 7 days.
- 6M-ELECTRIC, which reached 9.92 MPa in compressive strength, is the sample that gave the worst performance in 7 days.
- 10M-FIBER-ELECTRIC, which reached 7.22 MPa in flexural strength and 30.13 MPa in compressive strength, is the sample that gave the best performance in 28 days.
- 6M-ELECTRIC, which reached 3.68 MPa in Flexural strength and 14.10 MPa in compressive strength, is the sample that gave the worst performance in 28 days.

Size optimization of truss footbridge using BMR and BWR algorithms

Büşra Yakak[1], Barbaros Atmaca*[1], Hülya Aksoy[1]

[1]*Karadeniz Technical University, Department of Civil Engineering, 61080 Trabzon, Türkiye*

Abstract. Truss footbridges (TFBs) are widely preferred in engineering structures thanks to their features such as light weight and durability. However, material utilization and cost effectiveness are of great importance in the design of these structures. Therefore, size optimization is an important engineering problem in the design of TFBs. In this study, the Best-Mean-Random (BMR) and Best-Worst-Random (BWR) algorithms is proposed for the size optimization of the selected 132-element TFB. The size optimization process is carried out by integrating SAP2000 and MATLAB software using SAP2000's Open Application Programming Interface (OAPI) features. For the size optimization of TFB, the finite element model of the bridge was first created in the SAP2000 program and then the analysis results were transferred to the MATLAB programming language through SAP2000-OAPI. In the optimization process, the BMR and BWR algorithms optimized the size of the bridge elements in each iteration using this data. At each iteration, the structural suitability of the proposed new design was checked by re-analysis with SAP2000 and the optimization process was carried forward in this cycle. As a result, this study reveals that the integration of SAP2000 and MATLAB with the BMR and BWR algorithm provides an effective solution to the size optimization problem of TFBs. As a result of the study, it was seen that the BMR algorithm exhibited a more stable convergence and could produce lighter and therefore more efficient solutions compared to the BWR algorithm.

Keywords: BMR algorithm; BWR algorithm; SAP2000-OAPI; Size optimization; Truss footbridge

1. Introduction

Steel truss footbridges (TFBs) are engineering structures designed in an economical and durable way using triangular truss systems to span wide spans. They are widely used in railway and highway thanks to their advantages such as lightness and high carrying capacity. However, due to the high cost and maintenance requirements of steel materials, optimizing the use of materials in the design process is of great importance. At this point, it is necessary to determine the most suitable sections with engineering calculations and to increase structural performance (Megson, 2019).

Size optimization is a critical engineering problem to increase the cost-effectiveness of steel TFBs and ensure structural safety. Having more than necessary cross-sectional area of steel elements can lead to material waste and additional costs, while insufficient dimensioning can negatively affect structural strength. For this reason, optimization techniques focus on determining the dimensions of steel elements in a way that provides maximum efficiency with minimum material while maintaining the load-carrying capacity.

Although great advances have been made in the field of engineering today, the use of current optimization algorithms in the size optimization of steel TFBs is still not sufficient. Traditional methods usually include analytical solutions based on certain assumptions or numerical approaches with limited iterations, which makes it difficult to reach a global optimum solution in the design process. Especially in large-scale and complex truss systems, traditional optimization methods often get stuck in local minima. In addition, the integration of advanced techniques such as current metaheuristic algorithms into engineering applications is limited. This deficiency causes the cost-effectiveness of steel TFBs not to be fully achieved and ideal solutions in terms of structural performance not to be achieved. Therefore, the more widespread use of current algorithms in dimensional optimization will both increase engineering efficiency and contribute to sustainable design processes.

Farahmand-Tabar and Babaei (2023), developed the multi-verse optimizer (MVO) algorithm based on the multiverse theory and proposed its memory-assisted adaptive version (MAMVO). They showed that it provides superior performance compared to both classical MVO and other algorithms in truss structure optimization problems. Focusing on solving large-scale problems in rod systems, Etaati et al. (2024) integrated the cooperative

coevolutionary marine predators algorithm (CCMPA) with the greedy search (GS) method. This study addressed the problem of performance loss as the scale increases in the literature. Nemati et al. (2024) proposed the connected banking system(CBS) optimization algorithm in solving truss optimum design problems and tested it for both small-scale and large-scale structures and produced competitive results compared to existing methods in the literature. Ugur and Degertekin (2025) proposed the NCSBO algorithm, a new approach developed based on the circulatory system-based optimization (CSBO) algorithm, in order to improve the performance in shape and size optimization of truss structures. In the study, they demonstrated the effectiveness of the NCSBO algorithm in reaching the optimum design.

Structural optimization problems can be difficult to solve with classical deterministic methods due to their complex structure. For this reason, meta-heuristic algorithms have come to the fore in solving these problems, especially in recent years. The aim of this study is to perform the size optimization of the 132-element steel TFB system with minimum weight. In this context, two metaheuristic algorithms found in the literature, Best-Mean-Random (BMR) and Best-Worst-Random (BWR) algorithms, were used. The size optimization process was carried out by integrating SAP2000 (2016) and MATLAB (R2023b) software using SAP2000's Open Application Programming Interface (OAPI) features. First, the three-dimensional finite element model of the bridge was created in SAP2000 program, and then the analysis results were transferred to MATLAB via OAPI. In each iteration, the BMR and BWR algorithms optimized the cross-sections of the bridge elements. Similarly, Atmaca (2021a) and Atmaca (2021b) also performed optimization studies by integrating MATLAB and SAP2000 via OAPI, demonstrating the effectiveness of this approach in determining optimum post-tensioning cable force and minimizing the total cable weight in cable-stayed footbridges.

2. Description of the truss footbridge

In this study, a two-span steel TFB model consisting of 132 elements with 36 nodes is investigated within the scope of the optimum size problem. The elements forming the structural system of the bridge are divided into six main groups as G_1, G_2, G_3, G_4, G_5 and G_6. These groups are lower edge, upper edge, diagonal, middle zone lower edge, middle zone upper edge and middle zone diagonal elements respectively.

The length of each element of the TFB used in the model is 4 m, the total span is 32 m and the vertical height of the system is 4 m. Two different perspectives of the steel bridge, three dimensional and front view, are given in Fig. 1. Each group is defined with different colors and this information is given in detail in Table 1, and the profiles are listed in Table 2.

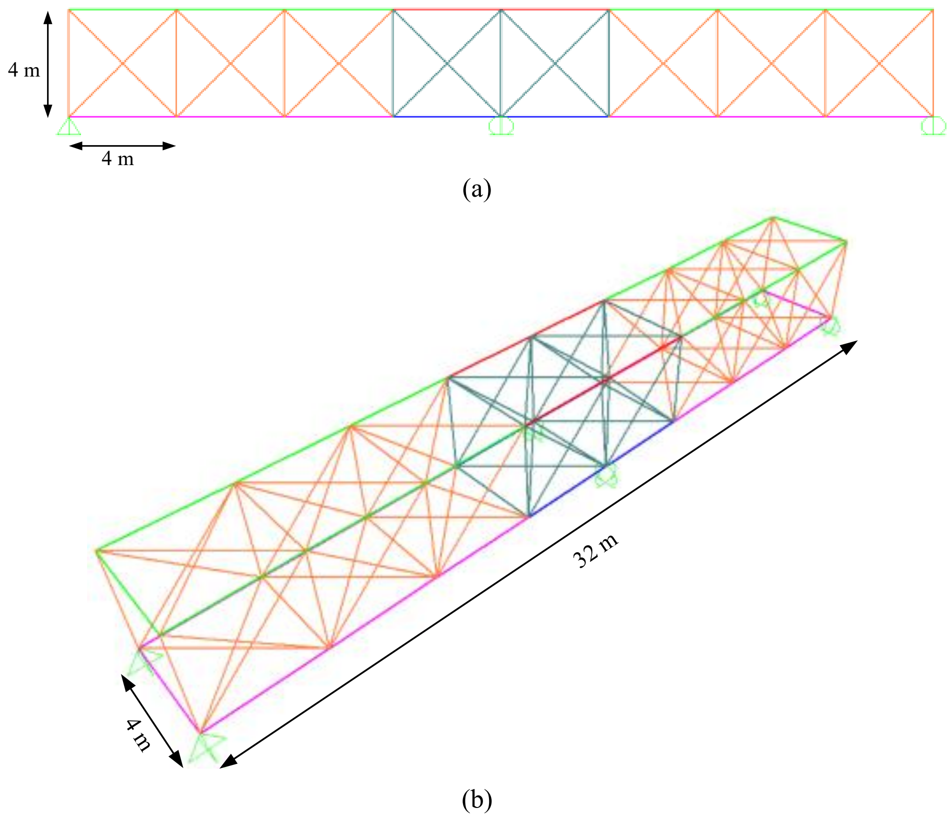

Fig. 1. TFB (a) front view and (b) three-dimensional view

Table 1. Definitions of element groups

Structural group	Assigned color	Number of element
Lower edge		14
Upper edge		14
Diagonal		68
Middle zone lower edge		4
Middle zone upper edge		4
Middle zone diagonal		28

Table 2. Defined steel profile sections

No	TUBO Profile	No	TUBO Profile	No	TUBO Profile
1	D76.1X3.2	9	D139.7X4	17	D298.5X5.9
2	D82.5X3.2	10	D152.4X4	18	D323.9X5.9
3	D88.9X3.2	11	D159X4	19	D355.6X6.3
4	D101.6X3.6	12	D168.3X4	20	D368X6.3
5	D108X3.6	13	D193.7X4.5	21	D406.4X6.3
6	D114.3X3.6	14	D219.1X5	22	D419X7.1
7	D127X4	15	D244.5X5.4	23	D457.2X7.1
8	D133X4	16	D273X5.6		

3. The finite element model of the truss footbridge

The finite element model (FEM) of the steel TFB was created in SAP2000 (Fig. 2). There are 36 nodes, each with six degrees of freedom (DOF). The model is fixed by two nodes at the left end and there is a sliding support at the middle region and right end. The density ρ = 7850 kg/m^3 and the modulus of elasticity E = 2.1x10^{11} kN/m^2.

The external loads applied to the bridge model are dead load (G) and live load (Q). In this context, the dead loads, representing the loads from the slab system of the bridge, were applied to the sub-nodes as 15 kN in the vertical direction. The live load, which represents the temporary loads on the bridge, was defined as 20 kN at the sub-nodes. A total of 30 kN dead load and 40 kN live load were applied to the nodes where two elements connect at each sub-node. In order to evaluate the structural performance of the structure, a linear static analysis was performed and the loading combination was based on G + Q. The data obtained as a result of this analysis formed the basis for determining the optimum cross-sectional dimensions of the bridge elements.

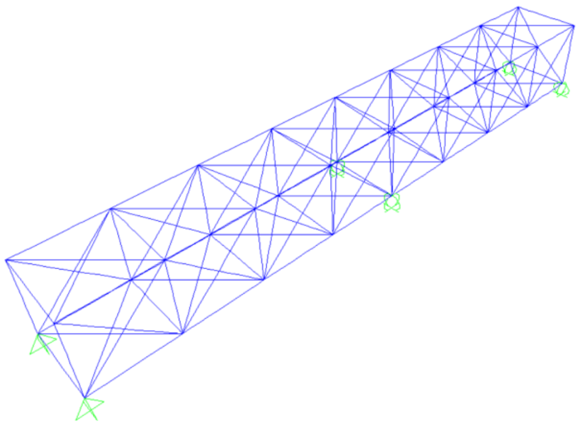

Fig. 2. FEM of the TFB

4. BMR and BWR algorithms

BMR and BWR optimization algorithms that do not include metaphors and algorithm-specific parameters were first developed by Rao and Shah (n.d.). BWR algorithm uses the best, worst and random solutions of the population when addressing a certain problem. On the other hand, BMR algorithm uses the best, average and random solutions of the population.

Let's assume that the objective function is $f(x)$ and for each iteration i there are 'm' design variables and 'n' candidate solutions. $f(x)_{best}$ is the best value among all possible solutions, while $f(x)_{worst}$ is the worst value. The random values for r_1, r_2, r_3, and r_4 can be any value between 0 and 1. U_j and L_j are the jth variable's lower and higher values, respectively. For the k^{th} candidate in the i^{th} iteration, the value of the jth variable is $V_{j,k,i}$. T is a factor that can randomly take either 1 or 2 during an iteration.

BMR algorithm;

$$V'_{j,k,i} = \begin{cases} V_{j,k,i} + r_{1,j,i}\left(V_{j,best,i} - T^{*}V_{j,mean,i}\right) + r_{2,j,i}\left(V_{j,best,i} - V_{j,random,i}\right), if \;\; r_4 > 0.5 \\ U_j - \left(U_j - L_j\right) r_3, \qquad otherwise \end{cases} \tag{1}$$

BWR algorithm;

$$V'_{j,k,i} = \begin{cases} V_{j,k,i} + r_{1,j,i}\left(V_{j,best,i} - T^{*}V_{j,random,i}\right) - r_{2,j,i}\left(V_{j,worst,i} - V_{j,random,i}\right), if \;\; r_4 > 0.5 \\ U_j - \left(U_j - L_j\right) r_3, \qquad otherwise \end{cases} \tag{2}$$

The modified value of $V_{j,k,i}$ is denoted by $V'_{j,k,i}$. For variable j^{th} variable, $V_{j,best,i}$ is the best value of $f(x)$ during the i^{th} iteration, $V_{j,mean,i}$ is the average value and $V_{j,worst,i}$ is the worst value. The value picked at random for the j^{th} variable in the i^{th} iteration is $V_{j,random,i}$.

In this study, two different metaheuristic optimization algorithms, called BMR and BMW, are used to perform the optimum design of a steel TFB by taking into account the structural constraints such as stress and buckling for compression members specified in American Institute of Steel Construction-Allowable Stress Design (AISC-ASD) (1989) standards. In the optimization process, the number of generations was set as 30 and the population size was set as 20.

5. Optimization results

In this study, the optimal design of a TFB system with minimum weight is realized using two different metaheuristic algorithms called BMR and BWR. Five runs were performed for each algorithm and the performances of the algorithms were evaluated based on the results obtained. The convergence behavior of the best solutions obtained during different iterations in the optimization process is examined.

First of all, the convergence graph showing the variation of the best solutions obtained in different runs of the BMR algorithm according to iteration is given in Fig. 3(a). The minimum structure weight, the number of iterations and the number of function evaluations (NFE) obtained in each run of the BMR algorithm are summarized in Table 3. When Fig. 3(a) and Table 3 are analyzed, the total structure weights obtained as a result of five different runs are quite close, ranging from 41.494 kN to 41.970 kN. Run-1 gives the best result with a minimum total structure weight of 41.494 kN. In this run, this solution was reached after only 5 iterations.

Then, the convergence graph showing the change of the best solutions obtained in different runs of the BWR algorithm according to the iteration is given in Fig. 3(b). The minimum structure weight, the number of iterations and NFE obtained in each run of the BWR algorithm are summarized in Table 4. When Fig. 3(b) and Table 4 are examined, it is seen that as a result of five different runs, Run-2 and Run-4 reached the best result in the first iteration and obtained a minimum total structure weight of 42.049 kN.

The selected profiles for six different groups and the weight of each group are shown in Table 5. When this table is examined, the BMR algorithm obtained a lighter weight of approximately 1.32% compared to the BWR algorithm.

G_1	14	D82.5X3.2	3.436	D88.9X3.2	3.714
G_2	14	D82.5X3.2	3.436	D88.9X3.2	3.714
G_3	68	D88.9X3.2	23.313	D88.9X3.2	23.313
G_4	4	D88.9X3.2	1.061	D88.9X3.2	1.061
G_5	4	D88.9X3.2	1.061	D88.9X3.2	1.061
G_6	28	D88.9X3.2	9.186	D88.9X3.2	9.186
			41.494		42.049

As a result of the optimization, when the sections obtained from both the BMR algorithm and the BWR algorithm are placed in FEM in SAP2000 and designed according to AISC-ASD, it is seen in Fig. 4 that all sections are sufficient.

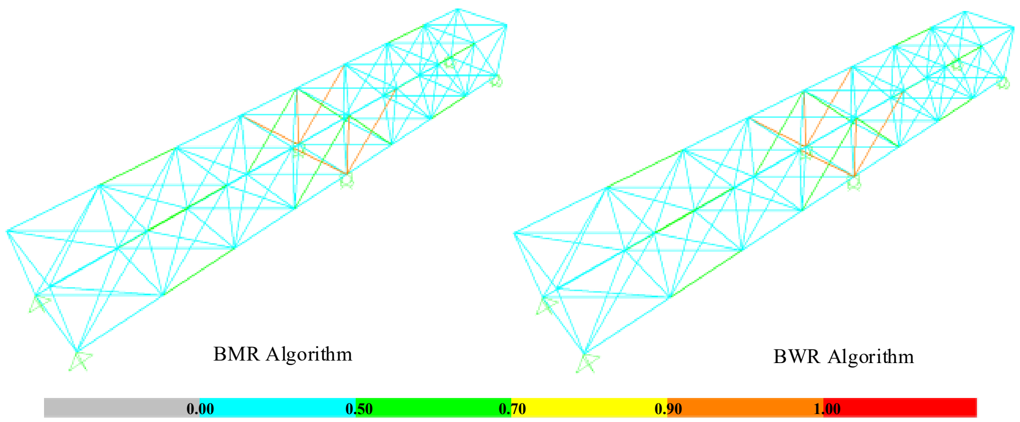

Fig. 4. Design check in SAP2000 according to AISC-ASD

6. Conclusions

In this study, the size optimization of a 132-element steel truss footbridge (TFB) system is performed using two metaheuristic algorithms, Best-Mean-Random (BMR) and Best-Worst-Random (BWR), which are available in the literature. By integrating SAP2000 and MATLAB software through SAP2000's Open Application Programming Interface (OAPI), a three-dimensional finite element model of the bridge was analyzed and in each iteration the algorithms optimized the cross-sections of the bridge elements. For each algorithm, five runs were conducted; the performance comparison was made based on the results obtained and the convergence behavior of the best solutions in the optimization process was examined. Based on this study, the following conclusions were reached:

- The total weights of the bridge obtained with the BMR algorithm in the five runs vary between 41.494 kN and 41.970 kN. This shows that the BMR algorithm exhibits a stable convergence performance.
- With the BWR algorithm, the total weight of the bridge obtained in all five runs was 42.049 kN and did not change at all. This may indicate that the algorithm is stuck to the same local optimum in each run.
- The weight of the best solution obtained with the BWR algorithm (42.049 kN) is higher than the best solution obtained with the BMR algorithm (41.494 kN). This shows that the BMR algorithm performs a more efficient search and can produce better results.
